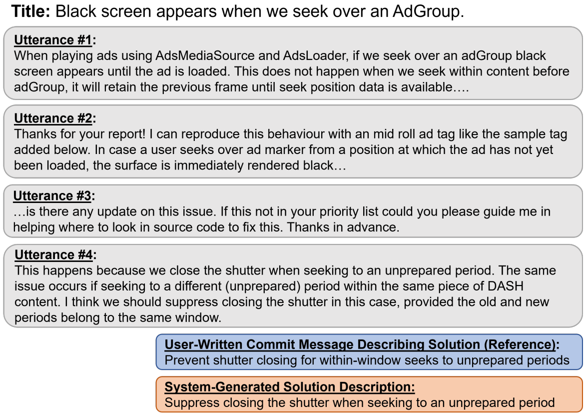
Abstract

When a software bug is reported, developers engage in a discussion to collaboratively resolve it. While the solution is likely formulated within the discussion, it is often buried in a large amount of text, making it difficult to comprehend and delaying its implementation. To expedite bug resolution, we propose generating a concise natural language description of the solution by synthesizing relevant content within the discussion, which encompasses both natural language and source code. We build a corpus for this task using a novel technique for obtaining noisy supervision from repository changes linked to bug reports, with which we establish benchmarks. We also design two systems for generating a description *during* an ongoing discussion by classifying when sufficient context for performing the task emerges in real-time. With automated and human evaluation, we find this task to form an ideal testbed for complex reasoning in long, bimodal dialogue context.

1 Introduction

Software bugs in open-source projects are reported through issue tracking systems like GitHub Issues. When a bug is reported, a discussion is initiated among developers to collectively resolve it (Noyori et al., 2019). The *bug resolution* process is often strenuous and time-consuming, involving extended deliberations (Liu et al., 2020b) among multiple participants (Kavaler et al., 2017), spanning long periods of time (Kikas et al., 2015). Although a solution often emerges within the discussion (Arya et al., 2019), this can easily get lost in a large amount of text (Liu et al., 2020b). Wading through a long discussion to determine whether a solution has been suggested, comprehending it, and then implementing it can be daunting, especially for developers who are not closely following the discussion (Arya et al., 2019; Tan et al., 2020). Consequently, the resolution can be delayed.



Title: Black screen appears when we seek over an AdGroup.

Utterance #1:
When playing ads using AdsMediaSource and AdsLoader, if we seek over an adGroup black screen appears until the ad is loaded. This does not happen when we seek within content before adGroup, it will retain the previous frame until seek position data is available.…

Utterance #2:
Thanks for your report! I can reproduce this behaviour with an mid roll ad tag like the sample tag added below. In case a user seeks over ad marker from a position at which the ad has not yet been loaded, the surface is immediately rendered black…

Utterance #3:
…is there any update on this issue. If this not in your priority list could you please guide me in helping where to look in source code to fix this. Thanks in advance.

Utterance #4:
This happens because we close the shutter when seeking to an unprepared period. The same issue occurs if seeking to a different (unprepared) period within the same piece of DASH content. I think we should suppress closing the shutter in this case, provided the old and new periods belong to the same window.

User-Written Commit Message Describing Solution (Reference):
Prevent shutter closing for within-window seeks to unprepared periods

System-Generated Solution Description:
Suppress closing the shutter when seeking to an unprepared period

Figure 1: ExoPlayer bug report discussion with user-written and system-generated solution descriptions.

As developers scan through the long discussion, it is desirable to have an automated system that guides them to more easily absorb information relevant towards implementing the solution. We propose automatically generating a concise natural language description of the solution by synthesizing relevant content as it emerges in the discussion. For example, as the discussion in Figure 1 progresses, the cause of the bug is identified as the shutter getting closed "when seeking to an unprepared period" and a solution emerges: "suppress closing the shutter in this case, provided the old and new periods belong to the same window." Our task aims to describe this solution: *Prevent shutter closing for within-window seeks to unprepared periods*.

To study this task, we build a corpus from bug report discussions on GitHub Issues. The changes made within the code base to resolve the bug are often linked to the bug report in the form of a commit or pull request. We develop a novel approach to ob-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2935 - 2952
May 22-27, 2022 ©2022 Association for Computational Linguistics

tain noisy supervision for the solution description from the associated commit message or pull request title which describe the bug-resolving changes in natural language. To control for noise, we apply filtering techniques. The dataset and code are publicly available for research use.[1]

With this data, we set benchmarks for generating solution descriptions, conditioned on the discussion. From the long context, a model must learn to tease out and condense information relevant to the solution. Handling long context is critical for tasks with dialogue as input, since the input grows rapidly with the number of interactions. Additionally, the context entails technical text, with natural language and source code often appearing in the same sentence (Li et al., 2018). So, deducing information from the context to articulate a meaningful description requires complex reasoning. We explore generation models including transformer models (Vaswani et al., 2017) and PLBART (Ahmad et al., 2021), which was pretrained on large quantities of code and technical text. We evaluate with automated metrics and human evaluation.

Furthermore, we investigate integrating our task into a real-time setting. An informative description can be generated only if there is sufficient context about the solution, so we must wait until this context is available. In Figure 1, generation should be performed only after utterance #4 is made in the discussion. Since the solution is not formulated until that point, there is insufficient context to reliably generate a description before then. We design two methods for integrating a classifier that determines *when* to generate with a generation model: (1) a *pipelined* system with independently trained classification and generation models; (2) a *joint* system that is simultaneously trained for both tasks.

By monitoring progress and later chiming into the discussion with a solution description, this combined system lays the groundwork for future work on developing an intelligent dialogue agent which participates in discussions to facilitate more efficient bug resolution. While there is growing interest in building tools to support development activities such as code summarization (Iyer et al., 2016; Ahmad et al., 2020), comment updating (Panthaplackel et al., 2020b), and commit message generation (Loyola et al., 2017), dialogue systems have been largely understudied in this domain. We consider our work as a step towards building more dialogue-based AI tools for software development.

2 Problem Setting

As shown in Figure 1, when a user reports a bug, they state the problem in the *title* (e.g., “Black screen appears when we seek over an AdGroup") and initiate a discussion by making the first *utterance* (U_1), which usually elaborates on the problem. Other participants join the discussion at later time steps through utterances ($U_2 ... U_T$), where T is the total number of utterances. Throughout the discussion, developers discuss various aspects of the bug, including a potential solution (Arya et al., 2019). We propose the task of generating a concise description of the solution (e.g., “Prevent shutter closing for within-window seeks to unprepared periods") by synthesizing relevant content within the title and sequence of utterances ($U_1, U_2 ...$).

3 Data

Following prior work on other tasks (Kavaler et al., 2017; Panichella et al., 2021), we mine issue reports corresponding to open-source Java projects from GitHub Issues. Issue reports can entail feature requests as well as bug reports. In this work, we focus on the latter. We identify bug reports by searching for “bug" in the labels assigned to a report and by using a heuristic for identifying bug-related commits (Karampatsis and Sutton, 2020).

3.1 Data Collection

A bug report is organized as an event timeline, recording activity from when it is opened to when it is closed. From comments that are posted on this timeline, we extract utterances which form the *discussion* corresponding to a bug report, ordered based on their timestamps. We specifically consider bug reports that resulted in code (or documentation) fixes (Nguyen et al., 2012). These changes are made through *commits* and *pull requests*, which also appear on the timeline. Changes made in a commit or pull request are described using natural language, in the corresponding commit message (Loyola et al., 2017; Xu et al., 2019) or pull request title (Kononenko et al., 2018; Zhao et al., 2019). In practice, commit messages and pull request titles are written after code changes. However, like contemporary work (Chakraborty and Ray, 2021), we treat them as a proxy for solution descriptions to drive bug-resolving code changes.

Table 1: Data statistics. In parentheses, we show metrics computed on the filtered subset.

Furthermore, we extract the position of a commit or pull request on the timeline, relative to the utterances in the discussion. We consider this as the point at which a developer acquired enough information about the solution to implement the necessary changes and describe these changes with the corresponding commit message or pull request title. So, if the implementation is done immediately after U_g on the timeline, then we take this position t_g as the "gold" time step for when sufficient context becomes available to generate an informative description of the solution. This leads to examples of the form *(Title,* $U_1 ... U_T$*,* t_g*, description)*.

We disregard issues with multiple commit messages/PR titles, so there is at most one example per issue. This is because the reason for needing multiple sets of changes is not clear (e.g., the solution could be implemented in parts or the first solution may have been incorrect and it is later corrected).[2]

3.2 Handling Noise

Due to significant noise in large online code bases like GitHub and StackOverflow, automatically extracted data from these sources is typically filtered both for more effective supervision and for more accurate evaluation (Panthaplackel et al., 2020a; Allamanis et al., 2016; Hu et al., 2018; Fernandes et al., 2019; Iyer et al., 2016; Yao et al., 2018; Yin et al., 2018). Upon studying the data, we also deemed filtering to be necessary. First, we apply simple heuristics to reduce noise, which we discuss in more detail in Appendix A. From this, we obtain the examples that are primarily used for training and evaluation in this work, which we refer to as the *full dataset*. Next, we identify three sources of noise that are more difficult to control with simple heuristics and use techniques described below to quantify them and build a *filtered subset* of the full dataset that is less noisy. This subset is used for more detailed analysis of the models that are discussed in the paper, and we find that training on this subset leads to improved performance (§4.3).

Generic descriptions: Commit messages and pull request titles are sometimes generic (e.g., *"fix issue."*) (Etemadi and Monperrus, 2020). To limit such cases, we compute normalized inverse word frequency (NIWF), which is used in prior work to quantify specificity (Zhang et al., 2018). The filter excludes 1,658 examples in which the reference description's NIWF score is below 0.116 (10th percentile computed from the training data).

Uninformative descriptions: Instead of describing the solution, the commit message or pull request title sometimes essentially re-states the problem (which is usually mentioned in the title of the bug report). To control for this, we compute the percentage of unique, non-stopword tokens in the reference description which also appear in the title. The filtered subset excludes 3,552 additional examples in which this percentage is 50% or more.

Discussions without sufficient context: While enough context is available to a developer to implement a solution at t_g, this context may not always be available in the discussion and could instead be from their technical expertise or external resources. For instance, in the discussion in the footnote[3], only a stack trace and personal exchanges between developers are present. From the utterance before the PR, "Or PM me the query that failed" suggests that an offline conversation occurred. Since relevant content is not available in such cases, it is unreasonable to expect to generate an informative description. We try to identify such examples with an approach (Nallapati et al., 2017) for greedily constructing an extractive summary based on a reference abstractive summary. The filtered subset excludes 1,262 more examples for which a summary could not be constructed (i.e., there is no relevant sentence that is extracted from the context). After applying all three filters, we have 5,856 examples.

---

[2] However, since such examples could be useful for future work, they are available in the data we release.

[3] `https://github.com/prestodb/presto/issues/14567`

		1	2	3	4
Full	Title	73.0	88.9	94.0	96.1
	$U_1...U_{t_g}$	54.7	87.6	95.0	97.6
	Title + $U_1...U_{t_g}$	47.9	82.0	91.2	94.8
Filtr.	Title	82.3	95.6	98.4	99.4
	$U_1...U_{t_g}$	49.9	87.4	95.1	97.8
	Title + $U_1...U_{t_g}$	47.5	86.0	94.5	97.5

Table 2: Percent of novel unigrams, bigrams, trigrams, and 4-grams in the reference description, with respect to the title, $U_1...U_{t_g}$, and title + $U_1...U_{t_g}$. High percentages show that generating solutions is an abstractive task.

3.3 Preprocessing

Since text in this domain can contain code tokens, we *subtokenize* (e.g., snake_case → snake case, camelCase → camel case) in the title, utterances, and description. We retain inlined code (on average 5.7 tokens/utterance); however, we remove code blocks and embedded code snippets (with markdown tags), as done in prior work (Tabassum et al., 2020; Ahmad et al., 2021). Capturing meaning from large bodies of code often requires reasoning with respect to the abstract syntax tree (Alon et al., 2019) and data and control flow graphs (Allamanis et al., 2018). However, markdown tags are not always used to identify code (Tabassum et al., 2020), and consequently, we observe some instances of larger code blocks within utterances that cannot be easily removed. We do not use source code files within a project's repository and leave it to future work to incorporate large bodies of code. We discard URLs and mentions of GitHub usernames from utterances. From the description, we remove references to issue and pull request numbers.

3.4 Partitioning

The dataset spans bug reports from April 2011 - July 2020. We partition based on the timestamp of the commit or pull request associated with a given example. Namely, we require all timestamps in the training set to precede those in the validation set and those in the validation set to precede those in the test set. Partitioning with respect to time ensures that we are not using models trained on future data to make predictions in the present, more closely resembling the real-world scenario (Nie et al., 2022). Dataset statistics are shown in Table 1.

4 Generating Solution Descriptions

We first generate informative solution descriptions in a static setting, in which we leverage the oracle context from the discussion (i.e., the title and $U_1...U_{t_g}$). From Table 1, the average length of a single utterance is ∼70 tokens while the average description length is only ∼9 tokens. Therefore, this task requires not only effectively selecting content about the solution from the long context (which could span multiple utterances) but also synthesizing this content to produce a concise description. Following See et al. (2017), we compute the percent of novel n-grams in the reference description with respect to the input context in Table 2. The high percentages underline the need for an *abstractive* approach, rather than an *extractive* one which generates a description by merely copying over utterances or sentences within the discussion.[4] Furthermore, this task requires complex, bimodal reasoning over the discussion, encompassing both natural language and source code.

4.1 Models

We benchmark various models for this task. To represent the input in neural models, we insert <TITLE_START> before the title and <UTTERANCE_START> before each utterance.

Copy Title: Though the bug report title usually only states a problem, we observe that it sometimes also puts forth a possible solution, so we evaluate how well it can serve as a solution description.

S2S + Ptr: We consider a transformer encoder-decoder model (Vaswani et al., 2017) in which we flatten the context into a single input sequence. Generating the output often requires incorporating project-specific out-of-vocabulary tokens from the input, so we support copying with a pointer generator network (Vinyals et al., 2015).

Hier S2S + Ptr: Inspired by hierarchical approaches for dialogue response generation (Serban et al., 2016), we consider a hierarchical variant of the S2S + Ptr model with two separate encoders: one for representing an individual utterance, and one for representing the whole discussion. We provide implementation details in Appendix B.

PLBART: Ahmad et al. (2021) proposed PLBART, which is pretrained on a large amount of code from GitHub and software-related natural language from StackOverflow, using BART-like (Lewis et al., 2020) training objectives. With fine-tuning, PLBART achieves state-of-the-art performance on many program and language understanding tasks. We fine-tune PLBART on our training set and evaluate its ability to comprehend bug report discus-

---

[4] We observe very low performance with extractive approaches, as shown in Appendix C.

sions and generate descriptions of solutions.[5] Note that PLBART has a 1024 token limit. We use left truncation to keep the most recent content.

PLBART (F): Since PLBART is pretrained on a large amount of data, we can afford to reduce the fine-tuning data. So we fine-tune on only the filtered subset of the training set (cf. §3.2), to investigate whether fine-tuning on this "less noisy" sample can lead to improved performance.

4.2 Results: Automated Metrics

We use text generation metrics, BLEU-4 (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE-L (Lin, 2004). We compute statistical significance with bootstrap tests (Berg-Kirkpatrick et al., 2012) with $p < 0.05$. Results are in Table 3. On the full test set, PLBART significantly outperforms other models, demonstrating the value of pretraining on large amounts of data. PLBART (F) underperforms PLBART on the full test set. On the filtered subset, it either beats or matches PLBART.

Performance drops across models between the full and filtered test sets. The relatively high performance of the naive Copy Title baseline shows that simply copying or rephrasing the title performs well in many cases, particularly for the full test. The filtered subset is designed to remove uninformative reference descriptions that merely re-state the problem, as illustrated in Table 2 with filtered reference descriptions having higher percentages of novel n-grams, with respect to the title. Nonetheless, keywords relevant to the solution are often also in the title, so the Copy Title baseline still achieves reasonable scores on the filtered subset. Although automated metrics provide some signal, they emphasize syntactic similarity over semantic similarity. So, we conduct human evaluation.

Model	Full	Filtered
Copy Title	8.1	6.0
S2S + Ptr	1.3^{*}	$1.2^{\dagger}$
Hier S2S + Ptr	1.3^{*}	$1.2^{\dagger}$
PLBART	11.9	10.5
PLBART (F)	**33.1**‡	**39.5**
All Poor	20.0	22.1
Insufficient Context	$31.9^{\ddagger}$	25.6

Table 4: Human evaluation results: Percent of annotations for which users selected predictions made by each model. This entails 160 annotations for the full test set, 86 of which correspond to examples in our filtered subset. Differences that are *not* significant are indicated with matching superscripts.

4.3 Results: Human Evaluation

Evaluators first read the title and discussion ($U_1 ... U_{t_g}$). For each example, they are shown predictions from the 5 models discussed in Section 4.1. From these, they must select one or more that are most informative towards resolving the bug. If all candidates are uninformative, they select a separate option: "All candidates are poor." There is also another option to indicate that there is insufficient context about the solution (§3.2), making it difficult to evaluate candidate descriptions. They also write a rationale for their response.

Since annotation requires not only technical expertise, but also high cognitive load and time commitment, it is hard to perform human evaluation on a large number of examples with multiple judgments per example. Similar to Iyer et al. (2016), we resort to having each example annotated by one user to obtain more examples. We recruited 8 graduate students with 3+ years of programming experience and familiarity with Java. They are not active contributors, so they will likely select the option of insufficient context more often than if they had a deeper understanding of the various software projects. However, it is difficult to conduct a user study at a similar scale with contributors. Nonetheless, there are developers aiming to become first-time contributors for a particular project (Tan et al., 2020). Our study better aligns with this use case.

Each user annotated 20 examples, leading to annotations for 160 unique examples in the full test set. In Table 4, we show that PLBART (F) substantially outperforms all other models, with users selecting its output 33.1% of the time. Even though the title typically only states a problem, users selected it 8.1% of the time. From rationales that users were asked to write, we found that there were cases in which the title not only posed the problem but also offered a solution. Users rarely preferred the output of S2S + Ptr and Hier S2S + Ptr as they

---

[5] We focus on PLBART rather than vanilla BART because it achieves higher performance, as shown in Appendix D.

	Title ↓		$U_1 ... U_{t_g}$ only ↑

Table 6: Model outputs for the example shown in Figure 1.

usually just rephrased the problem. PLBART also appears to be re-stating the problem in many cases; however, less often than other models.

Though we see similar trends across the full test set and the filtered subset, all models except PLBART (F) tend to perform worse on the filtered subset, as previously observed on automated metrics. Also, the average number of cases with insufficient context is lower for the filtered subset, confirming that we are able to reduce such cases through filtering. We find the results on the filtered data to align better with human judgment. By fine-tuning on the filtered training set, PLBART (F) learns to pick out important information from within the context and generate descriptions which reflect the solution rather than the problem.

4.4 Analysis

Of the 160 annotated examples, users found 109 to have sufficient context about the solution. We consider this the *context-sufficient subset (CS)*, which we will release for future research. To analyze how models exploit the provided context, we measure the percent of n-grams in the prediction which overlap with the title as well as $U_1 ... U_{t_g}$ (excluding n-grams already in the title) in Table 5. PLBART (F)'s predictions tend to have less n-gram overlap with the title and more overlap with the utterances. This suggests that this model predicts fewer uninformative descriptions which merely re-state the problem mentioned in the title and instead focuses on other content from the utterances.

In Table 6, we show model outputs for the example in Figure 1. SeqToSeq and Hier S2S + Ptr essentially rephrase aspects of the problem, which are described in the title. Both PLBART and PLBART (F) capture the solution, with PLBART (F) providing more information. When there is sufficient context, 62.4% of the time, either PLBART or PLBART (F) generates output that is informative towards bug resolution. While this demonstrates that fine-tuning this large, pretrained model on our data can be useful in supporting bug resolution in on-line discussions to some extent, it also shows that there is opportunity for improvement.

We manually inspected PLBART (F)'s outputs and associated user rationales. We observe that the model tends to perform better when the solution is clearly stated in 1-3 consecutive sentences (Table 7 (1) and (2)). When more complex synthesis is needed, it sometimes stitches together tokens from the input incorrectly (Table 7 (3)). Next, although the model picks up on information in the context, sometimes, it draws content from an elaboration of the problem from within the discussion rather than a formulation of the solution (Table 7 (4)). This demonstrates that it still struggles to disentangle content relevant to the solution from that about the problem. It also sometimes struggles to generate meaningful output when in-lined code is present, highlighting the challenge in bimodal reasoning about code and natural language (Table 7 (5)).

5 Supporting Real-Time Generation

Generating an informative description requires sufficient context about the solution being available in the discussion. In a real-time setting, this context is likely not immediately available but rather emerges as the discussion progresses, and we must wait until it becomes available to generate a solution description. However, the time step at which it becomes available (t_g) is not known beforehand, so we must instead predict it (t_p) in order to perform generation *during* ongoing discussions. For this, we consider classifying whether sufficient context is available upon each new utterance. In Figure 1, the solution is formulated in U_4, so the correct behavior is to predict the negative label at $t = 1, 2, 3$ and the positive label at $t = 4$. Once the positive label is predicted at t_p[6], the description is generated, conditioned on the title and $U_1 ... U_{t_p}$. We develop

---

[6] Classifications are not made at $t > t_p$. We leave generating at multiple time steps for future work.

Table 7: Output of PLBART (F) for a sample of examples in the test set. Derived from: https://github.com/quarkusio/quarkus/issues/10227, https://github.com/eclipse-openj9/openj9/issues/9294, https://github.com/Graylog2/graylog2-server/issues/7997, https://github.com/oracle/opengrok/issues/3172, https://github.com/ReactiveX/RxJava/issues/637.

two systems for integrating classification with a generation model: *pipelined* and *joint trained*.

5.1 Pipelined System

We design an independent classifier built on PLBART's encoder. When a new utterance U_t is made in the discussion, we encode the context so far (the title and all utterances up to and including U_t). We take the final hidden state, e_t, as the context representation at t, which we feed e_t through a 3-layer classification head and apply softmax to classify whether or not sufficient context is available. We train to minimize cross entropy loss. At test time, we use the already trained PLBART (F) model to generate a solution description with context available at t_p.

5.2 Joint System

We initialize an encoder-decoder model from PLBART with an additional classification head (§5.1). The encoder is shared among the two tasks. When classifying whether sufficient context about the solution is available, there is likely specific solution-related content that contributes to predicting the positive label. So, classification may enhance encoder representations, improving content selection for generating solution descriptions.

Furthermore, having sufficient context correlates with whether it can be used to generate an *informative* description. So, the informativeness of a description that can be generated with the available context can provide signal for classifying whether that context is sufficient. Additionally, if sufficient context was not previously available at $t-1$ but becomes available at t, we expect an improvement in the informativeness of the descriptions generated at the two time steps. We represent these descriptions with the final decoder states at the two time steps, d_{t-1} and d_t. We concatenate e_t, d_{t-1}, and d_t to form the input into the classification head. For training loss, we sum the generation and classification losses across time steps $t_1 ... t_g$. Sufficient context for generation may not be available at $t < t_g$, so we mask generation loss for earlier time steps.

5.3 Evaluation Setup

We train on filtered data since we found this to improve performance. At test time, a system can generate a solution description at $t_p \leq t_g$, or it can fail to predict the positive label before or at t_g. After a commit/PR for fixing the bug is made at t_g, the state of the discussion changes, with possible mentions of the solution that is implemented. Since using this as context to generate a solution description can be considered "cheating," we do not make predictions for time steps after t_g. We treat this as the system *refraining* from generating after not finding sufficient context.

5.4 Results: Automated Metrics

The pipelined and joint systems refrained from generating 33.3-35.4% and 36.4-39.8% of the time respectively. We present automated metrics for the remaining cases in Table 8. We find that $t_g - t_p$ is between 1.69 and 1.85 for the pipelined system and between 1.81 and 1.97 for the joint system. While a system should wait until sufficient context is available, sometimes, the last couple utterances before the implementation do not add context about the solution but are personal exchanges (e.g., "Thanks",

		$\mathbf{t_p \leq t_g}$	$\mathbf{t_g - t_p}$	**BLEU**	**METEOR**	**ROUGE**
Pipelined	Full	$@t_p$	1.69	$14.3^{\ddagger}$	$12.4^{\S}$	$25.1^{\P}$
		$@t_g$	**-**	$\mathbf{14.4}^{\ddagger}$	$\mathbf{12.5}^{\S}$	$\mathbf{25.3}^{\P}$
	Filtr.	$@t_p$	1.85	12.5^{*}	10.1	21.7
		$@t_g$	**-**	$\mathbf{12.6}^{*}$	**10.5**	**22.3**
Joint	Full	$@t_p$	1.81	13.1	11.4	$22.4^{\dagger}$
		$@t_g$	**-**	**13.2**	**11.7**	$\mathbf{22.5}^{\dagger}$
	Filtr.	$@t_p$	1.97	11.7	9.5	19.3
		$@t_g$	-	**11.9**	**9.9**	**19.7**

Table 8: Automated metrics for combined systems when $t_p \leq t_g$. We compare the generated description $@t_p$ with that if the system had generated $@t_g$. Differences that are *not* statistically significant are indicated with matching superscripts.

		$\mathbf{t_g - t_p}$	**BLEU**	**METEOR**	**ROUGE**
Full	Pipelined	2.09	**14.4**	**12.4**	**24.8**
	Joint	**1.86**	12.9	11.3	22.3
Filtr.	Pipelined	2.16	**12.4**	**10.0**	**21.0**
	Joint	**2.03**	11.4	9.2	18.7

Table 9: Performance at t_p on examples for which both systems predicted $t_p \leq t_g$ (614 of full and 304 of filtered test sets). All differences are statistically significant.

"I'll open a PR"). So, generating slightly before t_g is acceptable in some cases. Moreover, despite generating early in some cases, the generated output $@t_p$ achieves comparable performance to that $@t_g$, with respect to the generation metrics (BLEU, METEOR, and ROUGE).

Note that the numbers are not directly comparable across the two systems since the exact subset of examples for which $t_p \leq t_g$ varies between the two. In Table 9, we present results for the subset of examples for which both systems predict $t_p \leq t_g$. The joint system achieves lower average error ($t_g - t_p$) for classification while the pipelined system performs better on generation metrics.

5.5 Results: Human Evaluation

We also do human evaluation, for which we recruited 6 graduate students with 3+ years of Java experience. Each user evaluated outputs of the two systems for 20 random examples from the filtered test set. Users are given the same information as Section 4.3. If the system refrained from generating, we ask them if there is sufficient context about the solution at any time step $t \leq t_g$. Otherwise, we show them the generated description and ask if there is sufficient context about the solution at t_p and also to rate the informativeness of the description on a Likert scale: 1: incomprehensible, completely incorrect, irrelevant; 2: generic, rephrasing problem; 3: includes some useful information but does not capture the solution; 4: partially captures solution; 5: completely captures solution.

In the cases that the system generated a description, users found there to be sufficient context at t_p 39.0% and 33.8% of the time for the pipelined and joint systems, with average informativeness being 3.3 for both. This suggests that when sufficient context is available, these systems generate descriptions which can be useful for bug resolution.

Because a real-time system must act at a given time step agnostic to future activity, classifying *when to generate* is challenging. It should defer generation to later time steps if the optimal context is not available. Generating too early can result in output that is generic and re-states the problem. For the cases in which the system generated a description *without* sufficient context at t_p, the average informativeness ratings were 2.2 (pipelined) and 2.0 (joint). However, deferring generation for too long by expecting more context to emerge later also poses a risk. After the solution has already been implemented, it is too late for a generated description to be useful towards resolving the bug. In the cases that the pipelined and joint systems refrained from generating, there was sufficient context about the solution 34.2% and 37.0% of the time respectively.

Despite the pipelined and joint systems having nuanced differences, we find them to perform similarly. Through our evaluation of these systems, we demonstrate room for improvement, particularly for the classification component in determining the optimal time step for generation. We leave it to future work to develop more intricate end systems.

6 Related Work

Bug report summarization: To help developers gather information from bug reports, there is interest in automatic bug report summarization. Approaches for this are designed to generate holistic summaries of bug reports, with a summary being

25% of the length of the bug report (Liu et al., 2020b). We instead aim to generate a concise description that captures a specific aspect of the bug report. Next, bug report summaries are not widely available, so approaches for this task rely on unsupervised techniques (Li et al., 2018; Liu et al., 2020b) or supervision from a small amount of data (Rastkar et al., 2014; Jiang et al., 2016). Our approach for obtaining noisy supervision allows us to train supervised models on a large amount of data. Bug report summarization is a post hoc task, done after the bug has been resolved, to help developers address related bug reports in the future. In contrast, our goal is to help resolve the present bug report, so our system must learn *when* to perform generation during an ongoing discussion. Approaches for bug report summarization have been predominantly extractive whereas ours is abstractive. While we are interested in how bug report summarization techniques fair on our task, their implementations are not publicly available.

Commit message generation: Unlike the task of automatically generating commit messages to describe code changes that have already been made (Loyola et al., 2017; Xu et al., 2019), our system aims to generate natural language descriptions that can drive code changes.

Response triggering: Classifying when to generate a description relates to chatbots learning to respond at an appropriate time (Liu et al., 2020a) in dyadic conversations. The goal is to avoid interrupting a user who splits up an utterance across multiple turns. We instead consider multi-party dialogue in which an agent should wait until a specific type of content emerges in the discussion. Bohus and Horvitz (2011) studied turn-taking decisions in spoken dialogue systems, using audio-visual features, while ours is a text-based system.

Dialogue + software: We view our work as a step towards building a dialogue agent for streamlining software bug resolution. There has been minimal work in building interactive systems for this domain, with the exception of a few for tasks like query refinement (Zhang et al., 2020) and code generation (Chaurasia and Mooney, 2017; Yao et al., 2019). Wood et al. (2018) recently built a dialogue corpus through a “Wizard of Oz" experiment to study the potential of a Q&A assistant during bug fixing. Lowe et al. (2015) developed a dialogue corpus based on Ubuntu chat logs to study Q&A assistants for technical support. In contrast, our dataset is designed for building a collaborative agent that participates in multi-party conversations rather than one which answers directed questions.

7 Conclusion

We presented the novel task of generating concise natural language solution descriptions to guide developers in absorbing information relevant towards bug resolution from long discussions. We established benchmarks for this task using a dataset that we constructed with supervision derived from commit messages and pull request titles. Through automated and human evaluation, we demonstrated the utility of these models and also highlight their shortcomings, to encourage more research in exploring ways to address these challenges. We also simulated a real-time setting through two approaches for combining a generation model with a classification component for determining when sufficient context for generating an informative description emerges in an ongoing discussion. We believe this lays the groundwork for future work on building a dialogue agent that participates in bug report discussions to foster efficient resolution.

Acknowledgements

We would like to thank Tanya Goyal, Prasoon Goyal, Adrian Benton, and Eunsol Choi for early feedback on this work. We would also like to thank reviewers for their detailed comments and suggestions. This work was supported by NSF grant IIS-1850153, the Bloomberg Data Science Fellowship and a Google Faculty Research Award.

Ethics Statement

Our work aims to expedite bug resolution by mobilizing developers and guiding them in absorbing content in long discussions that is relevant towards implementing the solution. Through this, we hope to reduce the life span of software bugs and vulnerabilities that can significantly disrupt everyday operations. Our system is designed to *assist* developers and should not be considered as a replacement for the critical reasoning that is needed during bug resolution. Over-relying on this system to always alert developers when a solution has been recommended could have the opposite effect of causing delays in bug resolution for cases that the system is unable to handle. Additionally, if developers choose to rely solely on the system’s generated description and ignore the discussion context, the solutions they implement could potentially be incomplete or incorrect, if the system's output misses important details. Instead, developers should use the generated output to guide their focus and understanding as they read through the discussion.

To build our system, we used data from GitHub, in accordance with its acceptable use policy, and no additional permission was required. Namely, the policy states: "Researchers may use public, non-personal information from the Service for research purposes, only if any publications resulting from that research are open access."[7] We use only publicly available data and use it only for research purposes. Additionally, the data we used to train and evaluate models (and publicly release) does not contain personal information (e.g., usernames of users who authored utterances and linked mentions). We require that any future work using our dataset must abide by GitHub's official policy as well. For evaluation, we conducted human evaluation, for which participants willfully volunteered to be part of the study. They were not compensated for their participation.

A Data Cleaning

We focus on closed bug reports from the top 1,000 Java projects (in terms of number of stars), as a way of identifying well-maintained projects (Jarczyk et al., 2014). We require there to be at least two distinct “actors" in the discussion, in which the actor can either be a developer who makes an utterance in the discussion or an actor who implements the solution through a commit or pull request. We discard examples in which the reference description is identical to the title (disregarding stopwords), as these are cases in which either the reference description only states the problem and is uninformative or the title already puts forth a solution (in which case a generated description would not be useful). We remove examples with commits or pull requests which simultaneously address multiple bug reports.

We mined 141,389 issues (from 770 of the top 1,000 projects). After applying heuristics, we get 35,010 (from 525 projects), which will be released. Of these, 16,899 pertain to bugs and 18,111 pertain to non-bugs. From the 16,899 bug-related issues, we focus on the 12,328 issues with a single commit message/PR title. We explain our reasoning for discarding examples linked to multiple commits and/or pull requests in Section 3.1. However, such examples (which are available in the data we release) can be useful for supporting generating descriptions at multiple time steps in future work.

From an example's description, we remove references to issue and pull request numbers, as they do not contribute to the meaning and are instead used as identifiers for organizational purposes.

B Details of Hier S2S + Ptr Model

We encode U_t using a transformer-based encoder and feed the contextualized representation of its first token (<UTTERANCE_START>) into the RNN-based discussion encoder to update the *discussion state*, s_t. When encoding U_t, we also concatenate s_{t-1} to embeddings, to help the model relate U_t with the broader context of the discussion. Note that we treat the title as U_0 in the discussion. This process continues until U_{t_g} is encoded, at which point all accumulated token-level hidden states are fed into a transformer-based decoder to generate the output.

Unlike the S2S + Ptr model which is designed to reason about the full input at once, this approach reasons step-by-step, with self-attention in the utterance encoder only being applied to tokens within the same utterance. Since the input context for this task is often very large, we investigate whether it is useful to break down the encoding process in this way. We also equip this model with a pointer generator network.

C Additional Generation Baselines

We considered additional baselines; however, since they were performing much lower than other approaches (on wide statistically significant margins), we chose to exclude them from the main paper. We briefly describe these baselines below.

C.1 Extractive Baselines

Supervised Extractive: Using a greedy approach for obtaining noisy extractive summaries (Nallapati et al., 2017), we train a supervised extractive summarization model, similar to (Liu and Lapata, 2019).

LexRank: We use LexRank (Erkan and Radev, 2004), an unsupervised graph-based extractive summarization approach. We extract 1 sentence with threshold 0.1.

$\mathbf{U_1}$ (Lead 1): This entails simply taking the first sentence of the first utterance, intended to simulate the Lead-1 baseline that is commonly used in summarization.

$\mathbf{U_1}$ (Lead 3): This entails simply taking the first 3 sentences of the first utterance, intended to simulate the Lead-3 baseline that is commonly used in summarization.

$\mathbf{U_{t_g}}$: Since some part of the solution is often mentioned within U_{t_g}, we copy this utterance.

$\mathbf{U_{t_g}}$ (Lead 1): Since the length of an utterance is quite different than that of a description (Table 1), we extract only the lead sentence of U_{t_g}.

$\mathbf{U_{t_g}}$ (Lead 3): For the reason stated above, we also apply the Lead-3 baseline to this utterance.

$\mathbf{U_{t_g}}$ (Last sentence): Rather than extracting the lead sentence, we extract the last sentence of U_{t_g}.

$\mathbf{U_{t_g}}$ (Last 3 sentences): Rather than extracting the lead 3 sentences, we try extracting the last 3 sentences of U_{t_g}.

C.2 Retrieval Baselines

Retrieval (Title-Title): Using TF-IDF, we compute cosine similarity between the test example's title and titles in the training set, to identify the closest training example, from which we take the description.

	Model	BLEU	METEOR	ROUGE-1	ROUGE-2	ROUGE-L

Table 10: Comparing models in main paper with low-performing baselines for generating solution descriptions. Scores for Supervised Extractive are averaged across three trials.

Retrieval (Title-Desc): Using TF-IDF, we compute cosine similarity between the test example's title and *descriptions* in the training set, to identify the closest training example, from which we take the description.

Project Retrieval (Title-Title): Using TF-IDF, we compute cosine similarity between the test example's title and titles *for the same project* in the training set, to identify the closest training example, from which we take the description.

Project Retrieval (Title-Desc): Using TF-IDF, we compute cosine similarity between the test example's title and descriptions for the same project in the training set, to identify the closest training example, from which we take the description.

C.3 Baseline Results

We present baseline results in Table 10. In addition to the metrics used in the main paper, we report ROUGE-1 and ROUGE-2. All of these baselines substantially underperform models presented in the main paper, especially the Supervised Extractive model. We believe this model performs so poorly due to noise in the supervision and because the extracted summaries are longer and structured differently than the reference descriptions in our dataset. Additionally, there are many examples in which the model does not select a single sentence from the input, resulting in the prediction being the empty string. LexRank also performs poorly in terms of automated metrics against the reference description. This unsupervised approach aims to identify a "centroid" sentence that summarizes the full input context and is not designed to specifically focus on solution-related context.

All baselines that extract a whole utterance or sentences from specific utterances perform poorly, demonstrating the need for content selection from the broader context and content synthesis rather than relying on simple heuristics to produce a description of the solution. We find that the retrieval baselines tend to achieve higher scores, as retrieved

descriptions are from the same distribution as the reference descriptions. However, these numbers are still much lower than those in the main paper.

D BART Models

We use PLBART (Ahmad et al., 2021), which was pretrained on large amounts of code from GitHub and software-related natural language from StackOverflow. Compared to other pretrained models, fine-tuning PLBART achieves higher performance for various NL+code tasks, including code summarization, code generation, code translation, and code classification. Since our task also requires reasoning about code and technical text, we choose PLBART over other pretrained models in our work. We present automated metrics for PLBART and PLBART (F) in Table 3. The average length of PLBART's output is 9.0 and 8.6 tokens on the full and filtered test sets respectively, while it is 9.3 and 9.4 for PLBART (F).

For completion, we compare against BART-based models which are not pretrained on code or technical text. First, we consider mBART base (multilingual BART) (Tang et al., 2020), which is the underlying architecture of PLBART. Without pretraining (randomly initializing the same architecture), performance is very low, as shown in Table 11. The publicly released pretrained mBART model, which is pretrained on non-technical natural language, does not use the base architecture but rather large. We also fine-tune this model on our training set but find that it achieves lower performance than PLBART. Finally, we compare against BART base (Lewis et al., 2020), which is also pretrained on non-technical natural language. Again, this model underperforms PLBART. Because PLBART's performance is higher, we choose to focus on this model in our work.

E Human Evaluation Setup

In the user study, users are shown the title of the bug report, all utterances up till (and including) U_{t_g}, and the reference description in our dataset for the given example. We choose to provide this as a manual suggestion to help guide users in better understanding a bug report, for a software project with which they have minimal familiarity. However, we state in our instructions that this is merely provided for reference and is not necessarily the exact and only valid answer.

Next, we show them up to 5 model predictions and ask them to "select the one(s) which add(s) the most amount of useful information that will help resolve the bug, beyond just re-stating the problem itself." Note that these are presented in random order (per example), without any identifying information about the underlying models that generated them. We explain that we consider a description to be informative if it provides content that will be useful towards *fixing* the issue, beyond just rephrasing the problem itself. And we encourage users to select candidates based on content that is informative, rather than focusing on exact phrasing. If all candidates appear to be poor (completely unrelated to the resolving the bug, uninformative, incomprehensible, or plain wrong), users are asked to select another option: "All candidates are poor." If there is no useful information towards resolving the bug in the context and they are unable to evaluate candidate descriptions, they are asked to select another option: "The context does not have any useful information for resolving the bug." They must also justify their selection by writing a brief rationale.

This is a challenging task, as it requires reading through and reasoning about a large amount of text to evaluate each example. To prepare annotators, we first present a set of training examples and a training video in which we demonstrate how the task should be completed.

F Analyzing CS Subset

The CS subset consists of 109 examples from the test set spanning 45 projects, with average $T = 4.1$ and $t_g = 3.2$. We present automated metrics for

Model	BLEU	METEOR	ROUGE
Copy Title	12.6	12.2¶	22.1

PLBART (F)	14.2	12.3¶	25.1

Table 12: Automated metrics for generation on CS subset. Differences that are *not* statistically significant are indicated with matching symbols.

this subset in Table 12. Results are analogous to the full test set, except that the numbers are generally lower for all models other than for PLBART (F), which achieves consistent performance. PLBART (F) slightly underperforms PLBART on automated metrics overall. However, this is because these metrics are computed against the single reference description, which could diverge from how the solution is formulated in the discussion since the developer could have written an uninformative/generic description. To do more fine-grained analysis, in Figure 2, we plot automated metrics for varying percentages of token overlap between the reference description and $U_1...U_{t_g}$ (excluding tokens already present in the title which have been used to state the problem). Higher overlap suggests that the reference description draws more content from within the discussion. For higher percentages, PLBART (F) generally achieves higher scores against the reference than PLBART and all other models, indicating that this model is better at gathering information from within the discussion. In Table 13, we supplement the n-gram analysis from Section 4.4.

G Classification Performance

To benchmark performance on the classification task for determining when sufficient context is available for generating an informative description, we consider some simple baselines. We observe that there are many cases in which $t_g = 1, 2$, i.e., the solution is implemented immediately after the first or second utterance. So, we include the FIRST baseline which always predicts a positive label at $t = 1$, and SECOND which predicts negative at $t = 1$ and positive at $t = 2$, if $t_g \geq 2$ (otherwise it never predicts positive).

We include the RAND (uni) baseline which progresses through the discussion, randomly deciding between the positive and negative label after each utterance, based on a uniform distribution. We also include RAND (dist), which instead uses the probability distribution of labels at the example-level estimated from the filtered training set (pos = $\frac{1}{N}\sum_{n=1}^{N}\frac{1}{t_g}$=0.510, neg = 0.490). Results are averaged across 3 trials. We present results in Table 14.

H Reproducibility Checklist

H.1 Validation Performance

We report performances on the full validation set. Results for the generation task are in Table 15.

I Hyperparameters

All neural models were implemented using PyTorch. For S2S + Ptr and Hier S2S + Ptr, we use a batch size of 8, an initial learning rate of 3e-05, and a dropout rate of 0.2. Our transformer models have 4 encoder and decoder layers, 4 heads in multi-head attention, a hidden size of 64, and feedforward hidden size 256. We use Adam as the optimizer and have a learning rate scheduler with gamma 0.95 which decays after an epoch if the validation loss has not improved. We use early stopping with patience 5 during training.

For classification, the classification head consists of a linear layer (dimension 768), followed by a tanh non-linear layer, and a final linear projection layer (dimension 2). When computing cross entropy loss for classification, we weight the positive and negative labels using the inverse of the class proportion to handle class imbalance (1.70 and 0.71 respectively). For the joint model, loss for a given example is computed as follows, with $\lambda_1 = 0.8, \lambda_2 = 0.2$ (tuned on validation data).

$$L = \lambda_1 L_{gen}(t_g) + \lambda_2 \sum_{t=1}^{t=t_g} L_{class}(t)$$

.

I.1 Tuning

For S2S + Ptr and Hier S2S + Ptr, hyperparameters are tuned manually. For batch size, we consider {8,16,32}, learning rate {1e-03, 1e-04, 3e-05}, dropout {0.1, 0.2, 0.4, 0.5, 0.6}, encoder/decoder layers {2, 4, 6, 8}, number of heads {2, 4, 8}, hidden sizes {32, 62, 128}, and feedforward dimensions {128, 256, 512}. These hyperparameters are tuned on validation data, using the text generation metrics mentioned in Section 4.2 for generation. For tuning, we do not do grid search but rather compare performances between models trained with identical configurations, with the exception of a single parameter. Therefore, the number of hyperparameter tuning runs scales linearly. We ran

each configuration once. For PLBART-based models, we use the same configurations as the scripts released by Ahmad et al. (2021).

I.2 Random Seeds

For the randomly initialized models, random seeds are set according to the timestamp, and we average results across 3 trials. For S2S + Ptr, the seeds were: 1620001129, 1620001158, and 1620004022. For Hier S2S + Ptr, the seeds were: 1620001125, 1620001159, and 1620004024.

J Statistical Significance Testing

We compute statistical significance using bootstrap tests (Berg-Kirkpatrick et al., 2012) with $p < 0.05$ and 10,000 samples of size 5,000 each.

J.1 Running Times

Table 16 reports average training time, inference time, and # epochs for the various models considered in this work. The PLBART-based models were trained/fine-tuned on NVIDIA DGX GPUs (32 GB) and all other models were trained and evaluated using on GeForce GTX Titan GPUs (8 GB). All models used single-GPU training.

Perturbations in the Wild: Leveraging Human-Written Text Perturbations for Realistic Adversarial Attack and Defense

Thai Le **Jooyoung Lee** **Kevin Yen*** **Yifan Hu*** **Dongwon Lee**

Penn State University {thaile, jfl5838, dongwon}@psu.edu
Yahoo Research* {kevinyen, yifanhu}@yahooinc.com*

Abstract

We proposes a novel algorithm, ANTHRO, that *inductively* extracts over 600K human-written text perturbations in the wild and leverages them for *realistic* adversarial attack. Unlike existing character-based attacks which often deductively hypothesize a set of manipulation strategies, our work is grounded on actual observations from real-world texts. We find that adversarial texts generated by ANTHRO achieve the best trade-off between (1) attack success rate, (2) semantic preservation of the original text, and (3) stealthiness–i.e. indistinguishable from human writings hence harder to be flagged as suspicious. Specifically, our attacks accomplished around 83% and 91% attack success rates on BERT and RoBERTa, respectively. Moreover, it outperformed the *TextBugger* baseline with an increase of 50% and 40% in terms of semantic preservation and stealthiness when evaluated by both layperson and professional human workers. ANTHRO can further enhance a BERT classifier's performance in understanding different variations of human-written toxic texts via adversarial training when compared to the Perspective API. *Source code will be published at* `github.com/lethaiq/perturbations-in-the-wild`.

1 Introduction

Machine learning (ML) models trained to optimize only the prediction performance are often vulnerable to adversarial attacks (Papernot et al., 2016; Wang et al., 2019). In the text domain, especially, a character-based adversarial attacker aims to fool a target ML model by generating an adversarial text x^* from an original text x by manipulating characters of different words in x, such that some properties of x are preserved (Li et al., 2018; Eger et al., 2019; Gao et al., 2018). We characterize strong and practical adversarial attacks as three criteria: (1) *attack performance*, as measured by the ability to flip a target model's predictions, (2) *semantic preservation*, as measured by the ability to preserve the meaning of an original text, and (3) *stealthiness*, as measured by how unlikely it is detected as machine-manipulation and removed by defense systems or human examiners (Figure 1). While the first two criteria are natural derivation from adversarial literature (Papernot et al., 2016), stealthiness is also important to be a practical attack under a mass-manipulation scenario. In fact, adversarial text generation remains a challenging task under practical settings.

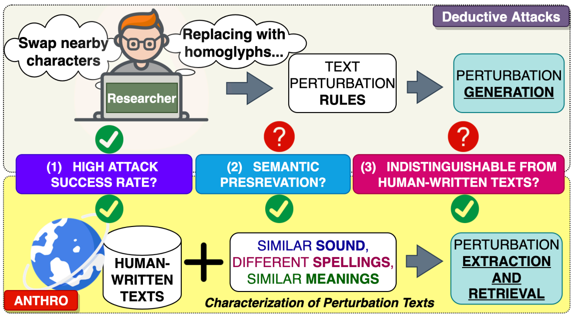

Figure 1: ANTHRO (Bottom) extracts and uses human-written perturbations for adversarial attacks instead of proposing a specific set of manipulation rules (Top).

Previously proposed character-based attacks follow a *deductive* approach where the researchers hypothesize a set of text manipulation strategies that exploit some vulnerabilities of textual ML models (Figure 1). Although these deductively derived techniques can demonstrate superior attack performance, there is no guarantee that they also perform well with regard to semantic preservation and stealthiness. We first analyze why enforcing these properties are challenging especially for character-based attacks.

To preserve the semantic meanings, an attacker can minimize the distance between representative vectors learned from a large pre-trained model–e.g., Universal Sentence Encoder (Cer et al., 2018) of the two sentences. However, this is only applicable in word- or sentence-based attacks, not in

Findings of the Association for Computational Linguistics: ACL 2022, pages 2953 - 2965

DISCLAIMER! THIS PAPER CONTAINS EXAMPLE TEXTS THAT ARE OFFENSIVE IN NATURE

character-based attacks. It is because character-based manipulated tokens are more prone to become out-of-distribution–e.g., morons→mor0ns, from what is observed in a typical training corpus where the correct use of English is often assumed. In fact, existing character-based attacks such as *TextBugger* (Li et al., 2018), *VIPER* (Eger et al., 2019) and *DeepWordBug* (Gao et al., 2018) generally assume that the meaning of the original sentence is preserved without further evaluations.

In addition, a robust ML pipeline is often equipped to detect and remove potential adversarial perturbations either via automatic software (Jayanthi et al., 2020; Pruthi et al., 2019), trapdoors (Le et al., 2021) or human-in-the-loop (Le et al., 2020). Such detection is feasible especially when the perturbed texts are curated using a set of fixed rules that can be easily re-purposed for defense. Thus, attackers such as *VIPER* and *DeepWordBug*, which map each Latin-based character to either non-English accents (e.g., ė, ā, d̃), or homoglyphs (characters of similar shape), fall into this category and can be easily detected under simple normalization techniques (Sec. 4.1). *TextBugger* circumvents this weakness by utilizing a set of more general character-editing strategies–e.g., replacing and swapping nearby characters to synthesize human-written typos and misspellings. Although texts perturbed by such strategies become less likely to be detected, many of them may distort the meaning of the original text (e.g., “garbage"→“gabrage", “dumb"→“dub") and can be easily flagged as machine-generated by human examiners. Therefore, we argue that generating perturbations that both preserve original meanings and are indistinguishable from human-written texts be a critically important yet challenging task.

To overcome these challenges, we introduce ANTHRO, a novel algorithm that *inductively* finds and extracts text perturbations in the wild. As shown in Figure 1, our method relies on human-written sentences in the Web in their raw form. We then use them to develop a character-based adversarial attack that is not only effective and realistic but is also helpful in training ML models that are more robust against a wide variety of human-written perturbations. Distinguished from previous research, our work considers both spellings and phonetic features (how a word sounds), to characterize text perturbations. Furthermore, we conducted user studies to quantitatively evaluate semantic preservation and stealthiness of adversarial texts. Our contributions are as follows.

- ANTHRO extracts over 600K case-sensitive character-based “real" perturbations from human-written texts.
- ANTHRO facilitates black-box adversarial attacks with an average of 82.7% and 90.7% attack success rates on BERT and RoBERTa, and drops the *Perspective API*'s precision to only 12%.
- ANTHRO outperforms the *TextBugger* baseline by over 50% in semantic preservation and 40% in stealthiness in human subject studies.
- ANTHRO combined with adversarial training also enables BERT classifier to achieve 3%–14% improvement in precision over *Perspective API* in understanding human-written perturbations.

2 Perturbations in the Wild

2.1 Machine v.s. Human Perturbations

Perturbations that are neither natural-looking nor resembling human-written texts are more likely to be detected by defense systems (thus not a practical attack from adversaries' perspective). However, some existing character-based perturbation strategies, including *TextBugger*, *VIPER* and *DeepWordBug*, follow a *deductive* approach and their generated texts often do not resemble human-written texts. Qualitatively, however, we find that humans express much more diverse and creative (Tagg, 2011) perturbations (Figure B.1, Appendix) than ones generated by such deductive approaches. For example, humans frequently (1) capitalize and change the parts of a word to emphasize distorted meanings (e.g.,“democrats“→“democRATs", “republicans"→“republiCUNTs"), (2) hyphenate a word (e.g., “depression"→“de-pres-sion"), (3) use emoticons to emphasize meaning (e.g., “shit"→“sh💩t"), (4) repeat particular characters (e.g., “dirty"→“diiirty", “porn"→“pooorn"), or (5) insert phonetically similar characters (e.g., “nigger"→“nighger"). Human-written perturbations do not manifest any fixed rules and often require some context understanding. Moreover, one can generate a new meaningful perturbation simply by repeating a character–e.g., “porn"→“pooorn". Thus, it is challenging to systematically generate all such perturbations, if not impossible. Moreover, it is very difficult for spell-checkers, which usually rely on a fixed set

Attacker #texts, #tokens	**Reddit Comts. »5B, N/A**	**News Comts. (34M, 11M)**

VIPER	3.2% (1/31)	0.13% (25/19K)
DeepWordBug	0% (0/31)	0.27% (51/19K)
ANTHRO	**82.4%** (266/323)	**55.7%** (16K/29K)

Table 1: Percentage of offensive perturbed words generated by different attacks that can be observed in real human-written comments on Reddit and online news.

of common spelling mistakes and an edit-distance threshold, to correct and detect all human-written perturbations.

We later show that human examiners rely on personal exposure from Reddit or YouTube comments to decide if a word choice looks natural (Sec. 4.2). Quantitatively, we discover that not all the perturbations generated by deductive methods are observed on the Web (Table 1). To analyze this, we first use each attack to generate all possible perturbations of either (1) a list of over 3K unique offensive words or (2) a set of the top 5 offensive words ("c*nt", "b*tch", "m*therf***er", "bast*rd", "d*ck"). Then, we calculate how many of the perturbed words are present in a dataset of over 34M online news comments or are used by at least 50 unique commentators on Reddit, respectively. Even though *TextBugger* was well-known to simulate human-written typos as adversarial texts, merely 51.6% and 7.1% of its perturbations are observed on Reddit and online news comments, implying *TextBugger*'s generated adversarial texts being "unnatural" and "easily-detectable" by human-in-the-loop defense systems.

2.2 The SMS Property: Similar Sound, Similar Meaning, Different Spelling

The existence of a non-arbitrary relationship between sounds and meanings has been proven by a life-long research establishment (Köhler, 1967; Jared and Seidenberg, 1991; Gough et al., 1972). In fact, Blasi et al. (2016) analyzed over 6K languages and discovered a high correlation between a word's sound and meaning both inter- and intra-cultures. Aryani et al. (2020) found that how a word sounds links to an individual's emotion. This motivates us to hypothesize that words spelled differently yet have the same meanings such as text perturbations will also have similar sounds.

Figure B.1 (Appendix) displays several perturbations that are found from real-life texts. Even though these perturbations are *spelled differently* from the original word, they all preserve *similar meanings* when perceived by humans. Such semantic preservation is feasible because humans perceive these variations *phonetically similar* to the respective original words (Van Orden, 1987). For example, both "republican" and "republikan" sound similar when read by humans. Therefore, given the surrounding context of a perturbed sentence–e.g., "*President Trump is a* republikan", and the phonetic similarity of "republican" and "republikan", end-users are more likely to interpret the perturbed sentence as "*President Trump is a republican*". We call these characteristics of text perturbations the *SMS* property: "*similar Sound, similar Meaning, different Spellings*". Noticeably, the SMS characterization includes a subset of "visually similar" property of perturbations as studied in previous adversarial attacks such as *TextBugger* (e.g., "hello" sounds similar with "he11o"), *VIPER* and *DeepWordBug*. However, two words that look very similar sometimes carry different meanings–e.g., "garbage"→"gabrage". Moreover, our characterization is also distinguished from *homophones* (e.g., "to" and "two") which describe words with similar sound yet *different meaning*.

3 A Realistic Adversarial Attack

Given the above analysis, we now derive our proposed ANTHRO adversarial attack. We first share how to systematically encode the sound–i.e., phonetic feature, of any given words and use it to search for their human-written perturbations that satisfy the SMS property. Then, we introduce an iterative algorithm that utilizes the extracted perturbations to attack textual ML models.

3.1 Mining Perturbations in the Wild

Sound Encoding with SOUNDEX++. To capture the sound of a word, we adopt and extend the case-insensitive SOUNDEX algorithm. SOUNDEX helps index a word based on how it sounds rather than how it is spelled (Stephenson, 1980). Given a word, SOUNDEX first keeps the 1st character. Then, it removes all vowels and matches the remaining characters *one by one* to a digit following a set of predefined rules–e.g., "B", "F"→1, "D", "T"→3 (Stephenson, 1980). For example, "Smith" and "Smyth" are both encoded as S530.

As the SOUNDEX system was designed mainly for encoding surnames, it does not necessarily

Word	SOUNDEX	SOUNDEX++ (Ours)
porn	P650	P650 (**k**=0), PO650 (**k**=1)
p0rn	P065(✗)	(same as above)
lesbian	L215	L245 (**k**=0), LE245 (**k**=1)
lesbbi@n	L21@(✗)	(same as above)
losbian	L215(✗)	L245 (**k**=0), LO245 (**k**=1)

(✗): Incorrect encoding

Table 2: SOUNDEX++ can capture visually similar characters and is more accurate in differentiating between desired (blue) and undesired (red) perturbations.

Key	TH000	DE5263	AR000	DI630	NO300
Value (Set)	the	democrats demokRATs	are arre	dirty dirrrty	not
ANTHRO(democrats,**k**=1,**d**=1)→{democrats, demokRATs}					
ANTHRO(dirty,**k**=1,**d**=2)→{dirty, dirrrty}					

Table 3: Examples of hash table $H_1(k{=}1)$ curated from sentences *"the demokRATs are dirrrty"* and *"the democrats arre not dirty"* and its utilization.

work for texts in the wild. For example, it cannot recognize visually-similar perturbations such as "l"→"1", "a"→"@" and "O"→"0". Moreover, it always fixes the 1st character as part of the final encodes. This rule is too rigid and can result in words that are entirely different yet encoded the same (Table 2). To solve these issues, we propose a new SOUNDEX++ algorithm. SOUNDEX++ is equipped to both recognize visually-similar characters and encode the sound of a word at different hierarchical levels **k** (Table 2). Particularly, at level **k**=0, SOUNDEX++ works similar to SOUNDEX by fixing the first character. At level **k**≥1, SOUNDEX++ instead fixes the first **k**+1 characters and encodes the rest.

Levenshtein Distance d and Phonetic Level k as a Semantic Preservation Proxy. Since SOUNDEX++ is not designed to capture a word's semantic meaning, we utilize both phonetic parameter **k** and *Levenshtein distance* **d** (Levenshtein et al., 1966) as a heuristic approximation to measure the semantic preservation between two words. Intuitively, the higher the phonetic level (**k**≥1) at which two words share the same SOUNDEX++ code and the smaller the Levenshtein distance **d** to transform one word to another, the more likely human associate them with the meaning. In other words, **k** and **d** are hyper-parameters that help control the trade-off between precision and recall when retrieving perturbations of a given word such

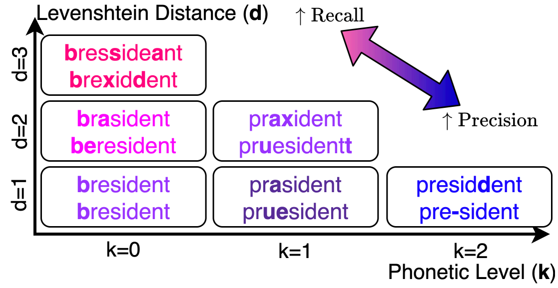

Figure 2: Trade-off between precision and recall of extracted perturbations for the word "president" w.r.t different **k** and **d** values. Higher **k** and lower **d** associate with better preservation of the original meaning.

that they satisfy the SMS property (Figure 2). We will later carry out a human study to evaluate how well our extracted perturbations can preserve the semantic meanings in practice.

Mining from the Wild. To mine all human-written perturbations, we first collect a large corpus $\mathcal{D}$ of over 18M sentences written by netizens from 9 different datasets (Table A.1 in Appendix). We select these datasets because they include offensive texts such as hate speech, sensitive search queries, etc., and hence very likely to include text perturbations. Next, for each phonetic level $\mathbf{k} \leq K$, we curate different hash tables $\{H\}_0^K$ that maps a unique SOUNDEX++ code **c** to a set of its matching unique *case-sensitive* tokens that share the same encoding **c** as follows:

$$H_{\mathbf{k}} : \mathbf{c} \mapsto \{w_j | S(w_i, k) = S(w_j, k) = \mathbf{c} \quad \forall w_i, w_j \in \mathcal{D}, w_i \neq w_j\}, \tag{1}$$

where $S(w, \mathbf{k})$ returns the SOUNDEX++ code of token w at phonetic level **k**, K is the largest phonetic level we want to encode. With $\{H\}_0^K$, **k** and **d**, we can now search for the set of perturbations $G^{\mathbf{d}}_{\mathbf{k}}(w^*)$ of a specific target token w^* as follows:

$$G^{\mathbf{d}}_{\mathbf{k}}(w^*) \leftarrow \{w_j | w_j \in H_{\mathbf{k}}[S(w^*, k)], \quad \text{Lev}(w^*, w_j) \leq \mathbf{d}\} \tag{2}$$

where $\text{Lev}(w^*, w_j)$ returns the Levenshtein distance between w^* and w^j. Noticeably, we only extract $\{H\}_0^K$ **once** from $\mathcal{D}$ via Eq. (1), then we can use Eq. (2) to retrieve all perturbations for a given word during deployment. We name this method of mining and retrieving human-written text perturbations in the wild as **ANTHRO**, aka *human-like* perturbations:

$$\text{ANTHRO} : w*, \mathbf{k}, \mathbf{d}, \{H\}_0^K \longmapsto G^{\mathbf{d}}_{\mathbf{k}}(w^*) \tag{3}$$

Algorithm 1 ANTHRO Attack Algorithm

```
1: Input: $\{H\}_0^K$, k, d
2: Input: target classifier $f$, original sentence $x$
3: Output: perturbed sentence $x^*$
4: Initialize: $x^* \leftarrow x$
5: for word $x_i$ in $x$ do:   $s_i \leftarrow \mathrm{Score}(x_i, f)$
6: $\mathcal{W}_{\mathrm{order}} \leftarrow \mathrm{Sort}(x_1, x_2, ..x_m)$ according to $s_i$
7: for $x_i$ in $\mathcal{W}_{\mathrm{order}}$ do:
8:     $\mathcal{P} \leftarrow \mathrm{ANTHRO}(x_i, \mathbf{k}, \mathbf{d}, \{H\}_0^K)$ // Eq.(3)
9:     $x^* \leftarrow$ replace $x_i \in x$ with the best $w \in \mathcal{P}$
10:    if $f(x^*) \neq f(x)$ then return $x^*$
11: return None
```

ANTHRO Attack. To utilize ANTHRO for adversarial attack on model $f(x)$, we propose the ANTHRO attack algorithm (Alg. 1). We use the same iterative mechanism (Ln.9–13) that is common among other black-box attacks. This process replaces the most vulnerable word in sentence x, which is evaluated with the support of $\mathrm{Score})(\cdot)$ function (Ln. 5), with the perturbation that best drops the prediction probability $f(x)$ on the correct label. Unlike the other methods, ANTHRO inclusively draws from perturbations extracted from human-written texts captured in $\{\mathcal{H}\}_0^K$ (Ln. 10). We adopt the $\mathrm{Score}(\cdot)$ from *TextBugger*.

4 Evaluation

We evaluate ANTHRO by: (1) attack performance, (2) semantic preservation, and (3) human-likeness–i.e., how likely an attack message is spotted as machine-generated by human examiners.

4.1 Attack Performance

Setup. We use BERT (*case-insensitive*) (Jin et al., 2019) and RoBERTa (*case-sensitive*) (Liu et al., 2019) as target classifiers to attack. We evaluate on three public tasks, namely detecting toxic comments ((TC) dataset, Kaggle 2018), hate speech ((HS) dataset (Davidson et al.)), and online cyberbullying texts ((CB) dataset (Wulczyn et al., 2017a)). We split each dataset to *train*, *validation* and *test* set with the 8:1:1 ratio. Then, we use the train set to fine-tune BERT and RoBERTa with a maximum of 3 epochs and select the best checkpoint using the validation set. BERT and RoBERTa achieve around 0.85–0.97 in F1 score on the test sets (Table A.2 in Appendix). We evaluate with targeted attack (change positive→negative label) since it is more practical. We randomly sample 200 examples from each test set and use them as initial sentences to attack. We repeat the process 3 times with unique random seeds and report the results. We use the *attack success rate (Atk%)* metric–i.e., the number of examples whose labels are flipped by an attacker over the total number of texts that are correctly predicted pre-attack. We use the 3rd party open-source *OpenAttack* (Zeng et al., 2021) framework to run all evaluations.

Baselines. We compare ANTHRO with three baselines, namely *TextBugger* (Li et al., 2018), *VIPER* (Eger et al., 2019) and *DeepWordBug* (Gao et al., 2018). These attackers utilize different character-based manipulations to craft their adversarial texts as described in Sec. 1. From the analysis in Sec. 3.1 and Figure 2, we set $\mathbf{k} \leftarrow 1$ and $\mathbf{d} \leftarrow 1$ for ANTHRO to achieve a balanced trade-off between precision and recall on the SMS property. We examine all attackers under several combinations of different normalization layers. They are (1) *Accents normalization* (A) and (2) *Homoglyph normalization* [1] (H), which converts non-English accents and homoglyphs to their corresponding ascii characters, (3) *Perturbation normalization* (P), which normalizes potential character-based perturbations using the SOTA misspelling correction model *Neuspell* (Jayanthi et al., 2020). These normalizers are selected as counteracts against the perturbation strategies employed by *VIPER* (uses non-English accents), *DeepWordBug* (uses homoglyphs) and *TextBugger*, ANTHRO (based on misspelling and typos), respectively.

Results. Overall, both ANTHRO and *TextBugger* perform the best. Being case-sensitive, ANTHRO performs significantly better on RoBERTa and is competitive on BERT when compared to *TextBugger* (Table 4). This happens because RoBERTa is case-sensitive (unlike the *base-uncased-bert* BERT model we used) and only ANTHRO is case-sensitive out of all attack baselines. For example, the perturbation “democrats"→“democRATs" is considered as a perturbation for RoBERTa but not for other case-insensitive models. This gives ANTHRO an advantage in practice because many popular commercial API services (e.g., the popular *Perspective API*, the sentiment analysis and text categorization API from Google) are case-sensitive–i.e., “democrats"≠“democRATs". (See more at Table 8).

(-) BERT already has the accents normalization (A normalizer) by default, (Red): Poor performance (Atk%<0.15)

Table 4: Averaged attack success rate (Atk%↑) of different attack methods

VIPER achieves a near perfect score on RoBERTa, yet it is ineffective on BERT because RoBERTa uses the accent Ġ as a part of its byte-level BPE encoding (Liu et al., 2019) while BERT by default removes all such accents. Since *VIPER* exclusively utilizes accents, its attacks can be easily corrected by the *accents normalizer* (Table 4). Similarly, *DeepWordBug* perturbs texts with homoglyph characters, most of which can also be normalized using a 3rd party homoglyph detector (Table 4).

In contrast, even under all normalizers–i.e., A+H+P, *TextBugger* and ANTHRO still achieves 66.3% and 73.7% in Atk% on average across all evaluations. Although *Neuspell* (Jayanthi et al., 2020) drops *TextBugger*'s Atk% 14.7% across all runs, it can only reduce the Atk% of ANTHRO a mere 7.5% on average. This is because *TextBugger* and *Neuspell* or other dictionary-based typo correctors rely on fixed deductive rules–e.g., swapped, replaced by neighbor letters, for attack and defense. However, ANTHRO utilizes human-written perturbations which are greatly varied, hence less likely to be systematically detected. We further discuss the limitation of misspelling correctors such as NeuSpell in Sec. 7.

4.2 Human Evaluation

Since ANTHRO and *TextBugger* are the top two effective attacks, this section will focus on evaluating their ability in semantic preservation and human-likeness. Given an original sentence x and its adversarial text x^* generated by either one of the attacks, we design a human study to *directly compare* ANTHRO with *TextBugger*. Specifically, two alternative hypotheses for our validation are (1) $\mathcal{H}_{\text{Semantics}}$: x^* generated by ANTHRO preserves the original meanings of x *better* than that generated by *TextBugger* and (2) $\mathcal{H}_{\text{Human}}$: x^* generated by ANTHRO is *more likely* to be perceived as a human-written text (and not machine) than that generated by *TextBugger*.

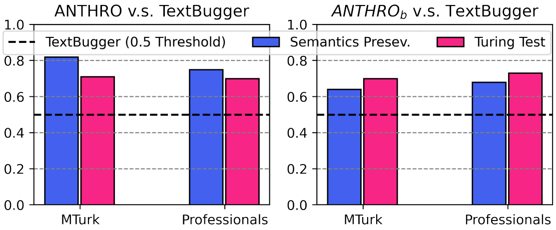

Figure 3: Semantic preservation and human-likeness

Human Study Design. We use the two attackers to generate adversarial texts targeting BERT model on 200 examples sampled from the TC dataset's test set. We then gather examples that are successfully attacked by both ANTHRO and *TextBugger*. Next, we present a pair of texts, one generated by ANTHRO and one by *TextBugger*, together with the original sentence to human subjects. We then ask them to select (1) which text *better* preserves the meaning of the original sentence (Figure B.2 in Appendix) and (2) which text is *more likely* to be written by human (Figure B.3

Attacker	Normalizer	BERT (*case-insensitive*)			RoBERTa (*case-sensitive*)		
		Toxic Comments	**HateSpeech**	**Cyberbullying**	**Toxic Comments**	**HateSpeech**	**Cyberbullying**
TextBugger	-	0.76±0.02	0.94±0.01	0.78±0.03	0.77±0.06	0.87±0.01	0.72±0.01
ANTHRO$_\beta$	-	**0.82±0.01**	**0.97±0.01**	**0.88±0.04**	**0.91±0.02**	**0.97±0.01**	**0.89±0.02**
TextBugger	A+H+P	0.73±0.02	0.64±0.06	0.70±0.04	0.68±0.06	0.57±0.03	0.66±0.04

Table 5: Averaged attack success rate (Atk%↑) of ANTHRO$_\beta$ and *TextBugger*

Reason	Favorable For ANTHRO	Unfavorable For TextBugger
Genuine Typos	stuupid, but, Faoggt	sutpid, burt, Foggat
Intelligible	faiilure	faioure
Sound Preserv.	shytty, crp	shtty, crsp
Meaning Preserv.	ga-y, ashole, dummb	bay, alshose, dub
High Search Results	sodmized, kiills	Smdooized, klils
Personal Exposure	ign0rant, gaarbage	ignorajt, garage
Word Selection	morons→mor0ns	edited→ewited

Table 6: Top reasons in favoring ANTHRO's perturbations as more likely to be written by human.

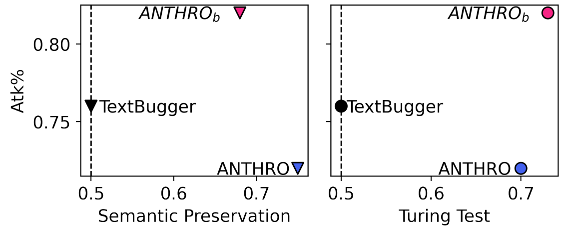

Figure 4: Trade-off among evaluation metrics

in Appendix). To reduce noise and bias, we also provide a *"Cannot decide"* option when quality of both texts are equally good or bad, and present the two questions in two separate tasks. Since the definition of semantic preservation can be subjective, we recruit human subjects as both (1) Amazon Mechanical Turk (MTurk) workers and (2) professional data annotators at a company with extended experience in annotating texts in domain such as toxic and hate speech. Our human subject study with MTurk workers was IRB-approved. We refer the readers to Sec. B.3 (Appendix) for more details on MTurks and study designs.

Quantitative Results. It is statistically significant (p-$value \leq 0.05$) to reject the null hypotheses of both $\mathcal{H}_{\text{Semantics}}$ and $\mathcal{H}_{\text{Human}}$ (Table A.3). Overall, adversarial texts generated by perturbations mined in the wild are much better at preserving the original semantics and also at resembling human-written texts than those generated by *TextBugger* (Figure 3, Left).

Qualitative Analysis. Table 6 summarizes the top reasons why they favor ANTHRO over *TextBugger* in terms of human-likeness. ANTHRO's perturbations are perceived similar to genuine typos and more intelligible. They also better preserve both meanings and sounds. Moreover, some annotators also rely on personal exposure on Reddit, YouTube comments, or the frequency of word use via the search function on Reddit to decide if a word-choice is human-written.

5 ANTHRO$_\beta$ Attack

ANTHRO$_\beta$. We examine if perturbations inductively extracted from the wild help improve the deductive *TextBugger* attack. Hence, we introduce ANTHRO$_\beta$, which considers the perturbation candidates from both ANTHRO and *TextBugger* in Ln. 10 of Alg. 1. Alg. 1 still selects the perturbation that best flip the target model's prediction.

Attack Performance. Even though ANTHRO comes second after *TextBugger* when attacking BERT model, Table 5 shows that when combined with *TextBugger*–i.e., ANTHRO$_\beta$, it consistently achieves superior performance with an average of 82.7% and 90.7% in Atk% on BERT and RoBERTa even under all normalizers (A+H+P).

Semantic Preservation and Human-Likeness. ANTHRO$_\beta$ improves *TextBugger*'s Atk%, semantic preservation and human-likeness score with an increase of over 8%, 32% and 42% (from 0.5 threshold) on average (Table 5, 3, Right), respectively. The presence of only a few human-like perturbations generated by ANTHRO is sufficient to signal whether or not the whole sentence is written by humans, while only one unreasonable perturbation generated by *TextBugger* can adversely affect its meaning. This explains the performance drop in terms of semantic preservation but not in human-likeness when indirectly comparing ANTHRO$_\beta$ with ANTHRO. Overall, ANTHRO$_\beta$ also has the best trade-off between Atk% and hu-

Model	ANTHRO			ANTHRO$_\beta$		
	TC↓	HS↓	CB↓	TC↓	HS↓	CB↓

ADV.TRAIN	0.41	0.30	0.35	**0.72**	**0.72**	**0.67**
SOUNDCNN	**0.14**	**0.02**	**0.15**	0.86	0.84	0.92

Table 7: Averaged Atk% of ANTHRO and ANTHRO$_\beta$ against different defense models.

man evaluation–i.e., positioning at top right corners in Figure 4, with a noticeable superior Atk%.

6 Defend ANTHRO, ANTHRO$_\beta$ Attack

We suggest two countermeasures against ANTHRO attack. They are **(i) Sound-Invariant Model (SOUNDCNN):** When the defender do *not* have access to $\{\mathcal{H}\}_0^K$ learned by the attacker, the defender trains a generic model that encodes not the spellings but the phonetic features of a text for prediction. Here we train a CNN model (Kim, 2014) on top of a embeddings layer for discrete SOUNDEX++ encodings of each token in a sentence; **(ii) Adversarial Training (ADV.TRAIN):** To overcome the lack of access to $\{\mathcal{H}\}_0^K$, the defender extracts his/her perturbations in the wild from a separate corpus $\mathcal{D}^*$ where $\mathcal{D}^* \cap \mathcal{D} = \emptyset$ and uses them to augment the training examples–i.e., via self-attack with ratio 1:1, to fine-tune a more robust BERT model. We use $\mathcal{D}^*$ as a corpus of 34M general comments from online news. We compare the two defenses against BERT and BERT combined with 3 layers of normalization A+H+P. BERT is selected as it is better than RoBERTa at defending against ANTHRO (Table 4).

Results. Table 7 shows that both SOUNDCNN and ADV.TRAIN are robust against ANTHRO attack, while ADV.TRAIN performs best when defending ANTHRO$_\beta$. Since SOUNDCNN is strictly based on phonetic features, it is vulnerable against ANTHRO$_\beta$ whenever *TextBugger*'s perturbations are selected. Table 7 also underscores that ANTHRO$_\beta$ is a strong and practical attack, defense against which is thus an important future direction.

7 Discussion and Analysis

Evaluation with *Perspective API*. We evaluate if ANTHRO and ANTHRO$_\beta$ can successfully attack the popular *Perspective API* [2], which has been adopted in various publishers–e.g., NYTimes, and platforms–e.g., Disqus, Reddit, to detect toxicity. We evaluate on 200 toxic texts randomly sampled from the TC dataset. Figure 5 (Left) shows that the API provides superior performance compared to a self fine-tuned BERT classifier, yet its precision deteriorates quickly from 0.95 to only 0.9 and 0.82 when 25%–50% of a sentence are randomly perturbed using human-written perturbations. However, the ADV.TRAIN (Sec. 6) model achieves fairly consistent precision in the same setting. This shows that ANTHRO is not only a powerful and realistic attack, but also can help develop more robust text classifiers in practice. The API is also vulnerable against both direct (Alg. 1) and transfer ANTHRO attacks through an intermediate BERT classifier, with its precision dropped to only 0.12 when evaluated against ANTHRO$_\beta$.

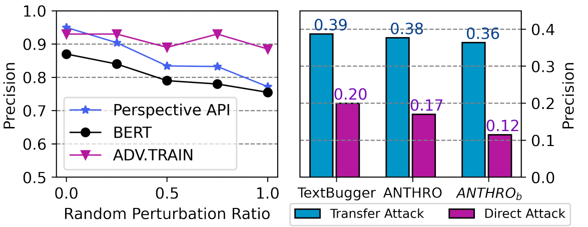

Figure 5: (Left) Precision on human-written perturbed texts synthesized by ANTHRO and (Right) Robustness evaluation of *Perspective API* under different attacks

Task	Sentiment Analysis	Categorization
ANTHRO	0.80	0.93
ANTHRO$_\beta$	0.86	1.00

Table 8: Averaged Atk% of ANTHRO and ANTHRO$_\beta$ in fooling Google Cloud[3]'s sentiment analysis API and text categorization API.

Generalization beyond Offensive Texts. Although ANTHRO extracts perturbations from abusive data, the majority of them are non-abusive texts. Thus, ANTHRO learns perturbations for non-abusive English words–e.g., hilarious->HiLarious, shot->sht. We also make no assumption on the task domains that ANTHRO can attack. Evidently, ANTHRO and ANTHRO$_\beta$ achieves 80%, 86% Atk% and 90%, 100% Atk% on fooling the sentiment analysis and text categorization API from Google Cloud (Table 8)

Computational Complexity. The **one-time** extraction of $\{\mathcal{H}\}_0^K$ via Eq. (1) has $\mathcal{O}(|\mathcal{D}|L)$

where $|\mathcal{D}|$, L is the # of tokens and the length of longest token in $\mathcal{D}$ (hash-map operations cost $\mathcal{O}(1)$). Given a word w and $\mathbf{k}, \mathbf{d}$, ANTHRO retrieves a list of perturbation candidates via Eq. (2) with $\mathcal{O}(|w|max(\mathcal{H}_k))$ where $|w|$ is the length of w and $max(\mathcal{H}_k)$ is the size of the largest set of tokens sharing the same SOUNDEX++ encoding in $\mathcal{H}_k$. Since $max(\mathcal{H}_k)$ is constant, the upper-bound then becomes $\mathcal{O}(|w|)$.

Limitation of Misspelling Correctors. Similar to other spell-checkers such as *pyspellchecker* and *symspell*, the SOTA NeuSpell depends on a fixed dictionary of common misspellings, or synthetic misspellings generated by random permutation of characters (Jayanthi et al., 2020). These checkers often assume perturbations are within an edit-distance threshold from the original words. This makes them exclusive since one can easily generate new perturbations by repeating a specific character–e.g., “porn"→“pooorn". Also, due to the iterative attack mechanism (Alg. 1) where each token in a sentence is replaced by many candidates until the correct label's prediction probability drops, ANTHRO only needs a single good perturbation that is not detected by NeuSpell for a successful replacement. Thus, by formulating perturbations by not only their spellings but also their sounds, ANTHRO is able to mine perturbations that can circumvent NeuSpell.

Limitation of ANTHRO. The perturbation candidate retrieval operation (Eq. (2)) has a higher computational complexity than that of other methods– i.e., $\mathcal{O}(|w|)$ v.s. $\mathcal{O}(1)$ where $|w|$ is the length of an input token w (Please refer to Sec. 7 in the Appendix for detailed computational complexity). This can prolong the running time, especially when attacking long documents. However, we can overcome this by storing all the perturbations (given $\mathbf{k}, \mathbf{d}$) of the top frequently used offensive and non-offensive English words. We can then expect the operation to have an average complexity close to $\mathcal{O}(1)$. The current SOUNDEX++ algorithm is designed for English texts and might not be applicable in other languages. Thus, we plan to extend ANTHRO to a multilingual setting.

8 Conclusion

We propose ANTHRO, a character-based attack algorithm that extracts human-written perturbations in the wild and then utilizes them for adversarial text generation. Our approach yields the best trade-off between attack performance, semantic preservation and stealthiness under both empirical experiments and human studies. A BERT classifier trained with examples augmented by ANTHRO can also better understand human-written texts.

Broad Impact

To the best of our knowledge, ANTHRO is the first work that extracts noisy human-written texts, or text perturbations, online. We further iterate what reviewer pvcD has observed: ANTHRO moves “away from deductively-derived attacks to data-driven inspired attacks". This novel direction is beneficial not only to the adversarial NLP community but also in other NLP tasks that require the understanding of realistic noisy user-generated texts online. Specifically, Sec. 6 and Figure 5 shows that our work enables the training of a BERT model that can understand noisy human-written texts better than the popular *Perspective API*. By extending this to other NLP tasks such as QA and NLI, our work hopes to enable current NLP software to perform well in real life settings, especially on social platforms where user-generated texts are not always in perfect English. Our work also opens a new direction in the use of languages online and how netizens utilize different forms of perturbations for avoiding censorship in this new age of AI.

Ethical Consideration

Similar to previous works in adversarial NLP literature, there are risks that our proposed approach may be unintentionally utilized by malicious actors to attack textual ML systems. To mitigate this, we will not publicly release the full perturbation dictionary that we have extracted and reported in the paper. Instead, we will provide access to our private API on a case-by-case basis with proper security measures. Moreover, we also suggest and discuss two potential approaches that can defend against our proposed attacks (Sec. 6). We believe that the benefits of our work overweight its potential risks. All public secondary datasets used in this paper were either open-sourced or released by the original authors.

Improving Chinese Grammatical Error Detection via Data augmentation by Conditional Error Generation

Abstract

Chinese Grammatical Error Detection(CGED) aims at detecting grammatical errors in Chinese texts. One of the main challenges for CGED is the lack of annotated data. To alleviate this problem, previous studies proposed various methods to automatically generate more training samples, which can be roughly categorized into rule-based methods and model-based methods. The rule-based methods construct erroneous sentences by directly introducing noises into original sentences. However, the introduced noises are usually context-independent, which are quite different from those made by humans. The model-based methods utilize generative models to imitate human errors. The generative model may bring too many changes to the original sentences and generate semantically ambiguous sentences, so it is difficult to detect grammatical errors in these generated sentences. In addition, generated sentences may be error-free and thus become noisy data. To handle these problems, we propose CNEG, a novel **C**onditional **N**on-Autoregressive **E**rror **G**eneration model for generating Chinese grammatical errors. Specifically, in order to generate a context-dependent error, we first mask a span in a correct text, then predict an erroneous span conditioned on both the masked text and the correct span. Furthermore, we filter out error-free spans by measuring their perplexities in the original sentences. Experimental results show that our proposed method achieves better performance than all compared data augmentation methods on the CGED-2018 and CGED-2020 benchmarks.

1 Introduction

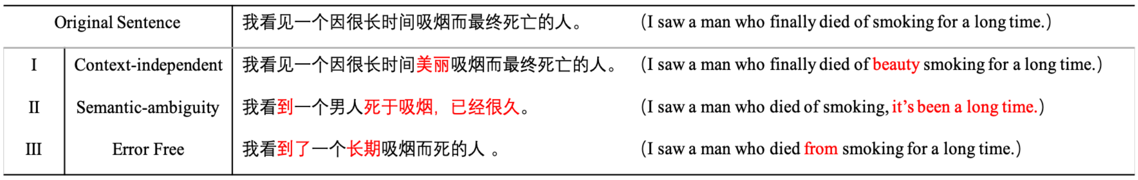
The goal of Grammatical Error Detection is to detect grammatical errors in texts (Rao et al., 2018). It is useful for many NLP applications such as writing assistant (Napoles et al., 2017), search engine (Gao et al., 2010), and speech recognition systems (Wang et al., 2020a), etc. Grammatical errors may appear in all languages (Dale et al., 2012; Bryant et al., 2019). In this paper, we only investigate the problem of Chinese Grammatical Error Detection (CGED).

我看过有一个因很长时间吸烟而终于死亡的人。 I have seen a person who finally died after smoking for a long time.
我看见一个因很长时间吸烟而最终死亡的人。 I saw a man who finally died of smoking for a long time.

Figure 1: An error-correction pair from CGED datasets. The first line is an erroneous sentence, tokens marked in blue color are selection errors, tokens marked in green color are redundant words. The second line is the corrected sentence.

Grammatical Error Detection is usually formulated as a sequence tagging task, where each erroneous token is assigned with an error type, e.g., selection errors and redundant words, as shown in Figure 1. Since annotating grammatical errors requires rich linguistic knowledge, it is expensive and time-consuming to annotate a large-scale corpus. Therefore, the scarcity of labeled data is one of the main challenges for this task. To handle this problem, previous works proposed various data augmentation methods to automatically generate more training samples (Kiyono et al., 2019; Wang et al., 2019; Lichtarge et al., 2019; Kasewa et al., 2018). The methods of generating erroneous sentences can be roughly categorized into the following two types: (1) **Rule-based methods**. These methods construct erroneous sentences by introducing noises into original texts, e.g., inserting, deleting, or replacing some words (Zhao et al., 2019; Wang et al., 2019). As the erroneous sentence shown in Figure 1, human grammatical errors are usually context dependent. On the contrary, the randomly introduced errors are context-independent (case I in Figure 2), therefore these noise-corrupted sentences are quite different from the erroneous sentences made by humans. (2) **Model-based methods**. In order to imitate human errors, many studies utilize neu-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2966 - 2975
May 22-27, 2022



Original Sentence		我看见一个因很长时间吸烟而最终死亡的人。	(I saw a man who finally died of smoking for a long time.)
I	Context-independent	我看见一个因很长时间美丽吸烟而最终死亡的人。	(I saw a man who finally died of beauty smoking for a long time.)
II	Semantic-ambiguity	我看到一个男人死于吸烟，已经很久。	(I saw a man who died of smoking, it's been a long time.)
III	Error Free	我看到了一个长期吸烟而死的人 。	(I saw a man who died from smoking for a long time.)

Figure 2: Illustration for some examples generated by various data augmentation methods. Tokens marked in red are the modifications against the original sentence. Example I is constructed by the rule-based method, and the introduced error is meaningless to the original sentence. It is too easy for the detection model to detect such error. Example II is constructed by the model-based method, which is quite different from the original sentence. It is difficult to judge which tokens are grammatical errors when comparing the generated sentence with the original sentence. Example III is also different from the original sentence, but it does not contain any grammatical errors.

ral generative models to generate grammatical errors, such as Seq2Seq models (Kasewa et al., 2018; Wan et al., 2020), and translation models which obtain erroneous sentences via round-trip translation through a bridge language (Zhou et al., 2020; Lichtarge et al., 2019). However, considering that the outputs of generative models are not usually faithful to the inputs (Weng et al., 2020), semantic and syntactic ambiguities may arise when the generative models bring too many changes to the original sentences (case II in Figure 2). Even human can not infer the correct sentences from these generated sentences, so it is also difficult for the detection model to automatically detect grammatical errors. Meanwhile, generated sentences may be error-free and become noisy data (case III in Figure 2). Therefore, these constructed samples have little contributions to improving the performance of detection models.

To handle the aforementioned problems, we propose CNEG, a novel **C**onditional **N**on-Autoregressive **E**rror **G**eneration (CNEG) model for generating Chinese grammatical errors. Figure 3 illustrates the architecture of the model. Specifically, to predict a context-dependent error, we first mask a span of a correct text, and utilize BERT (Devlin et al., 2019) to conduct non-autoregressive span prediction. In order to ensure that the generated sentence will be faithful to the original sentence, we force the model to generate span conditioned on the original span. Considering that the correct information is integrated into the model, we further introduce a penalty to encourage the model not to directly reconstruct the correct span. Our CNEG model is based on BERT, which is pre-trained on a large scale of Chinese corpus. Therefore, the model can generate errors that do not appear in the training dataset. Finally, in order to filter out the error-free spans, we also utilize a pre-trained BERT to measure the perplexities of generated spans.

The main contributions of this paper can be summarized as follows:

- We propose a new data augmentation method (CNEG) to tackle the data scarcity of CGED. We utilize BERT encoder with a non-autoregressive decoding layer as the backbone of our generative model to generate context-dependent errors.

- We incorporate the original span into our generative model, which enables the model to predict the erroneous span conditioned on the original span. And we introduce a filtering strategy to filter out error-free spans.

- Experimental results on the CGED datasets show that our method outperforms all previous methods, which demonstrates the effectiveness of our method. We release the source code for further use by the community[1].

2 Related Work

Chinese Grammatical Error Detection (CGED) aims at detecting grammatical errors in Chinese sentences (Rao et al., 2018). Most studies regard it as a sequence tagging task, where each token will be given a correct label or an error-type. Sequence labeling methods are widely used for CGED, such as feature-based statistical models (Chang et al., 2012), and neural models (Fu et al., 2018). Due to the effectiveness of BERT(Devlin et al., 2019) in many other NLP applications, recent studies adopt BERT as the basic architecture of CGED models (Fang et al., 2020; Wang et al., 2020b; Li and Shi, 2021). Wang et al. (2020b) propose a model that

---

[1] `https://github.com/tc-yue/DA_CGED`

combines ResNet and BERT to achieve state-of-the-art results on the CGED-2020 task. Li and Shi (2021) apply a CRF layer on BERT to introduce the dependency of tokens.

However, neural models usually require a large amount of training data, and manually annotating a large corpus is expensive and time-consuming. Therefore, many studies focus on data augmentation methods to automatically generate large-scale training samples to boost the performance of grammatical error detection models (Kiyono et al., 2019; Wang et al., 2019; Lichtarge et al., 2019; Kasewa et al., 2018). Kiyono et al. (2019) investigated different strategies of the incorporation of pseudo data, including the method of generating the pseudo data, the seed corpus for augmentation, and training strategies with these augmented samples. Wang et al. (2019) proposed a rule-based editing method that constructs the noise-corrupted text. Instead of directly adding noise into the sentence, Wan et al. (2020) introduce noise to the representation of a sentence and apply the Seq2Seq model to generate sentences with various error types. Lichtarge et al. (2019) use an intermediate language as a bridge to generate grammatical error samples. Zhou et al. (2020) consider that Neural Machine Translation (NMT) model is significantly better than the Statistical Machine Translation (SMT) model, then utilize NMT model and SMT model to generate correct and erroneous sentences respectively. Moreover, Wang and Zheng (2020) firstly identify the most vulnerable tokens by a seq2seq model, then replace these tokens with the grammatical errors which are collected from the training dataset.

3 Methodology

3.1 Problem Formulation

Our goal is to generate high-quality grammatical errors to improve the performance of CGED models. Given a sample $S = (E, C, Y)$ from CGED training dataset, where $E = [e_1, e_2, ..., e_m]$ is an erroneous sentence of m tokens. Each token e_i is assigned with a label $y_i \in \{0, ..., d\}$, where d is the number of error types and 0 represents non-error. $C = [c_1, c_2, ..., c_n]$ is the corresponding corrected text of n tokens. The goal of data augmentation method is to generate erroneous sentences based on the correct sentence C and the erroneous sentence E. And the goal of grammatical error detection model is to predict the label y_i of each token e_i.

In the following subsections, we first present the

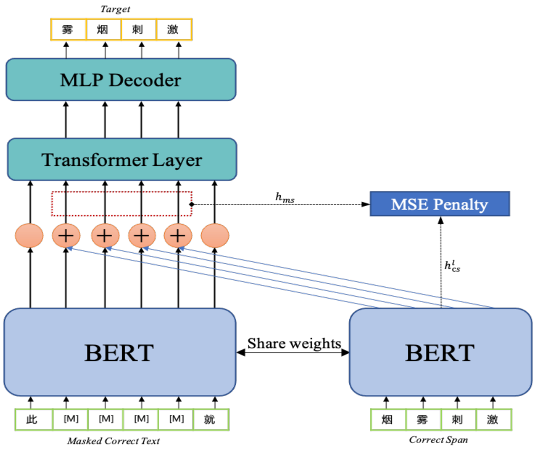


Figure 3: The architecture of our CNEG model.

architecture of our generative model, as described in §3.2, then introduce the method of constructing erroneous sentences with the trained model, as described in §3.3.

3.2 CNEG Model

Figure 3 illustrates the architecture of the proposed CNEG model. To imitate human errors, our model first masks a span in a correct text, then predicts the erroneous span conditioned on the masked context and the correct span. In this subsection, we first describe the training samples for the generative model, then present the architecture of the model, finally introduce the learning objectives.

Training Samples Construction Given an erroneous sentence and its corresponding correct sentence, we collect the erroneous spans and their corresponding correct spans. Then we sample an erroneous span E_{span} of n_e tokens, and its corresponding correct span C_{span} of n_c tokens. As shown in Figure 3, the target of the model is the erroneous span, and the inputs of the model are the correct span and the masked correct text. To get the masked correct text C_{masked}, we replace the correct span C_{span} in the correct text C with a masked span M_{span} consisting of n_m `[MASK]` tokens, where $n_m \geq n_e$ and $n_m \geq n_c$. Since the erroneous span E_{span} and the correct span C_{span} may be not aligned in token level (e.g. $E_{span} =$ "而于", $C_{span} =$ "而终于"), the model can hardly learn the token-level mappings of those span. To handle this problem, we propose a strategy to align them. Assuming $n_m = 4$:

1. When $n_e = n_c$ (e.g. $E_{span} =$ "死去的", $C_{span} =$ "死亡的"), we pad one special token

`[U]` to the tail of C_{span} and the tail of E_{span} separately:

$$E_{span} = [\text{死}, \text{去}, \text{的}, \texttt{[U]}]$$

$$C_{span} = [\text{死}, \text{亡}, \text{的}, \texttt{[U]}]$$

2. When $n_e > n_c$ (e.g. E_{span} = "终于了", C_{span} = "终于"), which means that some tokens can be added to the tail of correct span, we pad two `[U]` tokens to the tail of C_{span} and one `[U]` token to the tail of E_{span}:

$$E_{span} = [\text{终}, \text{于}, \text{了}, \texttt{[U]}]$$

$$C_{span} = [\text{终}, \text{于}, \texttt{[U]}, \texttt{[U]}]$$

3. When $n_e < n_c$ (e.g. E_{span} = "而于", C_{span} = "而终于"), which means that some tokens can be deleted from C_{span}. Then, we insert one `[U]` into the missing position of E_{span}, and pad one `[U]` to each span:

$$E_{span} = [\text{而}, \texttt{[U]}, \text{于}, \texttt{[U]}]$$

$$C_{span} = [\text{而}, \text{终}, \text{于}, \texttt{[U]}]$$

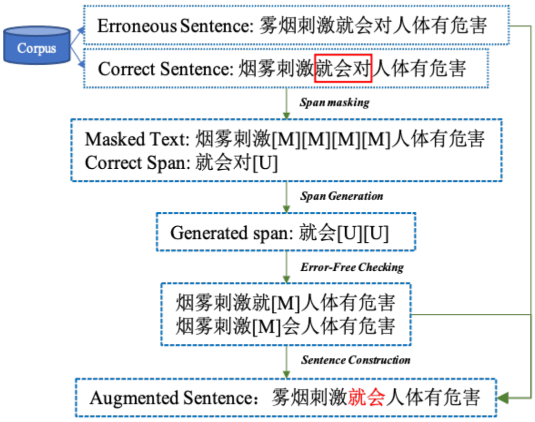
where `[U]` is a placeholder which means no character in the position.

Conditional Context Representation Our architecture adopts BERT (Devlin et al., 2019) as the basic encoding model, which is initialized with a pre-trained Chinese BERT (Cui et al., 2019) to make full use of linguistic information from large-scale Chinese texts. BERT is constructed with a stacked layer structure, which has deep bidirectional representations by learning information from left to right and from right to left.

To predict the erroneous span conditioned on the original context, we use BERT to encode the masked correct text C_{masked} to obtain contextual representations of the masked span M_{span}, denoted as $\mathbf{h^l_{ms}}$, where l is the number of BERT layers. Previous masked language model applies an MLP decoder on this vector to conduct non-autoregressive prediction. However, the predicted sequence may be quite different from the original span.

To alleviate this problem, we propose a conditional component to incorporate the correct span. Specifically, we apply the same BERT to encode the correct span C_{span} and get corresponding hidden vectors, denoted as $\mathbf{h^l_{cs}}$. Then we add this vector to the representation of the masked span:

$$h_{ms} = h^l_{ms} + h^l_{cs} \tag{1}$$



Erroneous Sentence: 雾烟刺激就会对人体有危害

Correct Sentence: 烟雾刺激就会对人体有危害

Masked Text: 烟雾刺激[M][M][M][M]人体有危害

Correct Span: 就会对[U]

Generated span: 就会[U][U]

烟雾刺激就[M]人体有危害

烟雾刺激[M]会人体有危害

Augmented Sentence: 雾烟刺激就会人体有危害

Figure 4: Data flow of the erroneous sentence construction. Token [U] in correct span is padding tokens to make the length of the correct span equal to that of the masked span.

As show in the left part of Figure 3, we further apply a transformer layer on the new representation, therefore the masked span representation $\mathbf{h^{l+1}_{ms}}$ is conditioned on both the context C_{masked} and the correct span C_{span}. Finally, we apply a MLP layer and a softmax layer to transform the vector $\mathbf{h^{l+1}_{ms}}$ to the generative probability p, it is defined as:

$$p = softmax(Wh^{l+1}_{ms} + b) \tag{2}$$

We adopt cross entropy loss as the objective function:

$$L_{MLM} = -\sum_{i=1}^{n_m}\sum_{j=1}^{c} log y^i_j log p^i_j \tag{3}$$

where c is the size of vocabulary and n_m is the length of masked span.

MSE Penalty As we integrate the original span into the model by Eq.1, the model will tend to directly reconstruct the correct span when $\mathbf{h_{ms}}$ and $\mathbf{h^l_{cs}}$ are too similar. To lead the model not to pay all attention to the correct span, we add a penalty to force $\mathbf{h_{ms}}$ to be different from $\mathbf{h^l_{cs}}$ by maximizing the distance between two vectors:

$$L_{MSE} = -MSE(h_{ms}, h^l_{cs}) \tag{4}$$

where MSE means the mean squared error loss function. Then the final loss of the model is:

$$Loss = \lambda \cdot L_{MSE} + L_{MLM} \tag{5}$$

where λ is a hyperparameter.

Algorithm 1 Erroneous sentence construction

```
Input:
  $f$: CNEG model
  $C$: a correct text of $n$ tokens
  $E$: an erroneous text
  $T$: a threshold to filter error-free span
  $M_{span}$: a span of [MASK] tokens
Output:
  $A$: augmented dataset
 1: Set length of masked correct span as $n_c$;
 2: Initialize an empty mapping $M$={}
 3: for $i \in [0, n - n_q]$ do
 4:     Get a correct span $C_{span} = C[i : i + n_c]$
 5:     Form a masked text $C_{masked} = C[: i] + M_{span} + C[i + n_c :]$
 6:     Predict $G_{span} = f(C_{masked}, C_{span})$
 7:     Add $(C_{span}, G_{span})$ into mapping $M$
 8: for $C_{span}, G_{span} \in M$ do
 9:     if $PPL(G_{span}) < T$ or $PPL(G_{span}) < PPL(C_{span})$ then
10:         continue
11:     if $C_{span} \in E$ then
12:         Replace $C_{span}$ in $E$ with $G_{span}$ and form a synthetic sentence $S$
13:         Get the label sequence $Y$ of $S$
14:         Add $(S, Y)$ to A
15: return A
```

3.3 Erroneous Sentence Construction

In this subsection, we describe our method of constructing erroneous sentences. As the example shown in Figure 4, we first mask a span in the correct text and generate a span with the trained model, then check if the span contain grammatical errors, finally we use the erroneous span to construct the erroneous sentence.

Erroneous Span Generation In this step, we utilize the trained model to generate grammatically erroneous spans for a correct text. Specifically, given an erroneous text and its corrected text, we first initial an empty correction-to-error mapping M, and mask a span within the correct text, then feed the correct span C_{span} and the masked correct text C_{masked} to the CNEG model to generate a span G_{span}, finally add the C_{span} and G_{span} pair to the mapping. Since the span masking can be conducted like a sliding window, we will get a correction-to-error mapping for each correct text (lines 3-7 in Algorithm 1).

Error-free Span Filtering Although our CNEG model takes the erroneous spans as the predicting targets, we cannot ensure that each generated span will contain at least one grammatical error. If we assign error-types to error-free spans, they will become noises for the detection model later. Therefore, it is necessary to filter out the error-free spans. Mita et al. (2020) compare the perplexities of generated sentences and correct sentences to determine whether the generated sentences are grammatically correct. However, since the sentence-level perplexity is affected by too many tokens, the sentence with larger perplexity may also be grammatically correct. To address this issue, we introduce a method that uses span-level perplexity to identify whether the generated span is erroneous (lines 9-10 in Algorithm 1). To calculate $PPL(G_{span})$, we replace the masked span M_{span} in the masked correct text C_{masked} with the generated span G_{span}, and mask the word w_i of the generated span one by one, then utilize pre-trained BERT to predict the probability $P(w_i)$ of the masked word w_i :

$$P(w_i) = P(w_i | w_1, ..., w_{i-1}, w_{i+1}, ..., w_N) \quad (6)$$

We calculate the perplexity of the generated span $PPL(G_{span})$ by the following equation:

$$PPL(G_{span}) = exp\{-\frac{1}{N}\sum_{i=1}^{N} P(w_i)\} \quad (7)$$

Where N is the length of the generated span. We use the same method to calculate the perplexity of the correct span $PPL(C_{span})$. Then we can filter out the generated span whose perplexity is smaller than corresponding $PPL(C_{span})$ and smaller than a threshold T, where T is a hyper-parameter. Finally, we will obtain a high-quality correction-to-error mapping for a correct text.

Synthetic Sentence Construction After obtaining the erroneous span, we can construct a training sample for CGED (lines 11-14 in Algorithm 1). Specifically, given an erroneous sentence E from training dataset, we select a generated span G_{span} and a corresponding correct span C_{span} from the mapping. If the erroneous sentence E contains the correct span C_{span}, we will replace the correct span C_{span} with the generated span G_{span} to form a synthetic sentence S. Then we use a rule-based method to automatically annotate the synthetic sentence S to obtain a label sequence Y. Finally, we add the sample (S, Y) to the augmented dataset.

Dataset	S	C	E	E_{span}
Train	21582	41	21541	53940
Validation	3154	1174	1980	4871
Test-2018	3546	1562	1984	5040
Test-2020	1457	307	1150	3660

Table 1: Distribution of datasets. S, C, E and E_{span} denote the amount of sentences, the amount of correct sentences, the amount of erroneous sentences and the amount of erroneous spans, respectively. Test-2018 and Test-2020 denote the test dataset of CGED-2018 and the test dataset of CGED-2020, respectively.

4 Experimental setup

4.1 Datasets

We conduct experiments on public datasets from CGED tasks (Lee et al., 2016; Rao et al., 2017, 2018, 2020), which contain thousands of Chinese text written by foreign language learners. Following the work of (Wang et al., 2020b), we select 2016, 2017, 2018 and 2020 training dataset as our training dataset.

CNEG Model We use error-correction sentence-pairs from the training dataset to train the generative model. Then we use the trained model to construct erroneous sentences by the same dataset.

CGED Model Each data augmentation method will generate some samples, we combine them with the training dataset to form a new dataset, which can be used for training the detection model later. For evaluating the performance of CGED model, we use the test dataset from CGED-2017 for validation, use the test dataset from CGED-2018 and the test dataset from CGED-2020 for testing separately. The statistics of datasets are given in Table 1.

4.2 Evaluation Metrics

We adopt the same evaluation method as used in (Rao et al., 2018). It includes three levels:

- **Detection level**. This level is to detect whether a sentence contains error, and can be considered as a binary-classification of a sentence.

- **Identification level**. This level is to identify all error-types of a sentence, and can be considered as a multi-label classification of a sentence.

- **Position level**. This level is to locate the erroneous words and identify their corresponding error types. However, there is no explicit word boundary in Chinese text, we measure this score on Chinese character-level in our experiment.

We use F1-score to measure each level.

4.3 Implementation Details

CNEG Model: The BERT encoder of our generative model is initialized with a Chinese BERT (Cui et al., 2019), which is also used for measuring the perplexities of generated spans later. We use the Adam optimizer with an initial learning rate of $5e^{-5}$ and train the generative model for 10 epochs. The λ in Eq. 5 is set to 0.5, and the threshold T in Algorithm 1 is set to 2.
CGED Model: We evaluate various data augmentation methods by training the BERT-based sequence labeling models on the augmented datasets. To predict the label of each token, we apply a fully-connected layer to perform token classification based on the representation of the last transformer layer, and the hidden size of the classification layer is 768. For all experiments, we use the Adam optimizer with an initial learning rate of $7e^{-5}$. All experiments are conducted for 5 runs and the averaged score is reported.

4.4 Compared Methods

We compare our augmentation method with several baseline methods.
Raw is the original training dataset without any other augmented samples.
DirectNoise (Wang et al., 2019) is an editing based method that introduces noise into a text by inserting, deleting or replace some words.
Seq2seq (Kasewa et al., 2018) takes the corrected sentences as the inputs and the erroneous sentences as the predicting targets of the model.
BackTranslation (Lichtarge et al., 2019) first translates the original sentence into a bridge language, the translated sentence will be translated back into the source language. In this experiment, we select English as the bridge language .
ADV (Wang and Zheng, 2020) is an adversarial method that constructs adversarial examples by targeting the weak spots of the models and replacing these weak tokens by correction-to-error mapping.
CNEG is our proposed augmentation method that first generates context-dependent erroneous spans, and constructs erroneous sentences.
CNEG w/o Filter is a variation of our method that constructs erroneous sentence without error-free span filtering strategy, as proposed in §3.3.

Method	CGED-2018			CGED-2020		
	D-F	I-F	P-F	D-F	I-F	P-F
Raw	80.66	64.93	49.77	87.39	60.27	32.78
DirectNoise	79.20	63.06	48.02	88.91	59.11	31.37
Seq2Seq	79.81	63.26	49.49	86.76	58.29	31.40
BackTranslation	80.20	64.01	48.81	87.03	59.89	31.92
ADV	80.71	64.79	50.10	87.11	60.20	32.81
CNEG (ours)	**80.9**	**66.88**	**52.26**	**88.12**	**62.00**	**33.99**
CNEG w/o Filter (ours)	80.47	66.37	51.92	87.03	59.16	33.14

Table 2: Main results on the CGED datasets. The best results are **in bold**. CGED-2018 denotes the test dataset of CGED-2018. CGED-2020 denotes the test dataset of CGED-2020. D-F denotes the F-score of detection-level. I-F denotes the F-score of identification level. P-F denotes the F-score of Position-level.

5 Experimental Results

5.1 Main Results

The experimental results on the CGED datasets are shown in Table 2. Our observations are as follows:

Whole-sentence generation methods degrade the performance on both of the test datasets. *Seq2Seq* and *BackTranslation* get worse results than *Raw* dataset because they treat the erroneous sentence generation as a whole sentence generation task, which is not controllable. By comparing our *CNEG w/o Filter* with *Seq2Seq*, we observe that span-generation method improves about 2.3% on the position-level of CGED-2018, and 1.7% on the position-level of CGED-2020.

Context-dependent errors are beneficial. Although *DirectNoise* shows effectiveness in some previous studies, it has no effect on the CGED dataset because the randomly introduced errors are context-independent, which are too easy for the detection model to detect such errors. Among the compared methods, *ADV* performs the best because it constructs errors considering about the contextual information. Even without filtering strategy, *CNEG w/o Filter* outperforms *ADV* by a large margin because it can generate more diversified errors, improving position-level F-score by 2.2% and 1.1% on the two test datasets.

Error-free filtering is necessary. We observe that *CNEG* further improves *CNEG-filter* by 0.6% on the position-level of CGED-2020. Without filtering strategy, the performance on detection-level shows significant decline. The reason is that the noisy augmented data can hurt the model performance. This result demonstrates the effectiveness of filtering out error-free span.

Method	**D-F**	**I-F**	**P-F**
CNEG (ours)	80.9	**66.88**	**52.26**
CNEG w/o Con	79.59	66.03	51.31
CNEG w/o Pen	**81.32**	65.83	51.86

Table 3: Ablation results on the CGED-2018.

Method	**Sentence**
Correct	烟雾刺激就会对人体有危害。
CNEG (ours)	雾烟刺激就会人体有危害。
CNEG w/o Con	雾烟刺激真的是对人体有危害。
CNEG w/o Pen	雾烟刺激就会对人体有危害。

Table 4: Examples generated by the models. The masked correct span are marked in green. The generated spans are marked in red. Errors from the original erroneous sentence are marked in blue.

5.2 Effects of Components of Generative Model

For further analyzing the effectiveness of the components of our proposed model, we also conduct ablation experiments as follows:

CNEG w/o Con is a variation of our model that predicts error not conditioned on the original span, which is described in §3.2.

CNEG w/o Pen is a variation of our method that trains generation model without the MSE penalty , which is described in §3.2.

Results are shown in Table 3. Experimental results show that *CNEG* significantly performs better than *CNEG w/o Con* and *CNEG w/o Penalty*. We also present several generated sentences in Table 4. *CNEG w/o Con* generates a grammatical error, which is quite different from the original span and should be corrected to "真的对", and we should assign a *redundant* label to the token "是". However, when comparing the generated span with the

Method	D-F	I-F	P-F
PSE	80.2	64.98	50.21
GME	**81.2**	65.62	50.94
PME	80.9	**66.88**	**52.26**

Table 5: Results of different sentence construction methods on CGED-2018.

original span, *selection-error* labels are automatically assigned to the tokens in the generated span, which will confuse the detection model. *CNEG w/o Pen* directly reconstructs the original span, which is useless for data augmentation. Our methods generates a grammatical error by missing an important token in the original span, which is beneficial for the detection model. These results demonstrate the effectiveness of our proposed components.

5.3 Effects of Multi-Error Sentences

Our augmentation method masks a span in a correct sentence and then predicts an erroneous span. To construct an erroneous sentence, the direct method is to replace the masked span with the predicted span, then the synthetic sentence will contain an erroneous span, we call this method *PSE* (Plug-in Single-Error). However, each sentence in CGED dataset contains over two errors on average, as shown in the Table 1. To make the synthetic sentences be consistent with multi-error sentences, we develop two multi-error sentences construction strategies. First, as described in §3.3, we locate the correct span in the corresponding erroneous sentence and replace it with the erroneous span. The synthetic sentence will contain original errors and a generated error, we call this method *PME* (Plug-in Multi-Error). Second, we mask a correct span in an erroneous sentence, and utilize the model to predict an erroneous span. Then the new sentence will contain the original errors and a generated error, we call this method *GME*(Generated Multi-error). To figure it out which is the better choice, we conduct experiments on the datasets augmented by those methods. We report the results in Table 5. We observe that the *PSE* gets the worst performance. The reason is that single-error is too easy for the detecting model. *PME* outperforms *GME*, the reason may be that *GME* can not predict beneficial spans with the noisy context. Therefore, we can conclude that inserting the erroneous span into the original erroneous sentence is the most effective method.

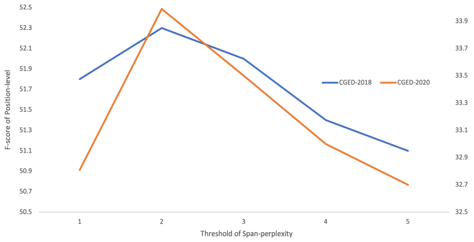


Figure 5: Performance of data augmentation with different filter threshold. The left axes is for CGED-2018, the right axes is for CGED-2020.

	Sentence
(a)	从小就是(形象)形影不离的一对。
(b)	从小就是(内容)形影不离的一对。
(c)	第二天(变)天气变得很好。
(d)	第二天(给)天气变得很好。

Table 6: Constructed examples. (a) and (c) are generated by our model. (b) and (d) are generated by direct noise method. Errors are marked in red.

5.4 Effects of Different Threshold For Filtering Strategy

Results on Table 2 show that with the help of filtering strategy, *CNEG* can further improve by 1% over *CNEG w/o filter*. In this subsection, to further evaluate the effectiveness of our filtering strategy, we set different filtering thresholds to construct several augmentation datasets, then train detection models with these datasets. The evaluation results are show in Figure 5.

We can observe that when threshold is around 2, the method achieves the best performance on both the CGED-2018 and CGED-2020. When the threshold is lower than 2, the performances of detection model decrease significantly. The reason is that there are many error-free spans whose perplexities are lower than 2, when these error-free spans are added into the training dataset, the detection model will be confused. When the threshold is higher than 4, the methods also achieve worse performance. The reason is that most generated errors are filtered out, the reserved erroneous spans are too limited for boosting the performance of detection models.

5.5 Case Study

As we demonstrated, our model can better imitate human grammatical errors. In Table 6, we list some augmented examples. The first two sentences are selection errors, sentence (a) replaces

"形影" with a near-synonym "形象", sentence (b) replaces "形影" with a random noun "内容". The last two sentences are redundant errors, sentence (c) inserts "变" in front of "天气" where "变天气" is a phrase but not correct for here, sentence (d) inserts a random verb “给” in front of "天气" to generate a obviously redundant error. Unlike human who usually makes context-dependent errors, the direct noise method always introduces random errors, while our model generates highly context-dependent errors. Hence, our method can generate high quality and diverse errors which could not constructed by direct noise method.

6 Conclusions

In this paper, considering that grammatical errors made by humans are usually context-dependent, we propose a conditional non-autoregressive error generation method (**CNEG**) for data augmentation of CGED. By introducing the correct span into the non-autoregressive model, the model will generate errors conditioned on both the context and the correct span. Observing that the model may generate correct spans, a filtering strategy is proposed to filter out error-free spans. Experimental results show that our method outperforms all compared data augmentation methods on the CGED datasets, which demonstrates the effectiveness of our method.

Abstract

Recent research has made impressive progress in large-scale multimodal pre-training. In the context of the rapid growth of model size, it is necessary to seek efficient and flexible methods other than finetuning. In this paper, we propose to use prompt vectors to align the modalities. Our method achieves comparable performance to several other multimodal fusion methods in low-resource settings. We further show that our method is modular and parameter-efficient for processing tasks involving two or more data modalities.

1 Introduction

The success of large-scale pretrained language models (PLMs; Devlin et al. (2019); Yang et al. (2019); Brown et al. (2020); Raffel et al. (2020)) and image encoders (Dosovitskiy et al., 2021; Liu et al., 2021b) has stimulated a surge of pretrained *multimodal models* (Lu et al., 2019; Tan and Bansal, 2019; Radford et al., 2021; Lin et al., 2021) that align text with data in other modalities.

The fast-growing number of parameters in the pretrained models encourages researchers to create more data- and parameter-efficient methods than finetuning (Houlsby et al., 2019; Zhao et al., 2020; Zaken et al., 2021; Li and Liang, 2021; He et al., 2022). Recently, prompting – concatenating manually designed prompt phrases (Schick and Schütze, 2021; Tam et al., 2021; Le Scao and Rush, 2021; Zhao and Schütze, 2021) or trained embedding vectors (Li and Liang, 2021; Lester et al., 2021) to the text input of PLMs – has become an important research direction.

Following this trend, Tsimpoukelli et al. (2021) introduce *Frozen*, successfully extending PLMs into few-shot learners (i.e., models that perform well with only a handful of data) for multimodal tasks, by pretraining a vision encoder whose outputs are prompts fed to the PLM. Frozen performs strongly on low-resource visual question answering through GPT3-style (Brown et al., 2020) priming (in-context learning). Frozen consists of two components: A vision encoder (VE) (in their case, NF-ResNet-50 (Brock et al., 2021)) and an off-the-shelf PLM like GPT3. When pretraining Frozen, the PLM takes the image representations extracted by VE as prompts, to generate captions describing the input image. PLM parameters are *fixed* and VE is pretrained from scratch. The success of Frozen shows the potential of prompting-based systems for solving multimodal tasks (Zhou et al., 2021; Yang et al., 2021; Salaberria et al., 2021).

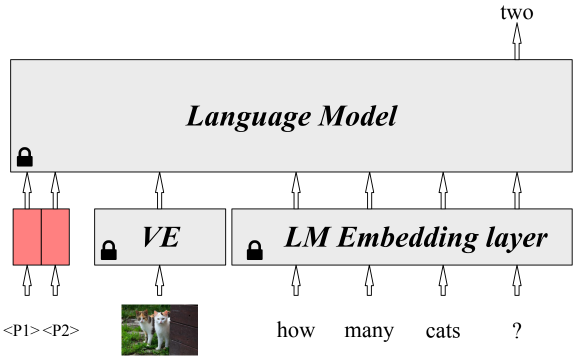

Figure 1: Model architecture. We disentangle VE's functionality by introducing prompt vectors. The only work of VE is to extract image representations. PLM and VE are fixed (grey) during training; two prompt vectors are the only trainable parameters (red).

One inherent discrepancy between Frozen and prompting for NLP tasks (Li and Liang, 2021; Lester et al., 2021) is that the prompt vectors in Frozen represent part of the input, the image: They are image features extracted by VE. In contrast, prompt vectors in NLP are agnostic to the input texts: They are trainable parameters of the PLM embedding layer to be optimized during training. Recall that the PLM in Frozen is fixed when pretraining VE. This implies that VE's trainable parameters serve two quite distinct purposes: (i) ex-

Findings of the Association for Computational Linguistics: ACL 2022, pages 2976 - 2985
May 22-27, 2022 ©2022 Association for Computational Linguistics

tract high quality image representations; (ii) align the image and text representation spaces.

We investigate the efficacy of *disentangling* the functionality of VE. Concretely, we fix the parameters of PLM and VE, and allocate extra free parameters for learning the alignment between spaces of different modalities when conducting a multimodal task; this is achieved by introducing additional prompt vectors. As a result, VE can dedicate itself to extract high quality image representations. We hypothesize that disentanglement has two benefits. First, *higher modularity* is achieved compared to Frozen because VE is freed from the objective of aligning modalities. Higher modularity brings higher flexibility, which is not applicable in systems like Frozen: We can easily change the type of VE, e.g., replacing a CNN with a Transformer; adding extra modalities like speech data is made possible as well. Our architecture meets the desideratum stated by Srivastava et al. (2014): It should be possible to modularly add modalities to an existing multimodal system. Second, higher *parameter efficiency* is achieved by fixing the encoders of different modalities during training; the prompt vectors are the only module to be trained for aligning the representation spaces.

We present **PromptFuse**, a prompting-based approach extending PLMs to multimodal tasks in a modular and efficient manner. Our contributions: (i) We show that the prompting paradigm of utilizing PLMs (Liu et al., 2021a) effectively strengthens PLMs with the ability of processing data in modalities besides text. With only ≈15K trainable parameters, PromptFuse performs comparably to several multimodal fusion methods in low-resource regimes. (ii) We further propose **BlindPrompt**, which enforces that the prompt vectors solely focus on task-specific information and is therefore less prone to overfitting.

2 Related Work

Prompting is a more data- and parameter-efficient method of using pretrained language models (PLMs; Devlin et al. (2019); Yang et al. (2019); Brown et al. (2020); Raffel et al. (2020)) than finetuning (Devlin et al., 2019). Concretely, Brown et al. (2020), Schick and Schütze (2021), Tam et al. (2021), Le Scao and Rush (2021), and Gao et al. (2021) show that prompting outperforms finetuning in many NLP tasks when annotations are limited, i.e., in *few-shot learning*. Li and Liang (2021) introduce prefix-tuning, only updating the prompt vectors, keeping the PLM fixed. Lester et al. (2021) introduce prompt-tuning – a simple form of prefix-tuning – achieving performance comparable to finetuning when scaling up the number of parameters in PLMs. As large PLMs remain unchanged during prefix- and prompt-tuning, high parameter-efficiency is achieved.

Multimodal pretraining. The success of PLMs and pretrained image encoders (Dosovitskiy et al., 2021; Liu et al., 2021b) encourage fast developments of multimodal pretraining, e.g., large-scale neural networks that align texts with data in other modalities like image (Tan and Bansal, 2019; Su et al., 2019; Cho et al., 2021; Wang et al., 2021; Kim et al., 2021), video (Sun et al., 2019) and speech (Bapna et al., 2021).

Prompting methods for multimodal models were recently devised. Zhou et al. (2021) learn continuous prompt vectors rather than natural language descriptions to model visual concepts. Yao et al. (2021) mark image regions as prompts, adapting pretrained vision-language models to downstream tasks. In Frozen, for a fixed PLM, Tsimpoukelli et al. (2021) pretrain a VE with image captioning where image representations from the VE are used as prompt vectors. The VE in Frozen needs to achieve two objectives: Extracting high quality image representations and properly aligning image/text spaces. In this work, we show that disentangling the two functionalities – instead of pretraining a VE like Frozen, we utilize pretrained VE as feature extractor and train prompt vectors to fuse the modalities – results in a more modular and efficient multimodal system.

3 Prompting as Multimodal Fusing

We propose to decompose the functionality of VE in Frozen into: (i) providing high quality image representations to the PLM; (ii) aligning the image and text spaces for a multimodal task. Achieving (i) is straightforward – we leverage off-the-shelf pretrained image encoders, e.g., Vision Transformer (ViT; Dosovitskiy et al. (2021)). We align the two representation spaces by prompt-tuning (Li and Liang, 2021; Lester et al., 2021), i.e., by introducing prompt vectors. Concretely, we randomly initialize N trainable vectors in the embedding layer of PLM. When processing downstream multimodal tasks, we *finetune the prompt vectors but fix PLM and VE*. Figure 1 illustrates our model. We call

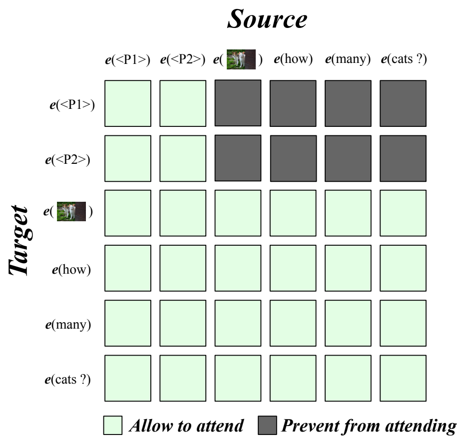

Figure 2: BlindPrompt attention mask in PLM encoder. Prompt vectors cannot attend to the input content, so their parameters solely serve to align the modalities.

our method **PromptFuse**. Having very few trainable parameters, PromptFuse is well suited for low-resource regimes.

We design a special attention mask for the PLM encoder, shown in Figure 2. While the attention of input data remains fully visible, we enforce prompt vectors to only access each other but be blind to the input data. We refer to this variant of PromptFuse as **BlindPrompt**. BlindPrompt fuses data in all modalities using the prompt vectors in self-attention layers. This further emphasizes that prompt vectors should be focusing on the *alignment* between modalities rather than on *specifics* of the content of a modality. As a result, BlindPrompt is more robust to spurious statistical cues (Niven and Kao, 2019). For example, given a picture that dogs run after a man, overfitting systems tend to answer “poodles” in response to the question “What do dogs chase?”.

4 Experiments: Two Modalities

4.1 Setup

Our model is designed to be modular, maximizing the utility of widely used pretrained vision and language models: ViT (Dosovitskiy et al., 2021) as our VE and BART (Lewis et al., 2020) as our PLM. For both models we use the pretrained *base* checkpoints from HuggingFace (Wolf et al., 2020). We use the embedding v of [CLS] as the image representation unless otherwise noted; we use cross-entropy loss during training and use greedy search when decoding.

We experiment with visual question answering (VQAv2; Goyal et al. (2017)), for which understanding both image and language is necessary when answering a question about an image. VQAv2 consists of 443,757 samples, categorized into three types: *Number*, *Yes/No*, and *Other*.

We simulate low-resource regimes by sampling 128 and 512 shots of training data. We show that PromptFuse and BlindPrompt are less prone to overfitting in low-resource scenarios than baseline methods, in which the model tends to place extra emphasis on samples of the majority answer type *Yes/No* but pays less attention to *Other*. This is because the two answering words of *Yes/No* have much higher frequency in the text corpus than the answers of the open-ended questions, i.e., *Other*.

We train the models for two epochs on the full dataset and 100 epochs on the sampled low-resource datasets. For prompting, we set the prompt length N to 20, and Appendix §A shows an ablation study. Similar to Lester et al. (2021), we empirically found that a large learning rate leads to better prompting performance. So we use learning rate 5e-1 for prompting; learning rate 5e-4 is used in all other experiments. Batch size is 32 and the Adam optimizer (Kingma and Ba, 2015) is used.

4.2 Baseline

We consider four baselines of fusing the modalities:

Finetune. As the baseline *Frozen*$_{\text{finetuned}}$ in Tsimpoukelli et al. (2021), we finetune *all parameters of VE*, such that the visual embedding space is expected to be aligned with PLM’s language embedding space.

Linear. We fix VE, but train a linear layer to project its output, i.e., the visual embedding, while retaining its dimensionality.

JointProj. We concatenate the visual embedding v to the embedding vector w_i of each (sub)word in the sentence. Next, we train a linear layer to project the concatenated vectors to the PLM hidden dimension. The resulting vectors are input to the PLM encoder layers.

BlackImage. To verify that the prompt vectors use visual information from VE (as opposed to simply conditioning on spurious features of the text, as in the above “poodle” example), we train the prompt vectors with black images.

Table 1 shows the number of trained parameters of the methods. Finetune requires the largest number of trainable parameters, followed by JointProj and Linear; PromptFuse and BlindPrompt are much more parameter-efficient.

Finetune	Linear	JointProj	PromptFuse	BlindPrompt
86M	0.5M	1M	15K	15K

Table 1: Number of trainable parameters of different fusion methods in million (M) and thousand (K).

Full dataset	Other	Yes/No	Number	Overall
Finetune	**20.3±0.5**	**69.3±0.3**	**29.5±0.2**	**40.1±0.3**
Linear	8.5±0.6	63.9±0.2	23.3±0.3	30.1±0.3
JointProj	19.2±0.4	67.7±0.2	28.9±0.4	38.9±0.1
BlackImage	8.3±0.7	60.4±0.5	15.3±0.4	23.7±0.5
PromptFuse	12.2±0.6	64.9±0.4	27.1±0.2	34.1±0.4
BlindPrompt	13.3±0.9	64.5±0.4	27.4±0.1	34.8±0.8
128 shots	Other	Yes/No	Number	Overall
Finetune	6.6±0.3	57.9±0.9	14.7±0.3	26.8±0.5
Linear	2.3±0.1	46.4±0.7	16.2±0.4	18.2±0.4
JointProj	3.9±0.5	63.3±0.1	19.4±0.6	**28.4±0.3**
BlackImage	0.9±0.1	38.9±0.8	6.2±0.4	14.4±0.5
PromptFuse	4.9±0.6	**63.7±0.3**	16.9±0.2	28.3±0.6
BlindPrompt	**8.0±1.1**	62.1±0.2	**19.8±0.3**	28.0±0.9
512 shots	Other	Yes/No	Number	Overall
Finetune	7.3±0.3	61.1±0.2	20.2±0.4	29.2±0.3
Linear	4.3±0.4	62.2±0.5	19.2±0.4	26.6±0.4
JointProj	3.8±0.1	63.8±0.3	**23.8±0.4**	28.7±0.3
BlackImage	3.5±0.6	48.2±0.6	10.3±0.5	18.8±0.5
PromptFuse	6.3±0.5	**63.9±0.1**	21.5±0.3	29.4±0.5
BlindPrompt	**8.4±0.9**	63.1±0.2	22.6±0.3	**29.7±0.6**

Table 2: Results (accuracy) on VQAv2 validation set. We report Overall and separate performance of the three types of questions: Other, Yes/No, Number.

4.3 Results

Table 2 compares the performance of baselines and our prompting methods. We report mean and standard deviation over three runs with different random seeds.

PromptFuse outperforms the BlackImage and Linear baselines on all experiments, showing that prompting successfully utilizes visual information and fuses the two modalities.

For 128 and 512 shots, PromptFuse achieves accuracy comparable with baselines Finetune and JointProj. However, *PromptFuse and BlindPrompt are more parameter-efficient* as shown in Table 1. Prompting methods perform worse than Finetune and JointProj on full data.[1] We conjecture that this is due to having much fewer parameters, i.e., 15K, which is even smaller than the training set size 443,757. Thus we argue that PromptFuse better suits low-resource scenarios.

In low-resource experiments, PromptFuse and BlindPrompt achieve higher accuracy on *Other* and *Number*; the performance drops on *Yes/No* compared with Finetune and JointProj. This also happens between PromptFuse and BlindPrompt. For example, on 128 shots, we find that BlindPrompt outperforms PromptFuse with 3% on *Number* and 3% on *Other*. The results indicate that our prompting methods, especially BlindPrompt, can better utilize the generalization capability of PLM to handle open-ended questions and are less prone to falling into *Yes/No* samples.

4.4 Qualitative Example

To understand how prompting helps in fusing different modalities, we compare PromptFuse and BlindPrompt to a **NoPrompt** baseline. NoPrompt directly concatenates the visual outputs from VE to the text input of the PLM without any training.

Concretely, we apply the **Integrated Gradients** method (Sundararajan et al., 2017), which measures the attribution of features to the neural network outputs. Traditional approaches define feature importance by the gradient of model outputs to input features. Integrated gradients extend this measure as the path integral of the gradient from a baseline – reflecting the absence of signal – to the actual input. In practice, we use the Captum package (Kokhlikyan et al., 2020) in our implementation.

Table 3 illustrates a qualitative example when applying NoPrompt, PromptFuse, and BlindPrompt on VQAv2. For NoPrompt, because no training is involved, visual embeddings from VE confuse the PLM, leading to a wrong prediction ("</s>"). The system is not able to correctly understand the image and question. In contrast, PromptFuse and BlindPrompt guide the PLM to pay attention to the image and identify the regions of "giraffe" and then correctly respond "Yes".

Interestingly, the attribution scores of the question from BlindPrompt are small, compared to PromptFuse. We conjecture the reason is that, understanding the question – which has a straightforward syntactic/semantic structures – is relatively simple for the PLM because it has been pretrained on a large volume of text. BlindPrompt thus enforces that the multimodal system focus more on the visual embeddings (i.e., the encoded image), which is a new source of information for answering the question.

5 Experiments: Three Modalities

Disentangling functionality of the modality data encoder, e.g., VE, makes PromptFuse and BlindPrompt more modular than Frozen. Applying our methods to tasks involving more than two modali-

---

[1] Finetune (40.1) performs worse than $\text{Frozen}_{\text{VQA}}$ (48.4). We hypothesize this is because Frozen uses a much larger PLM (7 billion) than ours (139 million).

	NoPrompt	PromptFuse	BlindPrompt
			Question	Do you see a giraffe in the picture?	Do you see a giraffe in the picture?	Do you see a giraffe in the picture?
Prediction	</s>	Yes	Yes

Table 3: Attribution score magnitude heat map for image and text inputs. Black/white image pixels indicate positive/negative influence on predicting "Yes", and the same goes for red/blue tokens. Integrated gradients are calculated only on the first prediction after decoder input "</s><s>" in an auto-regressive manner.

ties is straightforward. In contrast, Frozen incurs the high cost of pretraining encoders for new modalities. We experiment on the sarcasm detection dataset MUStARD (Castro et al., 2019) with video, audio, and text data.[2]

Setup. To process video, we first use OpenFace (Baltrusaitis et al., 2018) to sample important frames containing human faces. Next, ViT is leveraged to extract visual representations from each frame. We then average visual representations of all frames to represent the video. To process audio, we use librosa (McFee et al., 2015) to remove background noise and convert audio to waveform with a sampling rate of 16,000 Hz. We then use pretrained wav2vec2 (Baevski et al., 2020) to encode the waveform and apply the same averaging strategy as for video. BART is used as our PLM. We use a verbalizer of *True/False* in this experiment.

We adopt the speaker-dependent setup in MUStARD: 334 training and 356 testing samples. We compare PromptFuse, BlindPrompt, and Finetune for 8, 32, and 64 shots. Note that Finetune uses 180M trainable parameters in the vision and audio encoders. We also conduct an experiment training on the full dataset for 5 epochs. The remaining setup is the same as §4.1.

Results. Table 4 reports performance over ten runs. PromptFuse and BlindPrompt outperform Finetune in 8- and 64-shot experiments. Prompting methods perform comparably to Finetune in other experiments, *while they are clearly more parameter-efficient.* Overall, the three-modality experiment provides observations in line with §4.3. More importantly, it highlights two strengths of prompting: High modularity and parameter-efficiency.

Full dataset	Precision	Recall	F-Score
Finetune	65.6±0.2	73.9±2.7	**68.4±0.5**
PromptFuse	64.2±0.4	72.1±3.6	66.2±0.7
BlindPrompt	63.8±0.5	71.9±3.1	66.5±0.8
8 shots	Precision	Recall	F-Score
Finetune	42.8±4.3	69.5±9.9	52.7±5.5
PromptFuse	41.1±4.8	71.0±13.1	53.1±5.8

Finetune	59.5±2.3	70.4±7.7	61.4±2.8
PromptFuse	59.2±2.7	70.2±7.4	**62.0±3.3**
BlindPrompt	60.1±2.4	70.9±7.8	61.7±3.1

Table 4: Results on MUStARD test set.

6 Conclusion

We propose PromptFuse and BlindPrompt as methods for aligning different modalities in a modular and parameter-efficient manner. We show that prompting, which requires only a few trainable parameters, performs comparably to several multimodal fusion methods in low-resource scenarios. The high modularity property of prompting supports – by avoiding the need to finetune large pretrained models – flexible addition of modalities at low cost.

---

[2] To highlight modularity, we utilize pretrained encoders rather than the data preprocessing pipelines in Castro et al. (2019). For example, we use pretrained wav2vec2 (Baevski et al., 2020) rather than Mel-Frequency Cepstral Coefficients (Davis and Mermelstein, 1980) when processing audio data.

A Ablation Analysis

As an ablation analysis, we test variants of PromptFuse and BlindPrompt with full data on VQAv2 dataset. All experiment setup follows §4.1.

Prompt length. PromptFuse and BlindPrompt have an extremely limited number of trainable parameters, making it challenging to achieve performance as finetuning in high-resource scenarios. Intuitively, we would like to inject more prompt vectors to increase the number of trainable parameters. Table 5 shows that both PromptFuse and BlindPrompt obtain best accuracy when the prompt length is set to 60. Using a particularly large length (e.g., 100) harms performance. This is in line with Lester et al. (2021): They find that too much prompt information may bring negative effects. Since more prompt vectors also consume more training time, we use 20 in our experiments.

	5	10	20	40	60	80	100
PromptFuse	28.5	30.4	34.1	35.3	**35.8**	34.2	30.3
BlindPrompt	27.1	30.7	34.8	35.5	**35.6**	34.4	30.9

Table 5: Overall accuracy on VQAv2 validation set with prompt length ranging from 5 to 100. We report mean performance over three random seeds.

Prompt position. In this work we inject prompt vectors at the beginning of input fed to PLM (see Figure 1), here we test two alternative positions for injection: (i) middle, i.e., inserting between vision and (sub)word embeddings; (ii) end of the question. Results in Table 6 show that these positions yield similar performance, indicating that our approach is not largely affected by prompt positions.

Prompt encoder. Another approach to increase trainable parameters is to use an extra module to encode prompt vectors. We test two neural network modules: (i) a linear layer; (ii) an LSTM (Hochreiter and Schmidhuber, 1997). Both modules have the same hidden dimension as the PLM. However, these variants only bring small improvements, as presented in Table 6. Future work may explore more advanced methods of scaling up the number of parameters.

Visual embedding. In addition to utilizing the [CLS] embedding, there are two alternative ViT outputs can be used as the visual embeddings: (i) the entire embedded sequence; (ii) the embedding averaged over the sequence. Table 6 shows that these approaches achieve comparable results. To save computational resources, we use [CLS] for images in VQAv2. For video frames and speech signals in MUStARD, we use average due to large sequence lengths.

		PromptFuse	BlindPrompt
	Baseline	34.1±0.4	34.8±0.8
Prompt Position	Middle	33.7±0.4	34.9±0.7
	End	34.3±0.5	34.5±0.6
Prompt Encoder	Linear	34.7±0.5	35.0±0.6
	LSTM	34.9±0.4	35.1±0.4
Visual Embedding	Seq	34.6±0.6	34.7±0.5
	Avg	33.9±0.5	34.9±0.4

Table 6: Results on VQAv2 validation set with variants of prompt position, encoder, and visual embedding.

BART	Other	Yes/No	Number	Overall
PromptFuse	12.2±0.6	64.9±0.4	27.1±0.2	34.1±0.4
BlindPrompt	13.3±0.9	64.5±0.4	27.4±0.1	34.8±0.8
BERT	Other	Yes/No	Number	Overall
PromptFuse	-	67.5±0.3	28.4±0.2	-
BlindPrompt	-	67.8±0.4	28.6±0.2	-
T5	Other	Yes/No	Number	Overall
PromptFuse	15.8±0.7	65.4±0.2	27.3±0.3	36.5±0.4
BlindPrompt	16.2±0.8	65.2±0.3	27.4±0.2	36.6±0.6

Table 7: Results with BERT and T5 on VQAv2 validation set.

B Modularity

This section further demonstrates the modularity and flexibility of PromptFuse and BlindPrompt. Besides the ability of utilizing encoders of more than two modalities as shown in §5, the modular design allows PromptFuse and BlindPrompt to use PLMs other than BART. Concretely, we compare BERT/T5 to BART, by full data training on VQAv2 as §4.1. BERT is a masked language model, thus we train and evaluate only on *Number* and *Yes/No* samples, by filling the mask in pattern "Question: *input question* Answer: [MASK]".

As reported in Table 7, BERT performs well on *Number* and *Yes/No* compared to BART, indicating that PromptFuse/BlindPrompt can also be applied to encoder-only architecture. Also, T5 outperforms BART, especially on *Other*, further indicating that PromptFuse/BlindPrompt are compatible with new PLMs, which give increasingly better task performance.

C Experiment Setup

Table 8 shows the setup used in all of our experiments. We use 8 GEFORCE GTX 1080Ti GPUs and gradient accumulation is applied during training.

Dataset	Modalities	# Train	# Test	Runs	Batch Size	Epochs	Prompt Length	LR (Prompt)	LR (Other)

Abstract

Machine translation typically adopts an encoder-to-decoder framework, in which the decoder generates the target sentence word-by-word in an auto-regressive manner. However, the auto-regressive decoder faces a deep-rooted *one-pass* issue whereby each generated word is considered as one element of the final output regardless of whether it is correct or not. These generated wrong words further constitute the target historical context to affect the generation of subsequent target words. This paper proposes a novel synchronous refinement method to revise potential errors in the generated words by considering part of the target future context. Particularly, the proposed approach allows the auto-regressive decoder to refine the previously generated target words and generate the next target word synchronously. The experimental results on three widely-used machine translation tasks demonstrated the effectiveness of the proposed approach.

1 Introduction

Recently, the *encoder-decoder* framework has obtained impressive results over various machine translation tasks (Barrault et al., 2020; Akhbardeh et al., 2021). Typically, *decoder* first represents those generated target words as a dependent-time target representation, and then uses an attention mechanism to summarize a dependent-time context from the source input for generating the next target word. Since this generated target word is conditioned on previously generated target words at each time step, the decoding process is often called auto-regressive decoding. Finally, *decoder* generates a target language sentence word-by-word in the auto-regressive decoding manner (Bahdanau et al., 2015; Vaswani et al., 2017).

However, the auto-regressive *decoder* often encounters an inherent *one-pass* issue whereby each generated target word is one element of the final output of the machine translation model regardless of whether it is correct or not. These generated wrong target words are further added to the target historical context to affect the generation of subsequent target words, which hinders the performance of machine translation. Take a Chinese-to-English translation case in Figure 1 generated by a trained neural machine translation (NMT) model (Vaswani et al., 2017), we illustrate the *once-generation* issue. In the generated target translation "**Tgt**", there is first an inappropriate translation "*clean up*" compared with "*monitor*" in the reference "***Ref***". The "*clean up*" is regarded as the final translation to confuse the understanding of the meaning of the source sentence. When these inappropriate or incorrect target words constitute part of the target historical context, the *once-generation* issue further affects the generation of subsequent target words, for example, "*drivers' mobile phone*" is far away from the meaning of source sentence "*the driver plays mobile phone while driving*". To verify this issue, we artificially revised the inappropriate translation "*clean up*" as "*monitor*" during the decoding, and observed that the subsequent translation "*driver plays mobile phone while driving*" in "***Revised***" almost completely expresses the corresponding Chinese meaning. We believe that correcting the potential errors in generated translations will improve the quality of the translations.

Many efforts have been initiated on revising potential errors in the generated target translation for machine translation, for example, automatic post-editing (Niehues et al., 2016; Zhou et al., 2017; Junczys Dowmunt and Grundkiewicz, 2017) and two-pass decoding (Xia et al., 2017; Geng et al., 2018; Nema et al., 2019; Ghazvininejad et al., 2019). Despite their success, most of these approaches **asynchronously** simulated the generation of the next target word and the revision

of the generated target words or required a complex modification of the existing models. In this paper, we propose a novel method to refine the potential errors in the generated target words and generate the next target word **synchronously**. To this end, during the decoding, we consider their target future context for a part of previously generated target words, to synchronously obtain the refinement probabilities of the previously generated words and the generation probability of the next target word at each time step. When the refinement probability is greater than the previous generation probability on the same position, we replace the original generated target word with the revised target word. These refined target words together with the currently generated target word further provide an accurate target historical context for the generation of subsequent target words. Additionally, the proposed approach is easily introduced into the auto-regressive decoder without complex modification. We extensively evaluated it on three widely-used machine translation benchmarks, including WMT14 English-to-German, WMT14 English-to-French, and WMT17 Chinese-to-English, and the experimental results demonstrated the effectiveness of the proposed approach.

2 Background

In this paper, we use the advanced encoder-decoder framework, Transformer (Vaswani et al., 2017), to introduce the language generation models. To simplify the process, we simply format the main self-attention network (SAN) module and do not involve other modules (e.g., positional encoding, multiple stacked layers, and so on). *Encoder* represents the source input X=$\{x_1, \cdots, x_J\}$ as the source representation $\mathbf{H}$= $\{\mathbf{h}_1, \cdots, \mathbf{h}_J\}$ using SANs. *Decoder* then generates the target sentence word-by-word based on $\mathbf{H}$ with attention mechanism and the generated target fragment. Specifically, given a sequence of word vectors in the generated target fragment $\{\mathbf{E}[y_1], \cdots, \mathbf{E}[y_{i-1}]\}$ ($\mathbf{E}$ is the embedding matrix of the target language vocabulary), they are packed into key-value matrices $\mathbf{K}_{i-1}$ and $\mathbf{V}_{i-1}$ at the i-th time-step:

$$\mathbf{K}_{i-1} = \mathbf{V}_{i-1} = \mathrm{M}(\mathbf{E}[y_1], \cdots, \mathbf{E}[y_{i-1}]), \quad (1)$$

where the function $\mathrm{M}(\cdot)$ packs a sequence of word vectors into a matrix. Another $\mathrm{SelfATT}_s$ module is then used to learn the target representation $\mathbf{s}_i$:

$$\mathbf{s}_i = \mathrm{SelfATT}_s(\mathbf{c}_{i-1}, \mathbf{K}_{i-1}, \mathbf{V}_{i-1}), \quad (2)$$

where $\mathbf{c}_{i-1} \in \mathbb{R}^{d_{model}}$ is the previous context vector and d_{model} is the dimension of language generation model. $\mathbf{s}_i$ is then fed into another $\mathrm{SelfATT}_c$ to compute the dependent-time context vector $\mathbf{c}_i$:

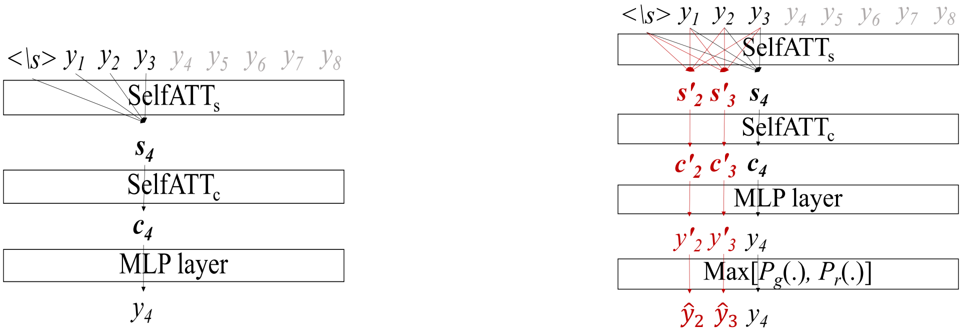
$$\mathbf{c}_i = \mathrm{SelfATT}_c(\mathbf{s}_i, \mathbf{K}_e, \mathbf{V}_e), \quad (3)$$

where $\mathbf{K}_e$ and $\mathbf{V}_e$ are key and value matrices, respectively, that are transformed from the source representation $\mathbf{H}$ according to Eq.(1). The probability distribution $P_g(y_i|y_{<i}, X)$ is then computed using the MLP layer:

$$P_g(y_i|y_{<i}, X) \propto \mathrm{MLP}(\mathbf{c}_i). \quad (4)$$

y_i with the maximum probability is selected as the output of *decoder* at the i-th time-step. To obtain the language generation model θ, the training objective maximizes the conditional generation probability over the training dataset $\{[\mathbf{X}, \mathbf{Y}]\}$:

$$\mathcal{J}(\theta) = P_g(\mathbf{Y}|\mathbf{X}; \theta). \quad (5)$$



(a) Auto-regressive decoder. (b) Auto-regressive decoder with synchronous refinement.

Figure 2: (a) The auto-regressive decoder; (b) The auto-regressive decoder with synchronous refinement where red and black arrows denote the refinement data flow and the generation data flow.

3 Methodology

Intuitively, when there is a target sentence with several incorrect target words, a native target language speaker often detects incorrect words according to the contextual information and tries to revise them. We infer that there are two key aspects in the artificial refinement process: i) How to identify those incorrect target words based on the context information; ii) How to revise the identified incorrect target words. To this end, we propose to simulate the above artificial refinement process, to refine the previously generated target words and generate the next target word synchronously.

3.1 Synchronous Refinement

Formally, at the i-th time step, given a key-value matrix pair $\{\mathbf{K}_{i-1}, \mathbf{V}_{i-1}\}$ (see Eq.(1)) of the generated target language fragment $\{\mathbf{E}[y_1], \mathbf{E}[y_2], \cdots, \mathbf{E}[y_{i-1}]\}$, we first pack the context vectors $\{\mathbf{c}_1, \mathbf{c}_2, \cdots, \mathbf{c}_{i-1}\}$ to generate the previous target words into a matrix $\mathbf{C}_{i-1}$ using Eq.(1):

$$\mathbf{C}_{i-1} = \mathrm{M}(\mathbf{c}_1, \mathbf{c}_2, \cdots, \mathbf{c}_{i-1}). \tag{6}$$

We then use $\mathbf{C}_{i-1}$ instead of $\mathbf{c}_{i-1}$ in Eq. (2) to learn the target representation matrix $\mathbf{S}_i$:

$$\mathbf{S}_i = \mathrm{SelfATT}_s(\mathbf{C}_{i-1}, \mathbf{K}_{i-1}, \mathbf{V}_{i-1}), \tag{7}$$

where $\mathbf{S}_i \in \mathbb{R}^{i \times d_{model}}$ is a matrix which includes the updated target representations of previously generated target words $\{\mathbf{s}'_1, \mathbf{s}'_2, \cdots, \mathbf{s}'_{i-1}\}$ in addition to the current target representation $\mathbf{s}_i$. Here, for each of the previously generated target words, $\mathrm{SelfATT}_s$ considers a subset of the future target context to update its target representation. For example, $\mathbf{s}'_3$ of y_3 encodes its future target words $\{y_3, \cdots, y_{i-1}\}$ in addition to its previous target words $\{y_1, y_2\}$. The target future context, which has been shown to be useful for generating the target language in machine translation (Zhang et al., 2018; Zheng et al., 2018; Zhou et al., 2019; Zheng et al., 2019), provides more evidence information for correcting one among all the generated target words in this paper.

Then, $\mathbf{S}_i$ is fed into Eq. (3) to learn a sequence of the context vectors $\mathbf{C}_i$:

$$\mathbf{C}_i = \mathrm{SelfATT}_c(\mathbf{S}_i, \mathbf{K}_e, \mathbf{V}_e), \tag{8}$$

where $\mathbf{C}_i \in \mathbb{R}^{i \times d_{model}}$ is a matrix which includes the updated context vectors of previously generated target words $\{\mathbf{c}'_1, \cdots, \mathbf{c}'_{i-1}\}$ in addition to the current context vector $\mathbf{c}_i$. We then use $\mathbf{C}_i$ as the input to Eq.4 to obtain the combined probabilities:

$$P_r(y'_1, \cdots, y'_{i-1}, y_i | y_{<i}, X) \propto \mathrm{MLP}(\mathbf{C}_i), \tag{9}$$

where $P_r(\cdot)$ includes $i-1$ additional refinement probability distributions at each time step i. That is, $\{y'_1, \cdots, y'_{i-1}\}$ provides a potential error set for revising the generated target words. Furthermore, we select target words with max probabilities from refinement probability distributions as the target candidate words to be refined. When each refinement probability of $\{y'_1, \cdots, y'_{i-1}\}$ is greater than its counterpart in the generation probability $\{y_1, \cdots, y_{i-1}\}$ at previous time step, the previously generated target word y_k (0<k<i) will be replaced with the refined target word y'_k. Finally, the revised target fragment $\{\hat{y}_1, \cdots, \hat{y}_{i-1}, y_i\}$ are computed:

$$\begin{aligned} P(\hat{y}_1, \cdots, \hat{y}_{i-1}, y_i | y_{<i}, X) = \\ \max[P_g(y_1, \cdots, y_{i-1}, 0 | y_{<i}, X), \\ P_r(y'_1, \cdots, y'_{i-1}, y_i | y_{<i}, X)]. \end{aligned} \tag{10}$$

(b) Refinement mask for local constraint.

Figure 3: Full refinement mask and refinement mask with local constraint (i.e., N=3) for learning the target representation during the training, and red number denotes the used future context in the proposed synchronous refinement.

Note that during the inference, the greedy search was used to refine previously generated target words while beam search was only used to generate the next target word. This makes the search complexity of decoding with refinement as consistent as that of the original decoding with beam search, thereby efficiently performing the synchronous refinement in the existing auto-regressive decoding.

3.2 Local Constraint

For the proposed synchronous refinement, most of the generated target words will be refined many times, that is, the number of refinement operations is proportional to the length of the final target sentence. However, the native target language speaker may only revise the previously generated target words a few times. Thus, there may be a potential risk of "*over-refinement*" in the synchronous refinement, that is, excessive refinement operations may lead to new errors. To reduce the risk of "*over-refinement*", we further design a local constraint (see Figure 2) that focuses on refining part of the previously generated target words closest to the target word to be omitted at each time step, inspired by the local attention (Luong et al., 2015) and the fixed iteration prediction (Ghazvininejad et al., 2019). Specifically, in the i-th time step, we select N previously generated target words $\{\mathbf{E}[y_{i-N}], \mathbf{E}[y_{i-N+1}], \cdots, \mathbf{E}[y_{i-1}]\}$ closest to the target word to be omitted, and pack the context vectors $\{\mathbf{c}_{i-N}, \mathbf{c}_{i-N+1}, \cdots, \mathbf{c}_{i-1}\}$ into $\boldsymbol{\mathcal{C}}'_{i-1}$:

$$\boldsymbol{\mathcal{C}}'_{i-1} = \mathrm{M}(\mathbf{c}_{i-N}, \mathbf{c}_{i-N+1}, \cdots, \mathbf{c}_{i-1}). \quad (11)$$

Then, we feed the local target representation matrix $\boldsymbol{\mathcal{C}}'_{i-1}$ into Eq. (7) instead of $\mathbf{C}'_{i-1}$, and thereby efficiently focus on the revision of part of generated target words according to Eqs.8, 9, and 10 in turn.

3.3 Model Training

When the local constraint of the synchronous refinement is set to N, each generated target word will be refined at most N times. This may be inefficient for the training of machine translation models. To efficiently inject this synchronous refinement capability into the training of machine translation models, we introduce an additional refinement mask to select the target future context words under the local constraint. Compared with the existing lower triangle mask, the local constraint contains additional target future context words closest to the target word to be omitted, as shown in Figure 3. After a target word is generated, it will be refined in the subsequent N sequential steps, which indicates that the number of future target words is different. Therefore, the refinement mask with local constraint is to randomly select future target words not greater than N to cover a variety of different future contexts as blue parts in Figure 3.

Then, we use the proposed refinement mask to learn the generation and refinement context vectors at each time step. This allows the machine translation models to synchronously simulate the generation of generated target words and the refinement of the current target word during the training. Thus, the training objective maximizes the generation and the refinement probabilities over the training dataset $\{[\mathbf{X}, \mathbf{Y}]\}$:

$$\mathcal{J}(\theta) = P_g(\mathbf{Y}|\mathbf{X};\theta) + P_r(\mathbf{Y}|\mathbf{X};\theta). \quad (12)$$

Note that the proposed refinement mechanism retains the auto-regressive property of *decoder*

Trans.base	27.67	13.2k	3.7k	65.0M	24.28	38.42
+Deliberation (Xia et al., 2017)	28.11	11.1k	3.1k	77.8M	24.62	38.94
+Two-stream (Song et al., 2020)	28.17	11.8k	3.4k	79.3M	24.76	39.17
+SynRefinement	28.37+	12.6k	3.5k	65.0M	24.98++	39.46++
Trans.big	28.57	11.2k	2.8k	221.2M	24.84	41.21
+Deliberation (Xia et al., 2017)	28.96	9.3k	2.2k	267.6M	24.97	41.59
+Two-stream (Song et al., 2020)	29.11	9.7k	2.3k	272.4M	25.06	41.55
+SynRefinement	29.22++	10.1k	2.5k	221.2M	25.18+	41.97+

Table 1: Main results of Trans.base/big, +SynRefinement, and comparison +Deliberation and +Two-stream models for standard machine translation tasks. "#Speed1." and "#Speed2." denote the training and decoding speeds (tokens/sec, k for thousand), and "#Param." denotes the size of model parameters (M for million). "+/++" after BLEU scores indicate that our approach was significantly better than Trans.base/big models at significance levels $p<0.05/0.01$ (Collins et al., 2005). Results were reported on average by conducting 3 runs of training.

to ensure the fluency of the target sentence. Meanwhile, the refinement of the generated target words is synchronized with the generation of the current target word at each time step. Particularly, the proposed approach can be easily introduced into the encoder-decoder machine translation models without complex modifications.

4 Experiments

4.1 Setting and Data set

We evaluated the proposed SynRefinement on three widely-used standard machine translation tasks: WMT14 En⇒De includes 4.43 million bilingual sentence pairs, and we used the *newstest2013* and *newstest2014* datasets as the dev set and test set, respectively; WMT14 En⇒Fr includes 36 million bilingual sentence pairs, and we used the *newstest2013* and *newstest2014* datasets as the dev set and test set, respectively; and WMT17 Zh⇒En includes 22 million bilingual sentence pairs, and we used the *newsdev2017* and *newstest2017* datasets as the dev set and the test set, respectively. The byte pair encoding algorithm (Sennrich et al., 2016) was adopted, and the vocabulary size was set to 40K. We set the dimension of all input and output layers to 512, the dimension of the inner feedforward neural network layer to 1024, and the total heads of all multi-head modules to 8 in both the encoder and decoder layers. Each training batch consisted of a set of sentence pairs that contained approximately 4000×8 source tokens and 4000×8 target tokens. To evaluate the test sets, following the training of 200,000 batches, we used a single model obtained by averaging the last five checkpoints, which validated the model with an interval of 2,000 batches on the dev set. We trained all models on eight V100 GPUs and evaluated them on a single V100 GPU. We chose the Transformer NMT model (Vaswani et al., 2017) as our baseline. For other configures of Transformer (e.g., Trans.base/big) models, we followed the settings in (Vaswani et al., 2017). We used the multi-bleu.perl script as the evaluation metric for the three translation tasks.

4.2 Translation Results

Table 1 showed BLEU scores of the baseline Trans.base/big models, +SynRefinement, +Deliberation (Xia et al., 2017) and +Two-stream (Song et al., 2020) attention models for comparison. First, +SynRefinement performed better than the baseline Trans.base/big models for three language pairs. This indicates that the proposed refinement mechanism improved the performance of NMT. Second, +SynRefinement was superior to the comparison +Deliberation network model, which confirms our hypothesis that jointly simulating generation and refinement of target sentence was better than the isolated multi-pass decoding way. Additionally, +SynRefinement outperformed the comparison +Two-stream attention model. Also, +SynRefinement did not increase any additional model parameters but +Two-stream attention increased about 19.7% model parameters compared to the baseline Trans.base model. Meanwhile, both training and decoding speeds of +SynRefinement were faster than those of +Deliberation and +Two-stream models. This means that the proposed refinement can more efficiently relieve the "*one-pass*" issue for the machine translation.

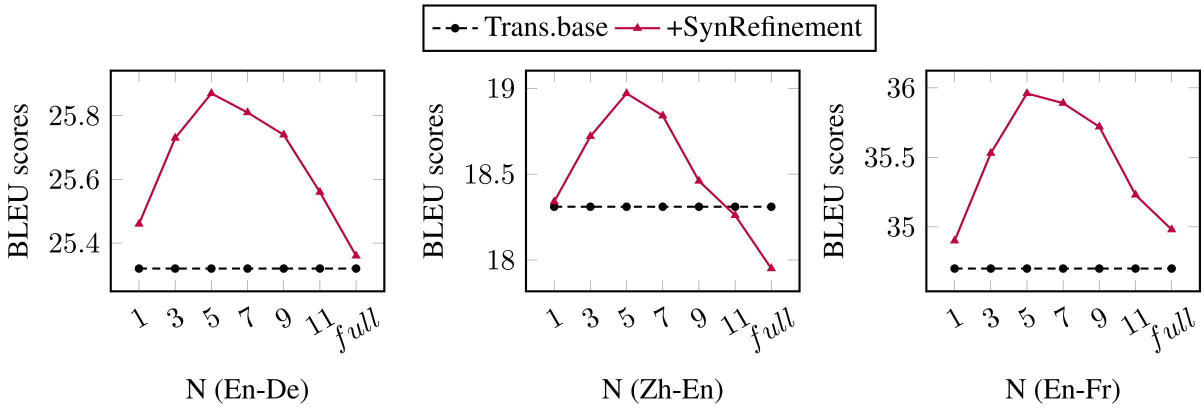

Figure 4: BLEU scores for Trans.base and +SynRefinement models for various hyperparameters N (x-axis) on three translation tasks.

4.3 Hyperparameter N of SynRefinement

In Section 3.3, we designed a local constraint to reduce the "*over-refinement*" risk. Thus, the hyperparameter N in Eq. (11) was used to control the range of refinement operations. Figure 4 shows BLEU scores for Trans.base and +SynRefinement models for various hyperparameter N (x-axis) on the WMT14 En-De, WMT17 Zh-En, and WMT14 En-Fr dev sets. +SynRefinement achieved the highest BLEU scores with N=5 for three dev sets. As a result, we set the hyperparameter N as five to conduct the main experiments shown in Table 1.

4.4 Ablation of Local Constraint and Refinement Mask

Methods	En-De	Zh-En	En-Fr
Trans.base	27.57	24.28	38.42
+Refinement Mask	27.73	24.39	38.78
+Local Constraint	27.89	24.62	38.95
+Both	28.37	24.98	39.46

Table 2: Ablation results of local constraint and refinement mask.

We incrementally added Refinement Mask and Local Constraint into the training and decoding passes of Trans.base model to evaluate their effectiveness. Table 3 showed the ablation results of Trans.base, +Refinement Mask, +Local Constraint, and Both (+Refinement Mask+Local Constraint) models. First, when Refinement Mask and Local Constraint were introduced to the training and the decoding, respectively, BLEU scores were higher than those of the Trans.base model on three translation tasks. The proposed approach was beneficial to the performance improvement of NMT. Second, when both Refinement Mask and Local Constraint were introduced into the training and decoding of the Trans.base model simultaneously, performance improved further. This means that maintaining consistent refinement operations in training and decoding helped NMT generate faithful and fluent target translation.

4.5 Investigation of SynRefinement Operation

Refinement times	En-De	Zh-En	En-Fr
#1	1,829	1,139	2,187
#2	1,121	621	1,431
#3	691	403	896
#4	277	189	382
#5	169	107	189
Total	4,087	2,459	5,085

Table 3: Statistical results for different refinement times on the same position for three translation tasks.

The proposed SynRefinement aims to revise potential errors in the generated target words. To investigate the effectiveness of synchronous refinement operations, we counted the number of different refinement times (e.g., replacement and deletion operation) on the same position during the inference. For example, "#2" denotes the number of BPE tokens that have been replaced (or refined) twice during the decoding. Table 3 showed statistical results for translations (include 74,487, 57,497 and 92,207 BPE tokens, respectively) of three translation tasks generated by Trans.base+SynRefinement models in Table 1. We observed that among the translations generated

Figure 6: Chinese-to-English translation cases generated by Trans.base and +SynRefinement models. Note: English words in color are translations from the corresponding Chinese words with the same color.

on the three tasks, total refinement operations of the same position occurred in 4,087, 2,459, and 5,058 positions, respectively. This indicates that the proposed SynRefinement worked during the decoding. When refinement times gradually increased from #1 to #5 on the same position, the number of such BPE tokens was greatly reduced.

4.6 Effect of Different Target Lengths

In the proposed SynRefinement, the number of refined words increased as the length of the generated target translation increased. To investigate the effect of SynRefinement on translations with different lengths, we divided each test set into six groups according to the length of the target translations. For example, “20” indicates that the length of target translations was between twenty and thirty. Figure 5 shows BLEU scores of the Trans.base and +SynRefinement models for the WMT14 En-De, WMT17 Zh-En, and WMT14 En-Fr test sets.

First, when the length of target translations was between zero and ten, BLEU scores of +SynRefinement were almost the same as those of Trans.base model. This reason may be that the refinement operation was performed from the fifth time step for three translation tasks. Second, when the length of the target translations was more than ten, BLEU scores of +SynRefinement were higher than those of Trans.base models for three translation tasks. Particularly, the extent of the improvement gradually increased as the length of the target translations increased. This means that +SynRefinement improved the quality of the target translations, especially long target translations.

4.7 Case Study

Figure 6 showed Chinese-to-English translation cases generated by Trans.base and +SynRefinement models. Trans.base first generated an inappropriate translation “*clean up*” and missed two key verbs “*plays*” and “*detected*”, and thereby generated a incorrect translation “*seizures*” compared to the “***Ref***”. Thus, the meaning in the target fragment was extremely confusing after “clean up” in the translation generated by the Trans.base model. +SynRefinement considered the future context “*that the driver mobile phone*” together with the past context "*traffic ... police to*" to revise "*clean up*" as the correct "*monitor*". "*monitor*" constituted part of the target historical context which allowed +SynRefinement model to generate two missed key verbs "*plays*" and "*discovered*". +SynRefinement further generated the correct target word "*cases*" compared to the inappropriate "*seizures*". As a result, the translation generated by +SynRefinement was closer to the reference than that generated by the Trans.base model.

5 Related Work

5.1 Automatic Post-Editing

For the refinement of target output in the classical machine translation (MT), a direct method is automatic post-editing (APE) (Simard et al., 2007). APE is the process of automatic correction of raw MT output, so that a closer resemblance to human post-edited MT output is achieved. Béchara et al. (2011) proposed to automatically create a new joined MT output and source token pairs to improve the automatic post-editing results (Béchara et al., 2012; Pal et al., 2017). Also, the MT output is refined by humans or another model (Niehues et al., 2016; Junczys Dowmunt and Grundkiewicz, 2017), which indicates that the generating and refining are two separate processes in APE.

5.2 Two-Pass Auto-regressive Decoding

As the encoder-decoder framework becomes the dominant machine translation method, the generated potential errors caused by the "*one-pass*" issue still is a challenge. Many studies proposed two-pass decoding to revise the fixed potential errors in the auto-regressive machine translation (Yang et al., 2016; Xia et al., 2017; Zhang et al., 2018; Geng et al., 2018; Zhou et al., 2019; Nema et al., 2019; Song et al., 2020). For example, review network (Yang et al., 2016) was proposed to refine the source representation for the caption generation model. Compared with reviewing the source information, a deliberation network (Xia et al., 2017) proposed two levels of decoders which generate a draft of the target sentence and polish the draft of the target sentence for MT, respectively. Additionally, most relevant to our work is that Song et al. (2020) leveraged the scheduled sampling to simulate the prediction errors during training and designed an additional content-stream attention network to correct the generated error information, which requires complex two-stream attention (Yang et al., 2019) or dual attention (Novak et al., 2016). The refinement network (Nema et al., 2019) for the QA task used a dual attention network to refine the question generated by the first decoder, thereby making the answer correct in the second decoder.

5.3 Iterative Refinement for Non-autoregressive Decoding

Non-autoregressive decoding (Gu et al., 2018) was introduced to generate all words at once, but its performance was far away from that of the auto-regressive decoding due to lack of sufficient dependency modeling among target words. Lee et al. (2018) designed an iterative inference strategy to minimize the generation latency. Then, Ghazvininejad et al. (2019) proposed to first predict all of the target words non-autoregressively, and then repeatedly masked out and regenerated the subset of words for iterative refining the target translation. Different from the refinement of discrete target words, the iterative inference (Lee et al., 2020) was proposed to iterative perform refinement in the continuous space for enhancing dependency between target words.

Discussion: Inspired by iterative refinement for non-autoregressive decoding, we proposed a novel synchronous refinement for machine translation. The proposed approach differs from previous studies in two ways. First, our method allows the machine translation models to refine the previously generated target words and to generate the current target word synchronously instead of APE with separate refinement and asynchronous two-pass (or multi-pass) decoding. Second, the proposed SynRefinement can be introduced to the machine translation models efficiently without complex modification of the existing machine translation models. Additionally, the proposed SynRefinement can help the real-time machine translation scenarios to satisfy the practical application requirements.

6 Conclusion

This paper explored part of the target future context to revise fixed potential errors in the generated target fragment caused by the "*one-pass*" issue of the auto-regressive decoder. We proposed a novel SynRefinement approach to the machine translation, where the refinement of generated target words is synchronized with the generation of the next target word at each time step. Meanwhile, the proposed SynRefinement can be easily introduced into the encoder-decoder framework without complex modifications. We evaluated the effectiveness of the proposed approach on three classical machine translation tasks. In the future, we will try to explore how to intelligently identify and correct generation errors.

Abstract

Recently, context-dependent text-to-SQL semantic parsing which translates natural language into SQL in an interaction process has attracted a lot of attention. Previous works leverage context-dependence information either from interaction history utterances or the previous predicted SQL queries but fail in taking advantage of both since of the mismatch between natural language and logic-form SQL. In this work, we propose a **H**istory **I**nformation **E**nhanced text-to-**SQL** model (**HIE-SQL**) to exploit context-dependence information from both history utterances and the last predicted SQL query. In view of the mismatch, we treat natural language and SQL as two modalities and propose a bimodal pre-trained model to bridge the gap between them. Besides, we design a schema-linking graph to enhance connections from utterances and the SQL query to the database schema. We show our history information enhanced methods improve the performance of HIE-SQL by a significant margin, which achieves new state-of-the-art results on the two context-dependent text-to-SQL benchmarks, the SparC and CoSQL datasets, at the writing time.

1 Introduction

Conversation user interfaces to databases have launched a new research hotspot in Text-to-SQL semantic parsing (Zhang et al., 2019; Guo et al., 2019; Wang et al., 2020; Lin et al., 2020; Xu et al., 2021; Cao et al., 2021; Hui et al., 2021; Yu et al., 2021b) and benefited us in industry (Dhamdhere et al., 2017; Weir et al., 2020). Most previous works focus on the context-independent text-to-SQL task and propose many competitive models. Some models (Wang et al., 2020; Scholak et al., 2021) even surprisingly work well on the context-dependent text-to-SQL task by just appending the interaction history utterances to the input. Especially, PICARD (Scholak et al., 2021) achieves state-of-the-art performances both in Spider (Yu et al., 2018b), a cross-domain context-independent text-to-SQL benchmark, and CoSQL (Yu et al., 2019a), a cross-domain context-dependent text-to-SQL benchmark, before our work. However, every coin has two sides. That implies underachievement of the exploration of context information in context-dependent text-to-SQL semantic parsing.

U_1: List the name of the teachers and the courses assigned for them to teach.

S_1 :
```
SELECT T3.Name, T2.Course FROM course_arrange AS T1
JOIN course AS T2 ON T1.Course_ID = T2.Course_ID
JOIN teacher AS T3 ON T1.Teacher_ID = T3.Teacher_ID
```

U_2: Arrange this list with the teachers name in ascending order.

S_2 :
```
SELECT T3.Name, T2.Course FROM course_arrange AS T1
JOIN course AS T2 ON T1.Course_ID = T2.Course_ID
JOIN teacher AS T3 ON T1.Teacher_ID = T3.Teacher_ID
ORDER BY T3.Name
```

U_3: Include teachers id in the same list.

S_3 :
```
SELECT T3.Name, T2.Course, T1.teacher_ID FROM course_arrange AS T1
JOIN course AS T2 ON T1.Course_ID = T2.Course_ID
JOIN teacher AS T3 ON T1.Teacher_ID = T3.Teacher_ID
ORDER BY T3.Name
```

Figure 1: An example of context-dependent text-to-SQL interaction in CoSQL where U_i is the utterance of turn i and S_i is the corresponding SQL query for U_i. The tokens with red color are the history information that should be considered in later predictions. It is context-independent if we just consider the prediction of S_1.

Compared with context-independent text-to-SQL semantic parsing, context-dependent text-to-SQL semantic parsing are more challenging since of the various types of dependence in utterances which make models vulnerable to parsing errors. As R^{2}SQL (Hui et al., 2021) considers, different context dependencies between two adjacent utterances require the model to establish dynamic connections between utterances and database schema carefully. However, context information is not only from the last utterance. Long-range dependence is

also the case in CoSQL as the prediction of S_3 depends on "the name of the teachers and the courses" in U_1 in Figure 1. A workable proposition for long-range dependence is to inherit context information from previous predicted SQL queries. But it is not a piece of cake to take advantage of previously predicted queries since of the mismatch between natural language and logic-form SQL. As Liu et al. (2020) conclude, roughly encoding the last predicted SQL query and utterances takes the wooden spoon while easily concatenation of interaction history utterances and current utterance appears to be strikingly competitive in their evaluation of 13 existing context modeling methods.

In this paper, we propose a history information enhanced network to make full use of both history interactive utterances and previous predicted SQL queries. We first treat the logic-form SQL query as another modality with natural language. We present SQLBERT, a bimodal pre-trained model for SQL and natural language which is able to capture the semantic connection and bridge the gap between SQL and natural language. It produces general-purpose representations and supports our context-dependent text-to-SQL semantic parsing.

Besides, we propose a history information enhanced schema-linking graph to represent the relations among current utterance, interaction history utterances, the last predicted query, and corresponding database schema. Considering it is weird to shift a topic back and forth in an interaction, we assume that the long-range dependence is successive. For example, that S_3 depends on U_1 implies that S_2 does too in Figure 1. In that case, we can leverage the long-range dependence from the last predicted query. Therefore, unlike the previous schema-linking graph just with utterances and database schema (Hui et al., 2021), the last predicted query takes part in our graph. Besides, we distinguish current utterance and interaction history utterances in the schema-linking graph. We encode the schema-linking relations with Relative Self-Attention Mechanism (Shaw et al., 2018).

In our experiments, the proposed methods of SQLBERT and the history information enhanced schema-linking substantially improve the performance of our model. At the time of writing, our model ranks first on both two large-scale cross-domain context-dependent text-to-SQL leaderboards, SparC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a). Specifically, our model achieves a 64.6% question match and 42.9% interaction match accuracy on SparC, and a 53.9% question match and 24.6% interaction match accuracy on CoSQL.

2 Related Work

Text-to-SQL semantic parsing follows a long line of research on semantic parsing from natural language to logical language (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007).

Recently, context-independent text-to-SQL semantic parsing has been well studied. Spider (Yu et al., 2018b) is a famous dataset for the complex and cross-domain context-independent text-to-SQL task. Some works (Bogin et al., 2019a,b; Chen et al., 2021) apply graph neural networks to encode database schema. Xu et al. (2021) succeed in appling deep transformers to the context-independent text-to-SQL task. Yu et al. (2018a) employ a tree-based decoder to match SQL grammar. Rubin and Berant (2021) improve the tree-based decoder by a bottom-up method. Scholak et al. (2021) refine the sequence-based decoder via carefully designed restriction rules. Guo et al. (2019) and Gan et al. (2021) propose SQL intermediate representations to bridge the gap between natural language and SQL. Lei et al. (2020) study the role of schema-linking in text-to-SQL semantic parsing. Wang et al. (2020) propose a unified framework to capture the schema-linking. Lin et al. (2020) represent the schema-linking as a tagged sequence. Cao et al. (2021) further integrate non-local and local features via taking advantage of both schema-linking graph and its corresponding line graph. Besides, many previous works (Deng et al., 2021; Yu et al., 2021a; Shi et al., 2021) focus on pre-train models for context-independent text-to-SQL semantic parsing.

With more attentions on context-dependent text-to-SQL semantic parsing, existing works have been devoted to the context-dependent text-to-SQL task. SparC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a) datasets are specially proposed for the task. EditSQL (Zhang et al., 2019) and IST-SQL (Wang et al., 2021) focus on taking advantages of the last predicted query for the prediction of current query. EditSQL tries to copy the overlap tokens from the last predicted query, while IST-SQL proposes an interaction state tracking method to encode the information from the last predicted query.

IGSQL (Cai and Wan, 2020) and R^{2}SQL (Hui et al., 2021) leverages the contextual information among the current utterance, interaction history utterances and database schema via context-aware dynamic graphs. Notably, R^{2}SQL simulates the information by connecting the schema graphs with the tokens in interactive utterances. Yu et al. (2021b) creatively propose a context-aware pre-trained language model. However, the problem of making full use of both interaction history utterances and predicted queries for the context-dependent text-to-SQL task remains open.

3 HIE-SQL

First, we formally define the conversational text-to-SQL semantic parsing problem. In the rest of the section, we detail the architecture of history information enhanced text-to-SQL model (HIE-SQL).

3.1 Preliminaries

Task Definition. Given the current user utterance u_τ, interaction history $h_\tau = [u_1, u_2, ..., u_{\tau-1}]$, the schema $D = \langle T, C\rangle$ of the target database such that the set of tables $T = \{t_1, ..., t_{|T|}\}$ and the set of columns $C = \{c_1, ..., c_{|C|}\}$, our goal is to generate the corresponding SQL query s_τ.

Model Architecture. Figure 2 shows the encoder-decoder framework of HIE-SQL. We will introduce it in four modules: (i) **Multimodal Encoder**, which encodes SQL query and natural language context in a multimodal manner, (ii) **SQLBERT**, a bimodal pre-trained encoder for SQL and natural language, (iii) **HIE-Layers**, which encode pre-defined schema-linking relations between all elements of the output of Language Model, and (iv) **Decoder**, which generates SQL query as an abstract syntax tree.

3.2 Multimodal Encoder

Since of the huge syntax structure differences between SQL and natural language, using a single language model to encode both languages at the same time increases the difficulty and cost of training the model. Inspired by the efficiency of the works (Kiela et al., 2019; Tsimpoukelli et al., 2021) to solve the multimodal problems, we build an additional pre-trained Encoder named SQLBERT (we will detail it in the following section) to pre-encode SQL query. Then we learn weights $W \in R^{N\times M}$ to project the N-dimensional SQL query embeddings to M-dimensional token input embedding space of the language model:

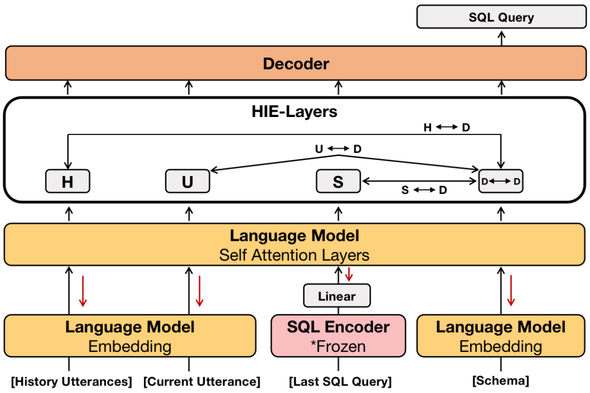

Figure 2: Structure and components of HIE-SQL. The red arrows represent the direction of back propagation during the training stage, witch means parameters of SQL Encoder will not be updated during training. Linear represents one fully connected layer. And we use SQLBERT as the SQL Encoder in the structure.

$$\mathcal{S} = Wf(s_{\tau-1}), \tag{1}$$

where $f(\cdot)$ is the last hidden state output of SQLBERT.

We arrange the input format of HIE-SQL as $x = (\texttt{[CLS]}, \mathcal{U}, \texttt{[CLS]}, \mathcal{S}, \texttt{[SEP]}, \mathcal{T}, \texttt{[SEP]}, \mathcal{C})$ in which

$$\begin{aligned} \mathcal{U} &= (u_1, \texttt{[CLS]}, u_2, ..., \texttt{[CLS]}, u_\tau), \\ \mathcal{T} &= (t_1, \texttt{[SEP]}, t_2, ..., \texttt{[SEP]}, t_{|T|}), \\ \mathcal{C} &= (c_1, \texttt{[SEP]}, c_2, ..., \texttt{[SEP]}, c_{|C|}). \end{aligned} \tag{2}$$

All the special separator tokens and language word tokens in x are converted to the word embedding by embedding layer of the language model. Gathering the embeddings of natural language and SQL, we feed them to self-attention blocks in a language model. In the training stage, we directly take the golden SQL query of the last turn as an input SQL query and set $\mathcal{S}$ to empty for the first turn. As for the inference stage, we apply the SQL query generated by HIE-SQL in the last turn.

3.3 SQLBERT

As mentioned above, we treat the SQL query as another modality that can provide information of the SQL query from the previous round as a reference for the model. So we need an encoder to extract the representation of the SQL query.

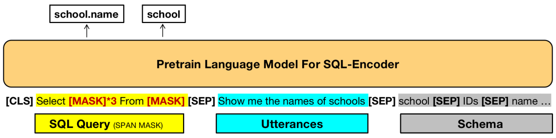

Figure 3: Input format and training objective of SQL-BERT.

Model Architecture. Considering the success of multi-modal pre-trained models, such as ViL-BERT (Lu et al., 2019) for language-image and CodeBERT (Feng et al., 2020) for natural language and programming language, we propose SQLBERT, a bimodal pre-trained model for natural language and SQL. We develop SQLBERT by using the same model architecture as RoBERTa (Liu et al., 2019). The total number of model parameters is 125M.

Input Format. As the training method showed in Figure 3, we set the same input as Code-BERT (Feng et al., 2020) does. To alleviate the difficulty of training and resolve inconsistencies between natural language and schema, we append the question-relevant database schema to the concatenation of SQL query and question. We represent the whole input sequence into the format as $x = (\texttt{[CLS]}, s_1, s_2, ..s_n, \texttt{[SEP]}, q_1, q_2, ..q_m, \texttt{[SEP]}, t_1 : c_{11}, c_{12}, ..., \texttt{[SEP]}, t_2 : c_{21}, ..., \texttt{[SEP]}, ...)$, in which s, q, t, and c are the tokens of SQL query, question, tables, and columns respectively.

Training Objective. The main training objective of SQLBERT is the masked language modeling (MLM). It's worth noting that we only mask the tokens of SQL query because we only need SQL-BERT to encode SQL query in the downstream task. Specifically, we utilize a special objective referenced span masking (Sun et al., 2019) by sampling 15% independent span in SQL clause except the reserved word (e.g., SELECT, FROM, WHERE), which aims to avoid leaking answers and help SQL-BERT learn the information structure of SQL better. In the training stage, we adopt a dynamic masking strategy via randomly shuffling the order of tables and columns in the original schema. We describe the masked span prediction loss as

$$\mathcal{L}(\theta) = \sum_{k=1}^{n} -log\mathcal{P}_\theta(s_k^{mask}|s^{\backslash mask}, q, t, c), \quad (3)$$

where θ stands for the model parameters, s_k^{mask} is the masked span of SQL input, $s^{\backslash mask}$ is the unmasked part.

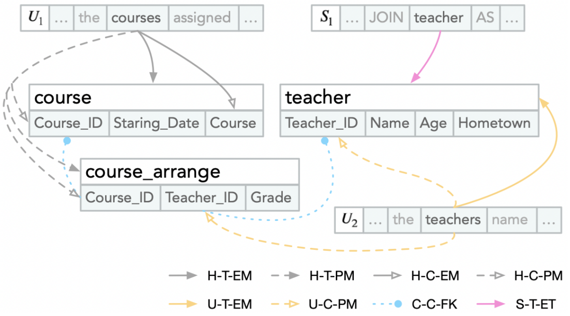

Figure 4: An example of the schema-linking graph for the prediction of S_2 in Figure 1. The graph is a subgraph of the whole schema-linking graph. We only respectively choose one token in the history utterance (U_1), the current utterance (U_2), and the last predicted SQL query (S_1) in the example. Besides, we omit all unequal relation edges (S-C-UC and S-T-UT) and default "no relation" edges.

Training Data. Unlike SCoRe (Yu et al., 2021b), which uses multiple open-source text-to-SQL datasets (WikiTables (Bhagavatula et al., 2015), WikiSQL (Zhong et al., 2017), Spider, SparC, and CoSQL) and data synthesis methods to obtain a large amount of pre-training data, we train SQLBERT only with the datasets including Spider, SparC and CoSQL. For each sample, we only use its question, SQL query, and the corresponding database schema. As for SparC and CoSQL, which is a context-dependent version, we simply concatenate the current utterance with the history utterances to build the question input. The size of the training dataset is 34,175.

3.4 HIE-Layers

Schema-Linking Graph. To explicitly encode the complex relational database schema. We convert it to a directed graph $\mathcal{G} = \langle \mathcal{V}, \mathcal{E} \rangle$, where $\mathcal{V} = C \cup T$ and $\mathcal{E}$ represents the set of pre-existing relations within columns and tables such as the foreign-key relation. In addition, we also consider the unseen linking to the schema in the contexts of current utterance, interaction history utterances, and the last predicted SQL query. Specifically, we define the context-dependent schema-linking graph $\mathcal{G}_c = \langle \mathcal{V}_c, \mathcal{E}_c \rangle$ where $\mathcal{V}_c = C \cup T \cup U \cup H \cup S$ and $\mathcal{E}_c = \mathcal{E} \cup \mathcal{E}_{U \leftrightarrow D} \cup \mathcal{E}_{H \leftrightarrow D} \cup \mathcal{E}_{S \leftrightarrow D}$. The additional relation edges are listed in Table 1. In Figure 4, we show an example of the proposed schema-linking graph.

Graph Encoding. The work (Wang et al., 2020) shows that Relative Self-Attention Mech-

	Current Utterance	Interaction History	SQL Query
Columns	U−C−EM U−C−PM U−C−VM	H−C−EM H−C−PM H−C−VM	S−C−EC S−C−UC
Tables	U−T−EM U−T−PM	H−T−EM H−T−PM	S−T−ET S−T−UT

Table 1: Edge types between current utterance U, interaction history H, SQL S, and database schema D (Columns C and Tables T). We set two match types between the language tokens of U, H, and D: **EM** for Exact Match, **PM** for Partial Match. When using database contents, we set **VM** (Value Match) for exactly matching the value of columns. As for SQL S, we simply match the words of tables and columns that appear in it to the target database schema: **EC** (Equal Columns) and **UC** (Unequal Columns) for columns, **ET** (Equal Tables) and **UT** (Unequal Tables) for tables. And we omit the pre-existing relations in schema such as the foreign-key relation (C-C-FK) in the table.

anism (Shaw et al., 2018) is an efficient way to encode graphs whose nodes are at the token level. It rebuilds the calculation of the self-attention module in the transformer layers as follows:

$$\begin{aligned} e_{ij} &= \frac{x_i W^Q (x_j W^K + r_{ij}^K)^T}{\sqrt{d_z}}, \\ \alpha_{ij} &= \underset{j}{softmax}\{e_{ij}\}, \\ z_i &= \sum_{j=1}^{n} \alpha_{ij}(x_j W^V + r_{ij}^V). \end{aligned} \tag{4}$$

HIE-Layers consist of 8 transformer layers, whose self-attention modules are described above. Specifically, we initialize a learned embedding for each type of edge defined above. For every input sample, we build a relation matrix $\mathcal{R} \subseteq (L \times L)$ where L is the length of the input token. $\mathcal{R}^{(i,j)}$ represents the relation type between $i-$th and $j-$th input tokens. While computing the relative attention, we set the $r_{ij}^K = r_{ij}^V = \mathcal{R}_e^{(i,j)}$ where $\mathcal{R}_e^{(i,j)}$ is the corresponding embedding of $\mathcal{R}^{(i,j)}$.

3.5 Decoder

To build the decoder of HIE-SQL, we apply the same work (Yin and Neubig, 2017) as Wang et al. (2020) propose, which generates SQL as an abstract syntax tree in depth-first traversal order by using LSTM (Hochreiter and Schmidhuber, 1997) to output sequences of decoder actions. We recommend the reader to refer to the work (Yin and Neubig, 2017) for details.

3.6 Regularization Strategy

We introduce R-Drop (Liang et al., 2021), a simple regularization strategy, to prevent the overfitting of the model. Concretely, we feed every input data x_i to go through our model twice and the loss function is as follows:

$$\begin{aligned} \mathcal{L}_{NLL}^i &= -\,log\mathcal{P}_1(y_i|x_i) - log\mathcal{P}_2(y_i|x_i), \\ \mathcal{L}_{KL}^i &= \frac{1}{2}(D_{KL}(\mathcal{P}_1(y_i|x_i) \| \mathcal{P}_2(y_i|x_i)) \\ &\quad + D_{KL}(\mathcal{P}_2(y_i|x_i) \| \mathcal{P}_1(y_i|x_i))), \\ \mathcal{L}^i &= \mathcal{L}_{NLL}^i + \mathcal{L}_{KL}^i, \end{aligned} \tag{5}$$

where -$log\mathcal{P}_1(y_i|x_i)$ and -$log\mathcal{P}_2(y_i|x_i)$ are two output distributions for input x_i at all decoder steps, $\mathcal{L}_{NLL}^i$ is the negative log-likelihood learning objective of decoder actions, and $\mathcal{L}_{KL}^i$ is the bidirectional Kullback-Leibler (KL) divergence between these two output distributions.

4 Experiment

4.1 Setup

Setting. We initialize the weights of Language Model with GraPPa (Yu et al., 2021a), an effective pre-training model for table semantic parsing that performs well on the context-independent text-to-SQL datasets (e.g. Spider). We stack 8 HIE-layers, which are introduced in section 3.4, on top of the Language Model. When training the model with R-Drop, we set the Dropout rate of 0.1 for the Language Model and HIE-Layers, 0.3 for the decoder. We use Adam optimizer to conduct the parameter learning and set the learning rate of $1e^{-5}$ for fine-tuning GraPPa and $1e^{-4}$ for HIE-Layers and Decoder. The learning rate linearly increases to the setting point at first $max\_steps/8$ steps, then decreases to 0 at max_steps, where $max\_steps =$ 50000 with 24 training batch-size. As for SQL-BERT, we fine-tune CodeBERT$_{BASE}$ (Feng et al., 2020) on the dataset we described in Section 3.3. We set the learning rate as $1e^{-5}$, a batch size of 64,

Dataset	System Response	Interaction	Train	Dev	Test	User Questions	Vocab	Avg Turn
CoSQL	✓	3007	2164	293	551	15598	9585	5.2
SparC	✗	4298	3034	422	842	12726	3794	3.0

Table 2: Details of SparC and CoSQL datasets.

Model	**SparC**				**CoSQL**			
	Dev		**Test**		**Dev**		**Test**	
	QM	**IM**	**QM**	**IM**	**QM**	**IM**	**QM**	**IM**
EditSQL + BERT (Zhang et al., 2019)	47.2	29.5	47.9	25.3	39.9	12.3	40.8	13.7
IGSQL + BERT (Cai and Wan, 2020)	50.7	32.5	51.2	29.5	44.1	15.8	42.5	15.0
IST-SQL + BERT (Wang et al., 2021)	-	-	-	-	44.4	14.7	41.8	15.2

Table 3: Performances of various models in SparC and CoSQL. QM and IM stand for question match and interaction match respectively. The models with † are proposed for the context-independent text-to-SQL task and applied to the context-dependent text-to-SQL task by just appending interaction history utterances to the input.

and train SQLBERT for 10 epochs. The shape of learned weights of the linear layer applied to the output of SQLBERT is 768×1024. We only need one V100 (32G) GPU to train our model. While inferring, we set the beam size to 3.

Datasets. We conduct experiments on two cross-domain context-dependent text-to-SQL datasets, SparC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a). Table 2 depicts the statistic information of them.

Evaluation Metrics. The main metric we used to measure model performance in SparC and CoSQL is interaction match (IM), which requires all output SQL queries in interaction to be correct. We also use question match (QM) to evaluate the accuracy of every single question.

4.2 Experiment Result

Results of our proposed HIE-SQL model are shown in Table 3. In terms of interaction match, our model achieves state-of-the-art performances on both development set and test set of SparC and CoSQL. For the test set of SparC, HIE-SQL outperforms the prior state-of-the-art (Yu et al., 2021b) by 4.8% in IM and 2.2% in QM. For CoSQL, compared with the previous state-of-the-art (Scholak et al., 2021), a rule-based auto-regressive method based on the large pre-trained model-T5-3B (Raffel et al., 2020) which contains 2.8 billion parameters, HIE-SQL improves IM of development set by 4.5% and IM of the test set by 0.9% with only 580M parameters. Besides, HIE-SQL surpasses RAT-SQL + SCoRe in all metrics of SparC and CoSQL. This demonstrates that properly integrating interaction utterances and predicted SQL queries is an effective way to enhance the model's ability for Context-Dependent Text-to-SQL Semantic Parsing.

To further explore the advantages of HIE-SQL, we test the performance on different turns and at different difficulty levels of utterances. As shown in Figure 5, with the increase of turns, the lead of our model gets greater and greater. When the indexes of turns are greater than or equal to 4, the accuracy of HIE-SQL is 17% higher than that of R^2SQL. It demonstrates that the main contribution of introducing SQL query is to improve the robustness of the model to long interaction. HIE-SQL is also robust to the varying difficulty levels of utterances. Our model performs equally in hard and extra hard levels, and achieves 39.6% accuracy on the extra hard level, which is 17.8% higher than that of R^2SQL.

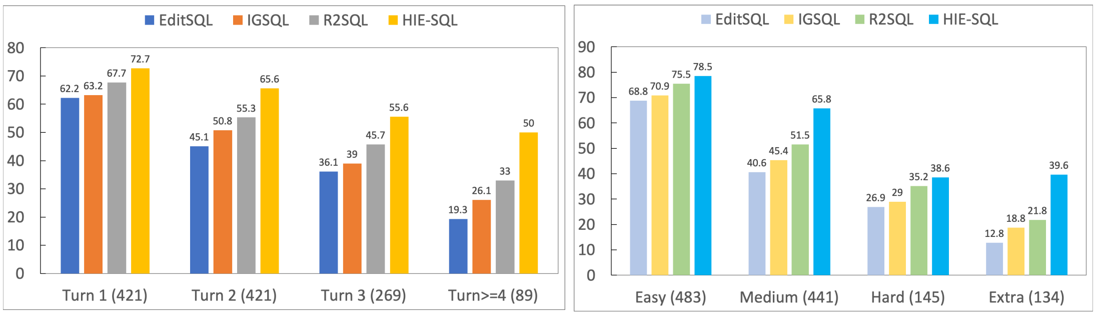

Figure 5: Performances of previous works and HIE-SQL in different turns (left) and different difficulty levels (right) on SparC.

	SparC		**CoSQL**	
Model	**QM**	**IM**	**QM**	**IM**
HIE-SQL	64.7	**45.0**	56.4	**28.7**
w/o SQL query	**65.8**	44.3	**56.5**	23.9
w/o SQLBERT	63.9	44.7	54.8	26.3
w/o $\mathcal{E}_{H\leftrightarrow D}$	64.0	44.3	56.0	26.3

Table 4: Ablation study of HIE-SQL in development sets of SparC and CoSQL. As for ablation on SQL query, we drop the SQL query and only feed utterances and database schema to the model. As for ablation on SQLBERT, we directly concatenate the tokens of SQL query and other context tokens for the input of the language model. And w/o $\mathcal{E}_{H\leftrightarrow D}$ means we treat historical utterances like the current utterance in our schema-linking.

4.3 Ablation Study

We provide ablation studies to examine the contribution of each component of HIE-SQL. We want to identify whether introducing the last SQL query has a significant impact on performance. Also, we would like to investigate whether the pre-trained SQL encoder, SQLBERT, can improve the model's ability to understand SQL queries. What's more, we conduct another ablation study regarding additional graph edges between historical utterances and database schema $\mathcal{E}_{H\leftrightarrow D}$ to check the necessity of the join of historical utterance information in schema-linking.

As shown in Table 4, Our full model achieves about 5 points and 1 point improvement of IM in CoSQL and SparC respectively compared with the model without the last SQL query input. The pre-encoding SQL query by SQLBERT can further improve the performance. It confirms SQLBERT's ability to efficiently represent SQL features. In addition, $\mathcal{E}_{H\leftrightarrow D}$ also plays a positive role.

Dataset	Model	T-F	F-T	T-T
SparC	HIE-SQL	125	88	**383**
	w/o SQL query	132	104	379
CoSQL	HIE-SQL	140	106	**278**
	w/o SQL query	161	128	254

Table 5: The counts of different switches in the pairs of adjacent predicted SQL queries. T-F stands for the match of the former predicted query and unmatch of the later predicted query with golden queries. F-T stands for the reverse case. T-T is the case of both matching.

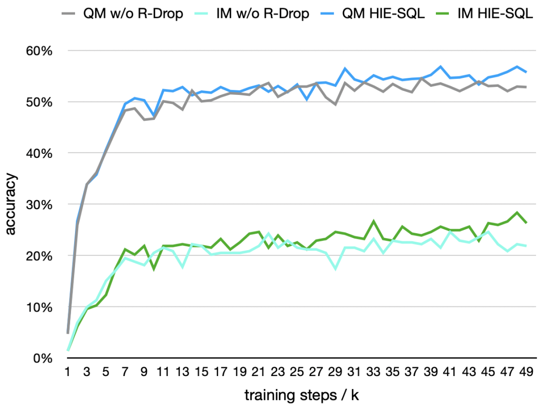

Figure 6: Ablation study result of regarding R-Drop in development set of CoSQL. We show the performances in QM and IM of two models at different training steps. We set the beam size = 1 in the inference stage.

Table 5 shows the continuity of performance of our model compared with that of the model without the last SQL query input. Our model has a higher rate of continuous match, but a lower rate of switching from mismatch to match. It illustrates that our model does use the SQL information and is sensitive to the accuracy of the last predicted SQL query which explains the higher question match without SQL query input.

As shown in Figure 6, the model with R-drop outperforms the model without R-Drop in both QM

U_{a1}	Which cartoon aired first?
HIE-SQL	SELECT title FROM cartoon ORDER BY original_air_date asc LIMIT 1
RAT-SQL	SELECT title FROM cartoon ORDER BY original_air_date asc LIMIT 1
U_{a2}	What was the last cartoon to air?
HIE-SQL	SELECT title FROM cartoon ORDER BY original_air_date desc LIMIT 1
RAT-SQL	SELECT title FROM cartoon ORDER BY original_air_date desc LIMIT 1
U_{a3}	What channel was it on?
HIE-SQL	SELECT channel FROM cartoon ORDER BY original_air_date desc LIMIT 1
RAT-SQL	SELECT channel FROM cartoon ORDER BY original_air_date desc LIMIT 1
U_{a4}	What is the production code?
HIE-SQL	SELECT production_code FROM cartoon ORDER BY original_air_date desc LIMIT 1
RAT-SQL	SELECT production_code FROM cartoon ORDER BY original_air_date asc LIMIT 1

U_{b1}	List the name of the teachers and the courses assigned for them to teach.
HIE-SQL	SELECT Name, Course FROM ...
RAT-SQL	SELECT Name, Course FROM ...
U_{b2}	Arrange this list with the teachers name in ascending order
HIE-SQL	ELECT Name, Course FROM ... ORDER BY Name Asc
RAT-SQL	ELECT Name, Course FROM ... ORDER BY Name Asc
U_{b3}	Include teachers ID in tha same list
HIE-SQL	SELECT Name, Course, Teacher_ID FROM ... ORDER BY Name Asc
RAT-SQL	SELECT Teacher_ID FROM ... ORDER BY Teacher_ID Asc

Table 6: Examples in CoSQL. U_{ij} is the input utterance of turn j of example i with corresponding predictions of HIE-SQL and RAT-SQL following. All predictions of HIE-SQL are the ground truth queries in the cases.

and IM. Additionally, the standard deviations of the IM in the last 20k steps are 0.014 and 0.015 of HIE-SQL and the one without R-Drop respectively even the curve of HIE-SQL has a more obvious upward trend. It shows that R-Drop improves the robustness of our model and stabilizes its performance in IM. What's more, when the key information the last SQL query is introduced, our model needs more training steps to fit the same training data. After adding R-drop, in the same training step, the model will forward the data twice to get the KL loss. This is equivalent to doubling the amount of training data in the same step. Therefore, our model has learned the training data more fully and is able to make full use of various historical interaction information.

4.4 Case Study

In Table 6, we offer some cast studies about the performance of HIE-SQL and RAT-SQL in the examples of CoSQL in order to demonstrate the superiority of HIE-SQL in context-dependent text-to-SQL semantic parsing problems more visually. As the examples show, RAT-SQL fails to distinguish the right one from two long-range dependences in U_{a1} and U_{a2} in the first example and fails to inherit the query information from U_{b2} in U_{b3}. By contrast, HIE-SQL inherits the right context-dependence from the last predicted query to avoid the confusion.

5 Conclusion

We present HIE-SQL, a history information enhanced context-dependent text-to-SQL model, which targets at explicitly capturing the context-dependence from both interaction history utterances and the last predicted SQL query. With the help of the proposed bimodal pre-trained model, SQLBERT, HIE-SQL bridge the gap between the utterances and predicted SQL despite the mismatch of natural language and logic-form SQL. Moreover, we also introduce a method of schema-linking to enhance the connections among utterances, SQL query, and database schema.

Taken together, HIE-SQL achieves consistent improvements on the context-dependent text-to-SQL task, especially in the interaction match metric. HIE-SQL achieves new state-of-the-art results on two famous context-dependent text-to-SQL datasets, SparC and CoSQL.

Abstract

Chinese spelling correction (CSC) models detect and correct a typo in texts based on the misspelled character and its context. Recently, Bert-based models have dominated the research of Chinese spelling correction (CSC). These methods have two limitations: (1) they have poor performance on multi-typo texts. In such texts, the context of each typo contains at least one misspelled character, which brings noise information. Such noisy context leads to the declining performance on multi-typo texts. (2) they tend to overcorrect valid expressions to more frequent expressions due to the masked token recovering task of Bert. We attempt to address these limitations in this paper. To make our model robust to contextual noise brought by typos, our approach first constructs a noisy context for each training sample. Then the correction model is forced to yield similar outputs based on the noisy and original contexts. Moreover, to address the overcorrection problem, copy mechanism is incorporated to encourage our model to prefer to choose the input character when the miscorrected and input character are both valid according to the given context. Experiments are conducted on widely used benchmarks. Our model achieves superior performance against state-of-the-art methods by a remarkable gain. We release the source code and pre-trained model for further use by the community[1].

1 Introduction

Chinese spelling correction (CSC) is a task to detect and correct spelling errors in texts(Chen et al., 2013; Yu and Li, 2014). It is a challenging yet important task, which plays an important role in various NLP applications such as optical character recognition(Afli et al., 2016; Dong and Smith, 2018), automatic speech recognition(Sarma and Palmer, 2004; Errattahi et al., 2018) and search engine(Martins and Silva, 2004; Gao et al., 2010). In Chinese, spelling error is mainly caused by the misuse of phonologically and visually similar characters(Liu et al., 2021). According to Liu et al. (2010), about 83% of errors are related to phonological similarity and 48% are related to visual similarity. Table1 illustrates two examples.

ID	**Text**	**Correction**
E1	我是你得(de)学生。	的(de)
E2	他很少座(zuo)捷运粗(cu)去玩。	坐(zuo), 出(chu)

Table 1: Examples of Chinese spelling errors, where error characters are marked in red and their phonics are given in brackets.

Corpus	**Sentence-level**			**Character-level**		
	me	te	$ratio$	me	te	$ratio$
S13	200	969	21%	450	1,219	37%
S14	155	535	29%	406	766	53%
S15	121	550	22%	284	704	40%

Table 2: The multi-typo statistics of SIGHAN13, SIGHAN14 and SIGHAN15, where me denotes the number of multi-typo sentences, te denotes the number of total misspelled sentences, $ratio = \frac{me}{te}$. The character-level me denotes the amount of misspelled characters in multi-typo sentences.

In recent years, BERT(Devlin et al., 2019) based models have dominated the research of Chinese spelling correction(Cheng et al., 2020; Zhang et al., 2020; Bao et al., 2020; Liu et al., 2021; Li and Shi, 2021; Huang et al., 2021), which follow the paradigm of non-autoregressive generation. Typically, these models generate corrected characters for all input characters in parallel, where the generated characters can be the same as the input characters. Thanks to the success of BERT, these models significantly improved the results of CSC benchmarks. However, they have two limitations.

First, multi-typo texts are very common in CSC datasets, which is defined as texts containing more than one typos. Table 2 presents

Zhang et al. (2020)	96.9	82.9	89.4	91.2	73.8	81.6
Cheng et al. (2020)	96.7	81.4	88.4	95.9	69.9	80.9
Liu et al. (2021)	97.2	85.0	90.7	94.0	75.9	84.0

Table 3: The correction performance of various CSC models on the whole and multi-typo evaluation set.

the multi-typo statistics of SIGHAN13(Wu et al., 2013), SIGHAN14(Yu et al., 2014) and SIGHAN15(Tseng et al., 2015). However, we find the performance of existing CSC models declines sharply on multi-typo texts. Table 3 illustrates the results of the latest CSC models on SIGHAN15 and a multi-typo subset extracted from it. We observe that all models in this table perform worse on multi-typo set than on the whole set. Generally, CSC models detect and correct a typo based on the misspelled character and its context. In multi-typo texts, the context of each character contains at least one typo, which results in noisy information. Take *E2* in Table 1 as an example, the context of “座" contains the typo “粗" and vice versa. Such noisy context leads to the declining performance on multi-typo texts. We call this problem *Contextual Typo Disturbance*.

Second, Bert is a masked language model(Devlin et al., 2019). It learned how to recover a masked token based on its context from large corpus. When there are multiple valid characters for a masked position, the model prefers to recover it with the most frequent one in the training corpus. As a consequence, Bert-based models tend to overcorrect an infrequent but valid expression to a more frequent expression. For instance, both BERT(Cheng et al., 2020; Liu et al., 2021) and PLOME(Liu et al., 2021) wrongly correct “这并非是说..." to “这并不是说...". We call this problem *Overcorrection*.

In this paper, we attempt to address the aforementioned problems by proposing a new model called CRASpell, which is short for **C**ontextual typo **R**obust **A**pproach for Chinese spelling correction. Figure 1 illustrates the framework. The *Contextual Typo Disturbance* problem is caused by the noise of contextual typos, therefore we try to make our model robust to such noise. To this end, our approach first generates a noisy context for each training instance, and then forces the correction model to yield similar outputs based on the original and noisy context. Moreover, to address the *Overcorrection* problem, we incorporate the copy mechanism(Gu et al., 2016; Zeng et al., 2018) in our model. Finally, the output for each position in a given text is the sum of generative distribution and copy distribution. Thus, our model has more chances to keep the input character unchanged when the miscorrected and input characters are both valid according to the given context.

We conduct experiments on the widely used benchmark dataset SIGHAN(Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015). The experimental results show that our model outperforms all the compared approaches. Furthermore, we extract samples containing multiple typos from SIGHAN to construct a multi-typo evaluation set. Experimental results show that our approach achieves 2.6% absolute improvement in detection and 2.7% absolute improvement in correction on the multi-typo set, which demonstrates the effectiveness of our approach for multi-typo texts.

We summarize our contributions as follows. (1) we point out two limitations of existing CSC approaches, which are called the *Contextual Typo Disturbance* problem and the *Overcorrection* problem; (2) we propose an effective model to address these limitations; (3) our model outperforms state-of-the-art methods with remarkable gains.

2 Related Work

Chinese spelling correction is a challenging task in natural language processing, which plays important roles in many applications, such as search engine (Martins and Silva, 2004; Gao et al., 2010), automatic essay scoring (Burstein and Chodorow, 1999; Lonsdale and Strong-Krause, 2003), and optical character recognition (Afli et al., 2016; Wang et al., 2018). It has been an active topic, and various approaches have been proposed in recent years (Yu and Li, 2014; Wang et al., 2018, 2019; Zhang et al., 2020; Cheng et al., 2020; Liu et al., 2021; Li and Shi, 2021; Huang et al., 2021).

Early work on CSC followed the pipeline of error identification, candidate generation and selection. Some researchers focused on unsupervised approaches, which typically adopted a confusion set to find correct candidates and employed language model to select the correct one (Chang, 1995; Huang et al., 2000; Chen et al., 2013; Yu and Li, 2014; Tseng et al., 2015). However, these methods failed to condition the correction on the input

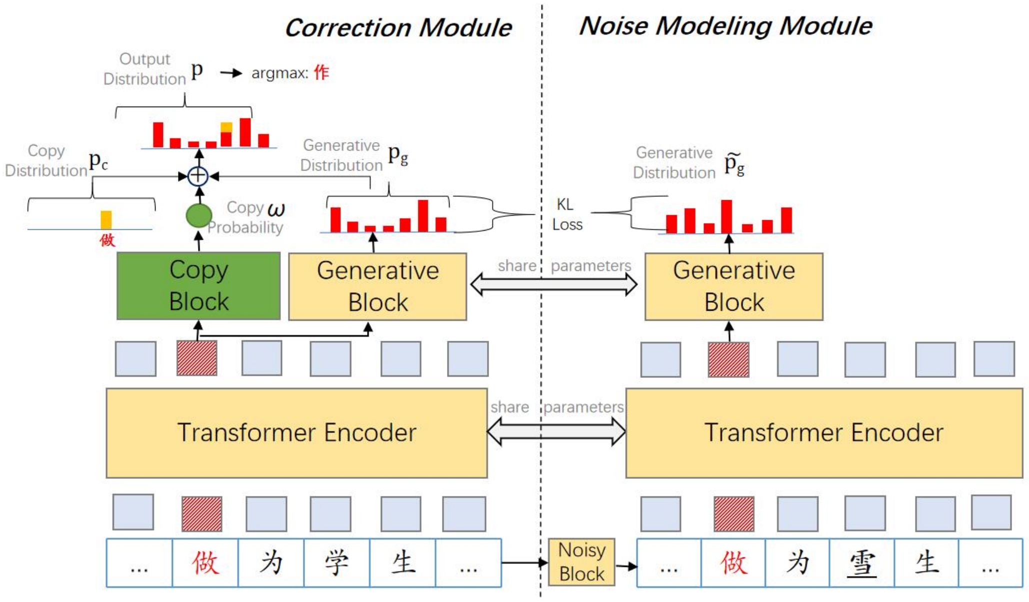

Figure 1: Framework of the proposed *CRASpell*. **Left**: This component presents the correction module, which illustrates how our model makes prediction for the red character “做". **Right**: This component presents the noise modeling module, which forces the model to yield similar distribution for “做" separately based on the original and noisy contexts. This module is only active in the training process.

sentence. In order to model the input context, discriminative sequence tagging methods (Wang et al., 2018) and sequence-to-sequence generative models (Chollampatt et al., 2016; Ji et al., 2017; Ge et al., 2018; Wang et al., 2019) were employed.

BERT (Devlin et al., 2019) is a bidirectional language model based on Transformer encoder (Vaswani et al., 2017). It has been demonstrated effective in a wide range of applications, such as question answering (Yang et al., 2019), information extraction (Lin et al., 2019), and semantic matching (Reimers and Gurevych, 2019). Recently, it has dominated the researches on CSC (Hong et al., 2019; Zhang et al., 2020; Cheng et al., 2020; Liu et al., 2021; Li and Shi, 2021; Huang et al., 2021). Hong et al. (2019) adopted the DAE-Decoder paradigm with BERT as encoder. Zhang et al. (2020) introduced a detection network to generate the masking vector for the BERT-based correction network. Cheng et al. (2020) employed graph convolution network (GCN) (Kipf and Welling, 2016) combined with BERT to model character inter-dependence. In our previous work (Liu et al., 2021), we proposed a task-specific pretrained model for Chinese spelling correction, which masked tokens by similar characters according to confusion set. Li and Shi (2021) proposed to decode with the CRF module. Huang et al. (2021) proposed to incorporate phonological and visual features via a multi-modal module. Although these models achieved some success on benchmarks, all of them suffer from the typo disturbance problem and overcorrection problem.

3 Approach

In this section, we describe the proposed approach and its detailed implementation. Figure 1 illustrates the framework of our model, which is composed of correction module and noise modeling module.

3.1 Task Formulation

Chinese spelling correction aims to detect and correct spelling errors in texts. Recent BERT-based approaches(Cheng et al., 2020; Zhang et al., 2020; Liu et al., 2021; Li and Shi, 2021; Huang et al., 2021) modeled it as a non-autoregressive generation task. Formally, given a character sequence $\mathbf{X} = \{x_1, x_2, ..., x_n\}$ consisting of n characters, the model is expected to generate a target sequence $\mathbf{Y} = \{y_1, y_2, ..., y_n\}$ with the same length as that of $\mathbf{X}$, where typos in $\mathbf{X}$ are corrected in $\mathbf{Y}$.

3.2 Correction Module

As illustrated in Figure 1(left part), the input of this module is the sequence of embeddings $\mathbf{E} = \{\mathbf{e_1}, \mathbf{e_2}, ..., \mathbf{e_n}\}$, where $\mathbf{e_i}$ denotes the embedding of character x_i in a given text $\mathbf{X} = \{x_1, x_2, ..., x_n\}$, which is the sum of word embedding, position embedding and segment embedding of the character. Then, $\mathbf{E}$ is fed into the transformer encoder, which has the same architecture and configuration as that of Bert$_{base}$(Devlin et al., 2019). The transformer encoder generates hidden representation matrix $\mathbf{H} = \{\mathbf{h_1}, \mathbf{h_2}, ..., \mathbf{h_n}\}$ for $\mathbf{X}$, where $\mathbf{h_i} \in \mathbf{R}^{768}$ is the representation of x_i. The final output of this module is the weighted sum of generative distribution and copy distribution, where the weight is the copy probability learned by the model.

Generative Distribution The generative distribution, $\mathbf{p_g} \in \mathbf{R}^{n_v}$, is computed by the generative block in Figure 1, which is an one-layer feed forward network with softmax normalization. The following equation describes how this block works:

$$\mathbf{p_g} = softmax(\mathbf{W_g}\mathbf{h_i} + \mathbf{b_g}) \qquad (1)$$

where $\mathbf{W_g} \in \mathbf{R}^{n_v \times 768}$ and $\mathbf{b_g} \in \mathbf{R}^{768}$ are generative parameters, n_v is the size of vocabulary.

Copy Distribution Denote the index of x_i in the vocabulary as $idx(x_i)$, then the copy distribution of x_i, $\mathbf{p_c} \in \{0, 1\}^{n_v}$, is a one-hot vector satisfying:

$$\mathbf{p_c}[k] = \begin{cases} 0 & k \neq idx(x_i) \\ 1 & k = idx(x_i) \end{cases} \qquad (2)$$

Copy Probability The copy probability, $\omega \in \mathbf{R}$, is computed by the copy block in Figure 1, which is a two-layer feed forward network with layer normalization. The following equations show how this block works:

$$\begin{aligned} &\mathbf{h_c} = \mathbf{W_{ch}} f_{ln}(\mathbf{h_i}) + \mathbf{b_{ch}} \\ &\mathbf{h_c^{'}} = f_{ln}(f_{act}(\mathbf{h_c})) \\ &\omega = Sigmoid(\mathbf{W_c}\mathbf{h_c^{'}}) \end{aligned} \qquad (3)$$

where $\mathbf{h_i}$ is the hidden representation of x_i generated by the transformer block, $\mathbf{W_{ch}} \in \mathbf{R}^{768 \times d_c}$, $\mathbf{b_{ch}} \in \mathbf{R}^{d_c}$, $\mathbf{W_c} \in \mathbf{R}^{d_c \times 1}$ are model parameters, f_{act} is the activation function, f_{ln} is the layer normalization function.

The final output distribution, $\mathbf{p}$, is computed by the following equation:

$$\mathbf{p} = \omega \times \mathbf{p_c} + (1 - \omega) \times \mathbf{p_g} \qquad (4)$$

In previous CSC models(Cheng et al., 2020; Zhang et al., 2020; Liu et al., 2021), the generative distribution $\mathbf{p_g}$ is the final output. These methods suffer the overcorrection problem due to the masked token recovering task of BERT. On contrast, our model incorporates the copy distribution $\mathbf{p_c}$ in the final output, which enables our model to have more chances to choose the input character when it is valid but not the best for BERT.

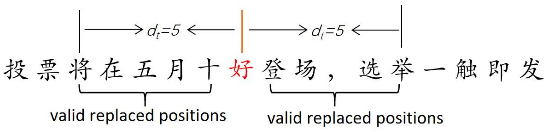

Figure 2: The illustration of valid replaced positions when $d_t = 5$, where the red character is a typo.

3.3 Noise Modeling Module

The noise modeling module is designed to solve the contextual typo disturbance problem by encouraging the correction model to yield similar distributions for the original and noisy contexts. As illustrated in Figure 1 (right part), this module first generates a noisy context based on the input sample, then takes the noisy context as input and yields a generative distribution. At last, the generative distribution is forced to be similar with that generated by the correction module. Note that the noise modeling module is only active in training process.

Noisy Block This component generates noisy contexts by replacing characters of the original training samples. There are two factors affect the quality of the generated noisy context, which can be represented by the following questions.

- Which positions should be replaced?
  Table 3 shows that contextual typo significantly declines the recall score on multi-typo set. We believe this phenomenon occurs because the noise around typos affects CSC models' correction of typos. Therefore, we sample from typo-around positions for replacing, which is defined as positions less than d_t tokens away from the nearest typo. Figure 2 illustrates the valid replaced positions when $d_t = 5$. If a text does not contain any typo, the noisy block will directly output the original text without replacing any positions.

  In our work, we replace at most one position for each typo. If there already exists a typo in the valid positions, we will not replace any position. Our preliminary experiments show that more replaced positions declines the performance. We believe the reason is that too many replaced positions results in too much noise in the context, which declines the performance on non multi-typo texts.

- What characters should be replaced with?
  Following our previous work (Liu et al., 2021), to simulate true contextual typos, we replace

each chosen position by a similar character according to a publicly available confusion set(Wu et al., 2013). Specifically, we replace a chosen position with (i) a random phonologically similar character 70% of the time (ii) a random visually similar character 15% of the time (iii) a random token in the vocabulary 15% of the time.

Generative Distribution Given a training sample $\mathbf{X}$, the noise modeling module first constructs a noisy instance $\widetilde{\mathbf{X}}$ via the noisy block, then yields a generative distribution, $\widetilde{\mathbf{p_g}}$, according to Equation 1 based on $\widetilde{\mathbf{X}}$. Both the transformer encoder and generative block in this module share parameters with that in the correction module.

KL-diverence Loss We force the correction module and noise modeling module to yield similar outputs by minimizing the bidirectional Kullback-Leibler divergence between the generative distributions (see Equation 5).

$$\mathcal{L}_{KL} = \frac{1}{2}(\mathcal{D}_{KL}(\mathbf{p_g}||\widetilde{\mathbf{p_g}}) + \mathcal{D}_{KL}(\widetilde{\mathbf{p_g}}||\mathbf{p_g})) \quad (5)$$

3.4 Learning

Given a training sample ($\mathbf{X}$, $\mathbf{Y}$), the correction loss of the i-th token is defined as:

$$\mathcal{L}_c^i = -\log \mathbf{p}(\mathbf{Y_i}|\mathbf{X}) \quad (6)$$

where $\mathbf{X}$ is a character sequence, $\mathbf{Y}$ is the corrected sequence of $\mathbf{X}$, $\mathbf{p}$ is the output distribution defined in Equation 4. The learning process is driven by optimizing two objectives:

$$\mathcal{L}^i = (1 - \alpha_i)\mathcal{L}_c^i + \alpha_i \mathcal{L}_{KL}^i \quad (7)$$

$$\alpha_i = \begin{cases} \alpha, & \widetilde{\mathbf{X}}_i = \mathbf{X}_i \\ 0, & otherwise \end{cases} \quad (8)$$

where α is a trade-off factor for $\mathcal{L}_c$ and $\mathcal{L}_{KL}$. Note that the constructed noise itself will not be involved in the training process but only active as context (see Equation 8). This strategy is designed to ensure that the constructed noise will not change the ratio of positive and negative samples in the training corpus.

4 Experiments

4.1 Datasets

Following previous work(Cheng et al., 2020; Liu et al., 2021; Li and Shi, 2021), the training data is composed of 10K manually annotated samples from SIGHAN(Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015), and 271K automatically generated samples from Wang et al. (2018). To evaluate the performance of the proposed method, we use the test set from the latest SIGHAN benchmark(Tseng et al., 2015) as in (Zhang et al., 2020; Li and Shi, 2021; Liu et al., 2021). This set contains 550 positive samples and 550 negative samples with 461 types of errors, where negative samples denote texts without any typos.

Dataset	*TotalSen*	*TypoSen*	*TypoChar*
SIGHAN15	1100	550	704
MultiTypo	242	121	284

Table 4: The statistics of evaluation datasets, where *TotalSen* is the amount of texts, *TypoSen* is the amount of texts containing typos, *TypoChar* is the amount of misspelled characters. MultiTypo is a subset of SIGHAN15.

Besides, we also construct a multi-typo test set by extracting all the samples containing multiple typos from SIGHAN. To make the ratio of positive and negative samples equal to that of SIGHAN, negative samples are also randomly sampled. Table 4 illustrates the statistics of SIGHAN and multi-typo test set.

4.2 Evaluation Metrics

The most widely used metrics in previous work are precision, recall and F1 scores. However, these metrics were calculated via different methods, which could be grouped into three groups: character-level scores(Wang et al., 2018, 2019; Cheng et al., 2020; Liu et al., 2021), sentence-level scores evaluated based the method from (Hong et al., 2019)[2](Hong et al., 2019; Cheng et al., 2020; Liu et al., 2021) and sentence-level scores based on the method from SighanHan Tools[3](Li and Shi, 2021; Huang et al., 2021).

In this work we choose the character-level scores for the following reasons. (1) Character is the minimum evaluation unit of CSC, thus character-level metrics can reflect the ability of a model in finer gained. (2) The CSC test corpus only contains about 1,000 sentences, but contains tens of thousands of characters. Therefore the results on character level are statistically more confident.

---

[3] http://nlp.ee.ncu.edu.tw/resource/csc.html

4.3 Hyper Parameter Settings

Following previous work(Cheng et al., 2020; Liu et al., 2021), we set the maximum sentence length to 180, batch size to 32 and the learning rate to 5e-5. The hidden size d_c in the copy block is set to 384. The window size d_t for sampling replaced positions is set to 5. The trade-off factor α in Equation 7 is set to 0.05. We initialize the transformer encoder by cBERT released in our previous work (Liu et al., 2021)[4], which has the same architecture with Bert$_{base}$(Devlin et al., 2019) but is pretrained with misspelled knowledge. Following (Cheng et al., 2020; Liu et al., 2021), all experiments are conducted for 4 runs with different seeds and the averaged metrics are reported.

4.4 Baseline Models

Recent researches have demonstrated that Bert-based models(Zhang et al., 2020; Cheng et al., 2020; Liu et al., 2021; Li and Shi, 2021; Huang et al., 2021) significantly outperform other models including LM-based models(Huang et al., 2000; Chen et al., 2013; Yu and Li, 2014) and non-Bert neural models(Wang et al., 2018, 2019). Therefore, we only compare with recent Bert-based methods. However, it is challenging to compare to all of them since they employed different evaluation methods as mentioned in Section 4.2. We compare with methods who either reported character-level results or released source codes.

- *SoftMask*(Zhang et al., 2020) introduced the soft-masking strategy in Bert to improve the performance of error detection.
- *SpellGCN*(Cheng et al., 2020) combined GCN network with BERT to model the relationship between characters.
- *Tail2Tail*(Li and Shi, 2021) applied the CRF decoder based on BERT.
- *cBERT* is a task-specific pretrained model for CSC proposed in our previous work (Liu et al., 2021), which has the same architecture with Bert but is pretrained with misspelled knowledge. Our model is initialized by cBERT.
- *PLOME*(Liu et al., 2021) is similar with cBERT but incorporates phonological and visual features based on the sequences of phonics and strokes.

As illustrated in Table 5, we also present the performances of these methods on multi-typo subset. All the results are obtained by running publicly available codes, which are SoftMaskBert[5], SpellGCN[6], Tail2Tail[7] and PLOME[8]. Besides, we also implement two baselines:

- *cBERTCopy* employs the copy mechanism (see Section 3.2) based on *cBERT*.
- *cBERTNoise* employs the noise modeling module (see Section 3.3) based on *cBERT*.

Moreover, our noise modeling loss is similar with that in Rdrop(Liang et al., 2021), which fed each sentence into the model twice with drop out operation and encouraged the model to yield similar outputs. To make comparison with Rdrop, we implement it based on cBERT, which is denoted by *cBERTRdrop*.

4.5 Main Results

Table 5 illustrates the performance of the proposed method and baseline models. From the table we observe that:

1) With the incorporation of copy mechanism, *cBERTCopy* achieves consistent improvements against *cBERT* on the precision of all evaluations. This result demonstrates that the copy mechanism can alleviate the overcorrection problem.

2) With the incorporation of noise modeling module, *cBERTNoise* outperforms *cBERT* on all metrics. Especially, *cBERTNoise* significantly improves the detection and correction score by 1.6% and 2.0% on the multi-typo dataset. This result demonstrates that the noise modeling module is very effective for multi-typo texts.

3) *cBERTRdrop* does not replace any positions in the noisy block. We observe that it fails to achieve improvements on the multi-typo set. This result indicates that noisy contexts are necessary to train an effective model for multi-typo texts.

4) The proposed *CRASpell* jointly incorporates the copy mechanism and noise modeling module. It achieves the best performance, indicating that the copy mechanism and noise modeling module are complementary to each other. Moreover, the proposed model outperforms all previous work on both datasets, especially with remarkable gains on the

Table 5: The performance of our approach and baseline models on SIGHAN15. Following (Cheng et al., 2020; Liu et al., 2021), we run the experiments 4 times and report the average metrics. All the results on multi-typo subset and results with '*' are obtained by our evaluations.

multi-typo subset. This result further demonstrates that our model is effective to solve the contextual typo disturbance problem.

To make more comprehensive comparisons, we also evaluate the proposed model on SIGHAN14(Yu et al., 2014). Similar with SIGHAN15, we construct a multi-typo test set by extracting a subset from SIGHAN14. Table 6 illustrates the result, from which we observe that *CRASpell* consistently achieves remarkable improvements.

4.6 Effects of Different Replaced Positions

In the noisy block (see Section 3.3), we sample typo-around positions for replacing. In this subsection, we implement a new sampling strategy called *Random* for comparison, which randomly samples positions from the whole text for replacing. Table 7 presents the result. We observe that both replacing strategies improve the performance, which demonstrates the effectiveness of the proposed noise modeling module. Furthermore, *Typo-around* strategy outperforms *Random* strategy, verifying our hypothesis in Section 3.3 that previous CSC models performed poorly on multi-typo texts because of the noise around typos.

Moreover, we also investigate the effects of contextual typos with different distances to target typos. To this end, we construct different test sets by adding a contextual typo via randomly replacing a character with different distances to each typo in the SIGHAN15 test set. Then we run *cBERT* on these test sets. Figure 3 illustrates the results, from which we observe that closer contextual typos cause more decrease. Furthermore, when the distance is more than 5, contextual typos nearly have no effects to the CSC model. Therefore, in our experiments we set d_t to 5.

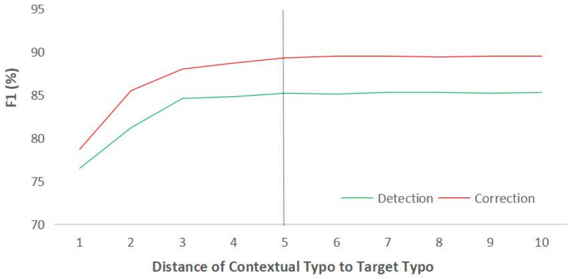

Figure 3: The effects of the contextual typo with different distance to target typos.

4.7 Effects of Different Replaced Characters

In the noisy block, each chosen position is replaced by characters based on confusion set. In this subsection, we implement a new replacing strategy called *Random* for comparison, which replaces each chosen position by a random character from the vocabulary. Table 8 presents the results. We observe that the *Random* strategy failed to achieve obvious improvements on the multi-typo set. The main reason is that contextual typos constructed by this strategy is significantly different from true contextual typos. On contrast, the *ConfusionSet* strategy achieves improvements with remarkable gains.

4.8 Effects of the Copy Block

Bert(Devlin et al., 2019) is a masked language model and learned lots of common expressions

Method	Whole Set (1,062 sentences)						Multi-typo Subset (310 sentences)					
	Detection-level			Correction-level			Detection-level			Correction-level

	D-F	C-F	D-F	C-F
cBERT	85.3	89.5	84.8	83.9
MultiRound	85.0	90.2	86.1	85.1
NoseTrain	85.2	89.7	85.4	84.5
cBERTNoise	**86.1**	**90.9**	**86.4**	**85.9**

Table 10: Results of different methods for multi-typo texts on SIGHAN15.

during pre-training on large corpus. As a consequence, Bert-based models tend to overcorrect an infrequent but valid expression to a more frequent expression. To solve this problem, we propose to incorporate the copy mechanism in our correction model. Besides *cBERT*, we also investigate the effects of the copy block on *BERT* to further demonstrate its effectiveness. Table 9 illustrates the results. We observe that with the incorporation of copy block, both *BERTCopy* and *cBERTCopy* achieve better performances. Moreover, *cBERTCopy* achieves less improvements than *BERTCopy*. This phenomenon occurs because *cBERT*(Liu et al., 2021) is pre-trained for CSC, thus the overcorrection problem is not as serious as that in *BERT*.

4.9 Comparison of Different Methods for Multi-typo Texts

In this subsection, we implement another two methods for multi-typo texts. (1) *MultiRound* is based on cBERT but repeatedly corrects a given text in multiple rounds until no error could be detected. (2) *NoiseTrain* is also based on cBERT, but is trained with the noisy texts generated by the noisy block. Table 10 presents the results. We observe that all these methods could achieve improvements on the multi-typo dataset. However, *MultiRound* and *NoiseTrain* fail to achieve improvements on the whole set, which indicates that these methods have negative effects on single-typo or zero-typo texts. On contrast, *cBERTNoise* achieves significant improvements on both test set. This result demonstrates the effectiveness of the proposed framework for multi-typo texts.

In *NoiseTrain*, the constructed noise itself is involved in the correction loss during training, which changes the ratio of positive and negative samples in the training corpus. Moreover, the quality of the constructed noise also will affect the correction model significantly. However, in the proposed approach *cBERTNoise*, the constructed noise only serves as a context (see Equation 8). Therefore, the aforementioned two problems no longer exist. We believe this is the most important factor that enables our model to achieve much better performance.

5 Conclusions

In this work, we first point out two limitations of previous CSC models, which are called *Contextual Typo Disturbance* problem and *Overcorrection* problem. To solve the first problem, we propose the noise modeling module to generate noisy context in training process. Experimental results show that this module is effective on multi-typo texts. To solve the *Overcorrection* problem, we incorporate a copy block in the correction model, which encourages our model to prefer to keep the input character when the miscorrected and input characters are both valid in the given context. Experimental results demonstrate its effectiveness on both BERT and cBERT. Moreover, the proposed model *CRASpell* outperforms all compared models and achieve new state-of-the-art performances on SIGHAN dataset.

Gaussian Multi-head Attention for Simultaneous Machine Translation

Shaolei Zhang [1,2], **Yang Feng** [1,2*]

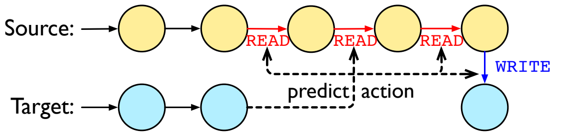
Abstract

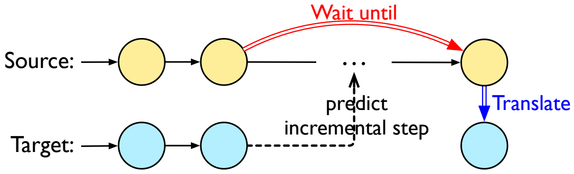
Simultaneous machine translation (SiMT) outputs translation while receiving the streaming source inputs, and hence needs a policy to determine where to start translating. The alignment between target and source words often implies the most informative source word for each target word, and hence provides the unified control over translation quality and latency, but unfortunately the existing SiMT methods do not explicitly model the alignment to perform the control. In this paper, we propose *Gaussian Multi-head Attention* (*GMA*) to develop a new SiMT policy by modeling alignment and translation in a unified manner. For SiMT policy, GMA models the aligned source position of each target word, and accordingly waits until its aligned position to start translating. To integrate the learning of alignment into the translation model, a Gaussian distribution centered on predicted aligned position is introduced as an alignment-related prior, which cooperates with translation-related soft attention to determine the final attention. Experiments on En→Vi and De→En tasks show that our method outperforms strong baselines on the trade-off between translation and latency.

1 Introduction

Simultaneous machine translation (SiMT) (Gu et al., 2017; Ma et al., 2019; Arivazhagan et al., 2019), which outputs translation before receiving the complete source sentence, is mainly used for streaming translation tasks, such as simultaneous interpretation, live broadcast and online translation. Different from full-sentence machine translation which waits for the complete source sentence, SiMT requires a policy to determine where to start translating when given the streaming inputs. The SiMT policy has to trade off between translation quality and latency and an ideal one should wait for the right number of source words, which are sufficient but not excess, until deciding to output target words (Arivazhagan et al., 2019).



(a) Predict READ/WRITE action



(b) Predict incremental step

Figure 1: Comparison diagram of previous and proposed SiMT policy. The previous policies always predict the READ/WRITE action step by step, while our method directly predicts *incremental step* (i.e., number of waiting words) between two adjacent target words.

For full-sentence translation, each target word is generated based on the attended source information, where each source word provides different amount of information for the target word. Among them, the most informative source word can be considered as an aligned word to the target word (Garg et al., 2019). Then for SiMT, the alignment can be a good guider for the policy to determine where to start translating. For high translation quality, the SiMT policy is supposed to start translating after receiving the aligned source word to ensure enough source information for the translation. To consider low latency, the SiMT policy is expected not to wait for too many words after receiving the aligned source word. Therefore, if the alignment can be modeled in the SiMT model explicitly, translation quality and latency can be controlled in a unified manner for an ideal SiMT policy.

However, the existing SiMT methods, mostly employing fixed or adaptive policy, do not reflect

May 22-27, 2022

the alignment information in the modeling, which makes them trade off between translation quality and latency in a separate way. Fixed policy, such as wait-k policy (Ma et al., 2019), waits for a fixed number of source words and then performs READ and WRITE operations one after another, so it is a rule-based policy and precludes alignment modeling. Adaptive policy, such as MILk (Arivazhagan et al., 2019) and MMA (Ma et al., 2020), determines READ/WRITE operations by sampling from a Bernoulli distribution, as shown in Figure 1(a), where the decisions are made independently and no relationship between the decision and translation is introduced, so it has to employ an additional loss to control the latency. Besides, some methods (Wilken et al., 2020; Arthur et al., 2021) apply external ground-truth alignment as an ideal position to start translating, but the performance is inferior to MMA since separating translation and alignment.

In this paper, to explicitly involve alignments in the SiMT modeling, we propose *Gaussian Multi-head Attention* (*GMA*) to develop a SiMT policy with the guidance of alignments. To determine where to start translating with alignment, GMA first models the aligned source position of the current target word via predicting the relative distance from the previous aligned source position, called *incremental steps*, shown in Figure 1(b). Meanwhile, a relaxation offset after the aligned position is set to allow the model to wait for some additional source inputs, thereby providing a controllable trade-off between translation quality and latency in practice. Accordingly, GMA starts translating after receiving the aligned source position and waiting for the extra relaxation offset. To jointly learn alignments (i.e., SiMT policy) and translation, a Gaussian distribution centered on predicted aligned position is introduced as a prior attention over the received source words. As a result, GMA finally uses the posterior attention for translation derived from the alignment-related Gaussian prior and translation-related soft attention. Experiments on En→Vi and De→En SiMT tasks show that GMA outperforms strong baselines on the trade-off between translation quality and latency.

2 Background

GMA is applied on the multi-head attention in Transformer (Vaswani et al., 2017), so we briefly introduce SiMT and the multi-head attention.

2.1 Simultaneous Machine Translation

In a translation task, we denote the source sentence as $\mathbf{x} = \{x_1, \cdots, x_J\}$ and the corresponding source hidden states as $\mathbf{z} = \{z_1, \cdots, z_J\}$ with source length J. The model generates a target sentence $\mathbf{y} = \{y_1, \cdots, y_I\}$ and the corresponding target hidden states $\mathbf{s} = \{s_1, \cdots, s_I\}$ with target length I. Different from the full-sentence machine translation, the source words received by SiMT model are incremental and hence the model needs to decide where to output translation.

Output position Define $g(i)$ (Ma et al., 2019) as a monotonic non-decreasing function of step i, to denote the number of source words received by SiMT model when translating y_i, i.e., $g(i)$ is the output position of y_i.

In SiMT, $g(i)$ is determined by the specific policy, and the probability of generating the target word y_i is $p\left(y_i \mid \mathbf{x}_{\leq g(i)}, \mathbf{y}_{<i}\right)$, where $\mathbf{x}_{\leq g(i)}$ is first $g(i)$ source words and $\mathbf{y}_{<i}$ is previous target words. Therefore, the decoding probability of $\mathbf{y}$ is calculated as:

$$p(\mathbf{y} \mid \mathbf{x}) = \prod_{i=1}^{|\mathbf{y}|} p\left(y_i \mid \mathbf{x}_{\leq g(i)}, \mathbf{y}_{<i}\right) \qquad (1)$$

2.2 Multi-head Attention

Multi-head attention (Vaswani et al., 2017) contains multiple attention heads, where each attention head performs scaled dot-product attention. Our method is based on the cross-attention, where the queries are the target hidden states $\mathbf{s}$, the keys and values both come from the source hidden states $\mathbf{z}$. The soft attention weight α_{ij} is calculated as:

$$\alpha_{ij} = \mathrm{Softmax}\left(\frac{Q(s_i)\, K(z_j)^\top}{\sqrt{d_k}}\right) \qquad (2)$$

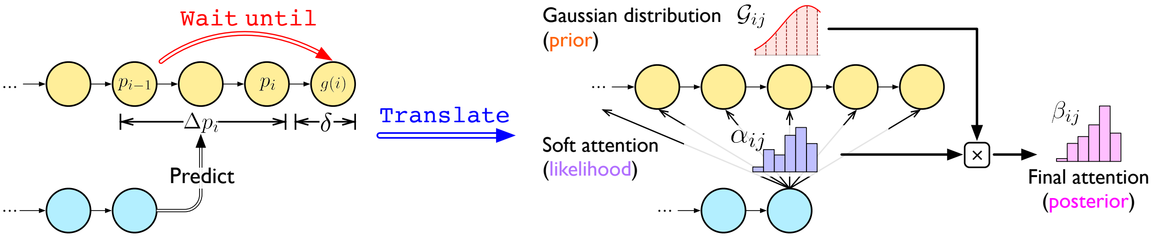
where $Q(\cdot)$ and $K(\cdot)$ are projection functions from the input space to the query and key space respectively, and d_k is the dimension of inputs. Then the context vector c_i is calculated as:

$$c_i = \sum_{j=1}^{J} \alpha_{ij} V(z_j) \qquad (3)$$

where $V(\cdot)$ is a projection function to value space.

3 The Proposed Method

The architecture of GMA is shown in Figure 2. For SiMT policy, GMA predicts the aligned source position of the current target word, and accordingly



(a) Predict incremental step

(b) Integrate alignment in translation

Figure 2: The architecture of GMA. (a) GMA first models the aligned source position of the current target word via predicting incremental step Δp_i, and then waits until the aligned position to start translating. (b) To integrate the learning of alignment (which determines the latency) in translation, we introduce a Gaussian distribution centered on aligned source position as alignment-related prior probability, which is multiplied with soft attention (likelihood probability) to get final attention distribution (posterior probability).

determines the output position. To integrate the learning of SiMT policy within the translation, we introduce a Gaussian prior centered on the predicted aligned position, which is multiplied with soft attention (Eq.(2)) to get final attention distribution. Due to the unimodality of Gaussian prior, it enables the model to learn the position that gets the highest soft attention (i.e., alignment), thereby developing a reasonable SiMT policy. Besides, since the Gaussian prior is continuous and differentiable, it can be integrated into the translation model directly and adjusted with the learning of translation.

3.1 Alignment-Guided SiMT Policy

Alignments prediction To develop a SiMT policy with alignments, GMA first predicts the aligned source position of the current target word. Due to the incrementality of streaming inputs in SiMT, it is unstable to directly predict the absolute position of the aligned source word. Instead, we predict the relative distance from the previous aligned source position, called *incremental step*.

Formally, we denote the aligned source position of the i^{th} target word as $p_i \in [1, J]$ and the incremental step as $\Delta p_i \in (0, +\infty)$. Therefore, the aligned source position p_i is calculated as:

$$p_i = \begin{cases} 1 & i = 0 \\ p_{i-1} + \Delta p_i & i > 0 \end{cases} \tag{4}$$

where we set the initial aligned position p_0 to the first source word, and the incremental step Δp_i is predicted through a multi-layer perceptron (MLP) based on the previous target hidden state s_{i-1}:

$$\Delta p_i = \exp\left(\mathbf{V_p}^\top \tanh(\mathbf{W_p}\ Q(s_{i-1}))\right) \tag{5}$$

where $\mathbf{W_p}$, $\mathbf{V_p}$ are learnable parameters of MLP.

Algorithm 1: SiMT Policy of GMA

```
Input  : Streaming inputs $\mathbf{x}$ (incremental),
         Initial aligned position $p_0 = 1$,
         $i = 1, y_0 = \langle \mathrm{BOS} \rangle$
Output : Target outputs $\mathbf{y}$
while $y_{i-1} \neq \langle \mathrm{EOS} \rangle$ do
    calculate incremental step $\Delta p_i$ as Eq.(5)
    $p_i \leftarrow p_{i-1} + \Delta p_i$
    $g(i) = \lfloor p_i + \delta \rfloor$
    if $g(i) > |\mathbf{x}|$ then                //▷Wait
        Wait Until receive $g(i)$ source words
        continue
    else                                         //▷Translate
        Translate $y_i$ with $\mathbf{x}_{\leq g(i)}$ and $\mathbf{y}_{<i}$
    end
    $i \leftarrow i + 1$
end
```

SiMT policy Besides the predicted aligned position p_i, we also introduce a *relaxation offset* δ to allow the model to wait for some additional source inputs, thereby providing a controllable trade-off between translation quality and latency in practice. Specifically, the output position $g(i)$ (i.e., wait for the first $g(i)$ source words and then translate the i^{th} target word) is calculated as:

$$g(i) = \lfloor p_i + \delta \rfloor \tag{6}$$

where $\lfloor \cdot \rfloor$ is a floor operation. In our experiments, relaxation offset δ is a hyperparameter we set to obtain the translation quality under different latency. Overall, the SiMT policy is shown in Algorithm 1.

3.2 Integrating Alignment in Translation

To jointly learn the SiMT policy (i.e., aligned positions which determine latency) with translation, we weaken the attention of source words far away from the predicted aligned position in advance, thereby forcing the model to move the predicted aligned position to the source word that is most informative for translation (i.e., with the highest soft attention).

To this end, for i^{th} target word, we introduce a Gaussian distribution $\boldsymbol{\mathcal{G}_i}$ centered on aligned position p_i as the prior probability, calculated as:

$$\mathcal{G}_{ij} = \begin{cases} \frac{1}{\sqrt{2\pi}\sigma_i} \exp\left(-\frac{(j-p_i)^2}{2\sigma_i^2}\right) & \text{if } j \leq g(i) \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

where the Gaussian distribution is limited in first $g(i)$ source words. σ_i is the variance used to control the attenuation degree of the prior probability as away from the aligned position. To prevent the prior probability of the furthest source word from being too small, we set $\sigma_i = p_i/2$ according to the "two-sigma rule" (Pukelsheim, 1994). We will compare the performance of different settings of prior probability in Sec.6.1. Note that since the source position is discrete, we normalize the Gaussian distribution with $\mathcal{G}_{ij}/\sum_{k=1}^{g(i)} \mathcal{G}_{ik}$.

Given the prior probability $\mathcal{G}_{ij}$ and soft attention α_{ij} (calculated as Eq.(2)), which is considered as likelihood probability, we calculate the posterior probability $\widehat{\beta}_{ij}$ and normalize it as the final attention distribution β_{ij}:

$$\widehat{\beta}_{ij} = \alpha_{ij} \times \mathcal{G}_{ij} \tag{8}$$

$$\beta_{ij} = \frac{\widehat{\beta}_{ij}}{\sum_{k=1}^{g(i)} \widehat{\beta}_{ik}} \tag{9}$$

Then, the context vector c_i is calculated as:

$$c_i = \sum_{j=1}^{g(i)} \beta_{ij} V(z_j) \tag{10}$$

3.3 Adaptation to Multi-head Structure

When GMA is integrated into the Transformer with L decoder layers and H attention heads per layer, if multiple heads (totally $L \times H$ heads) independently predict their alignments, some outlier[1] heads will cause unnecessary latency (Ma et al., 2020; Zhang and Feng, 2022a).

Therefore, to better adapt to multi-head attention and capture alignments, for each decoder layer, H heads in GMA jointly predict the aligned source position and share it among H heads, while the predicted alignments in each decoder layer still remain independent. Since the output position (determined by predicted alignments) in each layer may be different, the model starts translating after reaching the furthest one. We will compare the performance of different sharing settings in Sec.6.2.

4 Related Work

A reasonable policy is the key to the SiMT performance. Early policies used segmented translation (Bangalore et al., 2012; Cho and Esipova, 2016; Siahbani et al., 2018). Gu et al. (2017) used reinforcement learning to train an agent to decide read/write. Alinejad et al. (2018) added a predict operation to the agent based on Gu et al. (2017).

Recent SiMT policies fall into fixed and adaptive. For fixed policy, Dalvi et al. (2018) proposed STATIC-RW, which alternately read and write RW words after reading S words. Ma et al. (2019) proposed a wait-k policy, which translates after lagging k source words. Elbayad et al. (2020a) enhanced wait-k policy by sampling different k. Zhang et al. (2021) proposed future-guide training for wait-k policy. Han et al. (2020) applied meta-learning in wait-k. Zhang and Feng (2021a) proposed a char-level wait-k policy. Zhang and Feng (2021c) proposed mixture-of-experts wait-k policy.

For adaptive policy, Zheng et al. (2019a) trained an agent with golden READ/WRITE actions generated by rules. Zheng et al. (2019b) added a "delay" token to read source words. Arivazhagan et al. (2019) proposed MILk, using a Bernoulli variable to determine READ/WRITE. Ma et al. (2020) proposed MMA to implement MILK on Transformer. Bahar et al. (2020) and Wilken et al. (2020) used the external ground-truth alignments to train the policy. Zhang et al. (2020) proposed an adaptive segmentation policy MU for SiMT. Liu et al. (2021) proposed cross-attention augmented transducer for SiMT. Alinejad et al. (2021) introduced an full-sentence model to generate a ground-truth action sequence and accordingly train a SiMT policy. Miao et al. (2021) proposed a generative SiMT policy.

Previous methods often neglected to jointly model alignments with translation, and meanwhile introduce additional loss functions to control the latency. However, GMA jointly learns alignment and translation, and thereby controls the latency through a simple Gaussian prior probability.

---

[1] Outlier heads mean that most of the heads are aligned in the front position, while some individual heads are aligned to the farther position, which requires the model to wait until the farthest aligned word is received, causing unnecessary latency.

5 Experiments

5.1 Datasets

We evaluate GMA on the following public datasets.

IWSLT15[2] English → Vietnamese (En→Vi) (133K pairs) (Cettolo et al., 2015) We use TED tst2012 as validation set (1553 pairs) and TED tst2013 as test set (1268 pairs). Following the previous setting (Raffel et al., 2017; Ma et al., 2020), we replace tokens that the frequency less than 5 by $\langle unk \rangle$, and the vocabulary sizes are 17K and 7.7K for English and Vietnamese respectively.

WMT15[3] German→English (De→En) (4.5M pairs) Following Ma et al. (2019), Arivazhagan et al. (2019) and Ma et al. (2020), we use newstest2013 as validation set (3000 pairs) and newstest2015 as test set (2169 pairs). BPE (Sennrich et al., 2016) was applied with 32K merge operations and the vocabulary is shared across languages.

5.2 Systems Setting

We conduct experiments on the following systems.

Offline Conventional Transformer (Vaswani et al., 2017) model for full-sentence translation.

Wait-k Wait-k policy proposed by Ma et al. (2019), the most widely used fixed policy with strong performance and simple structure, which first waits for k source words and then translates a target word and waits for a source word alternately.

MU A segmentation policy proposed by Zhang et al. (2020), which classify whether the current inputs is a complete meaning unit (MU), and then fed MU into the full-sentence MT model for translation until generating ⟨EOS⟩. We compare our method with MU on De→En(Big) since they report their results on De→En with Transformer-Big.

MMA[4] Monotonic multi-head attention (MMA) proposed by (Ma et al., 2020), the state-of-the-art adaptive policy. At each step, MMA predicts a Bernoulli variable to decide whether to start translating or wait for the next source token.

GMA Proposed method in Sec.3.

The implementations of all systems are adapted from Fairseq Library (Ott et al., 2019) based on Transformer (Vaswani et al., 2017). The setting is the same as Ma et al. (2020). For En→Vi, we apply Transformer-small (6 layers, 4 heads per layer). For De→En, we apply Transformer-Base (6 layers, 8 heads per layer) and Transformer-Big (6 layers, 16 heads per layer). We evaluate these systems with BLEU (Papineni et al., 2002) for translation quality and Average Lagging (AL) (Ma et al., 2019) for latency. Average lagging is currently the most widely used latency metric, which evaluates the number of words lagging behind the ideal policy. Given $g(i)$, AL is calculated as:

$$\mathrm{AL} = \frac{1}{\tau} \sum_{i=1}^{\tau} g(i) - \frac{i-1}{|\mathbf{y}| \,/\, |\mathbf{x}|} \tag{11}$$

$$\text{where} \quad \tau = \underset{i}{\operatorname{argmax}} \left(g(i) = |\mathbf{x}| \right) \tag{12}$$

where $|\mathbf{x}|$ and $|\mathbf{y}|$ are the length of the source sentence and target sentence respectively.

5.3 Main Results

We compared GMA with the Wait-k, MU and MMA, the current best representative of fixed policy, segmentation policy and adaptive policy re-

---

[4] `github.com/pytorch/fairseq/tree/master/examples/simultaneous_translation`

spectively, and plot latency-quality curves in Figure 3, where GMA curve is drawn with various δ (in Eq.(6)), Wait-k curve is drawn with various lagging numbers k, MU curve is drawn with various classification thresholds of the meaning unit, MMA curve is drawn with various latency loss weights λ.

Compared with Wait-k, GMA has a significant improvement, since Wait-k ignores the alignments and thus the target word may be forced to be translated before receiving its aligned source word, which seriously affects the translation quality. Compared with MMA and MU, our method achieves better performance under most latency levels. Since MU first segments the source sentence based on the meaning unit, and then translates each segment with the full-sentence MT model, MU performed particularly well under high latency, but meanwhile it is difficult to extend to lower latency.

Compared with the SOTA adaptive policy MMA, GMA has stable performance and simpler training method. MMA introduces two additional loss functions to control the latency, and meanwhile applies the expectation training to train Bernoulli variables (Ma et al., 2020). GMA successfully balances the translation quality and latency without any additional loss function. Owing to the proposed Gaussian prior probability centered on predicted alignments, the source words far away from the aligned position get less Gaussian prior, so that the model is forced to move the aligned position close to the most informative source word, thereby capturing the alignments and controlling the latency. With GMA, the translation quality and latency are integrated into a unified manner and jointly optimized without any additional loss function.

6 Analysis

We conduct extensive analyses to study the specific improvements of GMA. Unless otherwise specified, all the results are reported on De→En(Base).

6.1 Ablation Study

We conduct sufficient ablation studies on the method of modeling aligned position and the proposed prior probability in Table 1. For modeling aligned source position, predicting incremental step performs better. Since the complete length of the streaming inputs in SiMT is unknown, predicting absolute position easily exceeds the source length, resulting in unnecessary latency. In practice, the value range of incremental step is more regular than absolute position and thus easier to learn.

Variants	**AL**	**BLEU**
Aligned Source Position		
Incremental step	**4.66**	**28.50**
Absolute position	7.33	25.61
Prior Probability		
Gaussian ($\sigma_i = p_i/2$)	**4.66**	**28.50**
$-\ \sigma_i = p_i/1$	6.87	28.96
$-\ \sigma_i = p_i/3$	4.55	27.61
$-$ Predicted σ_i	5.34	27.12
Laplace	8.14	29.19
Linear	12.83	27.86
None	1.48	20.84

Table 1: Ablation studies on modeling aligned position and the proposed prior probability, with $\delta = 1$.

Among the prior probabilities of different distributions, the Gaussian distribution performs best. The Laplace distribution is more fat-tailed than the Gaussian distribution (i.e., more prior probability on the position that far away from the aligned position), resulting in learning a later aligned position and higher latency. The linear distribution performs worse since its attenuation with distance is smoother. When removing the prior probability, since the parameters to predict alignments do not get the back-propagation gradient, the model cannot learn the alignments at all, resulting in very low latency and poor translation quality. Focusing on the best performing Gaussian prior probability, when $\sigma_i = p_i/1$ (the attenuation degree is small), the predicted aligned position is much later and the latency is higher. when $\sigma_i = p_i/3$, the translation quality declines since the prior of some source words far away from the aligned position is too small. When the σ_i is predicted, some small predicted σ_i will make the prior probability of the distant source words almost 0, resulting in poor translation quality. In comparison, the Gaussian prior ($\sigma_i = p_i/2$) we proposed not only guarantees a certain attenuation degree, but also assigns the furthest source word some prior probability.

6.2 Effect of Sharing Alignments

When integrated into multi-head attention, to reduce the overall latency of the model, GMA shares the predicted alignments among H heads in each layer. Table 2 reports the performance of sharing alignments in different parts (all independent, among heads, among layers or among all).

	#Predicted Alignments	AL	BLEU
All independent	$6 \times 8 = 48$	7.85	29.18
Share among heads	$6 \times 1 = 6$	4.66	28.50
Share among layers	$1 \times 8 = 8$	4.46	27.82
Share all	$1 \times 1 = 1$	3.07	27.26

Table 2: The performance of different alignments sharing settings with $\delta = 1$.

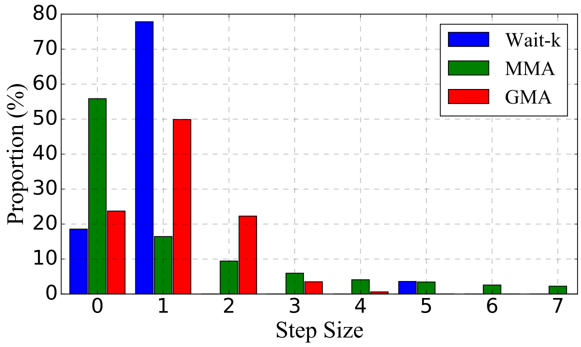

Figure 4: The distribution of the waiting source number between two adjacent outputs, on Wait-k ($k = 5$), MMA ($\lambda = 0.4$) and GMA ($\delta = 1$) with similar latency.

'All independent' achieves the best translation quality and also brings a higher latency, as the overall latency of the model is determined by the farthest one among all predicted positions. Besides, 'Share all' gets the lowest latency but loses translation quality. Comparing 'Share among heads' and 'Share among layers', sharing among heads performs better, which is in line with the previous conclusion that there are obvious differences between the alignments in each decoder layer (Garg et al., 2019; Voita et al., 2019; Li et al., 2019).

6.3 Statistics of Incremental Steps

Unlike MMA predicting the READ/WRITE action, GMA directly predicts the incremental step between adjacent target outputs. To analyze the advantages of modeling the incremental step, we show the distribution of step size (i.e., the number of waiting source words between two adjacent outputs) in Figure 4, where we select the SiMT models with the similar latency (AL ≈ 4.5).

For Wait-k, the step size is blunt and there are only three cases, which occur before the start of translation (step size$= k$: first lag k words), during translation (step size$=1$: wait and output one word alternately.), and after the end of the source inputs (step size$=0$: output the translation at one time). The proposed GMA and MMA have obvious differences in the step size distribution. The step size distribution of GMA is more even, only distributed between 0~4, which shows that each source segment is shorter and thus the translating process is more streaming. The step size of MMA is more widely distributed, most of which are 0 (consecutively output target words), and there is also a large proportion of step size greater than 5, which shows that MMA tends to consecutively wait for more source words and then output more target words, resulting in longer source segments. Therefore, although GMA and MMA have similar latency (AL), their performance in real applications is different, where the translation process of GMA is more streaming, while MMA is more segmented.

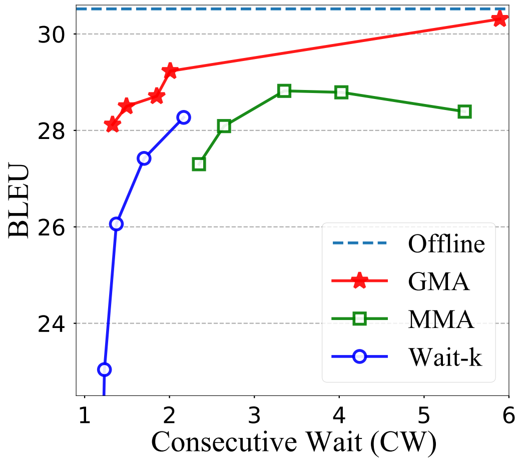

Figure 5: Translation quality against latency (CW), where CW reflects the streaming degree of SiMT.

Furthermore, to more accurately evaluate the streaming degree of the translation process, we apply Consecutive Wait (CW) (Gu et al., 2017) as the latency metric to evaluate the systems. Consecutive wait evaluates the number of source words waited between two target words, which reflects the streaming degree of SiMT. Given $g(i)$, CW is calculated as:

$$\mathrm{CW} = \frac{\sum_{i=1}^{|\mathbf{y}|}\left(g(i) - g(i-1)\right)}{\sum_{i=1}^{|\mathbf{y}|} \mathbb{1}_{g(i)-g(i-1)>0}} \tag{13}$$

where $\mathbb{1}_{g(i)-g(i-1)>0} = 1$ counts the number of $g(i) - g(i-1) > 0$. In other words, CW measures the average source segment length (the best case is 1 for word-by-word streaming translation and the worst case is $|\mathbf{x}|$ for full-sentence MT), where the smaller the CW, the shorter the average source segment, and the translation is more streaming.

As shown in Figure 5, GMA gets much smaller CW scores than MMA, where the average source

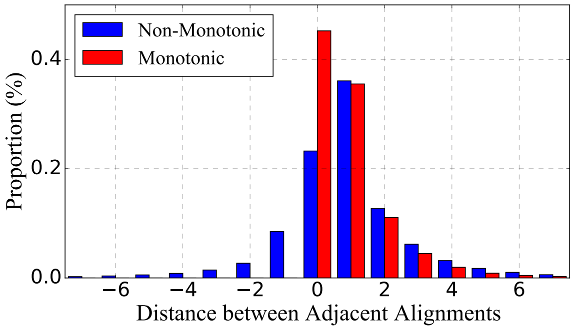

Figure 6: Distribution of distances between adjacent alignments (ground-truth) under monotonic and non-monotonic alignment setting.

segment length is about 2 words, which shows that GMA achieves more streaming translation than the previous adaptive policy.

Additionally, although the alignments between the two languages is not necessarily monotonic, we require the predicted incremental step $\Delta p_i \geq 0$ to guarantee the model performs READ/WRITE monotonically. This is due to two considerations. First, we don't want to waste any useful source content, i.e., to avoid the model moving p_i to the previous position and thereby ignoring some received source information caused by $\Delta p_i < 0$. Second, we argue that monotonic alignments are more friendly to SiMT learning. We use `fast-align`[5] (Dyer et al., 2013) to generate the ground-truth aligned source position of i^{th} target token, denoted as A_i, and then show the distribution of distances between adjacent alignments under monotonic and non-monotonic alignments in Figure 6, where 'Non-Monotonic' measures $A_i - A_{i-1}$ and 'Monotonic' measures $\max(A_i - \max_{j<i} A_j, 0)$. The distance distribution between adjacent alignments under monotonic alignment is more concentrated, between 0 and 4, which is easier for the model to learn incremental step. Actually, the incremental steps predicted by GMA almost distribute between 0 and 4 (see Figure 4), which shows that GMA successfully learns the relative distance between monotonic alignments.

6.4 Quality of Predicted Alignments

To evaluate the quality of the aligned source position p_i predicted by GMA, we measure the alignment accuracy on the RWTH De→En alignment dataset [6], whose reference alignment was manually annotated by experts (Liu et al., 2016; Zhang and Feng, 2021b). As shown in Table 3, we sample one decoder layer to calculate the alignments error rate (AER) (Vilar et al., 2006), and meanwhile count how many ground-truth aligned source words are located before the output position $g(i)$ (i.e., translate after receiving the aligned source word).

Latency	AER	% of ground-truth alignments within $g(i)$
Low	0.49	81.00%
Mid	0.61	88.27%
High	0.76	95.58%

Table 3: Alignment quality under different latency levels, where 'within $g(i)$' means that starting translating after receiving the aligned source word.

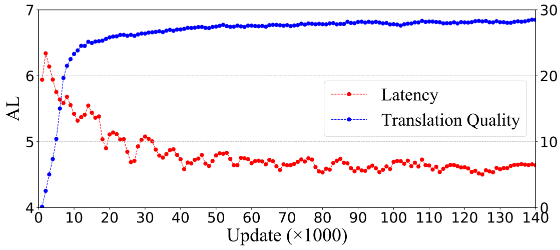

Figure 7: The learning curve of translation quality (BLEU) and latency (AL) during training, with $\delta = 1$.

GMA achieves good alignment accuracy, especially at low latency, since the model is required to output immediately after receiving the aligned source words (δ in Eq.(6) is small). More importantly, most of the ground-truth alignments is within $g(i)$, showing that GMA guarantees that in most cases, the model starts translating a target word after receiving its aligned source words, which is beneficial to translation quality.

6.5 Balancing Translation and Latency

To study how GMA learns to balance translation quality and latency without any additional loss function during training, we draw a learning curve for translation quality and latency in Figure 7.

Initially, the high latency indicates that the model first moves the predicted aligned position to a further position, to learn the translation by seeing more source words. Then, as the number of training steps increases, the translation quality improves and the latency gradually decreases, which shows that for better translation, the model moves the predicted aligned source position to a more appropriate position due to the introduced Gaussian prior

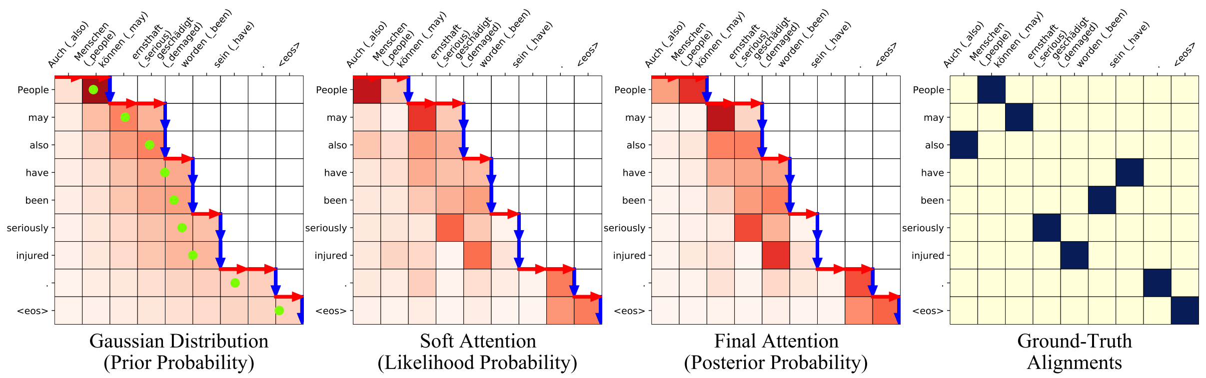
Gaussian Distribution (Prior Probability)   Soft Attention (Likelihood Probability)   Final Attention (Posterior Probability)   Ground-Truth Alignments

(a) An easy case with more monotonic alignments



Gaussian Distribution (Prior Probability)   Soft Attention (Likelihood Probability)   Final Attention (Posterior Probability)   Ground-Truth Alignments

(b) A hard case with more complex alignments

Figure 8: Attention visualization of GMA on De→En SiMT with $\delta = 1$. The shade of the color indicates the attention weight. '●': the predicted aligned source position p_i (mean of Gaussian distribution), note that p_i is a float number. '■': the ground-truth alignments. '→': wait for a source word, '↓': translate a target word.

probability. Overall, for better translation, GMA constantly adjusts the predicted aligned source position to a suitable position and thereby controls the latency, which is completely different from the previous method of introducing the additional latency loss to constrain the latency with translation (Ma et al., 2020; Miao et al., 2021).

6.6 Characteristics of Attention in GMA

We explore the characteristics of GMA by visualizing the attention distributions in Figure 8. We show two cases with the alignments of different difficulty levels, where the reverse orders in alignments are considered as a major challenge for SiMT (Ma et al., 2019; Zhang and Feng, 2021c).

For more monotonic alignments, GMA can predict the aligned source position well and output the target word after receiving the aligned word. Meanwhile, due to the characteristics of Gaussian distribution, GMA can also avoid focusing too much on source words in the front position, and strengthen the attention on the newly received source words, which is proved to be beneficial to SiMT performance (Elbayad et al., 2020b; Zhang and Feng, 2022b). For more complex alignments, the aligned position predicted by GMA is close to the ground-truth alignments, so that GMA starts translating after receiving most of aligned words. Besides, GMA learns some implicit prediction ability, e.g., before receiving "*worden sein*", GMA generates the correct translation "*have been*" based on the context. We consider this is because the predicted alignments during training are monotonic due to the incremental step, where modeling monotonic alignments forces the model to learn the correct translation from the incomplete source and previous outputs (Ma et al., 2019).

7 Conclusion

In this paper, we propose the Gaussian multi-head attention to develop a SiMT policy which starts translating a target word after receiving its aligned source word. Experiments and analyses show that our method achieves promising results on performance, alignments quality and streaming degree.

Abstract

Identifying the relation between two sentences requires datasets with pairwise annotations. In many cases, these datasets contain instances that are annotated multiple times as part of different pairs. They constitute a structure that contains additional helpful information about the inter-relatedness of the text instances based on the annotations. This paper investigates how this kind of structural dataset information can be exploited during training. We propose three batch composition strategies to incorporate such information and measure their performance over 14 heterogeneous pairwise sentence classification tasks. Our results show statistically significant improvements (up to 3.9%) - independent of the pre-trained language model - for most tasks compared to baselines that follow a standard training procedure. Further, we see that even this baseline procedure can profit from having such structural information in a low-resource setting.[1]

1 Introduction

Datasets that define pairwise relations between sentence-level text instances are widely used in Natural Language Processing (NLP). They describe the relation of sentence pairs with an annotated label. Common examples of such pairwise classification tasks are Paraphrase Identification (Wang et al., 2017; Dolan et al., 2004), Natural Language Inference (Williams et al., 2018a; Bowman et al., 2015), Semantic Textual Similarity (Cer et al., 2017; Reimers et al., 2019), or Argument Convincingness (Habernal and Gurevych, 2016).

In many such datasets (eq. six out of 11 GLUE tasks), single sentences can occur in multiple pairwise annotations. Figure 1 shows such an example where three annotated pairs share a common question. Besides the annotations themselves, such structural properties of datasets carry additional helpful information about the inter-relatedness of the text instances. We argue that the defined discriminative attributes of a text instance are learned most readily when the instance is encountered in multiple contexts. Therefore, we hypothesize that a (neural) learner can utilize such additional information when provided appropriately.

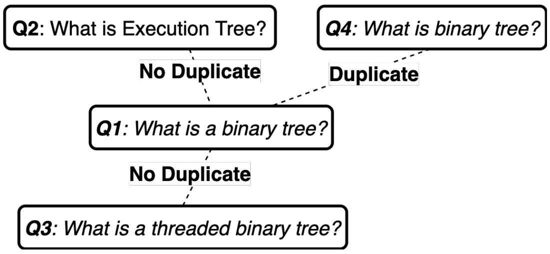

Figure 1: Example of three pairwise annotations (edges) using four unique questions (nodes), taken from the QQP dataset (Wang et al., 2018). Q1 is the common element of all annotations.

There are several ways to control the training process considering such external information. Contrastive learning (Chen et al., 2020; Giorgi et al., 2021; Gao et al., 2021) aims at learning text representations in a self-supervised fashion where similar instances are aligned and dissimilar pairs are separated using an external measure - i.e. semantic similarities. In Curriculum Learning (Bengio et al., 2009) the training data order is determined by the estimated difficulty of the instances using a additional heuristic. Inspired by such work, we want to examine whether considering the dataset-annotation structures affects the models' performance. But neither we create new pairs nor open a dependency to an external heuristic. More specifically, we present three different strategies to compile training batches that consider that text instances occur in multiple pairwise configurations. This approach is also motivated by recent work (Dodge et al., 2020; Zhou et al., 2020) investi-

gating the effect of training order and inter-instance correlations on model performance.

We evaluate the strategies on 14 heterogeneous tasks from different domains and in two different scenarios to measure the generalizability of our approach. Our experimental results show significant performance improvements on a wide range of tasks for both scenarios compared to a standard training setup. Our contributions can be summarized as follows:

1. we propose three different batching strategies for pairwise text classification tasks to integrate inter-instance relations into the training procedure
2. we show statistically significant performance improvements on a wide range of heterogeneous tasks in our experimental results
3. we discuss the role of dataset characteristics, additional computational complexity and the stability of our approach

To foster the reproducibility of our work, we publish all experimental code and hyperparameters.

2 Approach

By analysing different pairwise annotated datasets, we found that various ones contain single sentences that occur in multiple annotation instances (see *Degree* in Table 1). For example, every sentence of the QNLI dataset is annotated with 1.9 other sentences on average. With our approach, we want to exploit this untouched information to improve the tasks' performance. Thus, we show how we capture this information in a graph structure and strategies to implicitly present it to the neural network.

2.1 Annotation Graph (AG)

We use a graph structure to represent all annotations of a dataset - as in Figure 1. In this graph, nodes are unique sentences, edges represent a label for a pair of them, and the degree k indicates the number of connected edges of a node. Based on the typed of annotations, this graph can be directed or undirected.

In Figure 2 we show an example of such a graph structure and its construction. It includes six sentences $V = \{V_1, ..., V_6\}$ and seven pairwise annotations $E = \{(V_1, V_2), ..., (V_5, V_6)\}$. Within the graph, we define a nodes' neighbourhood as all directly connected nodes - like $\{V_1, V_2\}$ for node V_3. In the case of an edge, we consider edges connect to one of its starting points as the neighbours - for example, (V_4, V_5) and (V_5, V_6) are neighbours.

Using this structure, we define different operations: $f_e(n)$ returns all edges of a given node n, and $f_s(c, x)$ randomly samples x elements from a collection of edges c. Further, we use the average degree μ_k, its standard deviation σ_k, and coefficient of variation ($CV_k = \frac{\sigma_k}{\mu_k}$) to characterise an AG. Using these measurements, we can group the selected tasks into three groups (see Table 1). The first one (G_1) includes tasks (all in-domain tasks, UKP-A, BWS) that do not show extreme patterns in the graph ($CV \approx 1$). The second group, G_2 (Arg-Conv, and Evi-Conv), has a high average degree but a lower std. dev. ($CV < 1$). The third group G_3 fits tasks (Evi-St, ArgQ-St, Arg-KP) where a few nodes with a high *degree* are connected to many others with a small *degree* ($CV > 1$).

	Dataset	Label	Degree	Group	Metric
In-Domain	SICK-NLI	3-Class	3.2 ± 2.1	G_1	*acc*

Table 1: Overview of the 14 used datasets for the In-Domain and Cross-Topic Scenario. In the latter we train on different topics then we evaluate. *Degree* denotes average number of edges of a node and datasets marked with (*) are regression tasks.

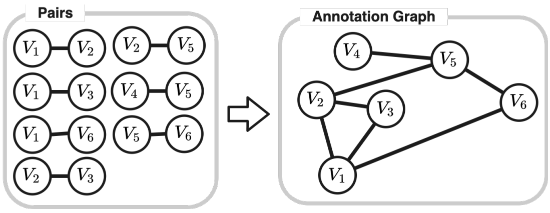

Figure 2: Construction of an annotation graph (AG) with a degree of 2.5 ± 0.84 and $CV_k = 0.34$.

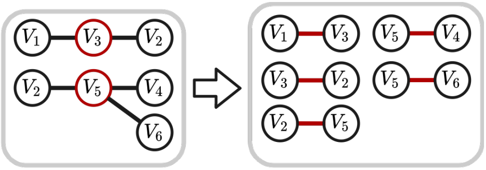

Figure 3: Example batch for the strategy NODE

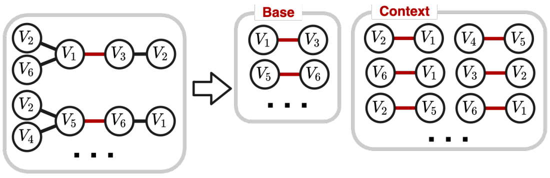

Figure 4: Example batch for the strategy EDGE-I

2.2 Batching Strategies

With the following strategies, we randomly traverse through the graph, either with the focus on the neighbourhood of nodes (NODE) or edges (EDGE-I, EDGE-II). Since NODE will incorporate all the neighbours of a node, it could overfit towards them - given a high μ_k. Thus, EDGE-I and EDGE-II focus on just a limited neighbourhood to reduce this potential dominance.

NODE This strategy composes a batch by focusing on common nodes within the AG. Figure 3 shows this process with a set of example nodes ($N = \{V_3, V_5\}$). For every node n, we select all connected edges ($\{(V_1, V_3), (V_3, V_2)\}$ for node V_3). The loss L is equal to the average error (using the cross-entropy objective function $\mathcal{J}$) for each edge e, as defined in Equation 1.

$$L = -\frac{1}{\sum_n^N |f_e(n)|} \sum_n^N \sum_e^{f_e(n)} \mathcal{J}(\hat{y_e}, y_e) \quad (1)$$

EDGE-I The second strategy starts from a set of randomly selected edges E to construct a single batch. For each base edge $e \in E$, a set of context edges E' is sampled from the neighbourhood of e. To select these neighbours, we consider the two nodes (i, j) that are the starting points of e - as in Equation 2. For both of them, we randomly select two[2] directly connected edges using f_s (Equation 3). Figure 4 shows an example batch that considers the two base edges $B = \{(V_1, V_3), (V_5, V_6)\}$. For base edge (V_1, V_3), the set of context edges is $E' = \{(V_1, V_2), (V_1, V_6), (V_3, V_2)\}$. To calculate the loss, we sum the average error of base and the context edges - as in Equation 4.

$$E' = \bigcup_{(i,j)}^{E} f'_e(i) \cup f'_e(j) \setminus \{(i, j)\} \quad (2)$$

$$f'_e = \begin{cases} f_e(n) & \text{if } |f_e(n)| \leq 2 \\ f_s(f_e(n), 2) \end{cases} \quad (3)$$

$$L = \frac{-1}{|E|} \sum_e^E \mathcal{J}(\hat{y_e}, y_e) + \frac{-1}{|E'|} \sum_{e'}^{E'} \mathcal{J}(\hat{y_{e'}}, y_{e'}) \quad (4)$$

EDGE-II Within EDGE-I all context edges are treated equally and independently of their base edge. In EDGE-II we adapt the calculation of the loss to focus on the fact that the neighbourhood size of base edges can vary. First we sum the error of an base edge e with the average error of its neighbours e' (as in Equation 5). Afterwards, we average this sum over all e in E (Equation 6).

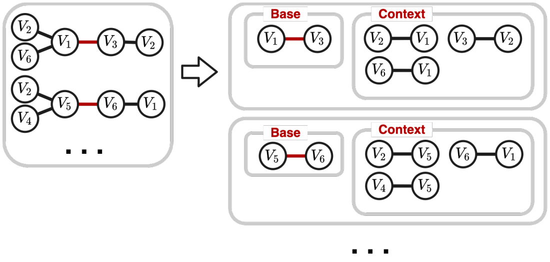

Figure 5: Example batch for the strategy EDGE-II

$$\mathcal{J}' = \mathcal{J}(\hat{y_e}, y_e) + \frac{1}{|E'^{(e)}|} \sum_{e'}^{E'^{(e)}} \mathcal{J}(\hat{y_{e'}}, y_{e'}) \quad (5)$$

$$L = \frac{-1}{|E|} \sum_e^E \mathcal{J}'(e) \quad (6)$$

Batch Composition Due to the nature of the described strategies, a single training instance can be contained in multiple batches. For NODE, every edge (i.e. training instance) is used twice as both contained nodes are sampled individually. In the case of EDGE-I and EDGE-II, the occurrence of one instance depends on how many times it is sampled as context edge and is affected by the AGs

---

[2] We check different node numbers during early preliminary experiments and found two works the best.

density. The chances to sample an edge as a context edge are higher in a more dense area. Thus, the effective number of instances processed within a batch can vary. Note, when we speak of batch size, we refer instead to the number of initially sampled nodes or edges, not the effective one.

3 Data and Training Setup

3.1 Datasets

We evaluate our approach on 14 heterogeneous pairwise classification tasks in two scenarios.[3] Table 1 shows an overview of the tasks including the label type, the degree (μ_k, σ_k), and evaluation metrics.

The first scenario aims at evaluating our general idea using standard natural language understanding tasks, e.g. GLUE (Wang et al., 2018). In the second scenario, we use tasks for the challenging cross-topic evaluation, where train, development, and test set covers different topics to measure the generalizability. For this scenario, we rely on Argument Mining tasks, which include sentence-level arguments assigned to a specific topic (Stab and Gurevych, 2017; Reimers and Gurevych, 2019a).

In-Domain Scenario The first scenario consists of five tasks (RTE, MNLI, QNLI, QQP) from the GLUE benchmark (Wang et al., 2018) and the SICK dataset (Marelli et al., 2014) that provides annotations for relatedness (SICK-REL) and natural language inference (SICK-NLI). As in Devlin et al. (2019), we exclude the WNLI dataset because of the problematic data structure.[4] The average degree of all tasks of these scenarios ranges from 1.1 to 3.2 (as in Table 1).

Cross-Topic Scenario We use two argument similarity datasets, UKP-A (Reimers et al., 2019) and BWS (Thakur et al., 2021). For UKP-A, we binarize the labels into *similar* and *not-similar* as suggested by the authors. Next, we use the evidence dataset from Gleize et al. (2019) that annotates topic, stance, and convincingness for a set of evidence pairs. Apart from the evidence convincingness task (Evi-Conv), we compose a stance prediction task (Evi-St) given evidence and a topic. Further, we use the stance annotations in Gretz et al. (2020) for a second stance prediction task (ArgQ-St) and the dataset provided by Bar-Haim et al. (2020) matching arguments with keypoints (Arg-KP). Finally, we use the argument convincingness dataset (Arg-Conv) by Habernal and Gurevych (2016). All cross-topic tasks are evaluated using multiple folds. We sample these folds on our own except for UKP-A and ArgQ-St - where the authors provide the folds. For all these tasks, we see a more diverse average degree (1.6 to 22.2).

3.2 Training Setup

We fine-tune BERT (Devlin et al., 2019) for the proposed batching strategies and the baseline BASE with random batch sampling. As we earlier described, single training instances can occur in several batches, depending on the batching strategy, Considering NODE every instance occur twice as well as approximately twice for EDGE-I and EDGE-II. In the case of BASE, we saw no sustainable difference of showing training instances once or twice per epoch in preliminary experiments. Eventhough, we want to ensure a fair and comparable setting and thereby include every instance twice for BASE. This is equal as for the NODE strategy and an approximation for EDGE-I and EDGE-II.

Due to computational expenses, we fine-tune the language models for large tasks (QNLI, MNLI-m, MNLI-mm, QQP) over three epochs and the remaining ones for five epochs. For all experiments we use four NVIDIA A4000 GPUs using *PyTorch* v1.8.1, *Huggingface* v4.9.1 (Wolf et al., 2019), and *Sentence-Transformer* v2.0.0 (Reimers and Gurevych, 2019a).

Model Architecture We use for our experiments both bi- and cross-encoder model architecture. *Bi-encoders* showed their computational efficiency for pairwise tasks (Reimers and Gurevych, 2019a) because they encode every distinct sentence separately and use efficient operations (like cosine similarity) to find a prediction. In comparison, *cross-encoders* increase the complexity by encoding every sentence pairs together. To select the pre-trained language model, we distinguish between NLI tasks (SICK-NLI, RTE, QNLI, MNLI) and others. For NLI tasks, we use the standard pretrained weights (i.e. *bert-base-uncased*) since SBERT (Reimers and Gurevych, 2019a) models were trained on NLI data.

The detailed architecture of the models looks as follows. For cross-encoders, we use the standard text pair separators following Devlin et al. (2019). In the case of bi-encoders, we use the cosine similarity of the text pair embeddings fol-

---

[3] We provide additional details and examples for each task in the Appendix § A.1.

[4] See https://gluebenchmark.com/faq

lowed by the sigmoid function for regression tasks (BWS, SICK-REL). For binary classification (UKP-A, Evi-St, Arg-KP, QQP) tasks, we determine an optimal threshold towards the development set as done by Reimers et al. (2019). For all multi-class tasks (RTE, QNLI, MNLI, SICK-NLI), we use softmax to aggregate both sentence embeddings and their difference as done by Reimers and Gurevych (2019a) and for capturing the annotation direction for tasks with a directed AG (Arg-Conv, Evi-Conv).

Hyperparameters We optimise the batch size for all experiments, strategies, and tasks with zero as random seed and keep the rest of the hyperparameters fixed following previous work (Mosbach et al., 2021; Dodge et al., 2020) (see Appendix § A.2 for details). To compare the different batch sizes, we take the best performing epoch considering the development set. For MNLI, we average the performance of the two development sets (MNLI-m & MNLI-mm). When having multiple folds, we select the optimal batch size according to the average performance overall folds, rather than optimising it separately for each fold.

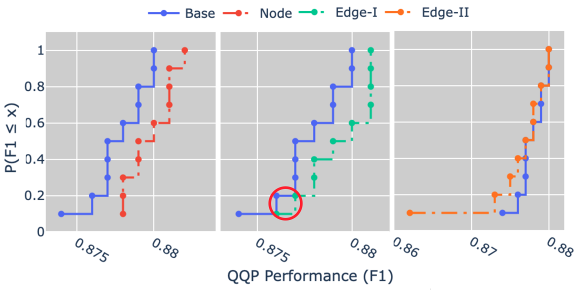

Figure 6: Comparison of the cumulative distribution functions (CDF) of Base with Node, Edge-I, and Edge-II for the QQP task. It shows for a given observation x the probability of observing x or a smaller value in the CDF.

Evaluation Setting We fine-tune every language model with the optimised batch size using ten random seeds, find the final results from the epoch with the highest development score, and report average and std. dev. on the test set. These metrics approximate the underlying results due to the non-gaussian distributed results and an expected performance variance (Dodge et al., 2020). Thus, we test whether an approach outperforms a baseline and vice-versa - i.e. in Figure 6. One option is using the Mann-Whitney U-test (Mann and Whitney, 1947) - also known as Wilcoxon Rank-Sum test (Wilcoxon, 1945; McKnight and Najab, 2010) - which checks whether our approach (i.e. Node) is stochastic larger than the baseline Base (Lehmann, 1955). To match this criterion, the cumulative distribution function (CDF) of the superior approach needs to be consistently below the other one - shown on the left of Figure 6. In Dror et al. (2019), the authors show the sensitivity of the U-test towards minor violations of this requirement. Thus, they proposed *Almost Stochastic Order* (*ASO*) Dror et al. (2019) that better adapts to results of neural networks by slightly allowing some violation ϵ. Such a situation is shown in the middle of Figure 6, where we observe Edge-I outperforming Node but its CDF is not constantly under the other one. Here, the U-test fails ($p < 0.05$) to make a decision due to the minor marked violation while *ASO* can confirm our observation. In contrast, on the right, we see our approach is underperforming the baseline (consistently above the blue line). Using *ASO* we can confirm this observation while the U-test can not gives us a decision ($p < 0.05$).

Since this desired softening of *ASO* increases the risk of type-I errors (i.e., we observe a significant improvement when there is none), we apply a strict test setting compared to other work (Dodge et al., 2020; Zhang et al., 2021). We use a p-value of 0.01 and adapt it with the Bonferroni correction (Bonferroni, 1936) (we provide additional details in the Appendix § B.1). For reference, we also apply the U-test and bootstrap-test (Efron and Tibshirani, 1994) - both with $p < 0.05$ - to test significant improvements and deteriorates apart of *ASO*.

4 Experiments

4.1 In-Domain and Cross-Topic Evaluation

In the first experiment, we evaluate the general effect of using our approach by fine-tuning a BERT bi-encoder. We report the task's mean, standard deviation, and significance with a publicly available test set (Table 2). As the test sets for datasets from the GLUE benchmark are not publicly accessible, we report results based on the development set and the ensemble performance (majority vote) on the test set (set Appendix § B.2 for the test results).[5]

Overall, the results show that Node significantly improves the baseline Base on nine tasks and is never outperformed statistically significant. For Edge-I and Edge-II, we see a statistically significant improvement in eleven and five tasks while being outperformed in zero and

---

[5] Evaluated with (`https://gluebenchmark.com/`)

four cases, respectively. Considering cross-topic results, we see that EDGE-I performs with a improvement/deterioration ratio of 5/0 better than NODE (4/0) and EDGE-II (2/1). Similar, EDGE-1 performs slightly better than NODE on in-domain tasks (6/0 vs. 5/0) and outperforms EDGE-II (2/3).

4.2 Low-Resource Scenario

In the second experiment, we examine the effect of our approach for the low-resource scenario. Therefore, we iterative select 25, 50, 75, and 100 instances from SICK-NLI, SICK-REL, BWS, and Evi-Conv in a way that these subsets match the average and std. dev. *degree* of the full dataset. In addition, we randomly sample for each subset a control subset (RANDOM) to verify the added value of having structural information within the training samples. These control subsets are trained in the same setting as BASE. We sample four folds for every subset and control subset of the four tasks to get more robust results.

Figure 7 shows the results for all the subsets on the four selected datasets where we see the proposed strategies underperforming BASE on the most subsets. Exceptions are EDGE-II for SICK-REL and NODE for Arg-KP with a ratio of 4/0, as well as the subsets with 25 instances. For them, we observe nine significant improvements and no deteriorations of our strategies in 12 cases, where NODE brings a significant improvement in overall tasks. Considering the control subsets RANDOM, we see that they perform significantly worse than BASE in 12 out of 16 cases.

4.3 Model Agnostic

Next, we want to check whether the success of batching strategy depends on the model type in use. We choose UKP-A, BWS, Evi-St, SICK-NLI, and SICK-REL to cover both scenarios and the overall performance spectrum reported in § 4.1. We compare the bi-encoder (BERT-bi) and cross-encoder (BERT-cross) architecture using BERT. Further, we examine the effect of having more parameters by evaluating BERT-Large in the bi-encoder setting. Finally, we investigate the influence of the model family by comparing BERT with ALBERT (Lan et al., 2020), and RoBERTa (Liu et al., 2019).

Table 3 shows the aggregated results of this experiment. It lists the improvements/deteriorations ratio of all language models and strategies. These results show that EDGE-I outperforms NODE for BERT (1/0 vs. 4/0) while performing on par for BERT-cross (2/0 both). EDGE-II achieves a ratio of 2/1. Looking at BERT-large, we see that NODE and EDGE-I have the same performance (1/2), while EDGE-II underperforms both (0/2). Considering the model family (BERT, ALBERT, RoBERTa), we see for EDGE-I (4/0, 3/2, 3/1) slightly better ratios that for NODE (1/0, 3/1, 3/1), while EDGE-II (2/1, 2/2, 3/2) perform worse. In general, we observe a better improvement/deterioration ratio on BERT (7/1) than on BERT-cross (6/1), RoBERTa (9/4), ALBERT (8/5), and BERT-large (2/6). Considering the strategies, we see an overall ratio of 10/4 for EDGE-I, 13/5 for NODE and 8/8 for EDGE-II.

4.4 Summary

Summarising the experiments shows our approach's significant effect on the performance of different tasks and language models. In detail, we see EDGE-I and NODE significantly improve the performance for a majority of the tasks while EDGE-II causes fewer improvements and all the significant deteriorations. Further, we see slightly better performance on the in-domain tasks than the cross-topics ones. One reason is that finding an optimal batch size is challenging for cross-topics due to the additional regularization coming from having multiple diverse folds. This fact could have a bigger effect on the batching strategies because the batch size has more influence than for BASE.

Considering the low-resource setting, we see the success of our strategies for the extreme case of 25 instances but can not find a clear trend for all the subsets. We see one reason in the face that BASE works similar to our proposed strategies when having a small instance number. In this case, the probability of selecting two instances with a common sentence is higher even with the standard batch sampling procedure. Further, we note that including structural information can provide an added value for the low-resource setting since we see RANDOM constantly underperforming BASE.

Overall, the EDGE-I strategy seems to be slightly superior over NODE, for bi-encoders. We note its significant performance gain on datasets with different task types and its' model agnostic capabilities. For cross-encoder, we see EDGE-I performing similar to NODE but on general with a larger margin. We can imagine that cross-encoders are more sensible when a distinct sentence appears multiple times.

Table 2: Results of BERT bi-encoder using different batching strategies on 14 heterogeneous tasks. Tasks in the upper table are evaluated in-domain, results in the lower part in a cross-topic scenario. We report Pearson Correlation (SICK-REL, RTE), micro-F1 (QQP), and macro-F1 (UKP-A, Evi-St, Arg-KP) as evaluation measures, for all others we report accuracy scores. The best performance for each task is marked in **bold** and statistically significant improvements (*ASO*$^{(1)}$, U-test$^{(3)}$, bootstrap$^{(5)}$) and deteriorations (*ASO*$^{(2)}$, U-test$^{(4)}$, bootstrap$^{(6)}$) are indicated. We find in 17 cases a significant improvement and one deterioration based on all tests. Further, in four and in two cases an improvement or deterioration only based on *ASO*.

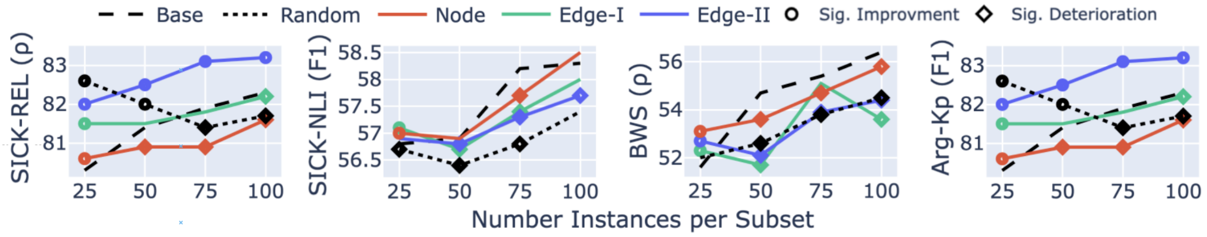

Figure 7: Performance of all strategies, the baseline, and the random sampled control sets SICK-REL, SICK-NLI, BWS, and Arg-KP for 25, 50, 75, and 100 instances (see § B.3 for raw results and details of the subsets). Circles indicates significant improvements and squares deteriorations (using *ASO* with $p < 0.01$).

	Improvement / Deterioration		
Model	Node	Edge-I	Edge-II
BERT-bi	1/0	4/0	2/1
BERT-cross	2/0	2/0	2/1
BERT-large	1/2	1/2	0/2
ALBERT	3/1	3/2	2/2
RoBERTa	3/1	3/1	3/2

Table 3: Overview of statistically significant improvements and deteriorations - using *ASO* - based on § B.4.

5 Further Analysis

Based on the previously shown experiments, we further analyse the influence of the graph structure and the stability & computational complexity of our approach.

5.1 Influence of Graph Structure

We observe for Node a moderate correlation (0.5) of the selected batch size with the *CV*. We see one reason for this coherence in the fact that having a high *CV* means that there are rare nodes with a high *degree*. Thus, when one of them are sampled in one batch, they can dominate it. Therefore, increasing the batch size can reduce this dominance. For Edge-I, and Edge-II we can not observe a notable correlation.

When considering previously showed patterns (Table 1) G_1 and G_2, we observe a slightly better ratio of Edge-I (7/0 and 2/0) than for Node (5/0 and 2/0). In case of the third group G_3, we observe similar performance of both (2/0) while Edge-I outperforms Node in absolute terms. Compared to Node, we see Edge-I better gaining from situations where the *degree* of a few nodes grows extremely ($k > 400$) like in ArgQ-St or Evi-St.

To summarise, we see that the structural patterns influence the training and performance of the different strategies. Thus, we can derive that the batch size of Node should grow with the *CV*, or that Edge-I is better suited for tasks where a few nodes have a large degree.

5.2 Stability

Previously work (Dodge et al., 2020; Zhou et al., 2020) identify the training instances' order as a reason for instabilities. Since we adopt this order for our approach, we verify whether the proposed batching strategies lead to additional instabilities. For this purpose, we verify the results of all experiments for a significant difference in the performance variance for every batching strategy compared to the baseline. Using the Brown-Forsyth test (Brown and Forsythe, 1974), we find in 15 out of 165 cases of all experiments a significant ($p < 0.01$) difference in the performance variance, where ten reduced and five raised the variance compared to the baseline. Thus, we conclude that our approach does not introduce new instabilities.

5.3 Computation Complexity

We keep the model size and structure unchanged and thereby do not add any new complexities during inference. For training, the complexity for NODE and BASE is $\mathcal{O}(2n)$ since both process every training instance twice. For EDGE-I and EDGE-II, the complexity depends on the AGs' density. In extreme cases without structure, it is equal to $\mathcal{O}(n)$ because no context edges are sampled, and only base edges are processed. For the other extreme, when every node has at least three connected edges, the complexity is $\mathcal{O}(n + 4n)$ since we sample for every training instance at most four context edges - two for both starting points. In the average case the complexity is approx. $\mathcal{O}(n + 2n(\mu_k - 1))$, since we sample for both starting point of every base edge on average (μ_k - 1) context edges - where μ_k is the average *degree* of all nodes. Note that we subtract one because we already consider, with the based edge, one of the connected edges for both starting points. Thus, NODE and the baseline has a higher complexity than EDGE-I and EDGE-II until μ_k exceeds 1.5.

6 Related Work

While not directly comparable, our work is related to (supervised) contrastive learning in natural language processing (Rethmeier and Augenstein, 2021). Most approaches in this domain (Pagliardini et al., 2018; Logeswaran and Lee, 2018; Giorgi et al., 2021; Gao et al., 2021) aim to learn text representations where related samples (positive pairs) are aligned while unrelated samples (negative pairs) are separated. This self-supervised learning uses training objectives like text reconstruction (Logeswaran and Lee, 2018) or using supervision signals (Conneau et al., 2017; Cer et al., 2018; Reimers and Gurevych, 2019b) from labelled data like Natural Language Inference (NLI) (Bowman et al., 2015; Williams et al., 2018b). In their setup with NLI data, Gao et al. (2021) adapt training batches such that entailment relations are treated as positive examples but contradiction relations and all other in-batch instances as negative examples. Compared to these approaches, our setup focus on the supervised learning setting for these downstream tasks, rather than learning text representations which can be used latter on for these tasks.

In general, our approach adapts the training instance order that a model processes. This idea is also at the core of Curriculum Learning (Bengio et al., 2009) where training instances are reordered according to their estimated difficulty. This has been shown to be beneficial for model performance (Tay et al., 2019; Xu et al., 2020) and faster convergence (Platanios et al., 2019). While Curriculum Learning approaches make use of heuristics to adapt the sample order in one epoch, our approach only relies on the dataset structure to control the composition of training batches.

Dodge et al. (2020) identified that the order of the training samples is a random factor that influences the non-deterministic learning process of neural networks. Further, Zhou et al. (2020) found that inter-instance correlations lead to instabilities during training. We acknowledge these effects and investigate if inter-instance relations can be leveraged in the batch composition to improve the task performance for pairwise text classification.

7 Conclusions

We presented three strategies that adapt the composition of batches to encode structural dataset information. We evaluated these batching strategies on 14 heterogeneous tasks from different domains. Our results confirm the usefulness of this structural information during model training. EDGE-I show the best overall results, including different model types (e.g. ALBERT or RoBERTa) and model architectures (bi- or cross-encoder). Further, we see its success on tasks with extreme characteristics (high degree) and in situations where annotated data is extremely scarce (25 instances). We interpret our results as a promising step to integrate structural dataset information besides instance-level annotations. Further, we encourage future annotation studies to consciously consider including pairs that share common text instances for two reasons. First, to exhaust all possibilities later and second, we showed that even baseline approaches can gain from such structures.

This work covered a broad set of pairwise classification datasets that provide a structure of annotation pairs that share text instances. We plan to employ our method on datasets that do not meet this requirement by inducing inter-instance relations using similarity metrics for future work.

Acknowledgments

The work has received financial support from two sources: (1) the effort of Andreas Waldis is supported by the Hasler Foundation Grant No. 21024, (2) Tilman Beck received support for his work from the German Research Foundation (DFG) as part of the Research Training Group KRITIS No. GRK 2222/2. Further, we thank Luca Mazzola, Leonardo Ribeiro, Kexin Wang, and the anonymous reviewers for their valuable feedback.

A Training Setup

We present additional information on the training setup, including details of the used datasets and hyperparameters.

A.1 Used Datasets

We outline additional detail of the used dataset complementary to § 3.1. Table 9 introduce examples for all used datasets, and Table 10 show additional details for all of them, like the average degree or the number of topics.

A.2 Hyperparameters

The Table 4 and Table 5 shows the evaluated hyperparameters for the different strategies and the used pre-trained language model for the different experiments. This information complements § 3.2

Parameter	Values
Batch Size	$\{8, 16, 32\}$ (BASE) $\{8, 10, 12, 14\}$ (NODE) $\{8, 16, 24, 32\}$ (EDGE-I & EDGE-II)
Learning Rate	$2e^{-5}$
Optimizer	*AdamW*
Optimizer Function	*Cross-Entropy*
Warmup	10% (linear)

Table 4: Overview of the different used hyperparameters.

	Tasks	bert-base-uncased	bert-large-uncased	albert-base-v2	roberta-base	stsb-bert-base	stsb-bert-large	stsb-roberta-v2	pharaphrase-albert-small-v2
Bi	NLI	1,2,3	3	3	3	-	-	-	-
	Other Tasks	-	-	-	-	1,2,3	3	3	3
Cross	NLI	3	-	-	-	-	-	-	-
	Other Tasks	3	-	-	-	-	-	-	-

Table 5: Overview of the used Huggingface model tags for fine-tuning during the different experiments. (1) refer to the first experiment *In-Domain and Cross-Topic Evaluation*, (2) to *Dataset Size*, and (3) to *Model Agnostic* .

B Additional Results of the Experiments

In this section, we show the additional details of the three Experiments (§ 4.1, § 4.2,§ 4.3).

B.1 Significance Testing Correction

Following the defined significance testing setting (see § 3.2) we use a corrected p-value ($p = 0.01$) for the different experiments. Thus, we divide it by 14 for the first experiment, 8 for the second one, and 6 and 4 for the cross- and in-domain tasks in the third one.

B.2 Experiment: In-Domain and Cross-Topic evaluation

The Table 6 shows the results for a significant improvement ϵ or deterioration ϵ', complementary to § 4.1.

Looking at the GLUE test results (Table 7), we see improvements in absolute numbers for RTE (all strategies), MNLI-m (EDGE-I & II), MNLI-mm (EDGE-II), and QQP (NODE).

B.3 Experiment: Low-Resource Scenario

We show in Table 11 the raw results for all subsets and control subsets (RANDOM) of the SICK-REL, SICK-NLI, BWS, and Evi-St task that we use to compose Figure 7 in § 4.2. The last four columns include results of testing for a significant improvement ϵ or deterioration ϵ'.

B.4 Experiment: Model Agnostic

Table 12 shows the result of the model agnostic experiments in detail. In addition, it lists the re-

		Significance (ϵ / ϵ')		
		NODE	EDGE-I	EDGE-II
SICK-NLI	*in-domain*	1.0/1.0	0.0/1.0	1.0/0.01
SICK-REL		0.0/1.0	0.0/1.0	0.04/1.0
RTE		1.0/1.0	1.0/1.0	1.0/1.0
QNLI		0.0/1.0	0.0/1.0	0.0/1.0
MNLI-m		0.0/1.0	0.0/1.0	1.0/1.0
MNLI-mm		0.0/1.0	0.0/1.0	1.0/0.09
QQP		0.0/1.0	0.0/1.0	1.0/0.04
UKP-A	*cross-topic*	1.0/1.0	1.0/1.0	1.0/1.0
BWS		0.82/1	0.09/1.0	1.0/1.0
Arg-Conv		0.0/1.0	0.23/1.0	1.0/1.0
Evi-Conv		0.0/1.0	0.0/1.0	1.0/1.0
Evi-St		1.0/1.0	0.0/1.0	0.05/1.0
Arg-KP		0.38/1.0	1.0/1.0	1.0/0.0
ArgQ-St		0.19/1.0	0.0/1.0	0.0/1.0

Table 6: Results the significance testing of in- and cross-topic tasks computed with *ASO* with $p < 0.01$.

	BASE	NODE	EDGE-I	EDGE-II
RTE	59.2	59.2	**60.7**	60.2
QNLI	80.7	80.2	80.6	80.1
MNLI-m	33.6	33.7	34.0	33.8
MNLI-mm	75.9	**76.2**	75.3	76.0
QQP	67.0	**67.7**	67.0	66.8

Table 7: Test results on the GLUE tasks. Best results per dataset are marked in **bold**.

	Size	**Degree**	**Random**
BWS	25	1.49 ± 0.09	1.03 ± 0.04
	50	1.54 ± 0.03	1.05 ± 0.02
	75	1.56 ± 0.04	1.10 ± 0.04
	100	1.54 ± 0.02	1.12 ± 0.04
SICK-NLI	25	1.88 ± 0.08	1 ± 0
	50	1.77 ± 0.04	1 ± 0
	75	1.78 ± 0.04	1 ± 0
	100	1.78 ± 0.06	1 ± 0
SICK-REL	25	1.88 ± 0.08	1 ± 0
	50	1.77 ± 0.04	1 ± 0
	75	1.78 ± 0.04	1 ± 0
	100	1.78 ± 0.06	1 ± 0
Arg-KP	25	4.01 ± 0.20	1.65 ± 0.11
	50	4.34 ± 0.11	1.93 ± 0.06
	75	4.79 ± 0.11	2.06 ± 0.09
	100	5.03 ± 0.09	2.15 ± 0.08

Table 8: Overview of the average and std. dev. of the degree for all subsets with 25, 50, 75, and 75 samples. Column *Degree* lists the details for the specific sampled subsets, and *Random* the ones for the random sample for the control subsets.

Dataset	**Sentence A**	**Sentence B**	**Label**
BWS	*We shouldn't penalize someone for life.*	*Abortions cause psychological damage.*	0.41
UKP-A	*Cleaner, Greener, Safer, Smarter.*	*The efficiency advantage of electric motors means excellent on-road "fuel" economy.*	Similar
Arg-Conv	*Spam and adware seems to be so much more compatible with IE.*	*If the Firefox is the best then why everybody tries to have IE compatible sites?*	1
Evi-Conv	*The recently independent country of Southern Sudan also recognizes polygamy.*	*A 2011 opinion poll showed that most Malaysians and Indonesians youth opposed polygamy.*	2
Evi-St	*A 2011 opinion poll showed that most Malaysians and Indonesians youth opposed polygamy.*	*We should legalize polygamy*	CON
Arg-KP	*anyone who contributes to ending a life should be punished*	*Assisted suicide is akin to killing someone*	Matching
ArgQ-St	*A majority of americans identify with a religion.*	*We should adopt atheism.*	CON
RTE	*Edward VIII became King in January of 1936 and abdicated in December.*	K*King Edward VIII abdicated in December 1936.*	Entailment
QNLI	*What portion of Berlin's population spoke French by 1700?*	*By 1700, one-fifth of the city's population was French speaking.*	Entailment
MNLI	*Sorry but that's how it is.*	*This is how things are and there are no apologies about it.*	contradiction
QQP	*What was the deadliest battle in history?*	*What was the bloodiest battle in history?*	Duplicated
SICK-REL	*Three kids are sitting in the leaves*	*Three kids are jumping in the leaves*	3.8
SICK-NLI	*Three kids are sitting in the leaves*	*Three kids are jumping in the leaves*	Neutral

Table 9: Examples of the different tasks annotated with the corresponding labels.

sults for the five selected datasets on five language models. The results of testing for a significant improvement ϵ or deterioration ϵ' are shown in the last three columns. These insights complements the aggregated results of Table 3 in the third experiment (§ 4.3).

	Dataset	Label	Pairs	Topics	Degree	Folds	Split	Metric

Table 11: Results of the evaluation concerning different dataset sizes for Arg-KP, SICK-REL, and SICK-NLI. The column size indicates for SICK-REL, and SICK-NLI how many training instances are used and for Arg-KP how many topics. For the first four rows pick just a portion of one topic. Statistically significant improvements ($ASO^{(1)}$, U-test$^{(3)}$) and deteriorations ($ASO^{(2)}$, U-test$^{(4)}$) are indicated. The best performance for each task is **bold** marked.

		Strategy				Significance (ϵ / ϵ')

Factual Consistency of Multilingual Pretrained Language Models

Constanza Fierro   Anders Søgaard
University of Copenhagen
{c.fierro,soegaard}@di.ku.dk,

Abstract

Pretrained language models can be queried for factual knowledge, with potential applications in knowledge base acquisition and tasks that require inference. However, for that, we need to know how reliable this knowledge is, and recent work has shown that monolingual English language models lack *consistency* when predicting factual knowledge, that is, they fill-in-the-blank differently for paraphrases describing the same fact. In this paper, we extend the analysis of consistency to a *multilingual* setting. We introduce a resource, mParaRel[1], and investigate (i) whether multilingual language models such as mBERT and XLM-R are more consistent than their monolingual counterparts; and (ii) if such models are equally consistent across languages. We find that mBERT is as inconsistent as English BERT in English paraphrases, but that both mBERT and XLM-R exhibit a high degree of inconsistency in English and even more so for all the other 45 languages.

1 Introduction

Pretrained Language Models (PLMs) enable high-quality sentence and document representations (Peters et al., 2018; Devlin et al., 2019; Yang et al., 2019; Raffel et al., 2020) and encode world knowledge that can be useful for downstream tasks, e.g. closed-book QA (Roberts et al., 2020), and commonsense reasoning (Zellers et al., 2019; Talmor et al., 2019), to name a few. Recent work has used language models as knowledge bases (Petroni et al., 2019; Kassner et al., 2021a; Roberts et al., 2020) and as the basis of neural databases (Thorne et al., 2021). Such usage of PLMs relies on the assumption that we can generally trust the world knowledge that is induced from these models.

Consistency is a core quality that we would like models to have when we use their stored factual knowledge. We want models to behave consistently on semantically equivalent inputs (Elazar et al., 2021), and to be consistent in their believes (Kassner et al., 2021b). Moreover we want them to be fair across languages or in other words to exhibit a consistent behaviour across languages (Choudhury and Deshpande, 2021). Nonetheless, recent work on consistency in PLMs has shown that models are brittle in their predictions when faced to irrelevant changes in the input (Gan and Ng, 2019; Ribeiro et al., 2020; Elazar et al., 2021; Ravichander et al., 2020). These works only considered English PLMs, while Jang et al. (2021) studied the consistency of Korean PLMs. There are, to the best of our knowledge, no resources available to measure the consistency of multilingual PLMs.

Contributions In this paper, we present mParaRel, a multilingual version of the ParaRel🤘 dataset (Elazar et al., 2021), which we construct by automatically translating the English data to 45 languages and performing a human review of 11 of these. We then evaluate how consistent mBERT is in comparison to its monolingual counterpart, and we study how the consistency of mBERT and XLM-R varies across different languages. Following previous work, we do this by querying the model with cloze-style paraphrases, e.g. "Albert Einstein was born in [MASK]" and "Albert Einstein is originally from [MASK]". We find that mBERT and XLM-R exhibit competitive consistency to English BERT, but consistency numbers are considerably lower for other languages. In other words, while consistency is a serious problem in PLMs for English (Elazar et al., 2021), it is a *much* bigger problem for other languages.

2 Probing Consistency

We use the same probing framework as defined by Petroni et al. (2019) and refined by Elazar et al. (2021), and query PLMs with cloze-test statements created from subject-relation-object Wiki-

data triples (Elsahar et al., 2018). That is, we have a set of different relations $\{r\}$, and each r has a set of templates or patterns $\{t\}$ and a set of subject-object tuples $\{(s, o)\}$. Each template t describes its corresponding relation r between the pairs (s, o). E.g. a relation r can be *born-in*, and two patterns could be $\{t_1 =$"[X] was born in [Y]", $t_2 =$"[X] is originally from [Y]"$\}$ (where [X] is the subject and [Y] the object to be replaced). Then the corresponding subject-object tuples $\{(s, o)\}$ are used to query and evaluate the model by replacing the subject and masking the object. We study the consistency of a PLM by querying it with cloze-test paraphrases and measuring how many of the predictions of the paraphrases are the same (details in §4).

3 mParaRel

We used the paraphrases in the ParaRel🤘 dataset (Elazar et al., 2021), which has 38 relations in total and an average of 8.6 English templates per relation. We translated these using the procedure below, obtaining paraphrases for 46 languages.

Translations We relied on five different machine translation models: Google Translate[2], Microsoft Translator[3], a pretrained mBART model that translates between 50 languages (Tang et al., 2020), a pretrained mixture of Transformers that translates between 100 languages (Fan et al., 2021), and OPUS-MT (Tiedemann and Thottingal, 2020). We fed models with templates, e.g.,"[X] died in [Y]"[4], automatically checking if the translation contained [X] and [Y]. We considered as valid: (1) translated paraphrases that were agreed upon by two or more different models, and (2) the translations from the Microsoft translator, as they were found to be of good quality in several languages as per manual inspection by native speakers. So for languages that Microsoft supports, we will have a template t from the Microsoft translator, as well as any other translation agreed upon by two or more other translators[5]. Finally, we also include the templates in the mLAMA dataset (Kassner et al., 2021a). Translations of subject-object entities were obtained from WikiData, using the entity identifiers. We kept only the languages that (i) covered at least 60% of the total 38 relations,[6], and (ii) covered at least 20% of the total original phrases in English.[7]

	mParaRel
Average #relations	37.13
Average total #patterns	343
Min. patterns in a relation	2
Max. patterns in a relation	33
Average patterns in a relation	9.2
Average string distance	13.9

Table 1: mParaRel statistics across languages.

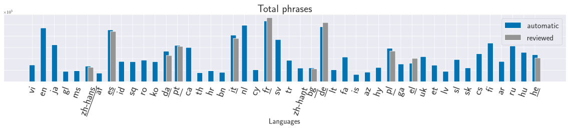

Figure 1: Number of examples per language. Manually reviewed languages are underlined. The order is given by the consistency results (see Figure 2).

Human Evaluation For assessing the quality of the translated paraphrases we carried out a human review. We had 14 native speakers review 11 different languages[8]. Each person reviewed a 50% random sample of the total templates of the language[9]. We asked whether the template was a correct paraphrase of the given relation, we requested corrections and optionally asked for new template suggestions. On average, 16%±8% of the reviewed templates were considered wrong, 20%±10% were amended, and the rest were considered correct. The statistics of the dataset after removing the wrong templates and including the corrections and suggestions can be found in Table 1. The total number of different phrases (templates with the subject and object replaced) per language is shown in Figure 1.

4 Experiments

We ran experiments with mBERT (Devlin et al., 2019), a multilingual BERT model of 110M parameters trained on 104 languages using Wikipedia, and XLM-RoBERTa (Conneau et al., 2020), a multilingual RoBERTa model of 560M parameters trained on 100 languages using 2.5TB of CommonCrawl data.

[2] `https://pypi.org/project/googletrans/`

[3] `https://docs.microsoft.com/en-us/azure/cognitive-services/translator/`

[4] Translating populated templates made alignment hard.

[5] In the final dataset, 60% of the templates are agreed by 2 or more translators

[6] Only relations with more than one template with subject-object tuples were included.

[7] A phrase is a populated template.

[8] There were 2 reviewers in Greek, German, and Spanish.

[9] The review took 50 minutes on average and the reviewers did it voluntarily.

Querying Language Models The prediction of a PLM for a cloze statement t is normally $\arg\max_{w \in V}(w|t)$ (Petroni et al., 2019; Ravichander et al., 2020), that is, the top-1 token prediction over the vocabulary. However, Kassner et al. (2021a); Elazar et al. (2021) used typed queries, where the prediction is $\arg\max_{w \in C}(w|t)$, with C a set of candidates that meets the type criteria of the pattern (e.g. cities, professions). In our case, C is all the possible objects in the relation. The motivation is that by restricting the output we can reduce the errors due to surface fluency, as when populating the template with different tuples small grammatical errors can occur (Kassner et al., 2021a).

It is common to only consider tuples (subject-object) for which the to-be-masked object is a single token in the models vocabulary (Petroni et al., 2019; Elazar et al., 2021). However, this reduces the number of valid tuples severely, and even more so when dealing with multilingual vocabularies. Therefore, we follow the multi-token prediction approach in Kassner et al. (2021a) and query the model with multiple masked tokens. The probability of an object instantiation is then the average probability of its tokens, i.e., for a given object $o = w_1 w_2 ... w_l$, $p(o|t) = \frac{1}{l}\sum_{i=1}^{l} p(m_i = w_i|t_l)$, where w_i is the i-th token of the word o, m_i is the i-th mask token, and t_l is the template with l mask tokens.

Evaluation For a given relation r the **consistency** is the percentage of pairs of templates that have the same prediction for every subject-object tuple (Elazar et al., 2021), i.e. the consistency of a given relation r is:

$$\frac{1}{|D|}\sum_{d \in D}\frac{2}{|T|(|T|-1)}\sum_{i=0}^{|T|}\sum_{j=i+1}^{|T|}\mathbb{1}_{f(t_i^d)=f(t_j^d)} \quad (1)$$

where t is a template, T the set of templates in the relation, d is a subject-object tuple, D the set of all tuples, so t_i^d is the i-th template populated with the subject-object data d, and $f(\cdot)$ is the prediction of the model. Next, **accuracy** measures the factual correctness of the predictions and is defined as the percentage of correct predictions over all the templates and data, i.e. $\sum_{d \in D}\sum_{t \in T}\mathbb{1}_{f(t^d)=o}$, where o is the object of the tuple d. Finally, **consistency-accuracy** is the subset of the accurate predictions that is also consistent. Thus, it is computed similarly to Equation 1 but in the indicator's condition we also add the condition imposed in the accuracy.

Metric		BERT	mBERT		
		en	en	ja	zh-hans
Consistency	w/ .	**0.57**	**0.54**	**0.55**	0.46
	w/o .	0.53	0.53	0.52	**0.51**
Accuracy	w/ .	**0.39**	**0.37**	0.13	0.22
	w/o .	0.32	0.35	**0.15**	**0.27**
Consistency-acc	w/ .	**0.32**	**0.3**	0.09	0.15
	w/o .	0.24	0.28	**0.1**	**0.2**

Table 2: Performance comparison of BERT to mBERT, as well as of removing sentence-final punctuation in our input examples, with mBERT results on English, Japanese, and Chinese Simplified.

This metric is useful to account for trivial cases of consistency: A model can be really bad in a language and predict the same token despite the input, and thus be perfectly consistent. For all metrics, we report the *macro average* across relations.[10]

5 Results and Discussion

Table 2 compares the consistency of BERT and mBERT on English data, showing little to no difference, depending on whether we use sentence-final punctuation or not. Sentence-final punctuation is not fully consistent in the machine translation output, so we ran experiments comparing the performance of including sentence-final punctuation or removing it. Since languages vary in how they use punctuation, and sentence-final punctuation causes variance in consistency (e.g., Japanese +3%, but Chinese Simplified -5%), we decided to remove all sentence-final punctuation for the cross-lingual consistency results.

Consistency across languages The consistency results in the mPARAREL dataset are presented in Figure 2. First of all, we can see that the manual corrections don't change the results much (as also experienced by Kassner et al. (2021a)). Nevertheless, they do improve the consistency and accuracy by 1%-2% in a couple of languages, probably because some noise was reduced when correcting and adding new templates. Consistency numbers remain very low, however, especially for other languages than English and Vietnamese. XLM-R is much more consistent than mBERT in *some* languages (e.g. Greek ('el')), yet their average consistency is the same (0.43). The standard deviation of XLM-R's consistency is 8% lower than that of mBERT, i.e., XLM-R has a more fairly

---

[10] Our results are *not* directly comparable to those reported in Elazar et al. (2021), even if we use the same metric, since we filter tuples with the same subject, but two different objects.

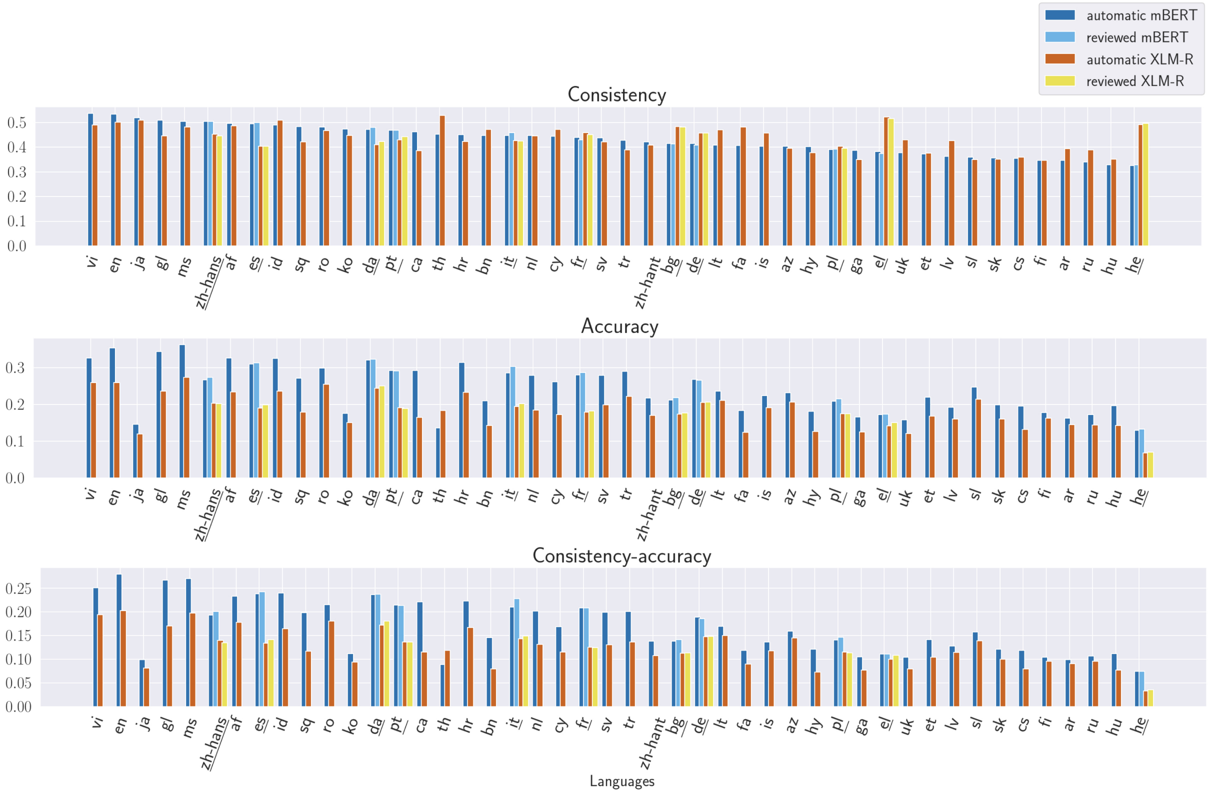

Figure 2: mBERT and XLM-R results on mParaRel after and before the human review (§3). The order of the languages follows the consistency results in mBERT, and the languages underlined were manually reviewed.

distributed consistency. Somewhat surprisingly, the accuracy of mBERT is superior to XLM-R's, nevertheless, this aligns to the findings of Elazar et al. (2021) where English base BERT obtained higher accuracy than a large English RoBERTa model. We note the importance of controlling for accuracy in our consistency results (reported as *consistency-accuracy*): Japanese, for example, has high consistency, but in part, because it wrongly predicts the same (frequent) token across paraphrases; consistency-accuracy reranks Japanese as one of the most inconsistently encoded languages in both mBERT and XLM-R.

6 Related Work

Petroni et al. (2019); Davison et al. (2019) first studied to what extent PLMs store factual and commonsense knowledge, proposing the LAMA probe and dataset. Then further analysis followed it, Kassner and Schütze (2020) studied probing PLMs factual knowledge on negated sentences, Shin et al. (2020); Reynolds and McDonell (2021); Jiang et al. (2020b) optimized the prompts so to improve the knowledge retrieval, and Bouraoui et al. (2020); Heinzerling and Inui (2021) explored other approaches different than the cloze-test probing. Then, Kassner et al. (2021a); Jiang et al. (2020a) studied the knowledge memorized in multilingual PLMs, presenting the mLAMA dataset which is a translated version of LAMA.

Consistency in PLMs has been studied in English. Gan and Ng (2019) created a paraphrased version of SQuAD and showed that the state-of-the-art models had a significant decrease in performance, Ribeiro et al. (2020) proposed a framework to test the robustness in the predictions when faced with irrelevant changes in the input. Elazar et al. (2021); Ravichander et al. (2020) showed that monolingual English PLMs are inconsistent in fill-in-the-blank phrases. Then, Newman et al. (2021) proposed using adapters to better handle this inconsistency.

There are paraphrase datasets available in English (Dolan and Brockett, 2005; Quora, 2012) and in multiple languages (Ganitkevitch and Callison-Burch, 2014), but they cannot be easily linked to subject-object tuples in order to measure consistency.

7 Conclusion

In this work, we measured the consistency of *multilingual* Pretrained Language Models when queried to extract factual knowledge. We constructed a high-quality multilingual dataset containing 46 different languages, to assess the consistency of models predictions in the face of language variability. Finally, we experimented with mBERT and XLM-R and concluded that their consistency is poor in English, but even worse in other languages.

Abstract

With the increasing popularity of online chatting, stickers are becoming important in our online communication. Selecting appropriate stickers in open-domain dialogue requires a comprehensive understanding of both dialogues and stickers, as well as the relationship between the two types of modalities. To tackle these challenges, we propose a multitask learning method comprised of three auxiliary tasks to enhance the understanding of dialogue history, emotion and semantic meaning of stickers. Extensive experiments conducted on a recent challenging dataset show that our model can better combine the multimodal information and achieve significantly higher accuracy over strong baselines. Ablation study further verifies the effectiveness of each auxiliary task. Our code is available at `https://github.com/nonstopfor/Sticker-Selection`.

我看到箱子了？你还多久回家呢？！
哈哈是不是回家然后一起出来耍喃？
(I saw the suitcase? When will you be home?!
Ha ha let's hang out together when you arrive home?)

(It depends. I may be a little busy this time)

放那么多天假你忙啥子嘛
(What are you up to with so many days off)

家里回来了两个重量级的人物
(Two VIPs have returned home)

啥子重量级嘛？
(What does VIP mean?)

你不懂
(You don't get it)

你说了我就懂了嘛
(I will if you explain to me)

Figure 1: An example of the sticker selection task. Given a dialogue history, the model needs to add a sticker to the last textual message which is the most appropriate one among a collection of candidate stickers (the one marked in the red rectangle). The words below in red denote the emotion or meaning of each sticker.

1 Introduction

With the development of mobile messaging apps (e.g., WhatsApp and Messenger), visual content is getting more and more frequently used in our daily conversation, such as emojis and stickers. Compared with emojis, stickers are larger images consisting of drawing characters, symbolic icons, and text titles, and are hence more expressive and versatile (Konrad et al., 2020). Users send stickers along with text to show intimacy, express strong emotion, and experience the enjoyment of creativity (Tang and Hew, 2019).

Despite the importance of stickers in daily communication, selecting stickers in open-domain dialogue hasn't been widely explored. In this paper, we address the task of selecting an appropriate sticker from a candidate set for an open-domain multi-turn dialogue. This task is a typical setting for various applications, e.g., automatically recommending stickers in messaging apps and building more interesting and human-like chatbots which could respond with stickers. As shown in Figure 1, this task requires an understanding of dialogue context, emotion and semantic meaning of stickers, and a jointly modeling ability for the multimodal information. Only a few previous works have explored this task (Gao et al., 2020; Wang and Jurgens, 2021). However, existing models are only trained on an end-to-end matching objective and lacks finer-grained supervision signals which could guide models to understand multimodal information better.

Considering the challenges of this task and the shortcomings of previous work, we propose a novel multitask learning method to improve sticker selection in open-domain multi-turn dialogue. We design three auxiliary tasks: **1) masked context prediction**, which uses multimodal context to predict masked tokens in the dialogue history, aiming to understand the dialogue in the presence of the sticker;

Findings of the Association for Computational Linguistics: ACL 2022, pages 3053 - 3060
May 22-27, 2022

2) sticker emotion classification, which utilizes the sticker's contextualized representation to predict its emotion, aiming to improve the model's understanding of sticker emotion; **3) sticker semantic prediction**, which explicitly instills semantic understanding of stickers by training the model to reconstruct a sticker's semantic label based on the multimodal inputs. Moreover, all these tasks help improve our model's joint modeling capability, as both our model architecture and task design require multimodal inputs and deep interactions between them. We evaluate the performance of our method on a recently proposed and challenging dataset. Extensive experiments show that our multitask method achieves state-of-the-art performance.

There are two contributions of this paper:

- We propose a multitask learning method to help select appropriate stickers in open-domain multi-turn dialogue.
- Experiment results on a challenging dataset demonstrate the effectiveness of each auxiliary task and combining all the tasks achieves state-of-the-art performance.

2 Related Work

Sticker selection. Previous works proposed to recommend emojis in dialogue systems based on textual or multimodal context (Barbieri et al., 2018; Xie et al., 2016; Barbieri et al., 2017). However, emojis are limited in variety and are much less expressive than stickers. Laddha et al. (2020) retrieved stickers for generated text utterances by simply matching the text tags of stickers. Several works have proposed improved matching methods for stickers. Gao et al. (2020) utilized co-attention to capture the interaction between a sticker and each utterance, and used a fusion network to combine the features. Wang and Jurgens (2021) followed the matching framework of CLIP (Radford et al., 2021) and designed a multimodal encoder for animated GIFs. Fei et al. (2021) proposed to generate special sticker tokens along with text utterances using one single GPT (Wang et al., 2020) for emotion prediction and retrieval of stickers. However, existing models are only trained on an end-to-end matching objective that implicitly guides the models to understand multimodal information. In our work, we design finer-grained auxiliary tasks that instill knowledge of stickers and their contextualized usage in a more efficient way.

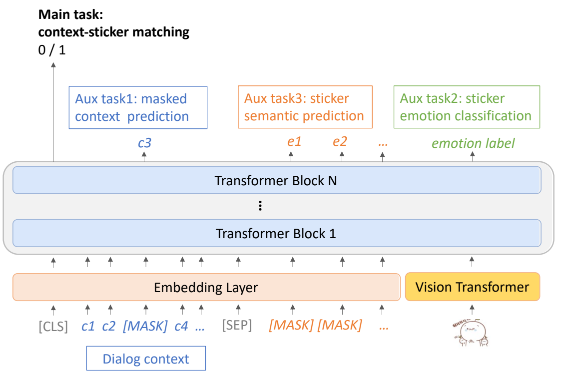

Figure 2: An overview of our training task design. The base model architecture is a multimodal BERT that learns to predict whether the candidate sticker is appropriate given the dialogue context. Three auxiliary tasks are proposed to enhance the model's ability to understand multimodal input. c_i and e_i represent tokens of dialogue context and semantic label respectively.

Visual Dialogue. Visual dialogue is a task to answer questions about the factual content of the real-world image (Liang et al., 2021; Das et al., 2017a,b). In contrast, selecting appropriate stickers in open-domain dialogue requires understanding sentiment and semantic expression of user-generated, artistic style images.

3 Method

3.1 Task Definition

We assume there is a multi-turn dialogue context $C = \{u_1, ..., u_N\}$, and a candidate sticker set $S = \{s_1, ..., s_M\}$, where u_i represents the i-th utterance in the dialogue, and s_i represents the i-th candidate sticker. N is the number of utterances in the dialogue and M is the number of candidate stickers. In this work, we suppose that there is only one appropriate sticker $s^* \in S$, and s^* and u_N belong to the same speaker. The goal is to train a model that can select the right sticker s^* among all candidates S given the dialogue history C.

3.2 Method Overview

An overview of the design of our training tasks is shown in Figure 2. Our main task is to decide whether the candidate sticker is appropriate given the dialogue context. To accomplish this task, we concatenate the embedded dialogue context and the sticker embedding as inputs to BERT. Then we apply a binary classification layer on top of the hidden state of the [CLS] token. In order to enhance the model's ability to understand the multimodal input, we design three auxiliary tasks: **1) masked context prediction**, which improves the model's understanding of dialogue context; **2) sticker emotion classification**, which aims to make the model better understand sticker's emotion; **3) sticker semantic prediction**, which instills semantic information of stickers to the model. Next, we will introduce our three auxiliary tasks in detail.

3.3 Task 1: Masked Context Prediction

The masked context prediction task follows the masked language modeling (MLM) task in BERT (Devlin et al., 2019). One difference is that we additionally append the embedding of the appropriate sticker to the input embeddings. In this way, the model can learn to utilize stickers for dialogue reconstruction, and thus the interaction between the two modalities is enhanced. The loss for this task is denoted as $\mathcal{L}_{ctx}$, and takes the same form of cross-entropy loss as in the original MLM task.

3.4 Task 2: Sticker Emotion Classification

In the dataset we used, stickers are annotated with one context-dependent emotion, which means one sticker could have different emotions in different dialogue contexts. Therefore, we design a sticker emotion classification task to enable the model to utilize the text and sticker information simultaneously for understanding sticker emotion. Specifically, we take the hidden state corresponding to the sticker and apply a softmax layer with cross-entropy loss on top of it for emotion classification. The loss for this task is denoted as $\mathcal{L}_{emo}$.

3.5 Task 3: Sticker Semantic Prediction

Task 1 and Task 2 emphasize learning the implicit meaning of stickers and their correlation with dialogue text. However, many stickers express a clear intention that indicates their proper usage context, e.g., greetings and declines. We believe empowering our model to predict and utilize the semantic meaning of stickers is beneficial for our task. Hence, we further design a semantic label prediction task. We modify our model's inputs by inserting a fixed-length sequence of [MASK] tokens after the dialogue. The model is trained to recover the label text from the hidden states of the [MASK] tokens. The loss is formulated as the sum of cross-entropy loss for each token in label and is denoted as $\mathcal{L}_{sem}$. Since the dataset we used has no ground truth semantic labels for stickers, we take the textual information recognized by an OCR tool as semantic labels for stickers. Note that $\mathcal{L}_{sem}$ is only applied for those stickers with text recognized.

3.6 Total Loss

Besides the above three auxiliary tasks, our main task is a binary classification of whether a candidate sticker is appropriate given the dialogue context. We take all dialogue-sticker pairs in the dataset as positive samples and randomly sample stickers to create an equal number of negative samples. The cross-entropy loss is denoted as $\mathcal{L}_{main}$.

Our final loss is a combination of the four loss:

$$\mathcal{L} = \mathcal{L}_{main} + \alpha\mathcal{L}_{ctx} + \beta\mathcal{L}_{emo} + \gamma\mathcal{L}_{sem} \tag{1}$$

where α, β, γ are manually tuned hyperparameters.

4 Experiments

4.1 Dataset

We use the Chinese version of the MOD dataset from DSTC10-Track1[1]. The dataset is grounded in a dialogue scenario and contains various stickers with contextualized emotion annotation. We split each dialogue into several samples, each containing a text sequence of dialogue history and an accompanying sticker. Note that this dataset is revised from the unpublished one used in Fei et al. (2021).

4.2 Baselines

We compare our model with the following baselines from recent related work: **1) SRS** (Gao et al., 2020), which encodes dialogue history and candidate sticker separately, and then employs a deep interaction network and a fusion network to score each candidate sticker; **2) MOD-GPT** (Fei et al., 2021), which uses one single GPT to generate response text and match sticker; **3) CLIP**, which finetunes pretrained CLIP (Radford et al., 2021) for sticker selection using the same contrastive loss.

4.3 Results and Analysis

The result is shown in Table 1. Our full model (MMBERT+*ctx*+*emo*+*sem*) outperforms all baselines on two test sets, and achieves the best performance in almost all settings. As expected, all the results get worse on the hard test set and when selecting one amongst all stickers. As only one

Table 1: Performance of the models on DSTC10 dataset. All the numbers are scaled by 100. The easy test set contains only the same stickers seen during training, while the hard test set has unseen stickers. The footnotes $_{10}$ and $_{\text{ALL}}$ indicate the numbers of candidate stickers considered for each train and test case, which are 10 (ground truth sticker plus 9 randomly sampled stickers) or all available stickers respectively. R@k is the recall rate of top-k predicted stickers and MRR the Mean Reciprocal Rank of ground truth stickers. The abbreviations *ctx*, *emo* and *sem* correspond to the auxiliary task 1, 2 and 3 respectively in Section 3. A paired t-test is conducted between the full model (MMBERT+*ctx*+*emo*+*sem*) and CLIP (*: $p < 0.05$, **: $p < 0.01$).

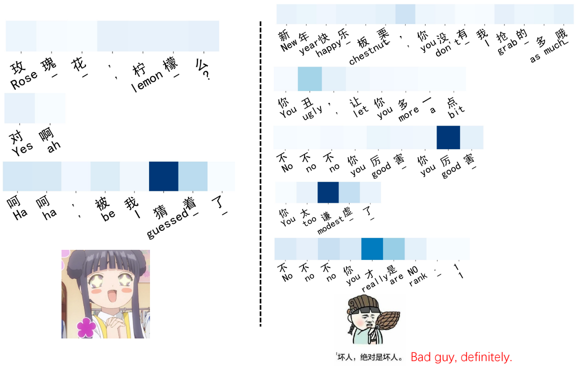

Figure 3: Examples of word saliency in the dialogue history. Word saliency is computed as Frobenius norm of its gradient with regard to the main task loss. Darker color indicates the word is more important. The words in red denote the text in the sticker.

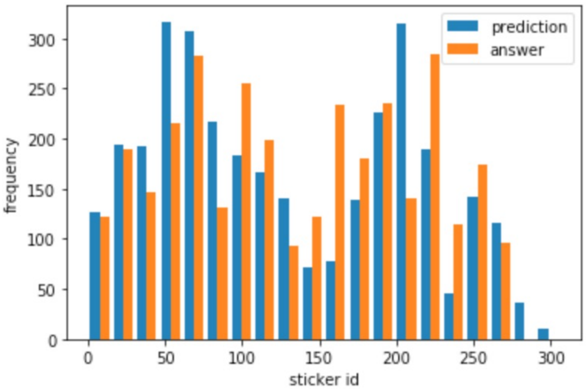

Figure 4: The diversity of the predicted and ground truth stickers in the easy test set.

out of the numerous and various online stickers is considered correct, the task is inherently challenging. We find that CLIP is a strong baseline due to its better generalization ability on the hard set, compared with our base model which has no auxiliary task (MMBERT). This may be because CLIP is pretrained on a large number of image-text pairs. However, with multitask learning, our full model outperforms CLIP, although BERT has never seen images during pretraining. Thus, we conclude that our multitask learning method can improve sticker selection by explicitly guiding the model to understand multimodal information.

We also perform an ablation study to verify the effect of each auxiliary task. A clear trend emerges that the performance improves as each auxiliary training task is added to MMBERT, verifying the efficacy of our task design. One exception is that MMBERT+*ctx*+*emo* performs slightly better than our full model in terms of R$_{10}$@2, R$_{10}$@5, and MRR$_{10}$. However, the inconsistency disappears when considering all stickers as candidates. Furthermore, our full model performs significantly better on the hard test set which contains unseen stickers. Hence, we conclude that introducing semantic information improves the model's generalization ability. We also find that our full model achieves 60% accuracy on the validation set for the auxiliary

sticker emotion classification task with 52 emotion labels in total, which is reasonable and confirms our model can learn from the auxiliary tasks.

We visualize the saliency of different words in the dialogue history in Figure 3, which shows that the more relevant words (e.g., *guessed*, *good* and *modest*) in the dialogue history contribute more to our model's prediction. Notably, our model could attend to some distant words (e.g., *good*), not just the words inside the previous utterance.

We also analyze the prediction diversity of our full model. As shown in Figure 4, the predictions of our model are diverse in general, covering almost all stickers in the whole candidate set. We note that a few stickers are predicted significantly more times than other stickers, which is because they appear much more frequently than other stickers in the training set. We leave addressing the imbalance problem of the training set as our future work.

4.4 Case Study

We present a successful case in Figure 1, where the ground truth sticker has no OCR information, making it challenging for the model to understand its semantic meaning. Moreover, the model needs to understand that the dialogue is in a delighted context, and the stickers' emotions and meanings in order to distinguish the most appropriate sticker from the others. This case suggests our model has a good understanding of dialogue history and sticker emotion and semantic meaning with the help of auxiliary tasks.

We show a failing case of our model in Figure 5. In this case, the appropriate sticker never appears in the training set. Considering the hard test set is more challenging than the easy test set, improving the generalization ability of our model is thus an important direction of future work. The same is true for baselines.

In the dataset we used, only one sticker is considered correct. However, we observe cases where the model's selection is not the same as the answer but is also appropriate. An example is shown in Figure 6. Therefore, the results in Table 1 indicate a lower bound performance and our model may perform better in practice.

5 Conclusion

In this paper, we address the challenging task of selecting appropriate stickers in open-domain multi-turn dialogue. We propose a multitask learning method with three auxiliary tasks to enhance the understanding of dialogues and stickers. Experiments show that our model outperforms strong baselines, confirming the effectiveness of our multitask learning method for sticker selection. Although our experiments are conducted on a Chinese dataset, our methods are expected to work for other languages.

A Dataset Details

Statistics of the dataset are shown in Table 3. There are 307 stickers in total and 228 out of them have textual information extracted by OCR. For stickers without emotion labels or semantic labels, we simply ignore the emotion classification loss or the semantic prediction loss. A better way to deal with the missing labels is left as future work.

For each dialogue sample, we ignore stickers in the middle of the dialogue history, as we found in preliminary experiments that removing them has no significant impact on the performance.

B Implementation Details

For all the models implemented by ourselves in our experiments, we set the batch size to 8 and use AdamW optimizer with cosine scheduler. For the CLIP baseline, as there is no available CLIP

Avg. # tokens	18.42	12.47	12.91	14.54

Table 3: Dataset statistics. Easy test set's stickers all appear in the train set, while the hard test set contains stickers which don't appear in the train set. One original dialogue could be split into several samples, each containing one sticker response. The token num is computed by the tokenizer of BERT. # emo samples means the number of samples containing emotion annotation. Avg. # tokens means the average number of tokens for each utterance.

model especially pretrained in Chinese, we use a multilingual version adapted via knowledge distillation (Reimers and Gurevych, 2020)[3]. We cut the dialogue history to take only the last sentence in order to fit the length limit of CLIP's text encoder. We also tried to use the last two or more sentences, but found that the performance decreased. All BERT-based models and MOD-GPT use the image encoder in the CLIP baseline. We set the CLIP image encoder's learning rate to 5e-7 and the text encoder's learning rate to 9e-6. For BERT-based models, we set the learning rate to 9e-6 and fix the image encoder following (Fei et al., 2021). The maximum epoch is set to 10. For the total loss, α is set to 0.05, β is set to 0.2 and γ is set to 0.1. All the hyperparameters are selected based on the validation set. The maximum training time for one epoch is about 5 hours on one single V100 GPU.

C Effect of Semantic Information

In our full model, we also added semantic labels to other tasks' inputs, i.e., the main task of context-sticker matching, the masked context prediction task and the sticker emotion classification task. It raises an interesting question of how the performance will change if we remove this information. The result is shown in Table 2. As we can see, the sticker semantic prediction task is more beneficial for the easy test set, while adding OCR information to other tasks is more beneficial for the hard test set. We conjecture that because of the relatively small number of stickers (less than 300), it could be easier for the model to memorize the meaning of all stickers in the dataset, which potentially damages the model's generalization ability on unseen stickers in the hard test set. Adding OCR information for other tasks greatly alleviates this phenomenon because it could offer semantic labels for unseen stickers and enhance the model's generalization ability.

We also tried to enhance the model's generalization ability by incorporating additional sticker-description pairs from another source into the

Table 4: Performance of our full model and CLIP on the divided dataset. **The three values divided by / correspond to the performance on the sub dataset where stickers have text, the performance on the sub dataset where stickers don't have text and their difference**. All the numbers are scaled by 100. The easy test set contains only the same stickers seen during training, while the hard test set has unseen stickers. R@k is the recall rate of top-k predicted stickers and MRR the Mean Reciprocal Rank of ground truth stickers. The abbreviations *ctx*, *emo* and *sem* correspond to the auxiliary task 1, 2 and 3 respectively in Section 3.

sticker semantic prediction task. As Table 2 shows, this method could increase the performance on the hard test set as expected, but the performance on the easy test set drops significantly, which may be attributed to the distribution difference between the additional data and our original data.

D Analysis of Sensitivity to the Text in Stickers

To explore whether stickers have text or not could affect the model's performance, we split each test set into two parts, i.e., stickers with recognized text labels versus those without text labels. The number of samples in each part is 2164 and 1051 for the easy set, and 4429 and 2599 for the hard set. We compare the performance of our full model with that of CLIP on the divided test sets in Table 4. To avoid randomness in candidate set construction, we only compare the two models with the whole candidate set. In general, our full model and CLIP work better when the stickers have text, which suggests that the text in the sticker could help the model better understand the sticker.[4] However, our model is less sensitive to whether stickers have text or not according to the smaller difference value compared with CLIP. This implies our model is more robust to different kinds of candidate stickers.

---

[4] Strictly speaking, there may be other factors that make the two parts inherently different in difficulty, but a fair comparison is difficult to make. Intuitively, stickers without text labels are generally harder to understand for the models.

ZiNet: Linking Chinese Characters Spanning Three Thousand Years

Abstract

Modern Chinese characters evolved from 3,000 years ago. Up to now, tens of thousands of glyphs of ancient characters have been discovered, which must be deciphered by experts to interpret unearthed documents. Experts usually need to compare each ancient character to be examined with similar known ones in whole historical periods. However, it is inevitably limited by human memory and experience, which often cost a lot of time but associations are limited to a small scope. To help researchers discover glyph similar characters, this paper introduces ZiNet, the first diachronic knowledge base describing relationships and evolution of Chinese characters and words. In addition, powered by the knowledge of radical systems in ZiNet, this paper introduces glyph similarity measurement between ancient Chinese characters, which could capture similar glyph pairs that are potentially related in origins or semantics. Results show strong positive correlations between scores from the method and from human experts. Finally, qualitative analysis and implicit future applications are presented.

1 Introduction

The evaluation of Chinese character can be divided into two stages: the ancient stage (before Han dynasty, 202 BC) and the clerical and standard script stage (after Han dynasty) (Qiu et al., 2000). At the former stage, ancient characters do not have a fixed shape, and their glyphs show several differences respect to modern characters: representatives include the Oracle bone script (Oracle) in the Shang Dynasty (about 1300 BC), which appears on animal bones or turtle shells (Boltz, 1986), the Chinese bronze script (Bronze, about 1000 BC) appeared on bronze wares (Shaughnessy, 1991) and the script belonging to the Warring States period (States), mainly recorded on wooden slips (about 400 BC) (Qiu, 2014). Evolution of glyphs of Chinese characters can be observed in Figure 1.

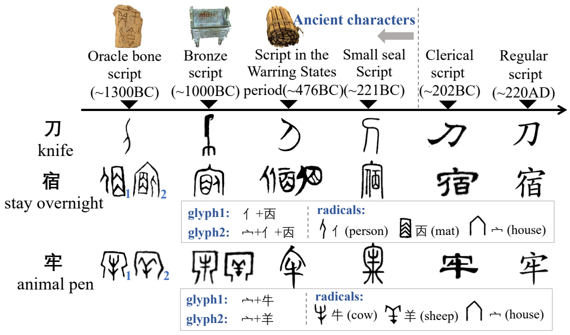

Figure 1: Examples of historical evolution of Chinese characters associated with unfixed glyphs and radical compositions (the pictures on the top show unearthed ancient characters respectively written on the turtle shell, bronze ware and wooden slips).

Ancient unearthed documents show a wealth of information regarding that historical periods (Boltz, 1986; Shaughnessy, 1991; Qiu, 2014), which is great significant for understanding the culture and history of China, as well as the whole world. Nevertheless, nearly half of ancient characters cannot be deciphered yet. The purpose of deciphering ancient character is to find the modern Chinese characters evolved from it and give enough interpretations and evidences in terms of glyphs, phonetics and semantics. According to the systematic nature and evolution law of Chinese characters, experts need to compare the character to be examined with similar known characters in history. However, there are tens of thousands of glyphs of characters appeared in history, discovering similar character heavily relies on expert experience, which is inevitably limited by human memory and reduces the comprehensiveness and efficiency.

To measure similarity between ancient characters, automatic methods face challenges: (1) it lacks available resources of ancient Chinese, which means existing algorithms, especially supervised al-

Findings of the Association for Computational Linguistics: ACL 2022, pages 3061 - 3070
May 22-27, 2022

gorithms cannot be directly used to solve this problem. And ancient characters do not have features such as standard code, pinyin and strokes, which have been widely used for describing the modern one. (2) it is complicated to represent and measure ancient characters. For instance, edit distance is widely used to measure orthographic similarity between words in Romance languages; however, it is not suitable for measuring glyph similarity between pictographic Chinese characters.

Based on above considerations, the main contributions of this paper are: (1) introduces ZiNet, the first diachronic knowledge base for linking Chinese characters and words across various historical periods. (2) as the first application of ZiNet, this paper introduces methods for glyph similarity measurement, which aims at giving glyph similar scores for ancient Chinese character pairs.

There are two main characteristics of ZiNet comparing to existing lexical resources: (1) it is designed based on the systematic nature of Chinese characters. The smallest unit of ZiNet is the radical, the component of character, which is of significance for analyzing semantics or phonics of characters (details will be discussed in Section 3.1). (2) ZiNet is diachronic, which integrates characters and words across historical periods, and aims to portray their evolution. Powered by knowledge of ZiNet, our glyph similarity measurement method could capture the glyphs that are potentially relevant in terms of origins or semantics, which is meaningful in researches of Chinese characters. Results shown a strong positive correlation between the methods scores and human experts.

The paper is organized as follows: Section 2 presents the state of the art; Section 3 describes key information of ZiNet; Section 4 describes glyph similarity measurement; results are proposed in Section 5; Section 6 shows implications and future works; Section 7 concludes the paper and Section 8 shows ethics.

2 State of the Art

2.1 Processing Ancient Chinese Character

Zhang et al. (2020) built a real-world dataset OB-Rejoin, which proposes an effective algorithm to rejoin Oracle fragments. Han et al. (2020) proposed an Oracle information system, known as IsOBS, which records Oracle rubbings, documents, Oracle characters and all their variants. Jiao et al. (2021) generated a network for Oracle characters according to their structures and documents. They classified the semantically-similar Oracle characters by analyzing the network module.

2.2 Lexical Resources and Cognate Discovery

WordNet-oriented (George, 1995) lexical resources are widely used in NLP tasks. Their architecture consists in synset as basic semantic units to integrate words senses, which are related to each other, thus forming a conceptual semantic network. Multilingual resources, such as Open Multilingual WordNet (Bond and Foster, 2013), BabelNet (Navigli and Ponzetto, 2012) and Universal Knowledge Core (Giunchiglia et al., 2017), which integrated words and concepts from all over the world, can support NLP tasks in languages that lack resources.

According to historical linguistics, cognate identification needs to consider three dimensions: semantic, phonetic and orthographic similarity (Arnaud et al., 2017), who dealt with researching ancient Chinese. Hauer and Kondrak (2011) designed rich set of features to capture similarity. Batsuren et al. (2020) considered evidence in the form of a combined orthographic and geographic relatedness. Snyder et al. (2010) designed a Bayesian model to incorporate linguistic constraints, which includes customized priors for alphabet matching and morphological structure. Luo et al. (2019) automatically deciphered ancient languages by evaluating the accuracy of aligning words from a lost language to their counterparts in a known language. According to these works, orthographic similarity is an important indicator; however, measurements like edit distance cannot be directly applied to Chinese characters.

3 ZiNet

3.1 Motivation

ZiNet has been created in order to link Chinese characters and words in history, according to their glyphs, semantics and phonetics to support knowledge-powered algorithms during processing of Chinese or ancient Chinese. Here we will give a general outline of key knowledge to help understand the structure of ZiNet and the reasons why it has been developed.

Relation between word and character: Chinese words are composed of one or more characters; the latter can also be regarded as monosyllable words when expressing semantics. For example, character (or monosyllabic word) "宿"

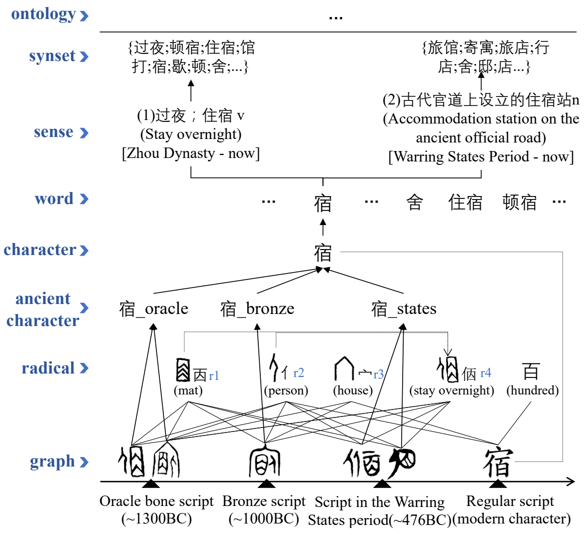

Figure 2: Structure of the ZiNet.

(stay overnight) in Figure 1 can participate in the formation of the polysyllabic word "住宿" (get accommodation).

Relation between character and radical: radical is the conventional structural unit that can participate in the characters composition; radicals themselves are also characters, or variants of characters. For instance, in ZiNet, the radical of the single modern character "刀" (knife) is itself "刀", and the radicals of the compound modern character "宿" (stay overnight) are "宀" (house), "亻" (person) and "百" (hundred).

Radical and deciphering: Radicals knowledge is crucial for related researches, because radical is related to the phonetics or semantics of the character. For instance, "宀" (house), "亻" (person) are related to the semantics of "宿" (stay overnight). Thus, through radicals and relationships between them, experts are able to discover further phonetic or semantic related characters that may implicit clues for deciphering.

Evolution: The glyph of character is evolving through historical periods. For instance, Figure 1 shows the radicals of Oracle character "宿". In that ancient period, the bottom-right radical of "宿" is not "百" (hundred), but another similar character that means "mat". these objects should be represented within a diachronic network, in order to explore their implicit evolution rules.

3.2 Structure of ZiNet

In the current stage, ZiNet is composed by seven layers and there are relations between layers (Figure 2); in the future, an eighth layer of Ontology is aimed to be added, in order to describe human life through varied historical periods, by linking synsets to concepts and topics.

- **Glyph:** Character writing shapes. ZiNet integrates rubbing images from unearthed artifacts for each glyph.

- **Radical:** The components of character. In ZiNet, all glyphs are associated with corresponding radicals at two levels of granularity (Compound radicals can be further split into finer-grained units. For instance, in Figure 2, r_4 is a compound radical, consisting of r_1 and r_2.).

- **Ancient Character:** Chinese characters in ancient historical periods. All ancient glyphs should be associated with the corresponding ancient character.

- **Character:** Including deciphered and undeciphered characters: the former is further divided into modern and dead character. Ancient characters belonging to different periods that represent the same character should be linked. If ancient character is deciphered, and is being currently used, it should be linked to modern character. Else, if the ancient character is deciphered but is not used, it should be linked to the corresponding dead character. Finally, undeciphered ancient characters should be linked to the corresponding undeciphered character.

- **Word:** Mono-syllable (character) and multi-syllable word in Chinese history.

- **Sense:** Meaning of word. All words should be associated with their corresponding senses.

- **Synset:** A set of at least one synonym. All senses should be associated with the corresponding synset.

The organization of Word, Sense, Synset layers are designed based on WordNet. One word might have several senses; senses associated to the same meaning are linked to the same synset.

Other bottom of layers is different with existing lexical resources, which are designed following the systematic nature of Chinese character. In order to research ancient Chinese characters, knowledge on glyphs and radicals must be explicitly provided.

The other key characteristic is diachronism, which is reflected in two ways: (1) At the glyph level, ZiNet aims at covering the critical period of evolution of Chinese characters: Oracle, Bronze, States and modern characters have been integrated up to now. (2) At the sense level, for each sense, the earliest and latest dynasty where it appeared are annotated, according to the records provided by dictionaries.

Here we introduce two relations inside ancient character layer, which are used to measure glyph similarity:

- **Derivation (分 化):** A proliferation phenomenon of Chinese characters: based on a certain glyph of a mother character, making one or several new characters that are glyph-consistent and related to the semantics of the mother character. In ZiNet, if character B (e.g., "東" (bag)) is derived from character A (e.g., "束" (tie)), there would be a Derivation relation between them.
$ancient\_char(B) \xrightarrow{D} ancient\_char(A)$.

- **Indication (指事):** An abstract method to create a new Chinese characters by directly adding a indicative symbol on a specific position of the glyph of the mother character, the new character meaning is related to the position indicated by symbol. If a new character B (e.g.,"刃" (knife edge)) is created by adding a symbol on the specific position(e.g., edge) of a pictographic character A(e.g., "刀" (knife)), there would be an Indication relation between them.
$ancient\_char(B) \xrightarrow{I} ancient\_char(A)$.

3.3 Statistics of ZiNet

ZiNet is constantly developing. All characters, glyphs and rubbings images were provided by experts on Chinese characters. Radicals of each ancient character and relations were also been split and proofread by experts, who referred to dozens of authoritative publications, of which the most representatives are (Chinese Academy of Social Science (CASS), 1984) and (Guo and Hu, 1978). Most of the words and senses in ZiNet were acquired from authoritative ancient dictionaries, such as Shuowenjiezi (Shen Xu, 1963) and a few original senses in far ancient periods were provided by experts. Synsets were automatically associated according to the definitions of the senses. Up to now, ZiNet includes three historical Chinese periods: Oracle, Bronze, and States. Table 1 lists statistical information. ZiNet is extensible, as Figure 2 shows, the Glyph and Ancient Character layers are independent for each historical period, which allows it to conveniently extend to other historical periods in future.

Object	Statistics
Rubbing image	15175=Oracle; 14289=Bronze; 28421=States
Glyph	2913=Oracle; 3225=Bronze; 7232=States
Radical	584=Oracle; 853=Bronze; 868=States
Ancient character	2543=Oracle; 2319=Bronze; 5632=States
Character	Deciphered character: 1283=Oracle; 2466≤ Bronze; 4478≤States; 18966≤Present Undeciphered character: 1260=Oracle; 1714≤ Bronze; 4118≤ States
Word	423997
Sense	69825≤206BC; 177570 ≤ 618AD; 315181 ≤ 1368AD; 386949≤1840AD; 570764≤ Present
Synset	366544

Table 1: ZiNet statistics ("=" means an object existed in that historical period; "≤" means an object had appeared before, or during that period).

4 Glyph Similarity Measurement

4.1 Key Points of Glyph Similarity

The task is to give glyph-similar scores for each ancient character pair: this does not only include the pictographic similarity of character shapes, but also between their radical systems. In this paper, we consider the following four points:

(1) Similar character shape: Two pictographic characters have similar shapes. For example, the pictographic character "刀"(knife) in Figure 1 is depicted in the form of a knife. If the shape of another character also resembles a knife, they are defined as glyph similar.

(2) Sharing radicals: Two characters sharing radicals. For instance, the character "宿" (stay overnight) in Figure 2 is formed by radicals ac-

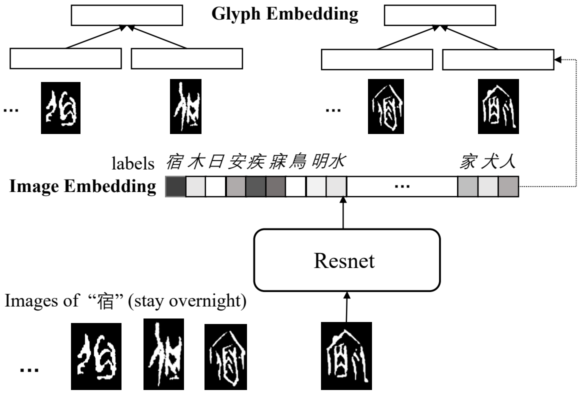

Figure 3: Procedure to generate glyph embedding for pictographic similarity.

cording to their respective meanings, rather than by directly drawing the object. If one character shares radicals with it, they are defined as glyph similar.

(3) There are Derivation or Indication relations between their radicals: In general cases, characters do not share radicals; however, their radicals are related in Derivation or Indication (Section 3.2). If two characters respectively contain related radicals, they are defined as glyph similar.

(4) Their radicals are universal when composing a character: In other cases, radicals of two characters do not have relations; however, when composing a character, they are universally used to show the same semantics. Universal radical pairs can be automatically discovered, by exploring radical pairs that are mutually substituted in synchronic, or diachronic different glyphs of the same character in ZiNet. For example, in Figure 1, the character "牢" (animal pen) has two different Oracle glyphs: the first contains the radicals of "宀" (house) and "牛" (cow), whereas the second contains "宀" (house) and "羊" (sheep). In this case, "牛" (cow) and "羊" (sheep) is a pair of synchronic substitutable radicals. We consider the characters respectively containing them as glyph similar.

Pictographic Similarity (PicSim), Radical LCS Similarity (RLCSSim) and Graph Similarity (GraphSim) will be introduced respectively in Section 4.2, 4.3 and 4.4, respectively. While the former aims at measuring the similarity between character shapes, RLCSSim and GraphSim focus on measuring similarities between radical systems.

4.2 Pictographic Similarity

The intuition to measure the similarity of pictographic characters is to consider them as pictures. Deep Residual Network (ResNet) (He et al., 2016) is used to obtain the high-dimensional vector of images of ancient characters, as shown in Figure 3. There are n ancient characters and m images of characters in total; the set of images is $X(x_1, x_2, \ldots x_m)$, and that of characters is $C(c_1, c_2, \ldots c_n)$. The network task is to classify each image x into the corresponding character c, $p(c|x, \varphi)$ is used to denote the probability that an image x belongs to the character c, where φ is the parameter that needs to be trained to acquire. The network input is the image x, while the output is the $|C|$-dimensional vector: each dimension represents the probability p of each character label c. At the training step, images and their associated Chinese character labels are provided. We minimize cross-entropy loss function to get the optimal parameters φ.

The $|C|$-dimensional vector output is then directly used as the image embedding, $\vec{I}$. As a next step, given the set $ImageSet$ that contains all images belonging to glyph g, the glyph embedding, $\vec{G}$ of g, is set to the average of embedding of images in $ImageSet$.

$$\vec{G_i} = \frac{1}{|ImageSet_i|} \sum_{x_j \in ImageSet_i} \vec{I_j} \tag{1}$$

After obtaining the glyph embedding $\vec{G}$, cosine similarity is used to get the similarity between glyph pairs. It is multiplied by a hyper-parameter α here. Only when two glyphs share the same or related radicals, then $\alpha = 1$, otherwise, α will be set as a value greater than 0, and less than 1. $RSet_i$ consists in the collection of radicals, and their related radicals (derivative, indicative or universal relations as introduced in Section 4.1) of g_i.

$$Sim(g_i, g_j) = \alpha Cosine(g_i, g_j), \tag{2}$$
$$\begin{cases} \alpha = 1, & RSet_i \cap RSet_j \neq \emptyset \\ 0 < \alpha < 1, & Otherwise \end{cases}$$

Finally, given the $GlyphSet$ that contains all glyphs belonging to character c, the PicSim between two characters is the maximum similarity of the combination between their glyph pairs.

$$PicSim(c_k, c_g) = Max\{Sim(g_i, g_j)\}, \tag{3}$$
$$(g_i \in GlyphSet_k, g_j \in GlyphSet_g)$$

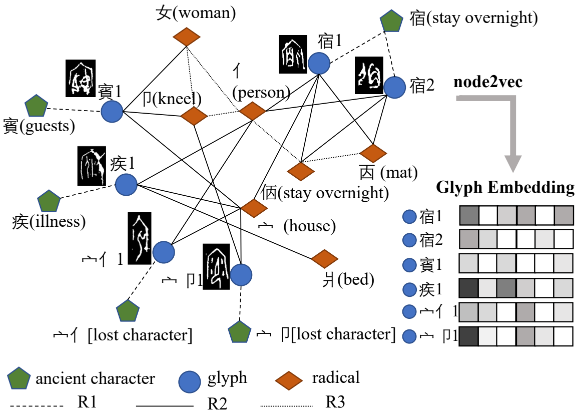

Figure 4: Procedure to generate glyph embedding for Graph similarity.

4.3 Radical LCS Similarity

RLCSSim aims at measuring the similarity between radical systems. Here we represent a character as a radicals sequence and use longest common subsequence (LCS) to measure glyph similarity of characters. In this paper, each glyph is represented as a sequence of their smallest unit of radicals: $Seq(r_1, r_2, \dots r_k)$. k is the number of radicals of that glyph. The sort order of the radicals r is determined by their positions within the character, which follows the rules of first left, then right; first up, then down; and first inside, then outside.

Eq.4 shows the RLCSSim between glyphs: RLCS means the longest common subsequence of same or related radicals between Seq_i and Seq_j. When calculating RLCS, we not only consider the same radical pairs, but also related radical pairs in derivative, indicative, or universal aspects (Section 4.1). If the corresponding two radicals are the same one, the RLCS will add 1, whereas if the two radicals are related, the RLCS will add a hyper-parameter $\theta, 0 < \theta < 1$. After getting the similarity of glyphs, the similarity between characters can be acquired according to Eq.3.

$$RLCSSim(g_i, g_j) = \frac{2 \times |RLCS(Seq_i, Seq_j)|}{|Seq_i| + |Seq_j|} \tag{4}$$

4.4 Graph Similarity

RLCSSim is discrete, and only covers character pairs sharing related radicals. In order to represent glyphs in high-dimensional vectors, and to acquire similarities among all character pairs, we introduces GraphSim. Here we construct an undirected graph $Graph$ based on ZiNet with the purpose of associating all Chinese glyphs through radicals. As shown in Figure 4, the set of nodes N includes character c, glyph g and radical r. There are three types of relations in $Graph$: $R_1(c, g)$, $R_2(g, r)$ $R_3(r, r)$: R_1 describes the inclusion relationship between characters and glyphs; R_2 describes the inclusion relationship between glyphs and radicals; R_3 contains derivative, indicative and universal relationships (Section 4.1) between radicals.

As the next step, based on the $Graph$, the random walk algorithm node2vec (Grover and Leskovec, 2016) is used to generate glyph embedding $\vec{G}$ of glyph nodes, while cosine similarity is used to obtain the similarity between glyphs. Finally, the GraphSim between characters can be acquired as the same way of Eq.3.

5 Evaluation

5.1 Design of Evaluation

We used Oracle data as the sample for evaluation, which contains 2543 Oracle characters, 2912 glyphs, 586 radicals and 15,175 character images; among them, 1283 characters are undeciphered up to now. The characters meanings cover each domain in that ancient age.

Experts were invited to further manually annotate the dataset: (1) There were 5400 Oracle character pairs randomly selected from the 2543 characters. Experts were asked to score them regarding glyph similarity. The corresponding value ranges from 0 to 10; the most similar character pair should be scored as 10. Three experts participated in this work, we selected the median as the final score for each pair of characters. (2) Experts were asked to provide less than five most similar characters to each Oracle character in sample. One expert firstly annotated similar characters. Then, another expert gave verification and deleted incorrect characters he thought. Finally, we got a total of 6405 similar pairs; on average, 2.5 similar characters were provided for each Oracle character, which have been represented as: $HSimSet\{(c_1, c_{11}), \cdots, (c_i, c_{in}), \cdots\}, i \leq 2543, n \leq 5$.

There are three quantitative and qualitative evaluation indicators:

- **Correlation:** Spearman's correlation was used to evaluate the correlation between similarity scores annotated by experts and our methods in 5400 pairs of Oracle characters.

Method	Top-5	Top-10	Top-20	Top-50	Top-100	Top-200
PicSim	19.53%	24.03%	29.74%	41.25%	50.27%	59.25%
RLCSSim	52.63%	65.21%	74.91%	86.15%	91.83%	95.93%
GraphSim	53.90%	64.84%	74.96%	85.92%	91.69%	96.03%
RLCSSim+PicSim	42.39%	52.51%	64.59%	78.61%	87.63%	94.53%
RLCSSim+GraphSim	**59.75%**	**70.37%**	78.86%	88.70%	93.99%	97.38%
RLCSSim+PicSim+GraphSim	57.13%	69.49%	**79.75%**	**89.41%**	**95.08%**	**97.86%**

Table 3: Results of coverage of the six methods in Top5–Top200 recommendations (the recommended size k was set to 5-200 according to the application scenarios in researches).

The value would be closer to 1 if it shows stronger positive correlation, conversely, it would be closer to -1.

- **Coverage:** The proportion of the 6405 similar character pairs appearing in the top-k similar character pairs provided by our methods (Eq.5), where the indicator aims at evaluating how much information that users need to browse to get the relevant one. $MSimSet\{(c_1, c_{11}), \cdots, (c_i, c_{ik}), \cdots\}, i \leq 2543, k \leq 2543$ to represent the top-k set of character pairs given by our methods.

$$Coverage = \frac{|HSimSet \cap MSimSet|}{|HSimSet|} \quad (5)$$

- **Qualitative analysis:** We show the top-5 recommendation examples to evaluate the performance and show potential semantic relations at radical level captured by the method.

5.2 Configuration

In the experiment, the number of layers of the ResNet network was 18, batch size was 64 and the learning rate was 0.001. The network was trained through 90 epochs. The hyper-parameter α was 0.4 and θ in RLCSSim was 0.7. The node2vec algorithm for GraphSim was implemented by using the OpenNE[1] tool; the dimension of the output glyph vector was 50.

In addition, this paper designed three combinations of basic methods: RLCSSim+PicSim, RLCSSim+GraphSim, and RLCSSim+PicSim+GraphSim. Their scores were set to the weights of basic methods. For the first two combinations, the weights of each basic method were 0.5 in both. Regarding RLCSSim+PicSim+GraphSim, the weights were respectively set to 0.4, 0.3 and 0.4. We extra annotated 100 ancient character pairs to set these hyper-parameters. The code of experiment can be acquired here[2].

Method	Correlation	
	score	p-value
PicSim	0.3241	<.001
RLCSSim	0.8188	<.001
GraphSim	0.7763	<.001
RLCSSim +PicSim	0.7614	<.001
RLCSSim+GraphSim	0.8391	<.001
RLCSSim+PicSim+Graph	**0.8422**	<.001

Table 2: Results of Spearman's correlation.

5.3 Results and Discussions

Spearman's correlations regarding the six methods are shown in Table 2; all of them show positive correlations respect to scores from experts. More in detail, RLCSSim+PicSim+GraphSim has the strongest positive correlation, corresponding to 0.8422, while the performance of PicSim method is not as good, with a 0.3241 value.

Table 3 shows the results of coverage indicator. RLCSSim+GraphSim achieved the best performance in the top5 and top10 recommendations, while, when dealing with larger recommendations size (top20 - top200), the effect of RLCSSim+PicSim+GraphSim has the most positive outcome. In a top-5 recommendation, four methods cover more than half of similar characters, while in top-200 recommendation, the coverage enhanced to more than 97% for RLCSSim+PicSim+GraphSim.

As results show, RLCSSim and GraphSim that are powered by knowledge of radical systems perform better than PicSim both in terms of corre-

---

[2] https://github.com/YangChiJLU/AncientChineseCharSim

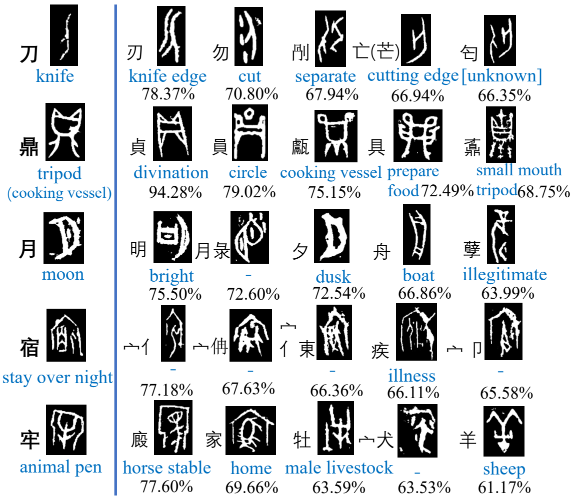

Figure 5: Cases of top-5 characters of glyph similarity (for each character, the Image, Title (e.g., "刀") in modern Chinese, English Annotation (e.g., "knife") and the Similarity Score (e.g., 78.37%) are shown. If the character is undeciphered, the English Annotation of it is "-" and the Title is written as the combination of the Titles of its Radicals (e.g., "宀亻" (house;person)).

lation and coverage. PicSim is suitable to comparing similarity between shapes of single pictographic characters. However, though some of character pairs show similar shapes, they are not similar at radical systems level. Thus, PicSim reduced the coverage of RLCSSim+PicSim, and RLCSSim+PicSim+GraphSim, in the case of small recommendations size. However, PicSim is meaningful to discover new similarities as the supplements of knowledge-powered methods. In larger size of scenarios, RLCSSim+PicSim+GraphSim performs better than only RLCSSim+GraphSim. Overall, the results show that radical systems are the crucial indicator for glyph similarity considered by human experts. It is necessary to represent, and calculate the potential relationships between radical systems of character pairs, rather than only consider characters as pictures. In application scenarios of small recommendations size, RLCSSim + GraphSim can be the best choice. In larger size of recommendations scenario, a combination of the three methods is the best choice.

5.4 Qualitative Analysis

Figure 5 shows five top-5 recommendations of the RLCSSim+PicSim+GraphSim method; the first three examples are single pictographic characters, while the other two are instances of compound characters which are formed with more than one radical. From the examples it can show many glyph similar character pairs are also related in semantics.

The first reason is that glyph similar pictographic characters always semantic related, which can be captured by PicSim method. As the figure shows, similar characters of "刀" (knife) are related to the knife edge, and the cut behavior, while similar characters of "鼎" (tripod) are mostly related to vessels for sacrifices and food. These characters have similar shapes, thus they can be recognized by PicSim. Another significant reason is that our method is also knowledge-powered, which can capture potential relations at the radical level. Regarding the compound character "宿" (stay overnight), at the radical level, all of meanings of recommended characters deal with a person doing activities in the house. Analogously, "牢" (animal pen) is formed by radicals "宀" (house) and "牛" (cow), and three similar characters are also combined by animals and houses: for instance, the most similar character "廄" (horse stable) is formed by "宀" (house) and "馬" (horse), whose meaning is also related to "animal pen". The character gets higher similar score because RLCSSim and GraphSim captured the semantic similarity between the radicals of "馬" (horse) and "牛" (cow).

In addition, this method is inclined to give higher scores for character pairs with potential relations. For instance, regarding the recommendations of character "月" (moon), the recommended character "夕"(dust) and "月" (moon) were derived from the same character. And another recommended character "舟"(boat) is the diachronic substitutable radical of "月": some Chinese characters (e.g., "前" (to forward)) were formed by "舟" (boat) in ancient age; however, today, their radicals have been changed to "月" (moon).

6 Implications and Future Work

This work firstly put forward a diachronic Chinese lexical resource, which expanded the architecture of Princeton WordNet by adding several layers to describe diachronic characters under the lexical layer. Word was regarded as the basic unit in most existing semantic lexical databases (George, 1995; Bond and Foster, 2013; Navigli and Ponzetto, 2012; Giunchiglia et al., 2017); however, based on our investigations, glyphs or radicals of Chinese characters can also show semantics, which have been used to enrich input information in several NLP tasks (Meng et al., 2019; Tao et al., 2019; Sun et al., 2021; Tao et al., 2021). Besides, in interdisciplinary researches with historical linguistics, Chinese history and paleography, etc., diachronic characters and words, glyphs and semantics were always discussed together because of their close links, while in the low-resources background, existing NLP algorithms have not been widely applied in these fields.

The significance of ZiNet is to give a more complete architecture to support diverse NLP tasks: it introduces not only lexical, but also glyph and character information, not only works for modern Chinese, but also ancient Chinese, or regarding them in the same diachronic space. We hope this work can enlighten diversity of the architecture of language resources and promote development of more NLP tasks in interdisciplinary researches.

At the application level, ZiNet hold potential for knowledge powered Chinese NLP and image processing algorithms, especially in interdisciplinary researches, such as cognate discovery, word sense tracking and rubbing character recognition. ZiNet can also support platforms and provide experts in related fields with domain knowledge and quick information suggestions. For instance, giving retrievals of the evolution timeline of characters and words, annotated unearth document corpus and recommendations of similar characters at various historical times.

In future work, ZiNet will be further expanded to other historical periods, and synsets will be linked into conceptual ontology layer to describe the topics of Chinese in varied historical periods. In application level, we will apply ZiNet in other knowledge powered tasks, for instance, using radical knowledge to enhance performance of ancient character image recognition. And we will further explore that how it can help research and decipher ancient characters. Meanwhile, we are developing a platform to support services of ZiNet, which will be open in near future.

7 Conclusion

This paper proposed ZiNet, a diachronic Chinese knowledge base, which is the first structured resource dedicated to describe the relations, and evolution of Chinese characters and words. Based on ZiNet, we demonstrated methods for calculating glyph similarity between ancient Chinese characters. Results show a strong positive correlation between the scores obtained from our method and from experts. We hope this work can serve experts in Chinese linguistics, history and related fields.

8 Ethics

Data of ZiNet was mainly from School of Archaeology, Jilin university, we got the permission for further development. Other data was processed from ancient dictionaries, which are open for access and researches. ZiNet also has limitations. Since the ancient characters were thousands of years away from now, lots of information was lost, and there are also disputes in existing academic theories, such as identity and meaning of a certain character, the character to which a glyph belongs, etc. As a result, inevitably, ZiNet is incomplete, and tends to be in line with the "mainstream" theories that is also possible to be incorrect proved in future. Therefore, in some cases, glyph similarity measurement and other applications based on ZiNet may produce misleading and omission. Relevant users can use ZiNet and applications to get suggestions efficiently; however, they need to rely on their own professional knowledge for judgment. All the same, we believe the positive impact of our work far outweighs the limitation.

Abstract

Cross-lingual Entity Typing (CLET) aims at improving the quality of entity type prediction by transferring semantic knowledge learned from rich-resourced languages to low-resourced languages. In this paper, by utilizing multilingual transfer learning via the mixture-of-experts approach, our model dynamically capture the relationship between target language and each source language, and effectively generalize to predict types of unseen entities in new languages. Extensive experiments on multilingual datasets show that our method significantly outperforms multiple baselines and can robustly handle negative transfer. We questioned the relationship between language similarity and the performance of CLET. With a series of experiments, we refute the commonsense that the more source the better, and propose the *Similarity Hypothesis for CLET*.

1 Introduction

Fine-grained Entity Typing (FET) aims at labeling entity mentions in a particular context with one or more specific types organized in a type hierarchy. For example, *Donald Trump* is classified as having the path of following types: *President*, *Politician*, *Person*. *President* is a subclass of *Politician* that in turn is a subclass of *Person*. FET provides accurate type information, and is therefore quite useful for various downstream NLP tasks, such as entity linking (Onoe and Durrett, 2020; Chen et al., 2020a; Zhu et al., 2020), relation extraction (Vashishth et al., 2018; Kuang et al., 2020), text generation (Dong et al., 2021; Elsahar et al., 2018), and so on.

Supervised learning approaches to FET need huge amount of labeled training data (Ren et al., 2016; Shi et al., 2020; Chen et al., 2020b), and can be applied for a few rich-resourced languages, e.g., English, which have enough qualified labeled data.

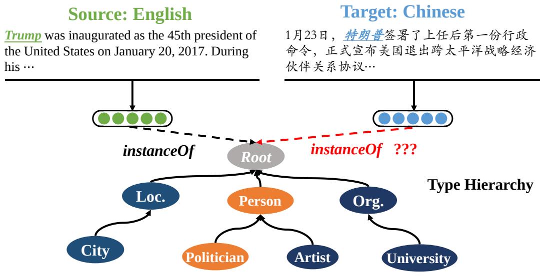

Figure 1: Example of Cross-lingual Entity Typing. We use knowledge from source language (English) to help with entity typing task in target language (Chinese).

For the vast majority of low-resourced languages, we have insufficient training data, or even do not have labeled data at all. However, languages are not independent, instead, some are more similar than others, and form a family tree. For example, Portuguese is similar to Spanish; Dutch can even be thought of as half way between German and English. This motivates us to utilize the knowledge from rich-resourced languages (source) to help to predict missing types in a low-resourced language (target), which is called the Cross-lingual Entity Typing (CLET). Previous research showed that transferring knowledge from multiple source languages could improve the performance of entity typing (Chen et al., 2019b). Recent research proposed a unified CLET model, trained with four rich source languages (English, Finnish, German, and Spanish), is able to accept over 100 different languages (Selvaraj et al., 2021). Behind such unified models is the assumption that the more rich-resourced languages a model has, the better the performance will be. This leads to the search of the best unified model for all low-resourced languages.

Here, we raise the question: How will the similarity between the source and the target languages affect the performance? To this end, we carefully select six languages as follows: German, English, and Dutch in the west Germanic family, Russian

---

May 22-27, 2022 ©2022 Association for Computational Linguistics

in the Slavic family, and Spanish in the Romance family. This five languages are in the European family[1]. We select Chinese in the Sino-Tibetan family, which is totally different from the other five languages, as illustrated in Figure 2. The more similar two languages are, the higher is their lowest common ancestor located in the language tree.

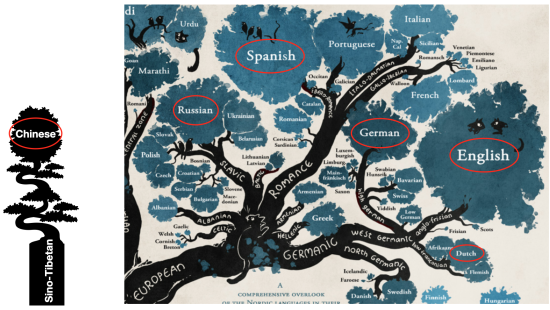

Figure 2: Six selected languages are marked with red circles.

Following the unsupervised multilingual transfer-learning setup, we use labeled data from source languages and unlabeled data from the target language, leverage multilingual BERT as feature encoder to produce language-independent features (Devlin et al., 2019), and use mixture-of-experts (MoE) approach (Jacobs et al., 1991; Shazeer et al., 2017) to capture the correlations between the target language and each source language. For each target example, the predicted posterior is a weighted combination of all the experts' predictions. Experts' weights reflect the proximity of the example to each source language. To further improve transfer quality, we apply a language discriminator to extract more language-invariant features from both source and target languages via adversarial learning. Extensive experiments show that our proposed method significantly outperforms multiple state-of-the-art monolingual methods.

In contrast to other cross-lingual FET researches, our work explores how the similarity between source and target languages would affect the FET performance. Our experiment results surprisingly refute the commonly accepted assumption that the more and the richer the source languages are, the better performance it will be. Our results suggests the importance of the similarity between source and target languages. The more similar the source and the target are and the richer the source is, the better performance it will be. Adding a rich but dissimilar source may reduce the performance. This observation refutes the existence of the best unified model for all target languages. The best cross-lingual source languages shall be rich and selected among the cluster of the most similar languages to the target language.

The rest of this paper is organized as follows. Section 2 formally defines the problem of cross-lingual fine-grained entity typing. Section 3 describes our approach. Section 4 reports two groups of experiments, one to evaluate our method, the other to explore the relation between language similarity and the performance of type prediction. Section 5 reviews some related works. Section 6 concludes our work.

2 Problem Formulation

We use $\mathbb{S} = \{\mathcal{S}_i\}_{i=1}^{N}$ as the set of source languages, in which N is the number of source languages, $\mathcal{T}$ as the target language. Types are organized into a tree-structured hierarchy $\mathbf{Y}$, shared by all languages.

Based on the assumption that each mention can only have one type-path depending on the context, we represent each type-path uniquely by the terminal type (which might not be a leaf node). For example, type-path `root-person-athlete` can be represented as just `athlete`, while `root-person` can be unambiguously represented as the non-leaf `person`.

For each source language $\mathcal{S}_i \in \mathbb{S}$, we have a set of training data $\mathcal{S}_i = \{(x_t, y_t)\}_{t=1}^{|\mathcal{S}_i|}$. $x_t = (m_t, c_t)$ contains two parts, $m_t = \langle w_l, \ldots, w_r \rangle$ is an entity mention and $c_t = \langle w_1, \ldots, w_L \rangle$ is its context, both m_t and c_t are word sequences, where L is the context length and $1 < l \leq r < L$. y_t is the most specific type of m_t, corresponding to a unique type-path in $\mathbf{Y}$. For target language $\mathcal{T}$, we create a set of unlabeled data $\mathcal{T} = \{x_t\}_{t=1}^{|\mathcal{T}|}$. We formulate cross-lingual fine-grained entity typing (CLET) problem as follows:

Definition 1 *Given training data from source languages* $\mathbb{S} = \{\mathcal{S}_i\}_{i=1}^{N}$, *and unlabeled data from target language* $\mathcal{T}$, *we aim at learning a model* $P(y|x)$ *using the source training data and generalizing well to the target language. Given* $x \in \mathcal{T}$, *our task is to predict its most specific type* $\hat{y}$ *depending on the learned model* $P(y|x)$.

Notations The superscript and the subscript of an example denote the language from which it is

---

[1] https://thelanguagenerds.com/2019/feast-your-eyes-on-magnificent-linguistic-family-tree/

sampled, and its index, respectively. For instance, $x_j^{\mathcal{S}_i} = (m_j^{\mathcal{S}_i}, c_j^{\mathcal{S}_i})$ is the j^{th} example in $\mathcal{S}_i$. Sometimes we omit superscripts for brevity.

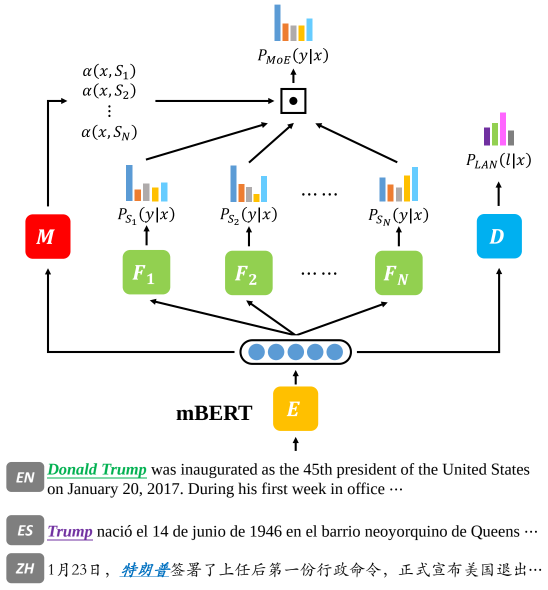

Figure 3: Framework of our proposed model. x is an example from any language. E is the shared encoder across all languages; $F_{\mathcal{S}_i}$ is the classifier on the i^{th} source language, the final prediction $P_{MoE}(y|x)$ is a weighted combination of all the classifiers' predictions; M is the metric learning component, which takes the encoding of x and source languages $\{\mathcal{S}_i\}_{i=1}^N$ as input and computes weight α; $\mathcal{D}$ is the language discriminator which is learned during adversarial training.

3 Methodology

3.1 Overview of Our Approach

We model the multiple source languages as a mixture of experts, and learn metric α to weight the experts for different target examples (Jacobs et al., 1991; Shazeer et al., 2017). Our model consists of four key components, as shown in Figure 3, namely the shared feature extractor E, a set of language-specific classifier $\{F_{\mathcal{S}_i}\}_{i=1}^N$, metric function M and language discriminator $\mathcal{D}$. Our model is a multi-task learning architecture, with a shared encoder of all languages, and language-specific classifier $F_{\mathcal{S}_i}$ for each language S_i. Each input is firstly encoded with E, and then fed to each classifier to obtain the language-specific predictions. The final predictions are then weighted based on the metric M.

3.2 Feature Extractor E

We use multilingual BERT (mBERT) as feature extractor (Devlin et al., 2019), since it follows the same model architecture and training procedure as BERT and produces an effective cross-lingual word representation. Different from BERT, mBERT is pre-trained on concatenated Wikipedia data in 104 languages. Formally, given an example $x_i = (m_i, c_i)$ in any language, we utilize mBERT encoder to get its representation $E(x_i)$. Given a mention $m_i = \langle w_l, \ldots, w_r \rangle$ with its context $c_i = \langle w_1, \ldots, w_L \rangle$, we simply feed the sequence ([CLS], c_i, [SEP], m_i, [SEP]) to mBERT encoder and use the output of [CLS] token as the representation of the mention with its context.

3.3 Expert Classifier F

Each source $\mathcal{S}_i$ has a language-specific classifier (expert) $F_{\mathcal{S}_i}$. With the representation $E(x_j^{\mathcal{S}_i})$ of an example in $\mathcal{S}_i$, we employ a softmax classifier parameterized by $\theta_f^{\mathcal{S}_i} = [W_f^{\mathcal{S}_i}, b_f^{\mathcal{S}_i}]$ to get the language-specific prediction (i.e. posterior).

$$P_{\mathcal{S}_i}(y|x_j^{\mathcal{S}_i}) = \text{Softmax}(W_f^{\mathcal{S}_i} E(x_j^{\mathcal{S}_i}) + b_f^{\mathcal{S}_i}) \quad (1)$$

$$\hat{y} = \arg\max_y P_{\mathcal{S}_i}(y|x_j^{\mathcal{S}_i}) \quad (2)$$

where $W_f^{\mathcal{S}_i} \in \mathbb{R}^{K \times d_z}$ can be treated as the type embeddings, $b_f^{\mathcal{S}_i} \in \mathbb{R}^K$ is the type bias, K is the number of types. The predicted type $\hat{y}$ is the type with maximum posterior probability. Since $F_{\mathcal{S}_i}$ is trained on labeled data from $\mathcal{S}_i$, so it will pay more attention on **language-specific** feature in $\mathcal{S}_i$.

3.4 Mixture of Experts

Given an entity x from the target language, we model its posterior distribution as a mixture of posteriors produced by experts trained on different source language data:

$$P_{MoE}(y|x) = \sum_{i=1}^{N} \alpha(x, \mathcal{S}_i) P_{\mathcal{S}_i}(y|x) \quad (3)$$

$P_{\mathcal{S}_i}(\cdot)$ is the posterior distribution produced by the i^{th} source classifier $F_{\mathcal{S}_i}$ (i.e., the i^{th} expert). $\alpha(\cdot)$ is calculated by metric function M, it measures the similarities between the target language example x and each source languages $\{\mathcal{S}_i\}_{i=1}^N$.

We utilize *point-to-set* distance as metric function (Guo et al., 2018) to define the distance between entity x and a source $\mathcal{S}_i$ is defined as follow.

$$d(x, \mathcal{S}_i) = ((E(x) - \mu^{\mathcal{S}_i})^\top \mathbf{M}_{\mathcal{S}_i} (E(x) - \mu^{\mathcal{S}_i}))^{\frac{1}{2}} \quad (4)$$

where $\mu^{\mathcal{S}_i}$ is the mean encoding of $\mathcal{S}_i$. Each source $\mathcal{S}_i$ has a parameter matrix $\mathbf{M}_{\mathcal{S}_i}$, which is used to measure the similarity between an entity and this source. Based on the distance metric, confidence score is defined as $e(x, \mathcal{S}_i) = -d(x, \mathcal{S}_i)$. The final metric values $\alpha(x, \mathcal{S}_i)$ are then obtained by normalizing these scores:

$$\alpha(x, \mathcal{S}_i) = \text{Softmax}(e(x, \mathcal{S}_i)) \tag{5}$$

This metric approach hypothesizes that both input entity and source language distribution are important in weight assignment.

3.5 Language Discriminator $\mathcal{D}$

To further improve the quality, we adopt a language adversarial training module to minimize the divergence between source and target languages. In other words, feature extractor E should capture more **language-invariant** information. Different from $\{F_{\mathcal{S}_i}\}_{i=1}^{N}$, $\mathcal{D}$, as a language classifier, can be trained on unlabeled data in both source and target languages. Given an entity x, it takes $E(x)$ as input and predicts the likelihood of the language label of x. $\mathcal{D}$ is defined as a softmax classifier parameterized by $\theta_d = [W_d, b_d]$, where $W_d \in \mathbb{R}^{(N+1)\times d_z}$ and $b_d \in \mathbb{R}^{N+1}$.

$$P_{LAN}(l|x) = \text{Softmax}(W_d E(x) + b_d) \tag{6}$$

3.6 Model Training

Our model's parameters include $\theta_f^{\mathcal{S}_i}$, θ_d and $\mathbf{M}_{\mathcal{S}_i}$. We utilize language-adversarial training method to optimize parameters in language discriminator $\mathcal{D}$ and other components, separately. During the training process, E aims at confusing $\mathcal{D}$, so that $\mathcal{D}$ cannot predict the language in which a sample is written. The hypothesis is that if $\mathcal{D}$ cannot recognize the language of the input, the extracted features will contain more language-invariant information. We propose to use meta-training approach to learn the parameters in experts ($\theta_f^{\mathcal{S}_i}$) and metric function ($\mathbf{M}_{\mathcal{S}_i}$) simultaneously. With each iteration through the training data, we update parameters in the mBERT encoder as well as parameters in our model. The training part is described in more detail in Appendix (Alg.1).

4 Experiments

A series of experiments are conducted to evaluate our CLET method and to examine how the language similarity affects the performance of CLET. Our source code is available[2] for reference.

Table 1: Dataset Statistics. **EN**: English, **DE**: German, **ES**: Spanish, **ZH**: Chinese, **NL**: Dutch, **RU**: Russian.

4.1 Model Evaluation

4.1.1 Experiment Setting

Dataset We construct our dataset based on the MVET dataset constructed from Wikipedia and Freebase (Yaghoobzadeh and Schütze, 2018). Each entity in MVET has an name in English, names in other languages, Freebase ID, and FIGER types. MVET contains 102 FIGER types (Ling and Weld, 2012), which forms a 3-level type hierarchy. For each entity, we utilize hyper-link in Wikipedia to find a sentence containing this entity mention. We collect data for six languages: English, German, Spanish, Chinese, Dutch, and Russian. Table 1 shows the statistics.

Metrics To evaluate the performance of our proposed method, we use Accuracy (**Strict-F1**), Micro-averaged F1 (**Mi-F1**) and Macro-averaged F1 (**Ma-F1**), which have been used in many FET systems (Ling and Weld, 2012; Ren et al., 2016; Xu and Barbosa, 2018; Xin et al., 2018).

Baselines We compare our model with five state-of-the-art monolingual methods and two our models as follows: (1) **AttNER** is an attentive neural model that utilizes a fixed attention mechanism to focus on relevant expressions in context (Shimaoka et al., 2017); (2) **NFETC** utilizes a variant of cross-entropy loss function and hierarchical loss normalization to handle *out-of-context* noise and *overly-specific* noise (Xu and Barbosa, 2018); (3) **LTR** utilises a hybrid classification method beyond binary relevance to exploit type inter-dependency with latent type representation (Lin and Ji, 2019); (4) **MLL2R** uses multi-level learning to rank approach that embraces type hierarchy during both training and prediction (Chen et al., 2020b); (5) **VAT** alleviates dataset shift problem in FET by combining the proposed masked VAT with denoising methods (Shi et al., 2020). **Our**$_{no\_adv}$ is a variant of our model **Our**, which removes language

---

[2] https://github.com/SIGKDD/CLET

discriminator $\mathcal{D}$. For each baseline, we apply the same feature extractor, given a mention m_i with its context c_i, we feed the sequence ([CLS], c_i, [SEP], m_i, [SEP]) to mBERT encoder and use the output of [CLS] token as the representation of the mention with its context.

Parameter Settings We implement our approach with PyTorch 1.2.0. In all experiments, Adam is used for optimizers, with learning rate 0.0002 for Chinese and 0.001 for European languages, and weight decay 10^{-8} for all languages. Batch size is 32 for Chinese experiment and 64 for European languages. We use the cased multilingual BERT-BASE with 12 Transformer blocks, 768 hidden units, 12 self-attention heads, GELU activations, a dropout rate of 0.1 and learned positional embeddings. WordPiece embeddings are employed to split a word into subwords, which are then directly fed into the model without any other preprocessing. Hyper-parameters are empirically selected and utilized in all experiments as follows: $\lambda = 0.2$ and $\gamma = 0.005$ for Chinese as the target language, $\lambda = 0.2$ and $\gamma = 0.01$ for Russian as the target language, $\lambda = 0.25$ and $\gamma = 0.005$ for Dutch as the target language.

4.1.2 Overall Comparison Results

We take English, German and Spanish as source languages ($N = 3$), and one of the three remaining as target language. Table 2 show that our model consistently outperforms the state-of-the-art monolingual entity typing methods on three target languages. This shows that our model has the strong ability to transfer knowledge to new languages. Our model outperforms the best baseline with 4.0% and 3.9% in Mi-F1 and Ma-F1 on *Chinese* dataset, with 6.4% and 5.2% in Mi-F1 and Ma-F1 on *Dutch* dataset, with 6.0% and 6.2% in Mi-F1 and Ma-F1 on *Russian* dataset, respectively.

4.1.3 Analysis

Compared with monolingual methods, our method has two advantages. First, it can explicitly capture the relationship between a target entity and different source languages via a mixture-of-experts approach. In testing, metric module will calculate the similarity between the target entity and each source language. If the test entity is more similar to $\mathcal{S}_i$ training examples, the trained metric function M will predict a higher α for the expert $F_{\mathcal{S}_i}$. Second, we utilize language discriminator to further improve transfer quality between different languages. We fine-tune all the parameters from mBERT as well as parameters in our model jointly. Our cross-language approach can be seen as an effective way to augment training data for entity typing using different languages of data available.

Our full model outperform its variant (which removes language discriminator $\mathcal{D}$) in all target languages consistently. This shows that language adversarial training really improve transfer quality on new language, because language adversarial training can be viewed as a kind of pre-training in target language.

4.1.4 Unseen Entities

We aim at testing whether our model is able to predict types for new entities.

Data We remove entities which appear during training (in any source language), we call this entity-level zero-shot learning. We take English, German and Spanish as source languages, and one of the three remaining as target language.

Results and Analysis Table 4 shows that the performance slightly decreased. This shows that our model has a degree of memory ability, in part because our model can extract and learn language-specific and language-invariant features for entities. These features appear in any source language training data, so in testing they help to make accurate judgements.

4.1.5 Type Size and Performance

The aim is to evaluate whether type size could effect the performance of type prediction.

Data We measure our model's performance on different types. They are grouped into two groups: Head Type Group and Tail Type Group. Head Type Group has 24 types, each has at least 300 entities; Tail Type Group has 15 types, each has at most 20 entities.

Results and Analysis Macro-averaged F1 metrics are reported in Table 3. Note that we use a different evaluation metric to calculate the F1 score for a type (Ren et al., 2016). Experiments results show that our model outperform other baselines and works for both type groups. Generally, the performance on Head Type Group is better than Tail Type Group. Our model consistently outperforms the other methods on Tail Type Group. This shows that our model can deal with rare types. As types in Head Type Group are more coarse-grained and

have more training data than types in Tail Type Group, our model performs better in predicting types in Head Type Group.

4.2 How does Language Similarity Affect Cross-lingual Type Prediction?

The idea of using rich source languages to predict entity types in low resource language may lead to following two hypotheses: (1) the richer the source is, the better predicting performance it will be; (2) the more sources, the better. Following experiments and the experiment results in Table 2 refute the two hypotheses and show that the similarity between source and target plays an important role.

4.2.1 Dataset

Languages are grouped into three level of similarity: (1) the similar level has three languages: English, German, and Dutch. All are in the west Germanic language family; (2) the less similar level consists of five languages in three language categories: Spanish in the Romance language family, Russian in the Slavic language family, and three languages from the similar level in the Germanic language family; (3) the dissimilar level consists of six languages in two language families: Chinese in the Sino-Tibetan language family, and the five European languages in the less similar level.

4.2.2 The Similar Group

Language similarity English, German, and Dutch are west Germanic languages. They are similar. Spanish is Romance language, and is less similar to English, German, and Dutch.

Experiments & results We conducted six experiments: (1) three experiments by selecting any one from {EN, DE, ES} as source; (2) three experiments select any two from {EN, DE, ES} as sources. Experiment results in Table 5 show that: (1) Comparing with using English or German as single source language, using both of them achieves the best performance. Dutch is one of the closest relatives of both German and English and is colloquially said to be "roughly in between" them. For Dutch, some linguistic features are similar with English, some features are more similar with Ger-

Table 5: Typing performance on target language with different source language combinations.

man, so take both of them into account is the best way; (2) Adding less similar language source, here, adding Spanish to English and German, decreases the performance from **0.652** (shown in Table 3) to **0.640** (shown in Table 2). This shows that we do not need to use all of the training data in different languages, sometimes it may mislead the model's judgment.

4.2.3 The Less Similar Group

Language similarity English and German are Germanic languages, Spanish is a Romance language. As a Slavic language, Russian is less similar to Spanish, and much less similar to English and German.

Experiments & results We conducted six experiments: (1) three experiments by selecting any one from {EN, DE, ES} as source; (2) three experiments by selecting any two from {EN, DE, ES} as source. Experiment results in Table 5 show that: (1) Using Spanish as the single source reaches the best performance **0.633**; (2) If Spanish appears in the source language set, the performance is better; (3) Adding less similar language source (adding EN and DE to SP) may decrease the performance. The performance **0.628** of using all three languages is shown in Table 2; (4) Adding similar language source (adding German to English, or vice versa) improves the performance.

4.2.4 The Dissimilar Group

Language similarity English, German, and Spanish as source in the European language family, and Chinese as the target in the Sino-Tibetan language family, and is significantly dissimilar from the European languages.

Experiments & results We conducted six experiments: (1) three experiments by selecting any one from {EN, DE, ES} as source; (2) three experiments by selecting any two from {EN, DE, ES} as source. Experiment results in Table 5 show adding dissimilar source consistently increases the performance. The best performance **0.636** is achieved by using all three source languages, shown in Table 2. English is relatively more important than German and Spanish, to predict Chinese entity types. Besides the fact that English has more training samples than German and Spanish, English has

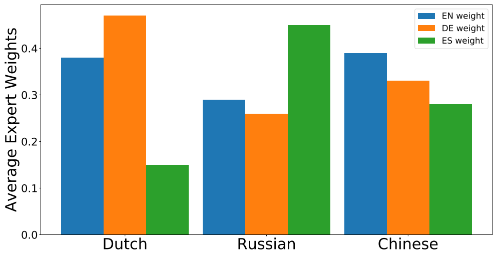

Figure 4: Average expert weights aggregated on language level.

the poorest inflection system among all of Indo-European and Ural-Altaic languages, and shares some similarity with Chinese, in the sense that the word-order plays the dominant role in conveying meanings (Bates et al., 1984; Li et al., 1993).

4.2.5 From Expert Weights to Peep How Language Similarity Affects Type Prediction

We take the setting of using three source languages, and compute the instance-level expert weights for each entity, then average across all entities in the validation set, resulting a final language-level average expert weight for each source language. Fig. 4 shows the average expert weights for each target language, and further strengthens our claim that the more similar between the source language and the target, the larger weight the source language expert will be. In particular, (1) for Dutch, German Expert has the largest weight, and English and German Experts have much larger weights than Spanish Expert; (2) for Russian, Spanish Expert has much larger weight than German and English Experts, and English Expert has lightly larger weight than German Expert; (3) for Chinese, English Expert has the largest weight that is slightly larger than German Expert that is slightly larger than Spanish.

4.2.6 Similarity Hypothesis for Cross-Lingual Entity Typing

As a summary, we propose the *Similarity Hypothesis for CLET* as follows: *The more similar the source and the target are, the better the performance will be; A large set of source languages with a high deviation of similarity performs worse than one of its subsets whose members are more similar to the target than other sources.*

5 Related Work

Fine-grained Entity Typing. FET research targets at utilising sentence-level context for making predictions (Ling and Weld, 2012) and (Gillick et al., 2014), in which they created the commonly used *FIGER* and *OntoNotes* datasets. (Shimaoka et al., 2017) proposed an attentive LSTM network model to encode an entity context, and proposed an attention mechanism to allow the model to focus on relevant expressions in a context. (Xu and Barbosa, 2018) studied two kinds of noises, namely, *out-of-context* noise and *overly-specific* noise in training data. (Wu et al., 2019) leveraged a novel cost function to jointly model the correlation among hierarchical types and label noises. (Xiong et al., 2019) presented an effective method to impose label-relational inductive bias on fine-grained entity typing models. (Onoe and Durrett, 2019) investigated the problem of denoising distant training data for entity typing tasks. (Chen et al., 2019a) regularized distantly supervised models with Compact Latent Space Clustering (CLSC) to effectively utilize noisy data. (Lin and Ji, 2019; Shi et al., 2020) employed contextualized word representations to further boosts the performance.

Cross-lingual task in NLP. To tackle the low-resourced problem, many cross-lingual transfer learning models have been proposed. Most of the research focuses on bilingual transfer case. (Xu and Yang, 2017) introduced a framework for distillation of discriminative knowledge across languages, focusing on the domain/distribution mismatch issues in cross-lingual text classification problem. (Chen et al., 2018) utilized an adversarial deep averaging network to extract language-invariant features for cross-lingual sentiment classification. (Wu et al., 2020) proposed a teacher-student learning method, where NER models in the source languages are used as teachers to train a student model on unlabeled data in the target language. Recently, some researches focus on the multi-source scenario, also known as multilingual transfer learning (MLTL). (Chen et al., 2019b) used both language-invariant and -specific features to improve the performance on the target language. (Karamanolakis et al., 2020) presented a cross-lingual text classification method, which extracts and transfers a small number of task-specific seed words, and creates a teacher that provides weak supervision to train a more powerful student in the target language.

6 Conclusions and Discussions

We address the problem of Cross-Lingual Entity Typing (CLET) in an unsupervised setting, and propose a mixture-of-experts (MoE) approach to dynamically capture the relation between the target language and each source language, which enables to acquire more knowledge from source languages. Experiments on multi-lingual datasets show that this approach outperforms various baselines and can effectively predict types of unseen entities in new languages. The presented work is the first to investigate how language similarity affects the performance of CLET, and propose the *Similarity Hypothesis*. This will be helpful for the empirical selection of source languages, and raises new questions, such as how we can quantitatively compute and compare similarities among languages.

Abstract

Abstract Meaning Representation (AMR) is a semantic representation for NLP/NLU. In this paper, we propose to use it for data augmentation in NLP. Our proposed data augmentation technique, called AMR-DA, converts a sample sentence to an AMR graph, modifies the graph according to various data augmentation policies, and then generates augmentations from graphs. Our method combines both sentence-level techniques like back translation and token-level techniques like EDA (Easy Data Augmentation). To evaluate the effectiveness of our method, we apply it to the English tasks of semantic textual similarity (STS) and text classification. For STS, our experiments show that AMR-DA boosts the performance of the state-of-the-art models on several STS benchmarks. For text classification, AMR-DA outperforms EDA and AEDA and leads to more robust improvements.[1]

1 Introduction

Data augmentation (DA) techniques automatically generate additional data from existing data set for training machine learning models. They are widely used in computer vision (see, e.g. Perez and Wang, 2017) and can boost the performance of the trained models.

In NLP, DA methods can be roughly classified into token-level ones and sentence-level ones (Chen et al., 2021). Token-level DA methods generate new sample sentences from the original ones by changing some of their tokens (words). They include the method in Zhang et al. (2015) that replaces some random tokens by their synonyms using a thesaurus, the now widely used Easy Data Augmentation (EDA) methods in Wei and Zou (2019) that allow some random token insertion, deletion and swaps, and the more recent one in Liu et al. (2020) that performs token replacement using their embeddings. One advantage of these token-level DA methods is that they are easy to implement. However, they can sometimes generate ill-formed or incoherent sentences as they do not take the sentence structures into account. In contrast, sentence-level methods generate new sample sentences by modifying the whole original sentences. They typically work by having an encoder that converts the input sentence to an intermediate representation and a decoder that generates new sentences from the intermediate representations. For example, in back translation (Sennrich et al., 2016), the intermediate representation is a sentence in another natural language. In generation methods (Kumar et al., 2020; Yang et al., 2020), the intermediate representation is a hidden state. One advantage of sentence-level DA methods is that they can preserve the semantics of the sentences. A major limitation of current sentence-level DA methods is that there is not much variation in the generated sentences as the intermediate representations used are not easily controllable (Li et al., 2021). For example, modifying the sentences in back translation requires knowledge of other languages, and minor changes of hidden states severely increase training difficulty.

In this paper, we propose a new DA method called AMR-DA that uses the Abstract Meaning Representation (AMR, Banarescu et al., 2013) as the intermediate language. AMR is a well-known semantic meaning representation. It aims to remove syntactic idiosyncrasies and to represent the semantic structure of a sentence as a rooted, directed graph. It works well as an intermediate language for data augmentation as it allows us to combine the token-level and sentence-level methods in a single framework. Like the sentence-level method, our method encodes the entire sentence as an AMR graph. Like the token-level methods, our method manipulates AMR graphs at the node

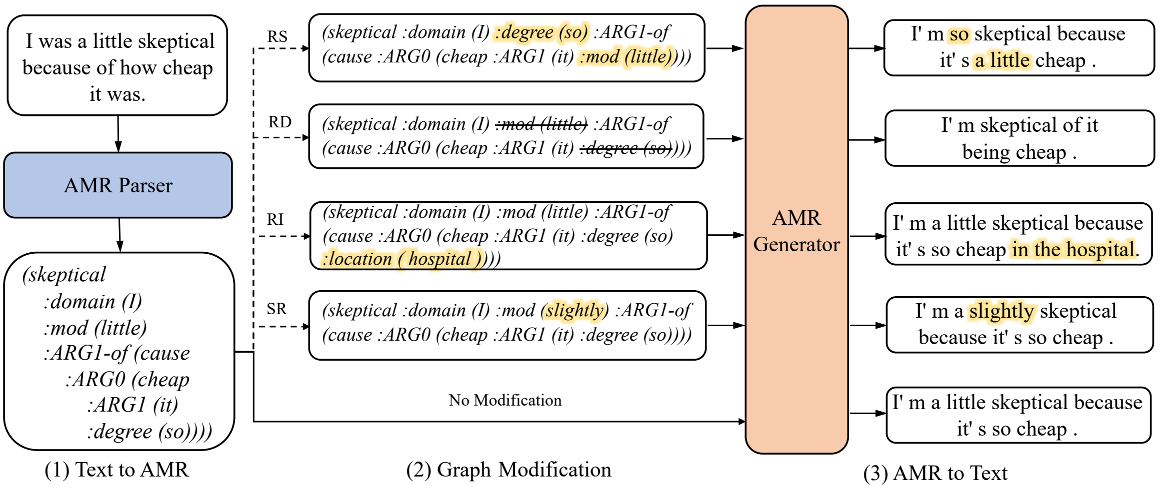

Figure 1: Overview of AMR-DA pipeline: (1) Text to AMR: the AMR parser captures the meaning of the input sentence and transduces it to an AMR graph. (2) Graph Modification: the fundamental choice is not to modify the AMR graph to preserve the entire semantics. Inspired by EDA (Wei and Zou, 2019), we apply four strategies to diversify the graph. RS: random swap; RD: random deletion; RI: random insertion; SR: synonym replacement. (3) AMR to Text: the AMR generator synthesizes sentences from AMR graphs.

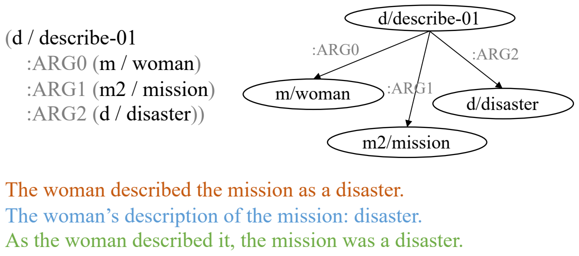
(token) level. Thus our method can augment the original sample sentence in various ways without the need to retrain the decoder. This overcomes a key weakness of the current sentence-level methods. Figure 1 shows an overview of our AMR-DA: AMR parser first transduces the sentence into an AMR graph, followed by an AMR graph extender to diversify graphs with different augmentation strategies; finally, the AMR generator synthesizes augmentations from AMR graphs.

To demonstrate the effectiveness of our method, we evaluated AMR-DA on two downstream tasks, semantic textual similarity (STS) and text classification tasks. Experimental results show that our methods boosted unsupervised contrastive learning models to achieve new state-of-the-art results on several benchmarks in STS tasks and outperformed EDA and AEDA in text classification tasks.

2 AMR-DA

2.1 Background

Abstract Meaning Representations (AMRs, Banarescu et al., 2013) are designed to abstract away from syntactic idiosyncrasies by encoding the concepts of the sentences into nodes and the relations between concepts into directed edges. They are represented as rooted, labeled graphs textually in PENMAN notation (Goodman, 2020) or graphically. Sentences with identical basic meanings are assigned to the same AMR graph. Figure 2 shows that three sentences with varied surface syntax share the same AMR. In AMR, variables are introduced for entities, events, properties, and states. For example, "d", "m" in the figure are variables. "d/describe-01" refers to an instance d of the AMR concept "describe-01". "describe" is the frame from Propbank (Kingsbury and Palmer, 2002) and "-01" is the sense of frame. AMR concepts can also be English words such as "woman". When an entity plays multiple roles in a sentence, we re-use the corresponding variable in graph notation, called reentrancy. The phrases begin with ":" are relations in AMR graphs. ":ARG0", ":ARG1", ":ARG2" are frame arguments, following PropBank conventions. AMR contains approximately 100 relations, in addition to the edges mentioned in the example, there are general semantic relations ("age", ":location"), relations for quantities (":quant") and relations for date-entities (":month", ":season"), etc.



The woman described the mission as a disaster.
The woman's description of the mission: disaster.
As the woman described it, the mission was a disaster.

Figure 2: Three sentences with varied surface syntax share the same AMR. Textual and graphical representations are equal.

2.2 AMR Parsing

AMR parser is the first component of AMR-DA (Figure 1). AMR parsing is the task of understanding the sentence and then transducing it to AMR graphs. Lack of explicit alignments between AMR nodes and tokens brings obstacles to AMR parsing. Previous AMR parsers always include complex and fine-grained pre- and post-processing processes. It is very brittle to extend and apply in other tasks. With the help of pretrained language models, sequence-to-sequence (seq2seq) methods win a continual growth of interests. This paper adopts SPRING[2] (Bevilacqua et al., 2021), which achieves state-of-the-art performance on AMR parsing, as our AMR parser. SPRING also implemented the generator in their work, however, we adopt another generator with better performance alternatively introduced in section 2.4.

SPRING first linearized AMR graphs to sequences through DFS-based PENMAN annotation. Nevertheless, when using seq2seq models, a lack of a clear distinction between variables and concepts may cause confusion. Considering that AMR variables have no semantics, SPRING proposed to use special tokens `<R0>, <R1>, ..., <R`n`>` to represent variables in the linearization graph and to handle co-referring nodes. They also abandoned the redundant slash token "/". Under this setting, AMR graph in Figure 2 became: `(<R0>` describe-01 :ARG0 (`<R1>` woman) :ARG1 (`<R2>` mission) :ARG2 (`<R3>` disaster)). Adjacency information was still preserved in the linearization process.

After linearizing AMR graphs, SPRING extended a pretrained model, BART (Lewis et al., 2020) which is a transformer-based encoder-decoder model. In order to make BART vocabularies suitable for AMR, they added relations and frames frequently occurring in the training data and initialized the vectors as the average of words embeddings. The results from the seq2seq model need only slight post-processing to transfer sequences to standard PENMAN notations. Details can be found in SPRING paper (Bevilacqua et al., 2021). AMR-DA adopts the model which achieves state-of-the-art performance on AMR 2.0 as AMR parser.

2.3 AMR Graph Modification

Discreteness in languages is the obstacle to transferring data augmentation methods from vision to NLP. Token-level methods attempt to apply modifications on tokens but ignore the entire structure of sentences. However, modifications in sentence-level methods always increase the difficulty of training. The benefit of AMR-DA is that intermediate AMR graphs can be modified through low-cost operations to obtain diverse augmentations; meanwhile, AMR generator will adjust the entire structure of sentences. We shift operations in EDA to AMR graphs. Following EDA, we introduce α to control the percentage of data that operations in AMR-DA will modify.

Keep Original (Ori) The fundamental choice is to preserve the entire intermediate AMR graph. In this way, AMR-DA will generate paraphrased text for the input sentence.

Random Swap (RS) Traditionally, RS operation randomly chooses words and swaps their positions. However, randomly swapping concepts may impact the performance of AMR generator. In Figure 1, if we want to swap positions of "I" and "so" in the original AMR graph, the final graph becomes ":domain (so)" and ":degree (I)" which are not expected to appear in a regular AMR graph. Therefore, we swap concepts and their immediately adjacent edges at the same time. More specifically, we swap edge-node pairs ":degree (so)" and ":domain (I)" instead of tokens. There are two types of effect: if swapping nodes are not siblings, RS operation would change the graph structure, while sibling nodes swapping changes the linearization sequence instead of the graph structure. For one augmentation, RS repeats n times the operation of randomly selecting two edge-node pairs and swapping their positions where $n = max(1, \alpha \times |\text{edge-node pairs}|)$. $|\text{edge-node pairs}|$ means the number of edge-node pairs.

Random Deletion (RD) Instead of removing concepts, we randomly delete concepts with their adjacent edges to guarantee that the rest of graph has necessary components. To control the effects on the AMR graph, RD only applies to leaf nodes. Non-leaf nodes with descendants will possibly have a severe impact on original AMR graphs. For one augmentation, RD repeats random leaf deletion n times where $n = max(1, \alpha \times |\text{edges-node pairs}|)$.

Random Insertion (RI) RI inserts edge-node pairs instead of concepts to preserve the rationality of AMR graph. We collect edge-node pairs (leaves) from AMR 2.0 training data and filter un-

---

[2] https://github.com/SapienzaNLP/spring

suitable pairs based on their edges. For example, ":polarity -" which converts the polarity of semantics, is discarded in RI operation. More examples are listed in Appendix A. For one augmentation, RI randomly inserts n pairs where $n = max(1, \alpha \times |\text{edge-node pairs}|)$.

Synonym Replacement (SR) SR only cares about concepts for that AMR edges are well-designed in AMR. In the linearized graph, we filter tokens that begin with ":" and parentheses, randomly select other tokens, and replace them with one of their synonyms correspondingly. SR randomly replace n concepts where $n = max(1, \alpha \times |\text{concepts}|)$. We substitute similar words according to PPDB synonym (Pavlick et al., 2015). The substitution function is included in nlpaug[3].

2.4 AMR Generation

AMR generation generates sentences from the AMR graph, which is the inverse task of AMR parsing. Pretrained transformer-based architectures gradually dominate the development trend of generators (Mager et al., 2020; Bevilacqua et al., 2021). Ribeiro et al.[4] proposed a generator based on pretrained language models (PLMs-generator) and added extra task-adaptive pretraining. Compared with SPRING, PLMs-generator simplifies PENMAN annotations without adding special tokens as pointers. They examined and compared two PLMs, BART and T5 (Raffel et al., 2019). PLMs-generator continued task-specific pretraining using language model adaptation (LMA) or supervised task adaptation (STA) training with silver data they collected. Details can be found in the paper (Ribeiro et al., 2021). The default AMR generator in our experiments is based on T5-base.

3 Experiments

We conduct experiments on two NLP tasks, semantic textual similarity tasks and text classification tasks, to evaluate our augmentation method.

3.1 Semantic Textual Similarity Tasks

Semantic textual similarity deals with determining how similar two pieces of sentences are. Recently, contrastive learning has become an influential formalism for unsupervised sentence representation, based on the idea of concentrating similar samples and pushing apart dissimilar samples in the vector space (Chen et al., 2020). That is, given a set of paired sentences $\mathcal{D} = \left\{(x_i, x_i^+)\right\}_{i=1}^{m}$ where x_i and x_i^+ are semantically related, we regard x_i^+ as "positive" of x_i and other sentences in the same mini-batch as "negatives". Let $\mathbf{h}_i$ and $\mathbf{h}_i^+$ denote the representations of x_i and x_i^+, then the training objective for a mini-batch of size N is:

$$\ell_i = -\log \frac{\exp^{sim(\mathbf{h}_i, \mathbf{h}_i^+)} / \tau}{\sum_{j=1}^{N} \exp^{sim(\mathbf{h}_i, \mathbf{h}_j^+)} / \tau}$$

where τ is a temperature hyperparameter and $sim(\mathbf{h}_1, \mathbf{h}_2)$ is the cosine similarity function.

Data augmentation, as the central issue in unsupervised contrastive learning, is utilized to construct "positive pairs". SimCSE (Gao et al., 2021) puts one sentence through pretrained model twice with varied standard dropout masks inside transformers as a minimal form of data augmentation. Although it performs quite well, there still exists a large margin between unsupervised and supervised models. Here we propose a hypothesis that an effective data augmentation in this task requires distinct syntax but related semantics. For this reason, we use AMR-DA as data augmentation to construct positive instances.

3.1.1 Experimental Settings

To verify the effectiveness of AMR-DA, we choose recently proposed models unsup-ConSERT (Yan et al., 2021) and unsup-SimCSE (Gao et al., 2021), which are referred as ConSERT and SimCSE for simplification, as our baseline models. We only replace the original data augmentation methods inside the two models with AMR-DA.

We evaluate on seven STS datasets including STS 2012–2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), STS Benchmark (Cer et al., 2017) and SICK-Relatedness (Marelli et al., 2014) and report Spearman's correlation.

Following ConSERT, we use a mixture of unlabeled texts from seven STS datasets as training data and average the token embeddings at the last two layers as the sentence embedding. Following SimCSE, we use 1-million sentences randomly sampled from English Wikipedia as training data and adopt the [CLS] representation with an MLP layer on top of it as the sentence embedding. More training details could be found in Appendix B.

3.1.2 Main Results

The first question is which operation we should choose for contrastive learning in the STS task. Table 1 shows the comparison on different augmentation strategies. ConSERT considered cutoff and shuffle token augmentations while we replaced their DA with AMR-DA. The results show that all operations in AMR-DA outperform ConSERT with token augmentations. Since we use AMR-DA to construct positive pairs for STS model training, Table 1 presents that AMR-Ori generates augmentations more similar to the original sentences than other operations. To access the diversity of augmented data, we adopt F1 measured between two bags of words as lexical overlap score. A higher lexical overlap F1 indicates more overlap between augmented data and original sentences and less diversity. Table 2 provides the summary statistics for various operations of AMR-DA.

AMR Operation	Ori	RS	RD	RI	SR

Table 3: The average sentence embedding performance on seven STS test sets, in terms of Spearman's correlation. †: results from Yan et al., 2021. ‡: results from Gao et al., 2021; ; §: results from Wu et al., 2021. Models begin with "AMR" are the models with AMR-DA.

Table 3 shows the main results, where the highest numbers among models with the same pretrained encoder are highlighted in bold. Only changing the data augmentation module in ConSERT and SimCSE to AMR-DA, the performance could be boosted substantially to the state-of-the-art. AMR-ConSERT obtains absolute improvements of 3.40 and 1.74 on BERT$_{base}$ and BERT$_{large}$ respectively compared with the original ConSERT that utilizes feature cutoff and shuffle on tokens as DA methods. While AMR-SimCSE outperforms SimCSE significantly on BERT$_{base}$ (1.70 ↑), BERT$_{large}$ (1.22 ↑), RoBERTa$_{base}$ (1.86 ↑) and RoBERTa$_{large}$ (0.80 ↑). We also make a comparison between our models and current state-of-the-art model ESimCSE (Wu et al., 2021), which uses word repetition to construct positive pairs and momentum contrast to expand negative pairs. Experimental results indicate that AMR-SimCSE surpasses ESimCSE on BERT$_{large}$ (0.33 ↑), RoBERTa$_{base}$ (0.99 ↑) and RoBERTa$_{large}$ (0.25 ↑). If we discard momentum contrast in ESimCSE and only compare the effectiveness of DA methods, AMR-SimCSE (77.95) outperforms ESimCSE (77.43) on BERT$_{base}$.

In addition, we implemented SimCSE with back translation based on WMT'19 English-German translation models (Ng et al., 2019) as the DA method. We use random sampling for decoding as recommended by (Edunov et al., 2018a), and set the temperature to 0.8. Other training settings are the same as those of SimCSE. As shown in Table 3, back translation is inferior to AMR-DA in STS tasks. The possible reason is that augmentations with limited diversity are hard to improve pretrained models.

3.2 Text Classification Tasks

Text classification tasks are widely studied in many real applications, such as document categorization, email spam filtering, etc. The performance of machine learning methods in this task always depends on the quality of training data. How to use DA techniques to improve machine learning systems attracts a number of studies (Wang and Yang, 2015; Wei and Zou, 2019; Liu et al., 2020; Karimi et al., 2021). AMR-DA is partly inspired by EDA, which explores text editing techniques for data augmentation. EDA performs SR, RI, RS, or RD operations on tokens, whereas AMR-DA performs these DA strategies on AMR graphs. In order to answer whether DA strategies on AMR graphs perform better than on tokens, we conduct a fair assessment on EDA and AMR-DA. In addition, to show the effectiveness of AMR-DA, we take AEDA (Karimi et al., 2021), another strong DA, into comparison.

3.2.1 Experimental Settings

We conduct experiments on four benchmark datasets: Standford Sentiment Treebank (SST-2, Socher et al., 2013); Customer Reviews Dataset (CR, Hu and Liu, 2004; Liu et al., 2015b), Subjectivity/Objectivity Dataset (SUBJ, Pang and Lee, 2004); Pros and Cons Dataset (PC, Ganapathibhotla and Liu, 2008). The detailed statistics are listed in Table F.5.

We chose Recurrent Neural Network (RNN, Liu et al., 2016), Convolutional Neural Network (CNN, Kim, 2014) and BERT (Devlin et al., 2019) as backbone models.

Data selection module has been modified to be close to application scenarios in real life. We select proportions of original training data and then add the corresponding augmentations for that only visible data can be extended. Experimental setups are identical to all DA methods. All experiments are run with five different random seeds and reported as average performance. Training details are in Appendix C.

3.2.2 Main Results

We ran CNN, RNN and BERT across all four datasets using three DA methods. First, we added one augmented sentence for each instance to assess the effectiveness of single augmentation. We reported the average performance of all different operations in EDA and AMR-DA as final one augmentation performance. As the top part of Table 4 shows, the average improvement of AMR-DA on three models is 0.55%, which is 0.91% better than EDA and 0.14% better than AEDA, respectively. How about using all operations to augment data in the training process? To answer this question, we added each operation augmentations together in AMR-DA and trained models with all five augmentations. Correspondingly, we randomly selected five augmentations using AEDA and EDA operations. We reported the average performance in the bottom part of Table 4. AMR-DA achieved 0.83% performance gain with five augmentations better than one augmentation, which means our operations brought diversified information to improve models. Regarding the effectiveness of operations (SR, RI, RS and RD), we made a detailed comparison on EDA and AMR-DA. Figure 3 shows that AMR-DA outperforms EDA remarkably on various fractions of the training set.

Model	CNN	RNN	BERT	Avg.
Original	88.15	86.49	93.19	89.28

4 Analysis

Effect of AMR Generators From the introduction in Section 2.1, paraphrased sentences correspond to the identical AMR graph. In other words, AMR graph to sentences is a one-to-many relationship. Since there is no uniform evaluation of AMR generators, it is necessary to study the impact of AMR generators on the performance of AMR-DA. We compared AMR-Ori with various generators based on BART$_{base}$, T5$_{small}$ and T5$_{base}$. Table 5 shows comparison on PLMs-generators. We found that pretrained models with larger sizes are capable of generating better quality augments. So we choose AMR generator with T5$_{base}$ as final generator in AMR-DA.

Model	Avg.
BERT$_{base}$-flow‡	66.55
SimCSE-BERT$_{base}$‡	76.25
AMR(BART$_{base}$ generator)-SimCSE	77.81
AMR(T5$_{small}$ generator)-SimCSE	77.65
AMR(T5$_{base}$ generator)-SimCSE	**77.95**

Table 5: Performance of AMR-DA (Ori) in STS tasks with various generators.‡: results from Gao et al., 2021 ;§: results from Wu et al., 2021.

Why does AMR-DA work in STS task? To answer this question, we use alignment and uniformity, which are proposed by (Wang and Isola, 2020) to measure the quality of representations. Alignment calculates how close the positive instances stay, while uniformity evaluates how uniformly the random instances are scattered on the hypersphere. For both metrics, *lower numbers are better*. We take the checkpoint of SimCSE and AMR-SimCSE every 10 steps during training (100 steps in total) and visualize the alignment and uniformity computed on STSB dataset. Figure 4 demonstrates that both SimCSE and AMR-SimCSE improve the uniformity steadily. Additionally, AMR-SimCSE provides a continuously decreasing alignment. It verifies our hypothesis that data augmentation with different syntax but highly related semantics results in better sentence embeddings.

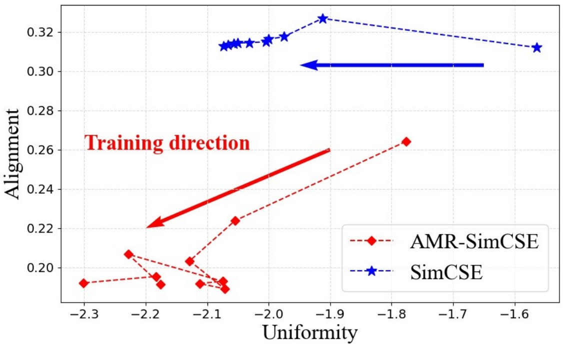

Figure 4: Alignment-uniformity plot on STSB dataset.

Analysis of Generated Outputs To analyze generated outputs by back-translation and AMR-Ori, we use supervised SimCSE-RoBERTa$_{large}$, which achieves the state-of-the-art performance on various semantic textual similarity benchmarks, to compute the sentence embedding cosine similarity between the generated sentences and the original ones. Figure 5 summarizes the results. First we can see that for both AMR-Ori and back-translation, their generated sentences have high similarity scores with the original sentences. However, AMR-Ori generates much more diversified outputs. For back-translation, more than 30% of the generated sentences have the similarity score of 1.0 (highest) with their original sentences, and more than 50% of them have the similarity score of 0.99 or above. While AMR-Ori is more uniform. The highest frequency rate, about 10%, is at the similarity score of 0.97.

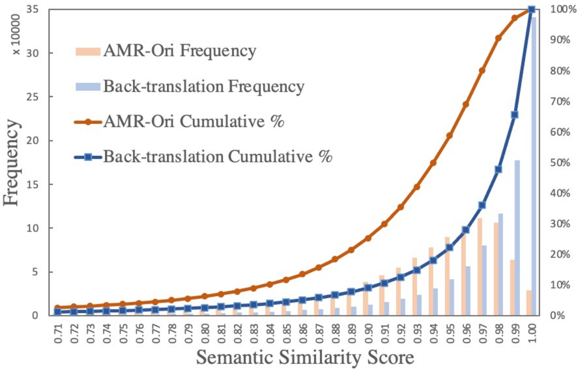

Figure 5: Semantic similarity scores of back-translation and AMR-Ori augmentations (data from Table 3).

We also computed the F1 scores measured between two bags of words. We find that the overlap score of back-translation method is 0.760, compared to 0.566 for AMR-Ori (evaluated using unsupervised SimCSE experiment data in Table 3).

For illutration, we list some examples of back-translation and AMR-Ori in Table 6 and more in Table D.3 in the appendix. One could see that back-translation paraphrases source sentences with little

modification. On the other hand, AMR-Ori can produce quite different sentences even though it does not modify the intermediate representations. A key factor is that AMR graphs abstract away from syntactic idiosyncrasies while retain semantic frame arguments.

Finally, Table D.4 in the appendix lists some example outputs from EDA and AMR-DA. The original sentence is the same as EDA-None. Except for between EDA-None and AMR-Ori, AMR-DA generated outputs are more fluent than their corresponding outputs by EDA.

5 Related Work

Our proposed data augmentation method is based on manipulating AMR graphs. Similar tree-edit techniques on syntax trees have been found to be useful in paraphrases generation (Heilman and Smith, 2010; Vila and Dras, 2012). Other applications of AMR have also been based on graph manipulation. For example, Liu et al. (2015a) used AMR in summarization task by first parsing the source text to a set of graphs, transforming it to a summary graph, and then generating a summary using the summary graph. Sachan and Xing (2016) represented text and questions as AMR graphs and reduced the machine comprehension problem to a graph containment problem. We have seen a growing body of work that makes use of AMR in other applications such as dialogue modeling, information extraction and commonsense reasoning (Bai et al., 2021; Zhang et al., 2021; Lim et al., 2020).

Based on the influence scope of augmentation, related data augmentation methods can be roughly classified into token-level and sentence-level methods (Chen et al., 2021).

In token-level, synonyms replacement, random swap, random insertion, random deletion (Zhang et al., 2015; Wei and Zou, 2019) have been proven to improve the performance in classification tasks. In STS task, plenty of data augmentation techniques have been utilized such as shuffling, cutoff (Yan et al., 2021), synonyms replace (Wang et al., 2021), word repetition (Wu et al., 2021), etc. However, these methods all risk impairing structure information, resulting in incoherent augmentations.

In contrast, sentence-level take the whole sentence into consideration. Widely used back translation (Sennrich et al., 2016; Edunov et al., 2018b; Qu et al., 2021) translates sentences into intermediate languages and then translates back. Some studies attempt to incorporate syntactic information (Chen et al., 2019) or latent variables (Gupta et al., 2018) to guide generators synthesize various augmentations. But these methods significantly increase the training difficulty. AMR-DA uses AMR as an intermediate language, which can modify graphs as easily as in token-level methods, and synthesizes high-quality and diversified augmentations without grinding in training.

6 Conclusion and Future Work

We propose a novel data augmentation method called AMR-DA. AMR-DA transduces sentences to AMR graphs, applies multiple strategies to modify graphs, and then generates diversified augmentations. To the best of our knowledge, this paper is the first work that utilizes AMR for data augmentation. AMR-DA overcomes the deficiency of previous sentence-level generation methods and diversifies augmentations without retraining decoders. Our experiments show that AMR-DA boosts the performance of models to achieve state-of-the-art results in several STS benchmarks and outperforms

EDA and AEDA in text classification tasks. In this paper, we mainly use AMR-DA to generate positive augmentations. Further research could use AMR-DA to carefully construct adversarial samples for specific tasks and.

A Discarding pairs in RI operation

We filter pairs based on edge properties. The discarding edges are listed in the following table.

Edge	Reasons
:ARGn	potential ambiguity of arguments
:polarity	convert the polarity of semantics
:wiki	Unsuitable for most graphs
:op$n$	Unsuitable for most graphs
:snt$n$	Unsuitable for most graphs
:value	Unsuitable for most graphs

B STS tasks Training Details

For AMR-SimCSE, grid-search of batch size $\in \{64, 96, 128, 160\}$ and learning rate $\in$ {5e-6, 1e-5, 3e-5, 5e-5} is carried out on STS-B development set, and the hyperparameter settings are listed in Table B.1. The dropout rate is set to 0.1 for base models and 0.15 for large models. We use the temperature $\tau = 0.05$ for all the experiments. During training, we found that a larger maximum sequence length equal to 96 benefits our AMR-SimCSE, while in SimCSE the value is 32. So we also enlarge the maximum sequence length to 96 in SimCSE but do not observe any improvement.

	BERT		RoBERTa	
	base	large	base	large
Batch size	96	128	160	96
Learning rate	3e-5	3e-5	5e-5	5e-6

Table B.1: Hyperparameters for AMR-SimCSE.

For AMR-ConSERT, we use hyperparameter settings that are the same as the original paper.

C Text Classification Training Details

For CNN models, we followed the architecture in EDA and modified filters. The entire architecture of our CNN: input layer; the concatenation of 1D convolutional layer of 128 filters of size 3, 4 and 5 with global 1D max pool layer for each convolutional layer; dropout layer with $\rho = 0.2$; dense layer of 20 hidden units with ReLU activation function, softmax output layer. Other CNN settings and RNN settings are identical to EDA. As for BERT experiments, we adopt base, uncased version BERT as backbone and the Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 2e-5. We pick the best checkpoint according to the validation loss. Random seeds are from 0 to 4. The default alpha setting for 4 operations are listed in the following table:

	RS	RD	RI	SR
α	0.05	0.1	0.05	0.1

Table C.2: Setting of α for four different operations.

D Comparison on Data Augmentation Outputs

More examples on generated outputs from back-translation and AMR-Ori are presented in Table D.3. Augmented examples using EDA and AMR-DA are presented in Table D.4.

E Effect of alpha in Augmentation Operations

We test each of operations individually for different training set sizes to determine their ability with α=0.05, 0.1, 0.2, 0.3, 0.4, 0.5. For each value, we randomly synthesized two augmentations and ran CNN models in this experiment. In Figure 6, all operations in AMR-DA contribute to performance gain. On average, operations achieve more significant gains in smaller datasets.

F Detailed Experimental Results

Table F.6 and F.7 are detailed versions of Table 3. Table F.8 is the detailed version of Table 5. Table F.9 is the detailed version of Table 1. Table F.10 is the detailed version of Table 4.

Abstract

In this work, we present an extensive study on the use of pre-trained language models for the task of automatic Counter Narrative (CN) generation to fight online hate speech in English. We first present a comparative study to determine whether there is a particular Language Model (or class of LMs) and a particular decoding mechanism that are the most appropriate to generate CNs. Findings show that autoregressive models combined with stochastic decodings are the most promising. We then investigate how an LM performs in generating a CN with regard to an unseen target of hate. We find out that a key element for successful 'out of target' experiments is not an overall similarity with the training data but the presence of a specific subset of training data, i. e. a target that shares some commonalities with the test target that can be defined *a-priori*. We finally introduce the idea of a pipeline based on the addition of an automatic post-editing step to refine generated CNs.

1 Introduction

Hate Speech (HS) has found fertile ground in Social Media Platforms. Actions undertaken by such platforms to tackle online hatred consist in identifying possible sources of hate and removing them by means of content deletion, account suspension or shadow-banning. However, these actions are often interpreted and denounced as censorship by the affected users and political groups (Myers West, 2018). For this reason, such restrictions can have the opposite effect of exacerbating the hostility of the haters (Munger, 2017). An alternative strategy, that is looming on the horizon, is based on the use of Counter Narratives. CNs are "all communicative actions aimed at refuting hate speech through thoughtful and cogent reasons, and true and fact-bound arguments" (Schieb and Preuss, 2016). As a de-escalating measure, CNs have been proven to be successful in diminishing hate, while preserving the freedom of speech (Benesch, 2014; Gagliardone et al., 2015). An example of $<HS, CN>$ pair is shown below:

HS: Women are basically childlike, they remain this way most of their lives. Soft and emotional. It has devastated our once great patriarchal civilizations.
CN: *Without softness and emotions there would be just brutality and cruelty. Not all women are soft and emotional and many men have these characteristics. To perpetuate these socially constructed gender profiles maintains norms which oppress anybody.*

Based on their effectiveness, CNs have started being employed by NGOs to counter online hate. Since for NGO operators it is impossible to manually write responses to all instances of hate, a line of NLP research has recently emerged, focusing on designing systems to automatically generate CN suggestions (Qian et al., 2019; Tekiroğlu et al., 2020; Fanton et al., 2021; Chung et al., 2021a; Zhu and Bhat, 2021). In this study, our main goal is to compare pre-trained language models (LM) and decoding mechanisms in order to understand their pros and cons in generating CNs. Thus, we use various automatic metrics and manual evaluations with expert judgments to assess several LMs, representing the main categories of the model architectures, and decoding methods. We further test the robustness of the fine-tuned LMs in generating CNs for an unseen target. Results show that autoregressive models are in general more suited for the task, and while stochastic decoding mechanisms can generate more novel, diverse, and informative outputs, the deterministic decoding is useful in scenarios where more generic and less novel (yet 'safer') CNs are needed. Furthermore, in out-of-target experiments we find that the similarity of targets (e.g.

`JEWS` and `MUSLIMS` as religious groups) plays a crucial role for the effectiveness of portability to new targets. We finally show a promising research direction of leveraging gold human edits for building an additional automatic post-editing step to correct errors made by LMs during generation. To the best of our knowledge, this is the first study systematically analysing state of the art pre-trained LMs in CN generation.

2 Related Work

In this section we first discuss standard approaches to hate countering and studies on CN effectiveness on Social Media Platforms, then the existing CN data collection and generation strategies.

Hate countering. NLP has started addressing the phenomenon of the proliferation of HS by creating datasets for automatic detection (Mathew et al., 2021; Cao et al., 2020; Kumar et al., 2018; Hosseinmardi et al., 2015; Waseem, 2016; Burnap and Williams, 2016). Several surveys provide a review on the existing approaches on the topic (Poletto et al., 2020; Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018), also addressing the ethical challenges of the task (Kiritchenko et al., 2021). Still, automatic detection of HS presents some drawbacks (Vidgen and Derczynski, 2020). First of all, the datasets might include biases, and the models tend to replicate such biases (Binns et al., 2017; Davidson et al., 2019; Sap et al., 2019; Tsvetkov, 2020). Moreover, the end goals for which HS detection is employed are often charged with censorship of the freedom of speech by concerned users (Munger, 2017; Myers West, 2018). In this scenario, NGOs have started employing CNs to counter online hate. CNs have been shown to be effective in reducing linguistic violence (Benesch, 2014; Gagliardone et al., 2015; Schieb and Preuss, 2016; Silverman et al., 2016; Mathew et al., 2019); moreover, even if they might not influence the view of extremists, they are still effective in presenting alternative and non-hateful viewpoints to bystanders (Allison and Bussey, 2016; Anderson et al., 2014).

CN data collection. The existing studies for collecting CN datasets employ four main approaches. *Crawling* consists in automatically scraping websites, starting from an HS content and searching for possible CNs among the responses (Mathew et al., 2018, 2019). With *crowdsourcing* CNs are written by non-expert paid workers as responses to provided hate content (Qian et al., 2019). *Nichesourcing* relies on a niche group of experts for data collection (De Boer et al., 2012), and it was employed by Chung et al. (2019) for CN collection using NGO's operators. *Hybrid approaches* use a combination of LMs and humans to collect data (Wallace et al., 2019; Dinan et al., 2019; Vidgen et al., 2020). Studies on CN collection are presented in more detail by Tekiroğlu et al. (2020); Fanton et al. (2021).

CN generation. Neural approaches to automatically generate CNs are beginning to be investigated. Fanton et al. (2021); Tekiroğlu et al. (2020); Qian et al. (2019) employ a mix of automatic and human intervention to generate CNs. Zhu and Bhat (2021) propose an entirely automated pipeline of candidate CN generation and filtering. Other lines of work include CN generation for under-resourced languages such as for Italian (Chung et al., 2020), and the generation of knowledge-bound CNs, which allows the production of CNs based on grounded and up-to-date facts and plausible arguments, avoiding the hallucination phenomena (Chung et al., 2021a). Instead, in our work we take a more foundational perspective, which is relevant for all the LM-based pipelines described above. Therefore, we compare and assess various state of the art pre-trained LMs in an end-to-end setting, which is developed as a downstream task for CN generation.

3 Methodology

In this section, we present the CN dataset, the language models, and the decoding mechanisms employed for our experiments.

3.1 Dataset for fine-tuning

For this study we rely on the dataset proposed by Fanton et al. (2021), which is the only available dataset that grants both the target diversity and the CN quality we aim for. The dataset was collected with a human-in-the-loop approach, by employing an autoregressive LM (GPT-2) paired with three expert human reviewers. It features 5003 $<HS, CN>$ pairs, covering several targets of hate including `DISABLED`, `JEWS`, `LGBT+`, `MIGRANTS`, `MUSLIMS`, `POC`, `WOMEN`. The residual categories are collapsed to the label `OTHER`. We partitioned the dataset into training, validation, and test sets with the ratio: $8 : 1 : 1$ (i. e. 4003, 500 and 500 pairs), ensuring that all sets share the same target distribution, and no repetition of HS across the sets is allowed.

3.2 Models

We experiment with 5 Transformer based LMs (Vaswani et al., 2017) representing the main categories of the model mechanisms: autoregressive, autoencoder, and seq2seq.

BERT. The Bidirectional Encoder Representations from Transformers was introduced by Devlin et al. (2019). It is a bidirectional autoencoder that can be adapted to text generation (Wang and Cho, 2019).

GPT-2. The Generative Pre-trained Transformer 2 is an autoregressive model built for text generation (Radford et al., 2019).

DialoGPT. The Dialogue Generative Pretrained Transformer is the extension of GPT-2 specifically created for conversational response generation (Zhang et al., 2020).

BART. BART is a denoising autoencoder for pretraining seq2seq models (Lewis et al., 2020). The encoder-decoder architecture of BART is composed of a bidirectional encoder and an autoregressive decoder.

T5. The Text-to-Text Transfer Transformer proposed by Raffel et al. (2020) is a seq2seq model with an encoder-decoder Transformer architecture.

While all the other models could be fine-tuned directly for the generation task, for BERT we warm-started an encoder-decoder model using BERT checkpoints similar to the BERT2BERT model defined by (Rothe et al., 2020). The fine-tuning details and hyperparameter settings can be found in Appendix A.1.

3.3 Decoding mechanisms

We utilize 4 decoding mechanisms: a deterministic (Beam Search) and three stochastic (Top-k, Top-p, and a combination of the two).

Beam Search (BS). The Beam Search algorithm is designed to pick the most-likely sequence (Li et al., 2016; Wiseman et al., 2017).

Top-k (Top$_k$). The sampling procedure proposed by Fan et al. (2018) selects a random word from the k most probable ones, at each time step.

Top-p (Top$_p$). Also known as Nucleus Sampling, the parameter p indicates the total probability for the pooled candidates, at each time step (Holtzman et al., 2020).

Combining Top-p and Top-k (Top$_{pk}$). At decoding stage, it is possible to combine the parameters p and k. This is a Nucleus Sampling constrained to the Top-k most probable words.

In our experiments we used the following parameters as default: Beam-Search with 5 beams and repetition penalty = 2; Top-k with $k = 40$; Top-p with $p = .92$; Top$_{pk}$ with $k = 40$ and $p = .92$.

4 Evaluation metrics

We use several metrics to evaluate various aspects of the CN generation.

Overlap Metrics. These metrics depend on the n-gram similarity of the generated outputs to a set of reference texts in order to assess the quality. We used our gold CNs as *references* and the CNs generated by the different models, as *candidates*. In particular, we employed three BLEU variants: BLEU-1 (B-1), BLEU-3 (B-3) and BLEU-4 (B-4) (Papineni et al., 2002), and ROUGE-L (ROU) (Lin, 2004).

Diversity metrics. They are used to measure how diverse and novel the produced CNs are. In particular, we utilized *Repetition Rate* (RR) to measure the repetitiveness across generated CNs, in terms of the average ratios of non-singleton n-grams present in the corpus (Bertoldi et al., 2013). It should be noted that RR is calculated as a corpus-based repetition score , i.e. inter-CN, instead of calculating intra-CN repetition of n-grams only. We also used *Novelty* (NOV) (Wang and Wan, 2018), based on Jaccard similarity, to compute the amount of novel content that is present in the generated CNs as compared to the training data.

Human evaluation metrics. Albeit more difficult to attain, human judgments provide a more reliable evaluation and a deeper understanding than automatic metrics (Belz and Reiter, 2006; Novikova et al., 2017). To this end, we specified the following dimensions for the evaluation of CNs. *Suitableness* (SUI): measures how suitable a CN is to the HS in terms of semantic relatedness and in terms of adherence to CN guidelines[1]; *Grammaticality* (GRM): how grammatically correct a generated CN is; *Specificity* (SPE): how specific are the arguments brought by the CN in response to the HS; *Choose-or-not* (CHO): determines whether the annotators would select that CN to post-edit and use it in a real case scenario as in the set up presented by Chung et al. (2021b); *Is-best* (BEST): whether the CN is the absolute best among the ones generated

---

[1] See for example `https://getthetrollsout.org/stoppinghate`

for an HS (i. e. whether the annotators would pick up exactly that CN if they had to use it in a real case scenario).

The first three dimensions are rated with a 5-points Likert scale and follow the evaluation procedure described by Chung et al. (2020), whereas both choose-or-not and is-best are binary ratings (0, 1). Choose-or-not allows for multiple CNs to be selected for the same HS, while only one CN can be selected for is-best for each HS.

Toxicity.[2] It determines how "rude, disrespectful, or unreasonable" a text is. Toxicity has been employed both to detect the bias present in LMs (Gehman et al., 2020) and as a solution to mitigate such bias (Gehman et al., 2020; Xu et al., 2020).

Syntactic metrics. A high syntactic complexity can be used as a proxy for an LM's ability of generating complex arguments. We used the syntactic dependency parser of spaCy[3] For the task, focusing on the following measures: *Maximum Syntactic Depth* (MSD): the maximum depth among the dependency trees calculated over each sentence composing a CN. *Average Syntactic Depth* (ASD): the average depth of the sentences in each CN. *Number of Sentences* (NST): the number of sentences composing a CN.

5 Experiments

We performed two sets of experiments: first, we assessed how LMs perform in the task of generating CNs with different decoding mechanisms. Then, we selected the best model from the first round of experiments and tested its generalization capabilities when confronted with an unseen target of hate.

5.1 LMs and decoding experiments

For the first round of experiments, in order to avoid possible unfair assessments given by the open nature of the generative task (i. e. a highly suitable CN candidate could be scored low due to its difference from the single reference/gold CN), at test time we allowed the generation of several candidates for each HS+LM+decoding mechanism combination. We loosely drew inspiration from the Rank-N Accuracy procedure and the 'generate, prune, select' procedure (Zhu and Bhat, 2021). In particular, given an LM and a decoding mechanism, we generated 5 CNs for each HS in the test set.

Automated evaluation and selection We set up the automatic evaluation strategy as displayed in Figure 1. First, we scored each CN with the overlap metrics presented in Section 4, using the gold CN as a reference. Next, we ranked the candidate CNs with respect to the overlap scores and computed the mean of the rankings. Then, we selected the *best* ones according to the following criteria:

Best$_{\mathbf{LM}}$ selects the single best CN for an HS among the 20 generated by the 4 models.

Best$_{\mathbf{D}}$ selects the single best CN for an HS among the 25 generated by the 5 decoding configurations.

Best$_{\mathbf{LM+D}}$ selects the single best CN among the 5 generated with each model-decoding combination.

Moreover, we assessed the overall corpus-wise quality of the generated CNs with respect to the models, to the decoding mechanisms, and to the model-decoding combinations via the diversity metrics.

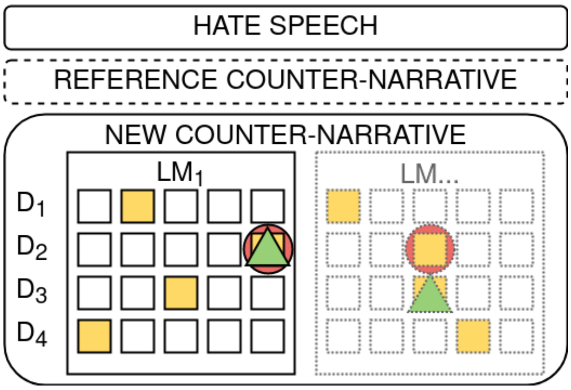

Figure 1: Given an HS, 5 CNs are generated for each model-decoding combination. ● indicates the best CN per model (∈ Best$_{\mathrm{LM}}$). ▲ indicates the best CN per decoding (∈ Best$_{\mathrm{D}}$). ☐ indicates the best CN per model-decoding combination (∈ Best$_{\mathrm{LM+D}}$).

Human evaluation on a sample To perform the human evaluation we referred to the Best$_{\mathrm{LM}}$ generations and sampled 200 instances from it. Each instance comprises an HS and 5 relevant CNs, each generated by a different model. We recruited 2 annotators who were trained extensively for the task following the procedure used by Fanton et al. (2021). The expert annotators were asked to evaluate the 5 CNs corresponding to the HS, according to the dimensions described in Section 4. We en-

riched the evaluation of this subset with the toxicity and the syntactic metrics.

5.2 Results of the first set of experiments

The results of the experiments on the LMs and the decoding mechanisms are reported in this section[4].

Best Model The results of the comparison of the models on the Best_{LM} generations can be found in Table 1. Regarding the overlap and diversity metrics, DialoGPT records the best or the second best score in all the metrics, apart from novelty where it still achieves a high score (0.643) close to the best performance (0.655). T5 also achieves high scores, especially on ROUGE, BLEU-1 and novelty.

BART, instead, is the best model according to human evaluation metrics, apart from specificity. On the other hand, it shows poor performances in terms of diversity metrics, indicating that it tends to produce grammatical and suitable but very generic responses.

BERT records the worst scores for all the overlap and diversity metrics apart from novelty. However, it also achieves the best syntactic metric results. Therefore, it is evident that BERT's output is more complex, but very repetitive. The combination of these aspects eventually affects the clarity of BERT's output such that it yields poor results in the human evaluation, in particular for grammaticality (4.2, while other models are above 4.6). This poor grammaticality can also explain the syntactic scores since the spaCy dependency parser was not trained to handle ungrammatical text and this could actually inflates the ASD and MSD scores.

GPT-2 overall yields very competitive results for several groups of metrics. It obtains the second-highest novelty score (0.653) and the best RR (7.736). It also achieves the second best results on BLEU-3, maximum syntactic depth and number of sentences, and the best results on toxicity and specificity (2.880) indicating the ability to produce complex, suitable, focused and diverse CNs.

After the human evaluation we ran a qualitative interview with the annotators, whose feedback on the data strengthened the results we observed and the conclusion we drew. For instance, they reported the repetition of simple, yet catch-them-all, expressions (e.g. "they are our brothers and sisters") regardless of the target. Further inspections found that those CNs were mainly produced by BERT, which is in line with BERT's RR score.

Best Decoding mechanism. The results calculated on Best_{D} output are presented in Table 2. Top_k is the best performing decoding mechanism achieving the best results on the diversity metrics, BLEU-3 and BLEU-4. It is also the best performing for specificity, maximum syntactic depth and number of sentences, and the second best for average syntactic depth and toxicity.

The other stochastic decoding mechanisms perform well too. Top_p yields competitive results on both diversity and overlap metrics; it is the second best for specificity, and achieves good results on the syntactic metrics. Top_{pk} has a good performance on the overlap metrics. It obtains the second-highest scores in most of the human evaluation metrics and the lowest in toxicity, and it reaches a reasonable specificity score.

On the other hand, BS does not achieve particularly good results, except for the ROUGE score. Even if it is the best decoding with respect to the human evaluation, this comes at the cost of specificity and diversity. Through a post-hoc manual analysis we observed that it was due to the deterministic nature of BS, that tends to choose the most probable sequences, i. e. the "safest", thus resulting in vague and repetitive outputs.

Best Model-Decoding combination Here we briefly discuss the results of the evaluation obtained on the $\text{Best}_{\text{LM+D}}$ generations. In particular, the autoregressive models GPT-2 and DialoGPT behave similarly with similar decoding mechanisms, such that BS outputs the best results for almost all the overlap metrics, and the worst for the diversity metrics. On the contrary, for the other models, the results achieved with stochastic decoding mechanisms are the best for the overlap metrics. In almost all the cases, we observe that the stochastic decoding mechanisms perform better on syntactic and diversity metrics and on toxicity, while for the human evaluation metrics BS tends to be the best, except for specificity. A detailed discussion can be found in Appendix A.2.

Discussion. In this set of experiments, we found that the autoregressive models perform the best according to a combination of several metrics that we deem particularly relevant (e.g. more novel, diverse, and informative outputs). Of course more repetitive and conservative outputs can be preferred

---

Table 2: The results for the overlap and diversity metrics are calculated on the Best$_{\text{D}}$ generations: for each decoding mechanism, there are 2500 CNs. The remaining metrics are calculated on a subset of 1000 CNs: the distribution of which is shown in the column "n".

when high precision of suitable CNs are required at the expense of being more generic and less novel. Still, for what concerns autoregressive models it could be argued that the good performance of the GPT-2 model we fine-tuned is due to the fact that generated CNs and gold CNs derive from a similar distribution (GPT-2 was employed in the human-in-the-loop process used to create the reference dataset from Fanton et al. (2021)). While we recognize that this could partially explain the performance of our GPT-2 model, it does not explain the performance of DialoGPT, which is pre-trained on a completely different dataset. Therefore, we can reasonably conclude that autoregressive models are particularly suited for the task, regardless of the pre-training data.

With respect to the decoding mechanisms, we record high repetitiveness and low novelty for the deterministic decoding BS. Even if it reaches high scores in most of the human evaluation metrics, it fails to produce specific CNs ending up in generating suitable, yet generic responses. On the contrary, stochastic decoding mechanisms produce more novel and specific responses.

Example CNs generated in this session of experiments, along with some qualitative analysis, can be found in Appendix A.3.

5.3 Leave One Target Out experiments

In the second stage, we built a set of cross-domain experiments to capture the generalization capabilities of the best LM determined in the previous experiments. Specifically, we concentrate on assessing how much a pre-trained language model fine-tuned on a pool of hate targets can generalize to an unseen target.

Thus, for the out of target experiment we selected the LM that we deem the most prominent in order to reduce the number of LM configurations to compare. In particular, since we want to examine the generalization capability of the LM, the generation of *novel* CNs, in comparison to the training data, is given primary importance. Secondly, *specificity* is also crucial since it signifies the ability of the LM/decoding mechanism in generating accurate CNs and avoiding vague yet suitable, catch-all CNs. In contrast, repetitiveness is an undesirable feature of CNs, as it signals the tendency of a model to produce less flexible content. Given these considerations, we chose to employ GPT-2 with Top$_k$ decoding for the Leave One Target Out (LOTO) experiments since it is the configuration achieving the best trade-off amongst all the others.

This set of experiments is structured in 3 steps, replicated for each of the selected targets. We selected the targets with the highest number of examples (`MUSLIMS`, `MIGRANTS`, `WOMEN`, `LGBT+` and `JEWS`) to have a sufficient sized test set for each configuration.

First, we sampled from the Fanton et al. (2021) dataset 600 pairs for each LOTO target, in order to have a balanced setting. Additionally, `POC` and `DISABLED` were always kept in the training set, and we removed multi-target cases from `OTHER`. The resulting dataset consists of 3729 instances (further details are provided in Appendix A.4). Secondly, we fine-tuned 5 different configurations of the LM, and in each configuration one of the 5 LOTO targets is not present in the training data: $\text{LM}_{\text{-JEWS}}$, $\text{LM}_{\text{-LGTB+}}$, $\text{LM}_{\text{-MIGRANTS}}$, $\text{LM}_{\text{-MUSLIMS}}$ and $\text{LM}_{\text{-WOMEN}}$. Finally, we tested each LOTO model on the 600 HSs in the test set made of "left out" target examples. For instance, the model $\text{LM}_{\text{-JEWS}}$ is used for generating the CNs for the target `JEWS`, after being trained on $<HS, CN>$ data without any instances with the label `JEWS`. We generated 5 CNs for each HS and selected the best CN according to the procedure described in Section 5.1.

Results of LOTO experiments

We analyse the CNs generated with the LOTO models through overlap and diversity metrics (Table 3). We refer to Appendix A.4 for the comparison between RR calculated on the candidate CNs and the reference CNs of the Fanton et al. (2021) dataset.

For all the targets we record higher novelty scores as compared to the previous experiments. Higher novelty ranges indicate that conditioning with new material (i. e. HS for the unseen targets) induces GPT-2 to produce new arguments. On the other hand, as expected, the overlap scores for LOTO are remarkably lower than those from the previous experiments (Table 3). Therefore, we can infer that generalizing to an unseen target is harder than generalizing to an unseen HS.

LOTO	Overlap				Diversity	
Target	**ROU**	**B-1**	**B-3**	**B-4**	**RR**	**NOV**
`JEWS`	0.1609	0.1842	0.0134	0.0035	4.796	0.718
`LGBT+`	0.1599	0.1828	0.0149	0.0055	**4.620**	0.718
`MIGRANTS`	0.1659	0.1915	0.0163	0.0038	4.707	**0.720**
`MUSLIMS`	**0.1743**	**0.1934**	**0.0197**	**0.0059**	5.314	0.712
`WOMEN`	**0.1755**	**0.1988**	**0.0195**	**0.0068**	**4.632**	**0.729**

Table 3: The overlap and diversity metrics scores for the various LOTO configurations.

We also found out that the CNs generated in the $\text{LM}_{\text{-MUSLIMS}}$ and $\text{LM}_{\text{-WOMEN}}$ configurations obtain the highest overlap scores (Table 3). We hypothesize that the high scores can be explained by the presence of a target in the LOTO training that is highly similar to the left out one. To this end, we computed the novelty between each target subset of the training data and the LOTO test data for that configuration (see Appendix A.4 for details). The reference CNs for $\text{LM}_{\text{-MUSLIMS}}$ record the lowest novelty scores with respect to the `JEWS` subset of the training set (i. e. 0.761). Thus, it can be interpreted as the most influential portion of training data for the target `MUSLIMS`. On the other hand, for $\text{LM}_{\text{-WOMEN}}$ the highest influence is recorded with the `LGBT+` subset of the training data (i. e. 0.763). These results can be explained by the semantic similarity of the target `MUSLIMS` to `JEWS`, both being religious groups; and of `WOMEN` to `LGBT+`, both being related to gender issues.

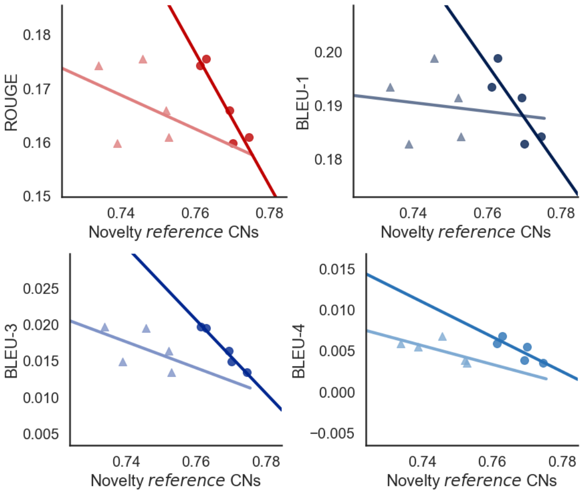

Figure 2: The correlation between the novelty of the reference CNs and overlap metrics: in each plot, the dots and the darker line correspond to the most influential target; the triangles and the lighter line correspond to the results calculated without it.

As a complementary analysis, we consider two different computations of the reference CN novelty: with respect to the most influential target for each LOTO configuration, and with respect to the LOTO training data without the most influential target. We computed the Pearson correlation between the overlap metrics and each of the two novelty computations. In Figure 2, we observe that removing the influential target from the training data strongly decreases the correlation with the overlap metrics (from an average of -0.889 to -0.416). Consequently, we can conclude that to obtain high overlap results in the LOTO experiments, it is necessary that the training data contains a target strongly connected to the left out one. Most importantly, this connection is not arbitrarily decided but it is based on an *a-priori* semantic similarity of the targets as exemplified before.

Finally, we chose to generate also with the BS decoding mechanism, to use it as a baseline and compare it to the stochastic decoding mechanism (Top-k). In particular, we computed the Pearson correlation between the novelty of the reference

CNs and the novelty of the candidate CNs with respect to the corresponding training data (Figure 3). We can observe that for the BS generation the novelty of the candidate CNs is lower than Top-k (0.67-0.74 vs. 0.75-0.77) and the correlation with the novelty of the reference is weaker (0.53 vs. 0.59). This confirms the lower generalization ability with the deterministic decoding mechanism (as compared to the stochastic) that tends to produce generic and repetitive responses regardless of the semantic distances of the LOTO targets from the training data.

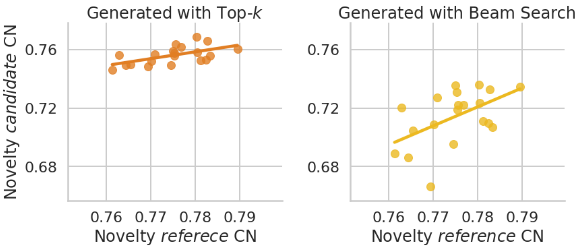

Figure 3: Reference and candidate CNs novelty, for Top-k and BS LOTO generations.

6 Automatic Post-Editing

In the previous experiments we fine-tuned our models making resort to $<HS, CN>$ pairs alone. Still the Fanton et al. (2021) dataset contains additional information that can be useful for our task: i. e. the original GPT-2 generation before undergoing human post-editing.

Thus, as a final experiment, we propose to further improve the CN generation by moving from an end-to-end framework to a two stage pipeline, by decoupling CN generation from its ‘final refinement’. In particular we propose the adoption of an Automatic Post-Editing (APE) stage in order to capture and utilize the nuances among the machine generated CNs and their human post-edited versions. APE, which is used for automatically correcting errors made by machine translation (MT) systems before performing actual human post-editing, has been an important tool for MT (Knight and Chander, 1994; do Carmo et al., 2021). Considering its effectiveness in MT, we hypothesize that building a pipeline with CN generation and APE could alleviate the requirement of the final manual post-editing (Allen and Hogan, 2000; Chatterjee et al., 2019) to achieve better constructed CNs.

To this end, we fine-tuned another instance of GPT-2 medium model specifically for the post-editing task using the $<HS, CN_{or}, CN_{pe}>$ triplets[5], where CN_{or} and CN_{pe} denote the CNs originally generated by an LM and their human post-edited versions, respectively. The triplets were then filtered by removing those for which $CN_{or} = CN_{pe}$. More details about the experiment settings can be found in Appendix A.5.

Data	CN_{ape}	CN_{or}	N/A
Fanton et al. (2021)	26	14	60
GPT-2 Top$_{\boldsymbol{k}}$	37	19	44

Table 4: The human annotation results for the APE experiments in terms of average preference percentages.

We have conducted two human evaluations over the subsets of: i) the CN_{or} of the Fanton et al. (2021) test samples, ii) the CN outputs of the best model and decoding mechanism combination provided as the results of the first set of experiments, that yielded the top 50 Translation Error Rate (TER) (Snover et al., 2006) scores with respect to the CN_{or}s. The two expert annotators were asked to state their preferences among the 2 randomly sorted CNs, CN_{or} and CN_{ape} (automatically post-edited output), for a given HS. The annotators were also allowed to decide on a tie. Results, shown in Table 4, indicate that, albeit there are often ties and only a subset of CN_{or} is actually modified, when there is a preference, it is predominantly in favour of the automatically post-edited versions over the GPT-2 generated CNs (26% vs. 14% for the test set, and 37% vs. 19% for the GPT-2 Top$_{\boldsymbol{k}}$ generations, on average). Regarding the experiment results, we believe that APE is a highly promising direction to increase the efficacy of the CN generation models where generation quality and diversity is crucial, and considering that obtaining/enlarging expert datasets to train better models is not simple.

7 Conclusion

In this work, we focus on automatic CN generation as a downstream task. First, we present a comparative study to determine the performances and peculiarities of several pre-trained LMs and decoding mechanisms. We observe that the best results (in term of novelty and specificity) overall are achieved

---

[5] This is in line with the APE paradigm where the triplet is made of <*source sentece*, MT_{output}, *human post-edits*>.

by the autoregressive models with stochastic decoding: GPT-2 with the Top$_k$ decoding mechanism, and DialoGPT with the combination Top$_{pk}$. At the same time deterministic decoding can be used when more generic yet 'safer' CNs are preferred.

Then, we investigate the performances of LMs in zero-shot generation for unseen targets of hate. Hence, we fine-tuned 5 different versions of GPT-2, leaving out the examples pertaining to one target at each turn. We find out that for each configuration/version, there is a subset of the training data which is more influential with respect to the generated data (i. e. a target that shares some commonalities with the test target that can be defined a-priori). Finally, we introduce an experiment by training an automatic post-editing module to further improve the CN generation quality. The notable human evaluation results paves the way for a promising future direction that decouples CN generation from its 'final refinement'.

Ethical Considerations

Although tackling online hatred through CNs inherently protects the freedom of speech and has been proposed as a better alternative to the detect-remove-ban approaches, automatization of CN generation can still raise some ethical concerns and some measures must be taken to avoid undesired effects during research. Thus, we address the relevant ethical considerations and our remedies as follows:

Annotation Guidelines: The well-being of the annotators was our top priority during the whole study. Therefore, we strictly followed the guidelines created for CN studies (Fanton et al., 2021) that were adapted from (Vidgen et al., 2019). The human evaluations have been conducted with the help of two expert annotators in CNs. These experts were already trained for the CN generation task and employed for the work presented by (Fanton et al., 2021). We further instructed them in the aims of each experiment, clearly explained the evaluation tasks, and then we exemplified proper evaluation of $<HS, CN>$ pairs using various types of CNs. Most importantly, we limited the exposure to hateful content by providing a daily time limit of annotation. Concerning the demographics, due to the harmful content that can be found in the data, all annotators were adult volunteers, perfectly aware of the objective of the study.

Dataset. We purposefully chose an expert-based dataset in order to avoid the risk of modeling the language of real individuals to (i) prevent any privacy issue, (ii) avoid to model inappropriate CNs (e.g. containing abusive language) that could be produced by non-experts. The dataset also focuses on the CN diversity while keeping the HSs as stereotypical as possible so that our CN generation models have a very limited diversity on the hateful language, nearly precluding the misuse.

Computational Task. CN generation models are not meant to be used in an autonomous way, since even the best models can still produce substandard CNs containing inappropriate or negative language. Instead, following a Human–computer cooperation paradigm, our focus is on building models that can be helpful to NGO operators by providing them diverse and novel CN candidates for their hate countering activities and speed up the manual CN writing to a certain extent. This approach also gives ground to some of the measures we used during evaluation (namely choose-or-not and is-best).

Model Distribution. In addition to the limited and simplified hateful content in the dataset we selected, we further reduce the risk of misuse by choosing a specific distribution strategy: i) we only make available the non-autoregressive models in order to eliminate the risk of using over-generation for hate speech creation, ii) we distribute such models only for research purposes and through a request based procedure in order to keep track of the possible users.

A Appendix

A.1 Fine-tuning details

Table 5 summarizes the details of the training of each model employed in the first session of experiments.

	BA	**EP**	**PAR**	**LR**	**PER**	**TL**	**EL**
BART (base)	4	4	139 M	2E-05	24.659	2.358	2.417
BERT Seq2Seq (base)	4	3	247 M	3E-05	11.209	2.845	3.205
T5 (base)	2	3	223 M	5E-05	10.9248	2.412	3.205
DialoGPT (medium)	4	2	**355 M**	5E-05	**6.085**	**1.425**	**1.806**
GPT-2 (medium)	2	2	**355 M**	5E-05	**8.929**	**1.320**	**2.189**

Table 5: The training details for all the models employed for the first collection of experiment: the batch size (BA), number of training epochs (EP), parameters (PAR), the learning rate (LR), perplexity (PER), training and evaluation loss (TL and EL).

Since LM sizes are very different for each model and since our main focus is not studying performances according to LM dimension growth, as a rule-of-thumb, we chose one version smaller than the large version of each model provided that they all have the same order of magnitude. This corresponds to the *medium* versions for both DialoGPT and GPT-2, and *base* versions for the other models. GPT-2 and DialoGPT achieve the lowest perplexity, training and evaluation loss, thus indicating a slightly more successful fine-tuning, which are reflected in the evaluations throughout the study.

We conducted a hyper-parameter search during the training phase of each model using the search space: learning-rate:$\{1e-5, 2e-5, 3e-5, 4e-5, 5e-5\}$, warm-up ratio:$\{0, 0.1\}$, batch-size:$\{2, 4\}$, epochs:$\{2, 3, 4, 5\}$. It has been conducted using Optuna, with 10 trials, optimized on minimizing the evaluation loss during training.

A.2 Best models-decoding combination

Here we discuss the results for the overlap and diversity metrics obtained on the Best$_{\text{LM+D}}$ generations (Table 6), and those calculated on the human evaluation subset (Tables 7 and 8).

BART. BART performs well with the stochastic decoding methods, in particular: Top$_p$ for overlap, diversity, syntactic metrics, and grammaticality; Top$_k$ for overlap metrics and toxicity, whereas Top$_{pk}$ is the best decoding approach on human evaluation and RR, and the second best on ROUGE and BLEU-1. On the contrary, BART does not achieve good results with deterministic approaches (i. e. BS).

	Overlap				**Diversity**	
	ROU	**B-1**	**B-3**	**B-4**	**RR**	**NOV**
BART BS	0.2108	0.2129	0.0486	0.0283	21.1102	**0.5692**
BART Top$_{pk}$	**0.2331**	**0.2300**	0.0605	0.0365	**20.2645**	0.5567
BART Top$_k$	**0.2349**	**0.2333**	**0.0652**	**0.0385**	20.6587	0.5575
BART Top$_p$	0.2329	0.2300	**0.0621**	**0.0374**	**20.5476**	**0.5586**
BERT BS	0.1735	0.2108	0.0249	0.0113	38.0349	0.5864
BERT Top$_{pk}$	**0.2034**	0.2311	**0.0484**	**0.0231**	**23.4417**	0.6098
BERT Top$_k$	0.2032	**0.2320**	0.0483	0.0229	**22.2546**	**0.6129**

T5 BS	0.2144	0.2007	0.0409	**0.0207**	21.5518	0.5827
T5 Top$_{pk}$	**0.2236**	**0.2454**	**0.0466**	**0.0228**	7.2996	0.6715
T5 Top$_k$	0.2076	0.2384	0.0376	0.0136	**5.3002**	**0.6922**
T5 Top$_p$	**0.2159**	**0.2390**	**0.0430**	0.0184	**6.8353**	**0.6743**
DialoGPT BS	**0.2192**	0.2272	**0.0528**	**0.0312**	21.6800	0.5280
DialoGPT Top$_{pk}$	**0.2132**	**0.2444**	**0.0437**	**0.0201**	6.4158	0.6737
DialoGPT Top$_k$	0.2023	0.2302	0.0320	0.0134	**4.7278**	**0.6956**
DialoGPT Top$_p$	0.2093	**0.2397**	0.0385	0.0159	**6.1472**	**0.6740**
GPT-2 BS	**0.2195**	0.2132	**0.0516**	**0.0313**	23.0605	0.5402
GPT-2 Top$_{pk}$	**0.2055**	**0.2342**	0.0384	0.0173	6.5899	0.6832
GPT-2 Top$_k$	0.1956	0.2271	0.0345	0.0153	**4.7624**	**0.7022**
GPT-2 Top$_p$	0.2014	**0.2329**	**0.0388**	**0.0177**	**6.1944**	**0.6846**

Table 6: The results computed on the Best$_{\text{M+D}}$ generations (2500 CN for each model-decoding mechanism combination).

BERT. With BS, BERT achieves the best or second best result on all human evaluation metrics, except for specificity. For BERT the best decoding is Top$_p$: it is the best performing on overlap metrics and the second best for novelty. It achieves good results both on syntactic metrics and human evaluation too.

T5. For T5, Top$_{pk}$ is the best decoding mechanism. It records the best results for overlap metrics and toxicity, and it has good results on syntactic and human evaluation metrics. For what regards Top$_k$, it is the best for diversity, while Top$_p$ is good on the syntactic metrics. BS achieves good results on human evaluation, except for specificity and is-best.

GPT-2. With Top$_{pk}$, GPT-2 performs well on ROUGE, BLEU-1, suitableness, grammaticality, and choose-or-not. With Top$_p$, GPT-2 records the second best result on BLEU scores and diversity metrics. With BS the model has the best performance on overlap metrics (except BLEU-1), and on suitableness, grammaticality, and choose-or-not, but it has also the worst results on diversity metrics. Above all, Top$_k$ is the decoding achieving the best compromise, reaching the best results for the diversity metrics, and with a superior specificity score (3.15) that is corroborated by the good performance on the other human evaluation metrics.

DialoGPT. Top$_k$ performs best with diversity metrics and specificity; it records the second high-

	Toxicity	**Syntactic metrics**			
	-	**ASD**	**MSD**	**NST**	**n**

DialoGPT BS	0.3635	4.2340	5.1277	1.8723	47
DialoGPT Top$_{pk}$	**0.3361**	4.7264	5.5094	1.7547	53
DialoGPT Top$_k$	0.3482	**4.9333**	**6.1778**	**2.0000**	45
DialoGPT Top$_p$	**0.3274**	**4.7970**	**5.5273**	**1.9636**	55
GPT-2 BS	0.3540	**4.8901**	5.3617	1.4468	47
GPT-2 Top$_{pk}$	**0.3119**	4.2530	5.4182	2.4000	55
GPT-2 Top$_k$	**0.3416**	**4.6771**	**5.8627**	**2.5686**	51
GPT-2 Top$_p$	0.3659	4.5663	**5.7447**	**2.4894**	47

Table 7: The results of the toxicity and the syntactic metrics calculated on the subset employed for the human evaluation and grouped by each combination of model and decoding mechanism. The size of each group is showed in the column “n”.

est score on grammaticality. Top$_p$ has the second best result on diversity metrics and BLEU scores. BS is the best on overlap metrics (except BLEU-1), and also on almost all human evaluation metrics: it is the worst on specificity and on diversity metrics. Top$_{pk}$ is the one working best with DialoGPT, since it reaches very good scores with human and overlap metrics, and this does not invalidate diversity, for which it ranks 3rd out of 4.

A.3 Examples of the generations

> **Hate speech**: Islam is a violent religion that promotes terror and war.
>
> **DialoGPT - BS**: *The vast majority of Muslims in the world are peaceful and friendly people. I don’t see how you can say such a thing about them.*
>
> **BART - Top$_k$**: *The vast majority of Muslims are peaceful people who have lived in peace and harmony for many years. How can you say this about a religion that promotes terror and war?*
>
> **BERT - Top$_k$**: *islam is a religion of peace, and it is not a peaceful religion of violence. it is about peace and understanding of the world’s problems, and peace is about bringing peace and peace.*

	Human evaluation					
	SUI	**SPE**	**GRM**	**CHO**	**BEST**	**n**
BART BS	3.7568	2.5270	4.9459	0.8108	0.2297	37

T5 Top$_k$	2.4600	2.3200	4.6400	0.5600	0.0500	50
T5 Top$_p$	2.8163	**2.4388**	**4.7449**	0.6122	**0.1224**	49
DialoGPT BS	**4.1596**	2.6064	**4.9894**	**0.8511**	**0.3085**	47
DialoGPT Top$_{pk}$	**3.3679**	**2.8019**	4.8396	**0.7830**	**0.2736**	53
DialoGPT Top$_k$	3.1333	**2.9222**	**4.8556**	0.7333	0.2111	45
DialoGPT Top$_p$	2.9727	2.7000	4.8455	0.7091	0.1909	55
GPT-2 BS	**4.3085**	2.5000	**4.9681**	**0.8830**	**0.2766**	47
GPT-2 Top$_{pk}$	**3.4909**	2.8000	**4.8727**	**0.8273**	**0.2273**	55
GPT-2 Top$_k$	3.0392	**3.1471**	4.8431	0.7255	0.2549	51
GPT-2 Top$_p$	3.4362	**3.0638**	4.7872	0.7447	0.3298	47

Table 8: For each model-decoding mechanism combination, these are the results of the metrics for the human evaluations. The size of each combination is showed in the column “n".

> **T5 - Top$_p$**: *The vast majority of Muslims in the UK are peaceful people who share many values and respect.*
>
> **GPT-2 - Top$_p$**: *This is not true, the vast majority of Muslims is peaceful and peaceful Muslims are happy to live in any country they wish. They do not need to be a part of a hostile state and they should be treated as equals in society.*

In these examples we can observe that the CN obtained with GPT-2, albeit not perfect, is the most complete and accurate. Those generated with T5 and DialoGPT are suitable as well. On the other hand, the CNs obtained with BART and BERT present some problems: the former has a clear contradiction in it and the latter is illustrative of some of the problems detected in BERT’s generations such that it is syntactically complex but very vague and repetitive, and it ends up not really conveying a clear message.

> **Hate speech**: The migrant crisis is not the fault of Western Europeans. Migrants are to blame for immigration.
>
> **DialoGPT - Top$_k$**: *What if an entire religion was to blame only for the migration crisis? So you think a large number of Muslims are responsible for all the problems of our world?*

> **BART - Top$_p$**: *The migrant crisis is caused by a lack of integration and lack of knowledge of the world.*
>
> **BERT - BS**: *many migrants come here to work and provide for their families. they are our brothers and sisters, and we should welcome them.*
>
> **T5 - Top$_k$**: *What evidence do you have for the evidence that migrants are to blame? Not all migrants have done anything wrong.*
>
> **GPT-2 - Top$_k$**: *The EU has put in place laws to combat illegal immigration and to prevent crimes committed by migrants. They have a duty to help stop crime and do what is necessary to solve the problems within their borders. Migrants are very intelligent and do what they can to support their families while they study and work.*

Once again, GPT-2 and DialoGPT generations where chosen as the best CNs by the annotators. Moreover, these CNs are all generated via Top$_k$ decoding mechanism. BART and T5 generated CNs are acceptable while requiring some post-editing to be employed. Finally, BERT's output is still very vague: we can notice the presence of the recurring expression *our brothers and sisters*.

A.4 Additional material for LOTO experiments

Table 9 displays the distribution of the examples with respect to the targets, in the reference dataset and in the configurations for the LOTO experiments (Section 5.3).

Table 10 presents the detailed results for the novelty of the reference CNs discussed in Section 5.3, while the RR for the CNs generated with the LOTO models and for the reference CNs are shown in Table 11. The rankings for these two RR computations are the same, and the ranges are almost overlapping. This means that leaving one target out does not impact the intra-corpora repetitiveness: instead, the CNs generated with a LOTO model gain a lower RR than the reference CNs. For the target MUSLIMS a high RR is recorded, both in candidate and in the reference CNs. A high repetitiveness in the data for this target can contribute to the good results observed on overlap metrics too (Table 3 in Section 5.3): it is easier that two outputs are similar if they use a limited and repeated number of words.

Target	Samples in original dataset	Samples in LOTO experiment
JEWS	594	600
LGBT+	617	600
MIGRANTS	957	600
MUSLIMS	1335	600
WOMEN	662	600
DISABLED	220	220
POC	352	352
other	266	157
Total	5003	3729

Table 9: The targets coverage in the reference dataset (Fanton et al., 2021) and in the LOTO configurations.

generation training	JEWS	LGBT+	MIGRANTS	MUSLIMS	WOMEN
JEWS	-	0.775	0.780	**0.761**	0.780
LGBT+	0.781	-	0.783	0.765	**0.763**
MIGRANTS	0.782	0.775	-	0.764	0.777
MUSLIMS	0.775	0.770	0.769	-	0.776
WOMEN	0.789	0.771	0.783	0.775	-

Table 10: The novelty of the reference CNs in the data from Fanton et al. (2021) (*generation*) with respect to the training data for the LOTO models (*training*).

Target	RR *reference CN*	RR *candidate CN*
JEWS	5.071	4.796
LGBT+	4.489	4.620
MIGRANTS	4.381	4.707
MUSLIMS	5.244	5.314
WOMEN	4.547	4.632

Table 11: The RR computed on the reference CN (pertaining the test set) and on the CN generated with the LOTO models.

A.5 APE Experiment Details

The dataset by (Fanton et al., 2021) contains three versions of the same CN: the original CN generated by a GPT-2 model (CN$_{or}$), the expert post-edited versions obtained during the human-in-the-loop cycles (CN$_{pe*}$), and the final version rechecked by NGO experts (CN$_{pe}$).

For fine-tuning our APE model, we have thus used the triplets $<HS, CN_{or}, CN_{pe}>$ and $<HS, CN_{pe*}, CN_{pe}>$. In this way, we managed to roughly double the number of the post-edit training samples, which is highly beneficial for a better model. When we filtered the triplets with a positive

TER score between CN$_{ed}$ and CN$_{pe}$, or CN$_{or}$ and CN$_{pe}$, we obtained 4185 training, 596 test, and 568 validation samples following the partition used in the first set of experiments as described in Section 3.1. Finally, the best fine-tuning configuration of the GPT-2 medium model for APE was obtained with a learning rate of 2e-5 for 3 epochs resulting in 3.34 train loss and 1.23 eval loss.

Improving Robustness of Language Models from a Geometry-aware Perspective

Abstract

Recent studies have found that removing the norm-bounded projection and increasing search steps in adversarial training can significantly improve robustness. However, we observe that a too large number of search steps can hurt accuracy. We aim to obtain strong robustness efficiently using fewer steps. Through a toy experiment, we find that perturbing the clean data to the decision boundary but not crossing it does not degrade the test accuracy. Inspired by this, we propose friendly adversarial data augmentation (FADA) to generate friendly adversarial data. On top of FADA, we propose geometry-aware adversarial training (GAT) to perform adversarial training on friendly adversarial data so that we can save a large number of search steps. Comprehensive experiments across two widely used datasets and three pre-trained language models demonstrate that GAT can obtain stronger robustness via fewer steps. In addition, we provide extensive empirical results and in-depth analyses on robustness to facilitate future studies.

1 Introduction

Deep neural networks (DNNs) have achieved great success on many natural language processing (NLP) tasks (Kim, 2014; Vaswani et al., 2017; Devlin et al., 2019). However, recent studies (Szegedy et al., 2013; Goodfellow et al., 2015) have shown that DNNs are vulnerable to crafted adversarial examples . For instance, an attacker can mislead an online sentiment analysis system by making minor changes to the input sentences (Papernot et al., 2016; Liang et al., 2017). It has raised concerns among researchers about the security of DNN-based NLP systems. As a result, a growing number of studies are focusing on enhancing robustness to defend against textual adversarial attacks (Jia et al., 2019; Ye et al., 2020; Jones et al., 2020; Zhu et al., 2020).

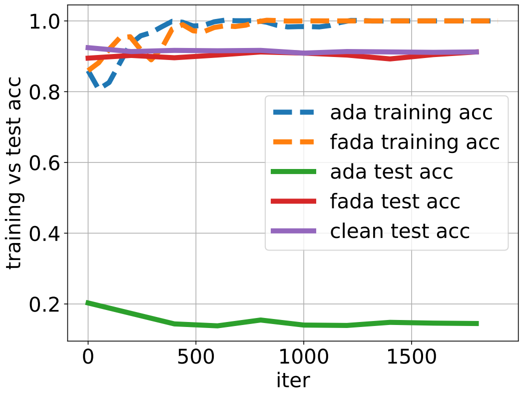

Figure 1: The clean accuracy achieved with ADA, FADA, and the original training set. During training, both ADA and FADA have close to 100% accuracy. However, ADA only achieves ∼15% accuracy during testing while FADA maintains the same test accuracy with the original training set. This indicates that training data which crosses the decision boundary hurts the accuracy significantly.

Existing adversarial defense methods fall into two categories: empirical and certified defenses. Empirical defenses include gradient-based adversarial training (AT) and discrete adversarial data augmentation (ADA). Certified defenses provide a provable guaranteed robustness boundary for NLP models. This work focuses on empirical defenses.

There was a common belief that gradient-based AT methods in NLP was ineffective compared with ADA in defending against textual adversarial attacks (Li and Qiu, 2021; Si et al., 2021). Li et al. (2021) find that removing the norm-bounded projection and increasing the number of search steps in adversarial training can significantly improve robustness. Nonetheless, we observe that increasing the number of search steps further does not significantly improve robustness but hurts accuracy.

We give a possible explanation from a geometry-aware perspective. Removing the norm-bounded projection enlarge the search space. Appropriately

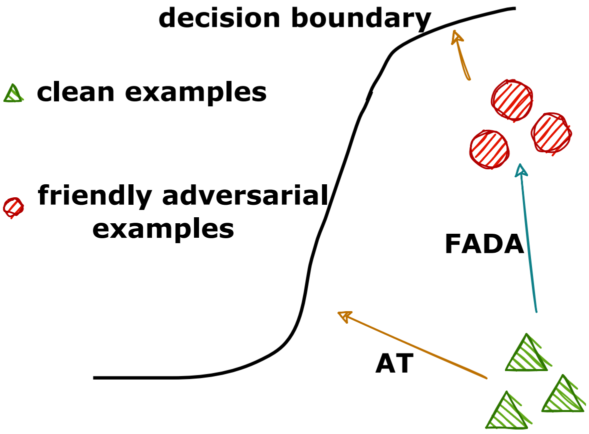

Figure 2: Illustration of GAT. Our GAT can save many search steps since friendly adversarial examples are located near the decision boundary.

increasing the number of search steps brings the adversarial data closer to the decision boundary. In this case, the model learns a robust decision boundary. Further increasing the number of search steps can make the adversarial data cross the decision boundary too far, hindering the training of natural data and hurting natural accuracy.

To verify our hypothesis, we train a base model using adversarial data, which are generated by adversarial word substitution (AWS) on the SST-2 (Socher et al., 2013) dataset. We report its training accuracy ("ada training acc") on adversarial data and test accuracy ("ada test acc") on the clean test set in Figure 1. Although achieving nearly 100% training accuracy, its test accuracy is only about 15%, which implicates the adversarial data make the test performance degraded. Then we train another base model, whose training data is more "friendly". We just recover their last modified words to return to the correct class, namely friendly adversarial data augmentation (FADA). It means that only one word is different in each sentence. Surprisingly, it achieves a high test accuracy of ~93%.

This preliminary inspired us to address two existing problems:

- **The number of search steps is always large, which is computationally inefficient**.
- **A too large number of steps leads to degraded test performance**.

Geometrically speaking, the friendly adversarial data are close to the ideal decision boundary. We can address the above two issues in one fell swoop if we perform gradient-based adversarial training on these friendly adversarial data. It is like we start one step before the end, allowing us to obtain strong robustness through a tiny number of search steps. We name it geometry-aware adversarial training (GAT). Figure 2 illustrates our proposed GAT.

In addition, the friendly adversarial data only need to be generated once per dataset. It can be reused, so it is computationally efficient. It can also be updated for every iteration or epoch but computationally expensive.

Our contributions are summarized as follows:

1) We propose FADA to generate friendly adversarial data which are close to the decision boundary (but not crossing it).

2) We propose GAT, a geometry-aware adversarial training method that adds FADA to the training set and performs gradient-based adversarial training.

3) GAT is computationally efficient, and it outperforms state-of-the-art baselines even if using the simplest FGM. We further provide extensive ablation studies and in-depth analyses on GAT, contributing to a better understanding of robustness.

2 Related Work

2.1 Standard Adversarial Training

Let $f_\theta(x)$ be our neural network, $\mathcal{L}(f_\theta(x), y)$ be the loss function (e.g., cross entropy), where $x \in X$ is the input data and $y \in Y$ is the true label. The learning objective of standard adversarial training is

$$\min_\theta \mathbb{E}_{(X,Y)\sim D}\left[\max_{\|\delta\|\leq\epsilon} \mathcal{L}(f_\theta(X+\delta), y)\right], \quad (1)$$

where D is the data distribution, δ is the minor perturbation, ϵ is the allowed perturbation size. To optimize the intractable min-max problem, we search for the optimal δ to maximize the inner loss and then minimize the outer loss w.r.t the parameters θ, step by step.

The gradient g of the inner loss w.r.t the input x is used to find the optimal perturbation δ. Goodfellow et al. (2015) proposed fast gradient sign method (FGSM) to obtain δ by one step:

$$\delta = \epsilon \cdot sgn(g), \quad (2)$$

where $sgn(\cdot)$ is the signum function. Madry et al. (2018) proposed projected gradient descent (PGD) to solve the inner maximization as follows:

$$\delta^{(t+1)} = \Pi\, \alpha \cdot g^{(t)} / \|g^{(t)}\|, \forall t \geq 0, \quad (3)$$

where $\alpha > 0$ is the step size (i.e., adversarial learning rate), Π is the projection function that projects the perturbation onto the ϵ-norm ball. Conventionally PGD stops after a predefined number of search steps K, namely PGD-K. In addition, TRADES (Zhang et al., 2019), MART (Wang et al., 2020) and FAT (Zhang et al., 2020) are also effective adversarial training methods for boosting model robustness.

Regarding FAT, the authors propose to stop adversarial training in a predefined number of steps after crossing the decision boundary, which is a little different from our definition of "friendly".

2.2 Adversarial Training in NLP

Gradient-based adversarial training has significantly improved model robustness in vision, while researchers find it helps generalization in NLP. Miyato et al. (2017) find that adversarial and virtual adversarial training have good regularization performance. Sato et al. (2018) propose an interpretable adversarial training method that generates reasonable adversarial texts in the embedding space and enhance models' performance. Zhu et al. (2020) develop FreeLB to improve natural language understanding.

There is also a lot of work focused on robustness. Wang et al. (2021) improve model robustness from an information theoretic perspective. Dong et al. (2021) use a convex hull to capture and defense against adversarial word substitutions. Zhou et al. (2021) train robust models by augmenting training data using Dirichlet Neighborhood Ensemble (DNE).

Besides, adversarial data augmentation is another effective approach to improve robustness (Ebrahimi et al., 2018; Li et al., 2019; Ren et al., 2019; Jin et al., 2019; Zang et al., 2020; Li et al., 2020; Garg and Ramakrishnan, 2020; Si et al., 2021). However, it only works when the augmentation happens to be generated by the same attacking method and often hurts accuracy.

It is worth noting that recent empirical results have shown that previous gradient-based adversarial training methods have little effect on defending against textual adversarial attacks (Li et al., 2021; Si et al., 2021). The authors benchmark existing defense methods and conclude that gradient-based AT can achieve the strongest robustness by removing the norm bounded projection and increasing the search steps.

Algorithm 1 Friendly Adversarial Data Augmentation (FADA)

```
Input: The original text $x$, ground truth label $y_{true}$, base model $f_\theta$, adversarial word substitution function $AWS(\cdot)$
Output: The friendly adversarial example $x_f$
Initialization:
$x_f \leftarrow x$
the last modified word $w^* \leftarrow$ None
the last modified index $i^* \leftarrow 0$
$x_{adv}, w^*, i^* = AWS(x, y_{true}, f_\theta)$
if $w^* =$ None then
    return $x_f$
end if
Replace $w_{i^*}$ in $x_{adv}$ with $w^*$
$x_f \leftarrow x_{adv}$
return $x_f$
```

3 Methodology

3.1 Friendly Adversarial Data Augmentation

For a sentence $x \in X$ with a length of n, it can be denoted as $x = w_1 w_2 ... w_i ... w_{n-1} w_n$, where w_i is the i-th word in x. Its adversarial counterpart x_{adv} can be denoted as $w'_1 w'_2 ... w'_i ... w'_{n-1} w'_n$. In this work, x_{adv} is generated by adversarial word substitution, so x_{adv} has the same length with x. Conventional adversarial data augmentation generates adversarial data fooling the victim model and mixes them with the original training set. As we claim in section 1, these adversarial data can hurt test performance. An interesting and critical question is **when it becomes detrimental to test accuracy**.

One straightforward idea is to recover all the x_{adv} to x word by word and evaluate their impact on test accuracy. We train models only with these adversarial data and test models with the original test set. We are excited that the test accuracy immediately returns to the normal level when we recover the last modified word. We denote these data with only one word recovered as x_f. Geometrically, the only difference between x_{adv} and x_f is whether they have crossed the decision boundary.

To conclude, when the adversarial data cross the

Algorithm 2 Ideal Geometry-aware Adversarial Training (GAT)

```
Input: Our base network $f_\theta$, cross entropy loss $\mathcal{L}_{CE}$, training
    set $D = \{x_i, y_i\}_{i=1}^{n}$, number of epochs $T$, batch size $m$,
    number of batches $M$
Output: robust network $f_\theta$
for epoch = 1 to $T$ do
    for batch = 1 to $M$ do
        Sample a mini-batch $b = \{(x_i, y_i)\}_{i=1}^{m}$
        for all $x_i$ in $b$ do
            Generate friendly adversarial example $x_i^f$ via Algorithm 1
            Apply an adversarial training method (e.g., FreeLB++) on both $x_i$ and $x_i^f$ to obtain their adversarial counterpart $\widetilde{x}_i$ and $\widetilde{x}_i^f$
        end for
        Update $f_\theta$ via $\nabla_x \mathcal{L}_{CE}(f_\theta(\widetilde{x}_i), y_i)$ and $\nabla_x \mathcal{L}_{CE}(f_\theta(\widetilde{x}_i^f), y_i)$
    end for
end for
```

decision boundary, they become incredibly harmful to the test performance. We name all the x_f as friendly adversarial examples (FAEs) because they improve model robustness without hurting accuracy. Similarly, we name the generation of FAEs as friendly adversarial data augmentation (FADA). We show our proposed FADA in Algorithm 1.

3.2 Geometry-aware Adversarial Training

3.2.1 Seeking for the optimal δ

Recall the inner maximization issue of the learning objective in Eq. (1). Take PGD-K as an instance. It divides the search for the optimal perturbation δ into K search steps, and each step requires a backpropagation (BP), which is computationally expensive.

We notice that random initialization of δ^0 is widely used in adversarial training, where δ^0 is always confined to a ϵ-ball centered at x. However, we initialize the clean data via discrete adversarial word substitution in NLP. It is similar to data augmentation (DA), with the difference that we perturb clean data in the direction towards the decision boundary, whereas the direction of data augmentation is random.

By doing so, we decompose the δ into two parts, which can be obtained by word substitution and gradient-based adversarial training, respectively. We denote them as δ_l and δ_s. Therefore, the inner maximization can be reformulated as

$$\max_{\|\delta_l + \delta_s\| \leq \epsilon} \mathcal{L}(f_\theta(X + \delta_l + \delta_s), y). \tag{4}$$

We aim to find the maximum δ_l that helps improve robustness without hurting accuracy. As we claim in Section 3.1, FADA generates friendly adversarial data which are close to the decision boundary. Furthermore, the model trained with these friendly adversarial data keeps the same test accuracy as the original training set (Figure 1). Therefore we find the maximum δ_l which is harmless to the test accuracy through FADA.

Denote X_f as the friendly adversarial data generated by FADA, Eq. (4) can be reformulated as

$$\max_{\|\delta_s\| \leq \epsilon} \mathcal{L}(f_\theta(X_f + \delta_s), y). \tag{5}$$

The tiny δ_s can be obtained by some gradient-based adversarial training methods (e.g., FreeLB++ (Li et al., 2021)) in few search steps. As a result, a large number of search steps are saved to accelerate adversarial training. We show our proposed geometry-aware adversarial training in Algorithm 2.

3.2.2 Final Learning Objective

It is computationally expensive to update friendly adversarial data for every mini-batch. In practice, we generate static augmentation (X_f,Y) for the training dataset (X,Y) and find it works well with GAT. The static augmentation (X_f,Y) is reusable. Therefore, GAT is computationally efficient.

Through such a tradeoff, our final objective function can be formulated as

$$\begin{aligned} \mathcal{L} = &\mathcal{L}_{CE}(X, Y, \theta) \\ &+ \mathcal{L}_{CE}(\widetilde{X}, Y, \theta) + \mathcal{L}_{CE}(\widetilde{X}_f, Y, \theta), \end{aligned} \tag{6}$$

where $\mathcal{L}_{CE}$ is the cross entropy loss, $\widetilde{X}$ and $\widetilde{X}_f$ are generated from X and X_f using gradient-based adversarial training methods, respectively.

4 Experiments

4.1 Datasets

We conduct experiments on the SST-2 (Socher et al., 2013) and IMDb (Maas et al., 2011) datasets which are widely used for textual adversarial learning. Statistical details are shown in Table 1. We use the GLUE (Wang et al., 2019) version of the SST-2 dataset whose test labels are unavailable. So we report its accuracy on the develop set in our experiments.

Dataset	**# train**	**# dev / test**	**avg. length**
SST-2	67349	872	17
IMDb	25000	25000	201

Table 1: Summary of the two datasets.

Table 2: Main defense results on the SST-2 dataset, including the test accuracy on the clean test set (**Clean %**), the robust accuracy under adversarial attacks (**RA %**), the attack success rate (**ASR %**), and the average number of queries requiring by the attacker (**# Query**).

4.2 Attacking Methods

Follow Li et al. (2021), we adopt TextFooler (Jin et al., 2019), TextBugger (Li et al., 2019) and BAE (Garg and Ramakrishnan, 2020) as attackers. TextFooler and BAE are word-level attacks and TextBugger is a multi-level attacking method. We also impose restrictions on these attacks for a fair comparison, including:

1. The maximum percentage of perturbed words p_{max}
2. The minimum semantic similarity ε_{min} between the original input and the generated adversarial example
3. The maximum size K_{syn} of one word's synonym set

Since the average sentence length of IMDb and SST-2 are different, p_{max} is set to 0.1 and 0.15, respectively; ε_{min} is set to 0.84; and K_{syn} is set to 50. All settings are referenced from previous work.

4.3 Adversarial Training Baselines

We use BERT$_{base}$ (Devlin et al., 2019) as the base model to evaluate the impact of the following variants of adversarial training on accuracy and robustness and provide a comprehensive comparison with our proposed GAT.

- Adversarial Data Augmentation
- ASCC (Dong et al., 2021)
- DNE (Zhou et al., 2021)
- InfoBERT (Wang et al., 2021)
- TAVAT (Li and Qiu, 2021)
- FreeLB (Zhu et al., 2020)
- FreeLB++ (Li et al., 2021)

ASCC and DNE adopt a convex hull during training. InfoBERT improves robustness using mutual information. TAVAT establishes a token-aware robust training framework. FreeLB++ removes the norm bounded projection and increases search steps.

We only compare GAT with adversarial training-based defense methods and leave comparisons with other defense methods (e.g., certified defenses) for future work.

4.4 Implementation Details

We implement ASCC, DNE, InfoBERT, and TAVAT models based on TextDefender (Li et al., 2021). We implement FGM, FreeLB, FreeLB++, and our GAT based on HuggingFace Transformers.[1] We implement ADA and FADA based on TextAttack (Morris et al., 2020).[2] All the adversarial hyper-parameters settings are following their original papers. All the models are trained on two GeForce RTX 2080 GPUs and eight Tesla T4 GPUs.

Regarding the training settings and hyper-parameters, the optimizer is AdamW (Loshchilov and Hutter, 2019); the learning rate is $2e^{-5}$; the number of epochs is 10; the batch size is 64 for

4.5 Main Results

Our proposed GAT can easily combine with other adversarial training methods. In our experiments, we combine GAT with FGM (GAT$_{FGM}$) and FreeLB++ (GAT$_{FreeLB++}$), respectively. We aim to evaluate if GAT can bring improvements to the simplest (FGM) and the most effective (FreeLB++) AT methods.

We summarize the main defense results on the SST-2 dataset in Table 2. When GAT works with the simplest adversarial training method, FGM, the resulting robustness improvement exceeds FreeLB++50. The effectiveness and efficiency of GAT allow us to obtain strong robustness while saving many search steps. Further combining FreeLB++ on GAT can obtain stronger robustness and outperform all other methods.

Regarding the accuracy, FreeLB++30 obtains the highest 93.4%. GAT also significantly improves accuracy.

In addition, ADA is effective in improving robustness but hurts accuracy. It is not surprising that ASCC and DNE suffer from significant performance losses. However, there is no improvement in robustness and even weaker robustness under TextFooler and TextBugger attacks than the other methods.

Table 3 shows the defense results on the IMDb dataset. The defense performances are generally consistent with that on the SST-2 dataset. It is worth noting that GAT$_{FGM}$ achieved an extremely high **RA %** with a medium **#Query**, which needs further exploration.

AWS	**AT method**	**Clean %**	**RA %**	**#Query**
None	None	92.4	38.5	44.3
None	FGM	92.5	39.6	44.7

Table 4: Ablation studies on the SST-2 dataset. The attacking method is TextBugger. We only report **RA %** and **#Query** due to the space limit. "AWS" means adversarial word substitution methods.

5 Discussions

We further explore other factors that affect robustness and provide comprehensive empirical results.

5.1 Ablation Studies

We conduct ablation studies on the SST-2 dataset to assess the impact of each component of GAT.

As shown in Table 4, "FADA" consistently outperforms "ADA" and "None" with different adversarial training methods. Furthermore, "FADA&FGM" achieve a higher **RA%** than "None&FreeLB++30", which implies that "FADA" can obtain strong robustness in one adversarial search step. "ADA" also helps improve robustness. However, as the number of search steps in-

Table 5: The defense results of different AT methods against two combinatorial optimization attacks. We remove **ASR %** due to the space limit.

creases, so does the hurt it does to **Clean %**. On the contrary, "FADA" does not harm **Clean %** but improves it, implying its friendliness.

5.2 Results with Other Attacks

We have shown that GAT brings significant improvement in robustness against three greedy-based attacks. We investigate whether GAT is effective under combinatorial optimization attacks, such as PSO (Zang et al., 2020) and FastGA (Jia et al., 2019).

We can see from Table 5 that GAT$_{FreeLB++}$30 obtain the highest **RA %** against the two attacks and GAT$_{FreeLB++}$10 has the highest clean accuracy. The results demonstrate that our proposed GAT consistently outperforms other defenses against combinatorial optimization attacks.

5.3 Results with More Steps

As we claim in Section 1, the accuracy should degrade with a large number of search steps. But what happens for robustness?

We aim to see if **RA %** can be further improved. Figure 3(a) shows that the **RA %** gradually increases against TextFooler and TextBugger attacks. However, **RA %** decreases against BAE with steps more than 30, which needs more investigation. As the steps increase, the growth rate of **RA %** decreases, and the **Clean %** decreases. We conclude that a reasonable number of steps will be good for both **RA %** and **Clean %**. It is unnecessary to search for too many steps since robustness grows very slowly in the late adversarial training period while accuracy drops.

5.4 Impact of Step Size

A large step size (i.e., adversarial learning rate) will cause performance degradation for conventional adversarial training. Nevertheless, what impact does it have on robustness? We explore the impact of different step sizes on robustness and accuracy. As shown in Figure 3(b), the clean test accuracy slightly drops as the step size increases. The robust accuracy under TextFooler attack increases, while the robust accuracy under Textbugger and BAE attacks decrease. Overall, the impact of step size on robustness needs further study.

5.5 Impact of Training Epochs

Ishida et al. (2020) have shown that preventing further reduction of the training loss when reaching a small value and keeping training can help generalization. In adversarial training, it is naturally hard to achieve zero training loss due to the insufficient capacity of the model (Zhang et al., 2021).

Therefore, we investigate whether more training iterations result in stronger robustness in adversarial training. We report the **RA %** achieved by GAT$_{FreeLB++}$30 at each epoch in Figure 3(c). We observe that the **RA %** tends to improve slowly,

implying that more training iterations result in stronger model robustness using GAT.

5.6 Results with Other Models

We show that GAT can work on more advanced models. We choose RoBERTa$_{base}$ (Liu et al., 2019) and DeBERTa$_{base}$ (He et al., 2021), two improved versions of BERT, as the base models. As shown in Table 6 and Table 7, GAT slightly improve robustness of RoBERTa and DeBERTa models.

5.7 Limitations

We discuss the limitations of this work as follows.

- As we clarify in Section 3.2.2, instead of dynamically generating friendly adversarial data in training, we choose to pre-generate static augmentation. We do this for efficiency, as dynamically generating discrete sentences in training is computationally expensive. Although it still significantly improves robustness in our experiments, such a tradeoff may lead to failure because the decision boundary changes continuously during training.

- GAT performs adversarial training on friendly adversarial data. It may help if we consider the decision boundaries when performing gradient-based adversarial training—for example, stopping early when the adversarial data crosses the decision boundary. We consider this as one of the directions for future work.

6 Conclusion

In this paper, we study how to improve robustness from a geometry-aware perspective. We first propose FADA to generate friendly adversarial data that are close to the decision boundary. Then we combine gradient-based adversarial training methods on FADA to save a large number of search steps, termed geometry-aware adversarial training (GAT). GAT can efficiently achieve state-of-the-art defense performance without hurting test accuracy.

We conduct extensive experiments to give in-depth analysis, and we hope this work can provide helpful insights on robustness in NLP.

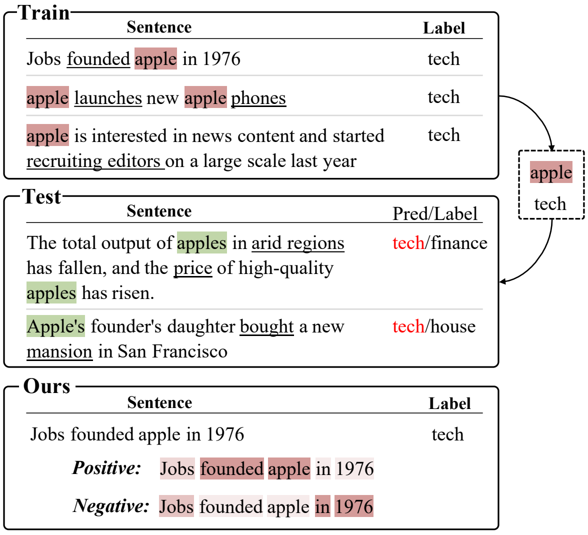
Abstract

Pretrained language models (PLMs) trained on large-scale unlabeled corpus are typically fine-tuned on task-specific downstream datasets, which have produced state-of-the-art results on various NLP tasks. However, the data discrepancy issue in domain and scale makes fine-tuning fail to efficiently capture task-specific patterns, especially in the low data regime. To address this issue, we propose **T**ask-guided **D**isentangled **T**uning (**TDT**) for PLMs, which enhances the generalization of representations by disentangling task-relevant signals from the entangled representations. For a given task, we introduce a learnable confidence model to detect indicative guidance from context, and further propose a disentangled regularization to mitigate the over-reliance problem. Experimental results on GLUE and CLUE benchmarks show that TDT gives consistently better results than fine-tuning with different PLMs, and extensive analysis demonstrates the effectiveness and robustness of our method. Code is available at https://github.com/lemon0830/TDT.

1 Introduction

In recent years, pretrained language models (PLMs) trained in a self-supervised manner like mask language modeling have achieved promising results on various natural language processing (NLP) tasks (Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019b), which learn general linguistic and semantic knowledge from massive general corpus. To adapt PLMs to specific NLP tasks, a commonly-used approach is fine-tuning, where the whole or part of model parameters are tuned by task-specific objectives. Despite its success, the fine-tuned models have been proven ineffective to capture task-specific patterns due to the gap between task-agnostic pre-training and the weak fine-tuning with limited task-specific data (Gu et al., 2020; Gururangan et al., 2020; Kang et al., 2020).



Sentence	Label
Jobs founded apple in 1976	tech
apple launches new apple phones	tech
apple is interested in news content and started recruiting editors on a large scale last year	tech

Sentence	Pred/Label
The total output of apples in arid regions has fallen, and the price of high-quality apples has risen.	tech/finance
Apple's founder's daughter bought a new mansion in San Francisco	tech/house

Sentence	Label
Jobs founded apple in 1976	tech

Positive: Jobs founded apple in 1976

Negative: Jobs founded apple in 1976

Figure 1: **An over-reliance example of news classification task**. The fine-tuned models tend to learn a simple rule that “Apple” (red) indicates “tech” class while ignore the real meaning of “apples” (green) A reliable model is expected to find out truly task-specific patterns (underlined words) instead of some high frequency but insignificant words (“apple”).

To address this problem, most existing methods focus on adapting PLMs to downstream tasks by continual pre-training on in-domain unsupervised data (Gururangan et al., 2020; Gu et al., 2020; Wu et al., 2021; Kang et al., 2020; Ye et al., 2021). For example, Gu et al. (2020) propose intermediate continual pre-training with a selective masking strategy, and Gururangan et al. (2020) adapt PLMs to in-domain tasks by domain-adaptive pretraining. Although straightforward, these kinds of methods heavily rely on the selection of large-scale additional domain corpora and the design of appropriate intermediate training tasks (Wang et al., 2019; Aghajanyan et al., 2021a).

In this paper, we propose a **T**ask-guided **D**isentangled **T**uning (**TDT**) for PLMs by automatically detecting task-specific informative inputs without the need of additional corpora and inter-

May 22-27, 2022 ©2022 Association for Computational Linguistics

mediate training. The core component of TDT is a confidence model which assigns each token a confidence score, and we construct distilled samples by retaining informative tokens with high confidence scores while perturbing the rest. The confidence model performs a "deletion game" strategy, which encourages the model to perturb inputs as much as possible and to maintain the performance of downstream tasks to the greatest extent with the distilled samples. Although the informative tokens are important for downstream predictions, existing work shows that over-relying on part of these words may result in pool generalization, i.e., over-reliance problem (Moon et al., 2020; Geirhos et al., 2020; Sun et al., 2019). Take the sentences in Figure 1 as an example, when the context word "Apple" frequently co-occurs with the label "tech", fine-tuned models may learn a spurious association by binding "Apple" and "tech", leading to incorrect predictions of sentences which contain "apple" but belong to other categories.

Based on the observation, we further enhance our method with a disentangled regularization, aiming to distinguish task-relevant and task-irrelevant features. First, we construct two variants of the original input in a complementary view: (1) *positive* variant, which maintains the high-confidence keywords, and (2) *negative* variant, derived by a "cut-out-keyword" operation on the original input. Next, we propose a "triplet-style loss", which makes predictions between the *original* input and the *positive* variant similar while the predictions between the *negative* variant and the other two different. To illustrate the mechanism of our disentangled regularization, we go back to Figure 1 and take the sentence "Jobs founded apple in 1976" as an example. Under the influence of the disentangled regularization, the *positive* variant tends to retain clue words for predictions (i.e., "founded apple"), while the *negative* variant, as the complement (i.e., "Jobs in 1976"), tends to be task-irrelevant.

We evaluate our TDT on a wide range of neural language understanding benchmark datasets in English and Chinese, i.e., GLUE and CLUE, and our TDT affords strong predictive performance compared with standard fine-tuning. Moreover, we conduct extensive analysis with respect to robustness to perturbation, domain generalization, and low-resource settings, from which we conclude:

- TDT learns reasonable confidence scores for input tokens.
- TDT is robust to input perturbation and domain shift by encouraging the model to learn more generalized features.
- TDT effectively captures the high-confidence decisive cues for downstream tasks, thus alleviating over-fitting in low-resource scenarios.

2 Method

In this section, we begin with a brief introduction of the vanilla Fine-tuning, and then introduce **T**ask-guided **D**isentangled **T**uning (**TDT**) in detail. Figure 2 shows the overall framework. **TDT** is composed of two parts: (1) token-level confidence model, which discovers the essential parts of inputs for the model prediction; (2) task-guided regularization, which promotes the model to decouple task-relevant keywords from non-keyword context.

2.1 Vanilla Fine-tuning

Given an example of training data $< X, y >$, where X=$\{x_1, ..., x_i, ..., x_n\}$ is the input sequence and y is its corresponding label. We first map each token x_i to a real-valued vector e_i by an embedding layer. Then, the packed embedding output E=$\{e_i\}$ is fed into the PLM to get the contextualized sentence representations H=$\{h_{cls}, h_1, ..., h_n\}$, and the hidden state h_{cls} is used to conduct classification with a MLP head. We fine-tune the parameters of the PLM with the cross entropy loss:

$$\mathcal{L}_{cla} = -\log P(y|H). \tag{1}$$

2.2 Token-level Confidence Model

For each token x_i, we generate a scalar $c_i \in [0, 1]$, coined confidence score, by stacking a single-layer feed-forward network with *sigmoid* activation on the top of the embedding layer:

$$c_i = \sigma(We_i + b), \tag{2}$$

where W and b are trainable parameters. Based on the confidence score, we obtain a distilled sample $\{e_i^+\}$ defined as

$$e_i^+ = c_i \odot e_i + (1 - c_i) \odot \mu_0, \tag{3}$$

where μ_0 is a perturbation term and $\odot$ denotes element-wise multiplication. Specifically, the perturbation term μ_0 can be a zero vector, a random Gaussian noise vector, or the average of the token

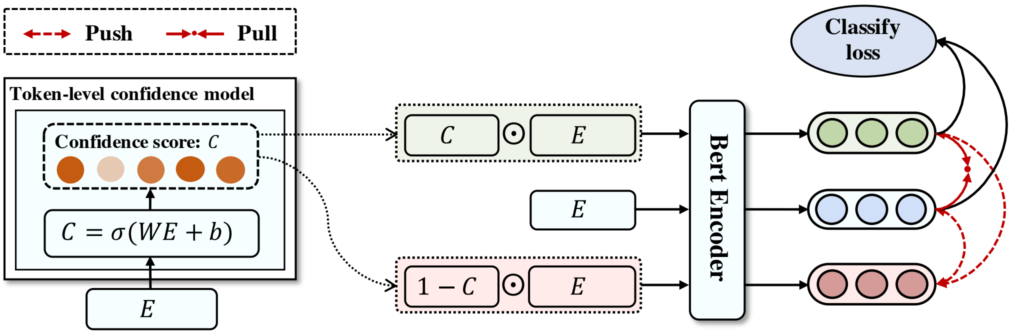

Figure 2: The overall framework of our proposed Task-guided Disentangled Tuning method.

embedding, and we choose the last one in this paper. In this manner, for the distilled sample of each training instance, the higher the c_i is, the more semantic information of the i-th token retains, while the tokens with lower scores are perturbed.

Then, the distilled sample $\{e_i^+\}$ is fed into the PLM to generate the sentence representations H^+=$\{h_i^+\}$. Inspired by "deletion game" (Fong and Vedaldi, 2017; Voita et al., 2019), the objective function of the confidence model is

$$\mathcal{L}_C = -\log P(y|H^+) + \gamma||C||_2, \qquad (4)$$

where $C = \{c_i\}$ is the set of confidence scores of X. The first term is the cross entropy loss of classification on the distilled sample to encourage the confidence model to assign higher scores to the more decisive part of the input, and the second term serves as a penalty to prevent the model from mode collapsing (i.e., always choosing c_i=1).

2.3 Task-Guided Regularization

It has been widely observed that the pretrained models tend to learn an easy-to-learn but not generalizable solution by vanilla fine-tuning on various NLP tasks (Sun et al., 2019; McCoy et al., 2019; Min et al., 2019; Niven and Kao, 2019). To alleviate this issue, we further propose a triplet-style loss on the model predictions.

Specifically, for each input sequence, we derive two different variants: a *positive* variant and a *negative* variant. The *positive* variant is expected to maintain the most informative tokens to task prediction and vice versa. As aforementioned, our confidence model removes the meaningless tokens by setting the corresponding confidence scores to zero. Based on the confidence scores, we directly treat the distilled sample generated by Eq. 3 as the *positive* variant and generate the *negative* variant as

$$e_i^- = (1 - c_i) \odot e_i. \qquad (5)$$

Given the original input and the two derived variants, we feed them into the PLM with the classifier, and obtain three prediction distributions $P(y|H)$, $P(y|H^+)$, and $P(y|H^-)$. Finally, we regularize these distributions by a triplet ranking loss

$$\begin{aligned}\mathcal{L}_R = \max(m + d(P(y|H^+), P(y|H)) - \\ d(P(y|H^-), P(y|H)) - \\ d(P(y|H^-), P(y|H^+)), 0) \quad (6)\end{aligned}$$

where m is a hyperparameter indicating a margin for the loss and $d(\cdot)$ denotes the Kullback-Leibler (KL) divergence. By minimizing $\mathcal{L}_R$, the positive variant will be closer to the original input while the negative variant will be farther from the other two. Thus, the model is encouraged to disentangle task-relevant signals from task-irrelevant factors, and generate more general representations.

2.4 Overall Training Objective

The final training objective is

$$\mathcal{L} = \mathcal{L}_{cla} + \alpha\mathcal{L}_C + \beta\mathcal{L}_{\mathcal{R}}, \qquad (7)$$

where α and β are non-negative hyper-parameters to balance the effect of each loss term.

3 Experiments

3.1 Datasets

We evaluate our proposed method by fine-tuning the pretrained models on the General Language Understanding Evaluation (GLUE) (Wang et al., 2018) and the Chinese Language Understanding Evaluation (CLUE) (Xu et al., 2020). Concretely, the GLUE benchmark has 8 different text classification or regression tasks including MNLI, MRPC, QNLI, QQP, RTE, SST-2, SST-B, and CoLA. The CLUE benchmark includes 9 tasks spanning several single-sentence/sentence-pair classification tasks, and we choose 5 tasks, OCNLI, IFLYTEK, CSL, TNEWS,

and AFQMC. The detailed data statistics and metrics are provided in Appendix A.

3.2 Model & Training

We use the pretrained models and codes provided by HuggingFace[1]. We take BERT-base (Devlin et al., 2019), BERT-large (Devlin et al., 2019) and RoBERTa-large (Liu et al., 2019b) as our backbones on GLUE, while BERT-wwm-base (Cui et al., 2019), MacBERT-large (Cui et al., 2020), and RoBERTa-wwm-large (Cui et al., 2019) on CLUE. We tune the task specific hyper-parameters $m \in \{0, 2\}$, $\alpha \in \{0.5, 2, 4\}$ and $\beta \in \{0.5, 1\}$. Detailed experimental setups are shown in Appendix B. Following previous work (Lee et al., 2020; Aghajanyan et al., 2020), we report results of the development sets, since the performance on the test sets is only accessible on the leaderboard with a limitation of the number of submissions.

3.3 Main Results

Results on GLUE. We illustrate the experimental results on the GLUE benchmark in Table 1. We can observe that the PLMs enhanced by *TDT* outperforms *FineTuning* by a large margin across all the tasks. Specifically, *TDT*s achieve 1.48 points, 1.19 points and 0.88 points (on average) improvement over BERT-base, BERT-large, and RoBERTa-large, respectively. In particular, *BERT-base+TDT* achieves competitive performance compared with *BERT-large+FineTuning*, showing that our method

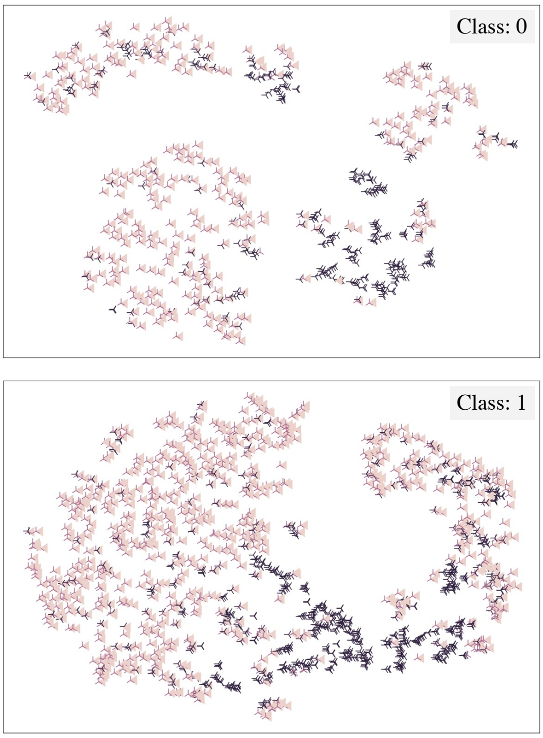

Figure 3: **Visualization of representations** of original input and two derived variants, where the triangle-shaped (pink), tri-up-shaped (purple), and tri-left-shaped (black) points denote the representations of *original input*, *positive variants*, and *negative variants*, respectively.

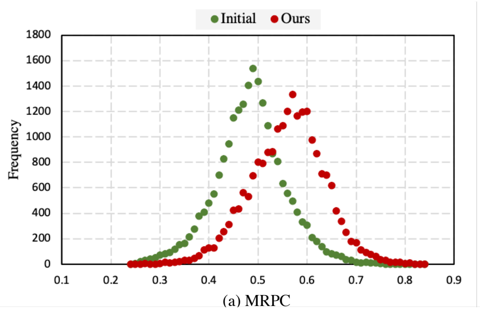
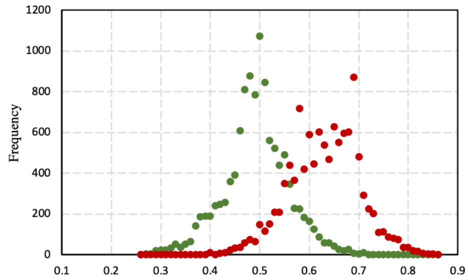
is more efficient to find task-specific information for downstream tasks. This may be because our training strategy prompts the models to predict with as little information as possible, isolating the task-related signals from the whole representations.

RoBERT-large trained with *TDT* surpasses XLNet-large (Yang et al., 2019) ALBERT-xxlarge (Lan et al., 2019), DeBERTa-large (He et al., 2020), and ELECTRA-large (Clark et al., 2020), which are specially designed with different architectures and pre-training objectives.

Results on CLUE. Table 2 shows the overall results on the 5 tasks of CLUE benchmark. Concretely, *TDT* significantly outperforms *FineTuning* on CSL, IFLYTEK, AFQMC, and OCNLI, and shows competitive results on the short text classification task TNEWS, indicating the advantage of extracting important parts from long text or multiple input sequences. Note that TNEWS generally requires additional knowledge (e.g., keywords) as a supplement due to the short input, and thus cannot show the superiority of *TDT*.



(a) MRPC



(b) CoLA

Figure 4: **Distribution of confidence scores** on MRPC and CoLA dev sets.

4 Analysis & Discussion

4.1 Visualization of Representations

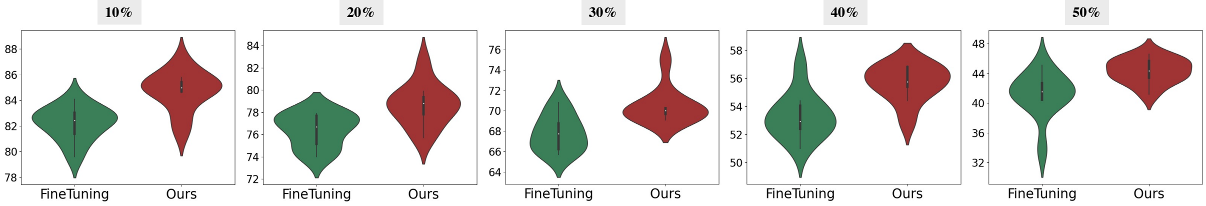
In Figure 3, we plot t-SNE visualizations (van der Maaten and Hinton, 2008) of three kinds of representations generated by BERT-large trained with TDT on CoLA dev set. We can see that the representations of the original input are close to those of the positive variant in the same class. Although the negative variant representations are really similar to the original ones which derive the former, they are clearly separated from the other representations. The learned disentangled representations reveal that **the model trained with TDT is able to distinguish task-specific keywords and non-keyword context, which plays an important role in increasing models' robustness**.

4.2 Distribution of Confidence Scores

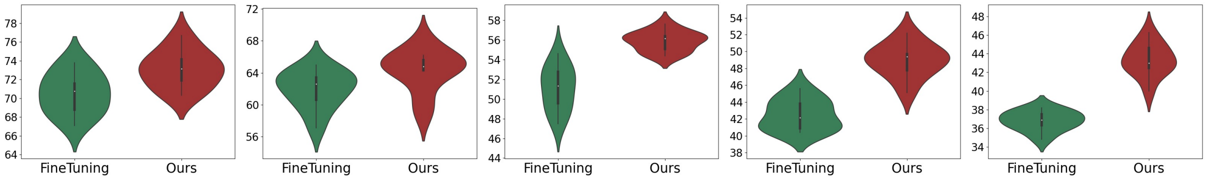
We investigate the learned confidence score distributions in Figure 4. It shows that although the initial distribution is consistent, the model learns different task-specific patterns (confidence distributions) on different tasks.

4.3 Does our Confidence Model make a meaningful estimation for input tokens?

In section 2.2, we mention that TDT uses a scalar for evaluating the contribution of each input token. To analyze whether the strategy can successfully learn a meaningful importance estimation, we con-



(a) Replacing token with "[MASK]"



(b) Replacing token with a sampled word

Figure 5: **Robustness to Input Perturbation**. The Y-axis is the accuracy on the development set.

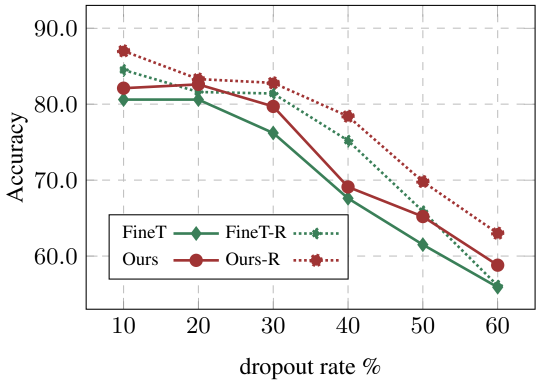


Figure 6: **Accuracy of BERT-large trained with different methods and evaluated on MPRC dev set with different drop rates**. We denote vanilla fine-tuning as FineT. The solid lines indicate results on the datasets constructed by dropping tokens in descending order of confidence scores. The dotted lines denotes results on the datasets constructed by dropping tokens in increasing order of confidence scores.

Task	FineTuning	TDT	Δ
MNLI (*BERT-large*)			
MNLI-m	85.8	86.4	**+0.6**
QQP	73.1	74.2	**+1.1**
OCNLI (*MacBERT-large*)			
CMNLI	70.6	71.8	**+1.2**
BUSTM	64.8	66.4	**+1.6**

Table 3: **Performance of Domain Generalization**. The models are trained on MNLI/OCNLI but tested on out-of-domain data.

struct two sets of datasets based on MRPC dev set and then evaluate the performance of BERT-large with TDT and standard fine-tuning. Specifically, we convert the confidence scores to probability distributions. We generate the first set of datasets by dropping input tokens in descending order of the distributions and generate the second set in ascending order. In order to ensure language fluency, we replace each dropped token with a "[MASK]" token. The results are shown in Figure 6 and we observe that:

- **TDT is more robust to incomplete input compared with Fine-tuning.** Specifically, although the performance of both *FineTuning* and *TDT* drops with the increase of dropout rate, our *TDT* achieves significantly better performance than *FineTuning* over all datasets.

- **Our learned confidence scores make reasonable assessments for each input token.** Particularly, regardless of the dropout rates and the training methods, dropping input tokens by the descending order of the masking scores always leads to worse performance.

4.4 Robustness to Input Perturbation

Based on the observation in Section 4.3, we further investigate the robustness of TDT on perturbed data. To construct perturbed data, we use the dev set of MRPC and possibly replace the input at each position with a "[MASK]" token or a token sampled from the input sequence. For each dropout rate, we construct 10 datasets with different random seeds and draw violin plots of the performance of BERT-large trained with TDT and fine-tuning (Figure 5). We can see that *Ours* is consistently better than *FineTuning* in all groups, indicating the superior robustness to noisy data.

Task	FineTuning	TDT	Δ
	CLUE (*MacBERT-large*)		
OCNLI	60.85 (±2.66)	63.38 (±0.90)	**+2.53**
IFLYTEK	54.12 (±0.75)	54.78 (±0.94)	**+0.66**
CSL	80.25 (±1.36)	81.45 (±0.62)	**+1.20**
TNEWS	53.50 (±0.58)	53.33 (±0.25)	**-0.17**
AFQMC	64.77 (±3.87)	66.45 (±0.93)	**+1.68**
Avg	62.70	63.88	**+1.18**

Table 4: **Experimental results in low-resource scenarios**. We run 4 times for each task with different random seeds and report the average accuracy and the standard deviation.

4.5 Domain Generalization

We evaluate how well the trained models generalizes to out-of-domain data on MNLI and OCNLI, Natural Language Inference (NLI) tasks of GLUE and CLUE respectively. In detail, we fine-tune BERT-large on MNLI, and test the accuracy of the fine-tuned models on other NLI datasets in different domains including MNLI-mismatch[2] and QQP. Besides, we fine-tune MacBERT-large on OCNLI and conduct an evaluation on CMNLI[3] and BUSTM[4]. Detailed of Label Mapping is provided in Appendix C. As Tabel 3 illustrates, TDT outperforms vanilla fine-tuning across different out-of-domain datasets. The results suggest that **TDT encourages the model to learn more generalized features rather than some superficial contextual cues unique to training data**.

4.6 Results in Low-resource Scenarios

Fine-tuning PLMs on very small amount of training data can be challenging and result in unstable performance due to the serious over-fitting issue. In this section, we explore the effectiveness of TDT in such scenarios. For each dataset in CLUE, we use MacBERT-large and sample 1k training examples as its training data. As Table 4 demonstrates, *TDT* improves the accuracy by 1.18 on average and reduces the standard deviation by up to 2.94. It suggests that **our TDT is more stable and efficient than vanilla fine-tuning when training PLMs on limited data**.

4.7 Compared with Variants

Ablation Studies. We first conduct ablation studies to explore the effectiveness of two additional loss functions introduced in this paper and show the results in Table 5. We find that removing any of them leads to a performance drop, which indicates their effectiveness on regularization for training.

Soft Perturbation vs. Hard Perturbation. The confidence score in this paper is continuous value ranging from 0 to 1, and we perturb the input in a soft way. It is straightforward to investigate the discrete counterpart. To this end, we model the discrete confidence score with the Gumbel-Softmax trick (Jang et al., 2017). More detailed is introduced in Appendix D. We denote the model trained with the hard strategy as TDT-*hard* and show the comparison in Table 5. From the table, both TDT-*hard* and TDT yield better performance than vanilla fine-tuning. This observation supports our claim that different tokens or phrases contribute differently to the final results, which can be detected by task-guided signal and then used to model more reliable encoders by our proposed regularization. Moreover, the inferior performance of TDT-*hard* shows that naively removing tokens has an adverse effect on context modeling and thus it is better to regularize the over-reliance in a soft manner.

4.8 Compared with Previous Methods

TDT vs. Token Cutoff. Our method can also be viewed as a soft variant of token cutoff (Shen et al., 2020), which is a data augmentation strategy. Table 5 shows the results where we find that *TDT* performs better than *TokenCutoff*, which demonstrates that the improvement of our method is not entirely due to the effect of data augmentation but stems from the design of the training objectives.

TDT vs. R-drop & R3F. Recently, Liang et al. (2021) proposed R-drop to regularize the consistency of sub-models obtained through dropout. Aghajanyan et al. (2021b) introduced R3F rooted in trust region theory, which adds noise into the input embedding and minimize the KL divergence between prediction distributions given original input and noisy input. Both of them are task-agnostic, while our proposed method constructs two derived variants with task signal, and concentrates on how to disentangle the task-relevant and task-irrelevant factors. The better performance of TDT compared with the strong R-drop and R3F baselines (Table 5)

verify the advantage of task-driven regularization.

TDT vs. Post-Training. Post-training is an effective approach to reduce the objective gap between pretrained model and downstream tasks (Gu et al., 2020), which continues to train PLMs on task (or in-domain) training data with mask language model (MLM) loss. The difference lies in that we focus on the fine-tuning stage. Here, we compare TDT with the model first post-trained via MLM on training set of each task and then fine-tuned. It is surprising that post-training does not always have a positive effect on downstream fine-tuning, while TDT shows effective performance without additional post-training time consumption.

5 Related Work

Fine-tuning large-scale PLMs tends to be a popular paradigm of various NLP tasks (Devlin et al., 2019; Liu et al., 2019a; Yang et al., 2019). However, the fine-tuned models fail to capture task-specific patterns due to the imbalanced nature between the large number of parameters and limited training data (Aghajanyan et al., 2020). To address this issue, two main research lines are proposed: (1) continual pretraining after general pre-training, (2) regularization techniques in fine-tuning.

Continual pretraining of PLMs on unlabeled data of a given downstream domain or task has been proved effective for the end-task performance (Gururangan et al., 2020), and various continual pre-training objectives designed for different downstream tasks have been proposed (Tian et al., 2020; Wu et al., 2021). For example, Gu et al. (2020) propose a selective masking strategy to learn task-specific patterns based on mid-scale in-domain data. However, such methods usually rely on extra in-domain data and manually designed training objectives.

Due to the overfitting problems of fine-tuning, lots of regularization techniques have been proposed. Lee et al. (2019) and Chen et al. (2020) regularize fine-tuned weights with original pretrained weights while others design adversarial training objectives or introduce noise into the input (Zhu et al., 2020; Jiang et al., 2020; Aghajanyan et al., 2020; Shen et al., 2020; Yu et al., 2021; Hua et al., 2021; Qu et al., 2020). Liang et al. (2021) regularize the training by minimizing the KL-divergence between the output distributions of two sub-models sampled by dropout and Xu et al. (2021b) only updates a sub-set of the whole network during fine-tuning by selectively masking out the gradients in both task-free and task-driven ways. Moon et al. (2020) handle the over-reliance problem by reconstructing keywords based on other words and making low-confidence predictions without enough context.

6 Conclusion

In this paper, we propose task-guided disentangled tuning for enhancing the efficiency and robustness of PLMs in downstream NLP tasks. Our method is able to efficiently distinguish task-specific features and task-agnostic ones, and bridges the gap between pretraining and adaptation without the need of immediate continual training. Experiments on GLUE and CLUE benchmarks demonstrate the effectiveness of our method, and extensive analysis shows the advantage in domain generalization and low-resource setting over fine-tuning.

Table 7: Hyperparameters settings for different pretrained models on variant tasks.

B Settings for Different Pretrained Models

In this paper, we fine-tuned different pretrained models with TDT, including BERT-base, BERT-large, RoBERTa-large for GLUE and BERT-wwm-base, MacBERT-large, RoBERTa-wwm-large for CLUE. The batch size, training steps, warmup steps, and learning rate are listed in Table 7.

C Label Mapping in Domain Generalization

QQP has two labels, *duplicate* and *not duplicate*. We map *entailment* to *duplicate* and map both *neutral* and *contradiction* to *not duplicate*. BUSTM [5] is a short text matching task of FewCLUE (Xu et al., 2021a). We use the public test set. BUSTM has two labels, *0* and *1*. We map *entailment* to label *1*, and map both *neutral* and *contradiction* to label *0*.

D Detailed of TDT-*hard*

Gumbel-Softmax trick (Jang et al., 2017) is an approximation to sampling from the *argmax*. Formally, we replace Eq. 2 by:

$$c_i = \operatorname{argmax}(\sigma_{\text{Gumbel}}(z(e_i))), \tag{8}$$

$$\sigma_{\text{Gumbel}}(z_i) = \frac{\exp((log(z_i) + g_i)/\tau)}{\sum_{j=1}^{K} \exp((log(z_j) + g_j)/\tau)}, \tag{9}$$

where $g_i \sim$ Gumbel(0,1), $z(\cdot)$ returns the logits produced for a given input, and τ is the temperature. By this way, if c_i is 0, the embedding of the i-th token is set to the embedding of the "[MASK]" token, otherwise the embedding remains unchanged.

Abstract

Contrastive learning is emerging as a powerful technique for extracting knowledge from unlabeled data. This technique requires a balanced mixture of two ingredients: positive (similar) and negative (dissimilar) samples. This is typically achieved by maintaining a queue of negative samples during training. Prior works in the area typically uses a fixed-length negative sample queue, but how the negative sample size affects the model performance remains unclear. The opaque impact of the number of negative samples on performance when employing contrastive learning aroused our in-depth exploration. This paper presents a momentum contrastive learning model with negative sample queue for sentence embedding, namely MoCoSE. We add the prediction layer to the online branch to make the model asymmetric and together with EMA update mechanism of the target branch to prevent the model from collapsing. We define a maximum traceable distance metric, through which we learn to what extent the text contrastive learning benefits from the historical information of negative samples. Our experiments find that the best results are obtained when the maximum traceable distance is at a certain range, demonstrating that there is an optimal range of historical information for a negative sample queue. We evaluate the proposed unsupervised MoCoSE on the semantic text similarity (STS) task and obtain an average Spearman's correlation of 77.27%. Source code is available here.

1 Introduction

In recent years, unsupervised learning has been brought to the fore in deep learning due to its ability to leverage large-scale unlabeled data. Various unsupervised contrastive models is emerging, continuously narrowing down the gap between supervised and unsupervised learning. Contrastive learning suffers from the problem of model collapse, where the model converges to a constant value and the samples all mapped to a single point in the feature space. Negative samples are an effective way to solve this problem.

In computer vision, SimCLR from Chen (Chen et al., 2020) and MoCo from He (He et al., 2020) is known for using negative samples and get the leading performance in the contrastive learning. SimCLR uses different data augmentation (e.g., rotation, masking, etc.) on the same image to construct positive samples, and negative samples are from the rest of images in the same batch. MoCo goes a step further by randomly select the data in entire unlabeled training set to stack up a first-in-first-out negative sample queue.

Recently in natural language processing, contrastive learning has been widely used in the task of learning sentence embedding. One of current state-of-the-art unsupervised method is SimCSE (Gao et al., 2021). Its core idea is to make similar sentences in the embedding space closer while keeping dissimilar away from each other. SimCSE uses dropout mask as augmentation to construct positive text sample pairs, and negative samples are picked from the rest of sentences in the same batch. The mask adopted from the standard Transformer makes good use of the minimal form of data augmentation brought by the dropout. Dropout results in a minimal difference without changing the semantics, reducing the negative noise introduced by augmentation. However, the negative samples in SimCSE are selected from the same training batch with a limited batch size. Our further experiments show that SimCSE does not obtain improvement as the batch size increases, which arouses our interest in using the negative sample queue.

To better digging in the performance of contrastive learning on textual tasks, we build a contrastive model consisting of a two-branch structure and a negative sample queue, namely MoCoSE

(**Mo**mentum **Co**ntrastive **S**entence **E**mbedding with negative sample queue). We also introduce the idea of asymmetric structure from BYOL (Grill et al., 2020) by adding a prediction layer to the upper branch (i.e., the online branch). The lower branch (i.e., the target branch) is updated with exponential moving average (EMA) method during training. We set a negative sample queue and update it using the output of target branch. Unlike directly using negative queue as in MoCo, for research purpose, we set an initialization process with a much smaller negative queue, and then filling the entire queue through training process, and update normally. We test both character-level (e.g., typo, back translation, paraphrase) and vector-level (e.g., dropout, shuffle, etc.) data augmentations and found that for text contrastive learning, the best results are obtained by using FGSM and dropout as augmentations.

Using the proposed MoCoSE model, we design a series of experiments to explore the contrastive learning for sentence embedding. We found that using different parts of samples from the negative queue leads to different performance. In order to test how much text contrastive learning benefit from historical information of the model, we proposed a maximum traceable distance metric. The metric calculates how many update steps before the negative samples in the queue are pushed in, and thus measures the historical information contained in the negative sample queue. We find that the best results can be achieved when the maximum traceable distance is within a certain range, reflected in the performance of uniformity and alignment of the learned text embedding. Which means there is an optimal interval for the length of negative sample queue in text contrastive learning model.

Our main contributions are as follows:

1. We combine several advantages of frameworks from image contrastive learning to build a more generic text unsupervised contrastive model. We carried out a detailed study of this model to achieve better results on textual data.

2. We evaluate the role of negative queue length and the historical information that the queue contains in text contrastive learning. By slicing the negative sample queue and using different positions of negative samples, we found those near the middle of the queue provides a better performance.

3. We define a metric called 'maximum traceable distance' to help analyze the impact of negative sample queue by combining the queue length, EMA parameter, and batch size. We found that changes in MTD reflects in the performance of uniformity and alignment of the learned text embedding.

2 Related Work

Contrastive Learning in CV

Contrast learning is a trending and effective unsupervised learning framework that was first applied to the computer vision (Hadsell et al., 2006). The core idea is to make the features of images within the same category closer and the features in different categories farther apart. Most of the current work are using two-branch structure (Chen et al., 2021). While influential works like SimCLR and MoCo using positive and negative sample pairs, BYOL (Grill et al., 2020) and SimSiam (Chen and He, 2021) can achieve the same great results with only positive samples. BYOL finds that by adding a prediction layer to the online branch to form an asymmetric structure and using momentum moving average to update the target branch, can train the model using only positive samples and avoid model collapsing. SimSiam explores the possibility of asymmetric structures likewise. Therefore, our work introduces this asymmetric idea to the text contrastive learning to prevent model collapse. In addition to the asymmetric structure and the EMA mechanism to avoid model collapse, some works consider merging the constraint into the loss function, like Barlow Twins (Zbontar et al., 2021), W-MSE (Ermolov et al., 2021), and ProtoNCE (Li et al., 2021).

Contrastive Learning in NLP

Since BERT (Devlin et al., 2018) redefined state-of-the-art in NLP, leveraging the BERT model to obtain better sentence representation has become a common task in NLP. A straightforward way to get sentence embedding is by the $[CLS]$ token due to the Next Sentence Prediction task of BERT. But the $[CLS]$ embedding is non-smooth anisotropic in semantic space, which is not conducive to STS tasks, this is known as the representation degradation problem (Gao et al., 2019). BERT-Flow (Li et al., 2020) and BERT-whitening (Su et al., 2021) solve the degradation problem by post-processing the output of BERT. SimCSE found that utilizing contrasting mechanism can also alleviate this problem.

Data augmentation is crucial for contrastive learning. In CLEAR (Wu et al., 2020), word and phrase deletion, phrase order switching, synonym substitution is served as augmentation. CERT (Fang and Xie, 2020) mainly using back-and-forth translation, and CLINE (Wang et al., 2021) proposed synonym substitution as positive samples and antonym substitution as negative samples, and then minimize the triplet loss between positive, negative cases as well as the original text. ConSERT (Yan et al., 2021) uses adversarial attack, token shuffling, cutoff, and dropout as data augmentation. CLAE (Ho and Nvasconcelos, 2020) also introduces Fast Gradient Sign Method, an adversarial attack method, as text data augmentation. Several of these augmentations are also introduced in our work. The purpose of data augmentation is to create enough distinguishable positive and negative samples to allow contrastive loss to learn the nature of same data after different changes. Works like (Mitrovic et al., 2020) points out that longer negative sample queues do not always give the best performance. This also interests us how the negative queue length affects the text contrastive learning.

3 Method

Figure 1 depicts the architecture of proposed MoCoSE. In the embedding layer, two versions of the sentence embedding are generated through data augmentation ($dropout = 0.1$ and $fgsm = 5e-9$). The resulting two slightly different embeddings then go through the online and target branch to obtain the query and key vectors respectively. The structure of encoder, pooler and projection of online and target branch is identical. We add a prediction layer to the online branch to make asymmetry between online and target branch. The pooler, projection and prediction layers are all composed of several fully connected layers.

Finally, the model calculates contrasting loss between query, key and negative queue to update the online branch. In the process, key vector serves as positive sample with respect to the query vector, while the sample from queue serves as negative sample to the query. The target branch truncates the gradient and updated with the EMA mechanism. The queue is a first-in-first-out collection of negative samples with size K which means it sequentially stores the key vectors generated from the last few training steps.

The PyTorch style pseudo-code for training MoCoSE with the negative sample queue is shown in Algorithm 1 in Appendix A.3.

Data Augmentation Comparing with SimCSE, we tried popular methods in NLP such as paraphrasing, back translation, adding typos etc., but experiments show that only adversarial attacks and dropout have improved the results. We use FGSM (Goodfellow et al., 2015) (Fast Gradient Sign Method) as adversarial attack. In a white-box environment, FGSM first calculates the derivative of model with respect to the input, and use a sign function to obtain its specific gradient direction. Then, after multiplying it by a step size, the resulting 'perturbation' is added to the original input to obtain the sample under the FGSM attack.

$$x' = x + \varepsilon \cdot sign\left(\nabla_x \mathcal{L}\left(x, \theta\right)\right) \tag{1}$$

Where x is the input to the embedding layer, θ is the online branch of the model, and $\mathcal{L}(\cdot)$ is the contrastive loss computed by the query, key and negative sample queue. ∇_x is the gradient computed through the network for input x, $sign()$ is the sign function, and ε is the perturbation parameter which it controls how much noise it added.

EMA and Asymmetric Branches Our model uses EMA mechanism to update the target branch. Formally, denoting the parameters of online and target branch as θ_o and θ_t, EMA decay weight as η, we update θ_t by:

$$\theta_t \leftarrow \eta\theta_t + (1 - \eta)\theta_o \tag{2}$$

Experiments demonstrate that not using EMA leads to model collapsing, which means the model did not converge during training. The prediction layer we added on the online branch makes two branches asymmetric to further prevent the model from collapsing. For more experiment details about symmetric model structure without EMA mechanism, please refer to Appendix A.2.

Negative Sample Queue The negative sample queue has been theoretically proven to be an effective means of preventing model from collapsing. Specifically, both the queue and the prediction layer of the upper branch serves to disperse the output feature of the upper and lower branches, thus ensuring that the contrastive loss obtains features with sufficient uniformity. We also set a buffer for the initialization of the queue, i.e., only a small portion of the queue is randomly initialized at the beginning, and then enqueue and dequeue normally until the end.

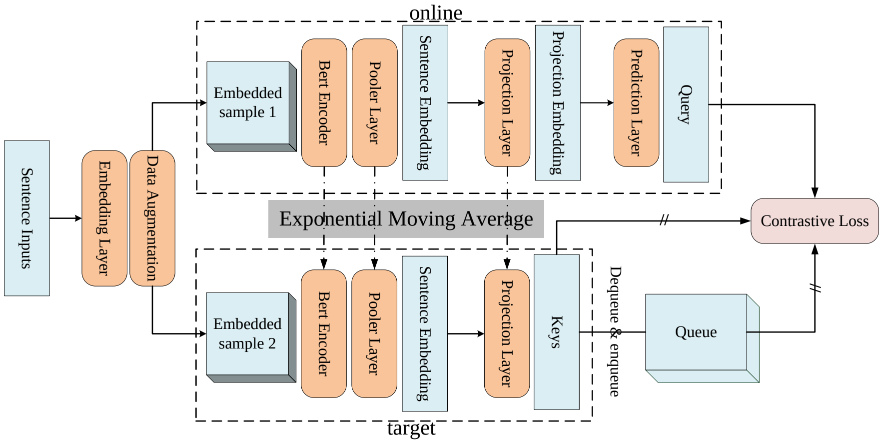

Figure 1: The model structure of MoCoSE. The embedding layer consists of a BERT embedding layer with additional data augmentation. The pooler, projection, and predictor layers all keep the same dimensions with the encoder layer. The MoCoSE minimizes contrastive loss between query, queue and keys (i.e. InfoNCE loss).

Contrastive Loss Similar to MoCo, we also use InfoNCE (Oord et al., 2018) as contrastive loss, as shown in eq.(3).

$$\mathcal{L} = -\log \frac{exp\,(q \cdot k/\tau)}{exp\,(q \cdot k/\tau) + \sum_l exp\,(q \cdot l/\tau)} \tag{3}$$

Where, q refers to the query vectors obtained by the online branch; k refers to the key vectors obtained by the target branch; and l is the negative samples in the queue; τ is the temperature parameter.

4 Experiments

4.1 Settings

We train with a randomly selected corpus of 1 million sentences from the English Wikipedia, and we conduct experiments on seven standard semantic text similarity (STS) tasks, including STS 2012—2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), STSBenchmark (Cer et al., 2017) and SICK-Relatedness (Wijnholds and Moortgat, 2021). The SentEval[1] toolbox is used to evaluate our model, and we use the Spearman's correlation to measure the performance. We start our training by loading pre-trained BERT checkpoints[2] and use the $[CLS]$ token embedding from the model output as the sentence embedding. In addition to the semantic similarity task, we also evaluate on seven transfer learning tasks to test the generalization performance of the model. For text augmentation, we tried several vector-level methods mentioned in ConSERT, including position shuffle, token dropout, feature dropout. In addition, we also tried several text-level methods from the nlpaug[3] toolkit, including synonym replace, typo, back translation and paraphrase.

Training Details The learning rate of MoCoSE-BERT-base is set to 3e-5, and for MoCoSE-BERT-large is 1e-5. With a weight decay of 1e-6, the batch size of the base model is 64, and the batch size of the large model is 32. We validate the model every 100 step and train for one epoch. The EMA decay weight η is incremented from 0.75 to 0.95 by the cosine function. The negative queue size is 512. For more information please refer to Appendix A.1.

4.2 Main Results

We compare the proposed MoCoSE with several commonly used unsupervised methods and the current state-of-the-art contrastive learning method on the text semantic similarity (STS) task, including average GloVe embeddings (Pennington et al., 2014), average BERT or RoBERTa embeddings, BERT-flow, BERT-whitening, ISBERT (Zhang et al., 2020a), DeCLUTR (Giorgi et al., 2021), CT-BERT (Carlsson et al., 2021) and SimCSE.

As shown in Table 1, the average Spearman's correlation of our best model is 77.27%, outperforming unsupervised SimCSE with BERT-base. Our model outperforms SimCSE on STS2012, STS2015, and STS-B, and SimCSE perform better on the STS2013 task. Our MoCoSE-BERT-

Table 2: Performance of MoCoSE on the seven transfer tasks. We compare the performance of MoCoSE and other models on the seven transfer tasks evaluated by SentEval, and MoCoSE remains at a comparable level with the SimCSE.

large model outperforms SimCSE-BERT-Large by about 0.7 on average, mainly on STS12, STS13, and STS14 tasks, and maintains a similar level on other tasks.

Furthermore, we also evaluate the performance of MoCoSE on the seven transfer tasks provided by SentEval. As shown in Table 2, MoCoSE-BERT-base outperforms most of the previous unsupervised method, and is on par with SimCSE-BERT-base.

5 Empirical Study

To further explore the performance of the MoCo-like contrasting model on learning sentence embedding, we set up the following ablation trials.

5.1 EMA Decay Weight

We use EMA to update the model parameters for the target branch and find that EMA decay weight affects the performance of the model. The EMA decay weight affects the update process of the model, which further affects the vectors involved in the contrastive learning process. Therefore, we set different values of EMA decay weight and train the model with other hyperparameters held constant. As shown in Table 3 and Appendix A.5, the best result is obtained when the decay weight of EMA is set to 0.85. Compared to the choice of EMA decay weight in CV (generally as large as 0.99), the value of 0.85 in our model is smaller, which means that the model is updated faster. We speculate that this is because the NLP model is more sensitive in the fine-tuning phase and the model weights change

EMA	0.5	0.8	**0.85**	0.9	0.95	0.99
Avg.	75.76	75.19	**76.49**	76.05	76.08	75.12

Table 3: Effect of EMA decay weight on model performance. The best results are obtained with the EMA decay weight at 0.85.

Proj.	Pred.	Corr.	Proj.	Pred.	Corr.
	1	60.46		1	66.96
0	2	62.67	2	2	66.29
	3	63.62		3	61.57
	1	76.74		1	31.51
1	**2**	**76.89**	3	2	43.97
	3	76.24		3	39.13

Table 4: The impact of different combinations of projection and predictor on the model.

more after each step of the gradient, so a faster update speed is needed.

5.2 Projection and Prediction

Several papers have shown (e.g. Section F.1 in BYOL (Grill et al., 2020)) that the structure of projection and prediction layers in a contrastive learning framework affects the performance of the model. We combine the structure of projection and prediction with different configurations and train them with the same hyperparameters. As shown in Table 4, the best results are obtained when the projection is 1 layer and the prediction has 2 layers. The experiments also show that the removal of projection layers degrades the performance of the model.

5.3 Data Augmentation

We investigate the effect of some widely-used data augmentation methods on the model performance. As shown in Table 5, cut off and token shuffle do not improve, even slightly hurt the model's performance. Only the adversarial attack (FGSM) has slight improvement on the performance. Therefore, in our experiments, we added FGSM as a default data augmentation of our model in addition to dropout. Please refer to Appendix A.7 for more FGSM parameters results. We speculate that the reason token cut off is detrimental to the model results is that the cut off perturbs too much the vector formed by the sentences passing through the embedding layer. Removing one word from the text may have a significant impact on the semantics. We tried two parameters 0.1 and 0.01 for the feature cut off, and with these two parameters, the results of using the feature cut off is at most the same as without using feature the cut off, so we discard the feature cut off method. More results can be found in Appendix A.6.

Augmentation Methods	Avg.
Dropout only	76.76
+ **FGSM** (ε=5e-9)	**77.04**
+ Position_shuffle (True)	73.80
+ Token dropout (prob=0.1)	41.32
+ Feature dropout (prob=0.01)	76.33
+ Feature dropout (prob=0.1)	71.62
+ Typos	22.32
+ Synonym replace (roberta-base)	28.70
+ Paraphrasing (xlnet-base-cased)	60.45
+ Backtranslation (en->de->en)	69.35

Table 5: The effect of different data augmentation methods.

The token shuffle is slightly, but not significantly, detrimental to the results of the model. This may be due to that BERT is not sensitive to the position of token. In our experiment, the sentence-level augmentation methods also failed to outperform than the drop out, FGSM and position shuffle.

Among the data augmentation methods, only FGSM together with dropout improves the results, which may due to the adversarial attack slightly enhances the difference between the two samples and therefore enables the model to learn a better representation in more difficult contrastive samples.

5.4 Predictor Mapping Dimension

The predictor maps the representation to a feature space of a certain dimension. We investigate the effect of the predictor mapping dimension on the model performance. Table 6.a shows that the predictor mapping dimension can seriously impair the performance of the model when it is small, and when the dimension rises to a suitable range or larger, it no longer has a significant impact on the model. This may be related to the intrinsic dimension of the representation, which leads to the loss of semantic information in the representation when the predictor dimension is smaller than the intrinsic dimension of the feature, compromising the model performance. We keep the dimension of the predictor consistent with the encoder in our experiments. More results can be found in Appendix A.8.

5.5 Batch Size

With a fixed queue size, we investigated the effect of batch size on model performance, the results is in Table 6.b, and the model achieves the best per-

Dim	Avg.
256	73.91
512	76.07
768	**77.04**
1024	77.02
2048	77.03

(a)

Size	Avg.
32	73.86
64	**77.25**
128	76.78
256	76.62

(b)

Table 6: (a) Impact of prediction dimension on model performance. (b) Impact of batch size on the model with fixed queue size. Both table under a batch size setting to 512.

formance when the batch size is 64. Surprisingly the model performance does not improve with increasing batch size, which contradicts the general experience in image contrastive learning. This is one of our motivations for further exploring the effect of the number of negative samples on the model.

5.6 Size of Negative Sample Queue

The queue length determines the number of negative samples, which direct influence performance of the model. We first test the size of negative sample queue to the model performance. With queue size longer than 1024, the results get unstable and worse. We suppose this may be due to the random interference introduced to the training by filling the initial negative sample queue. This interference causes a degradation of the model's performance when the initial negative sample queue becomes longer. To reduce the drawbacks carried out by this randomness, we changed the way the negative queue is initialized. We initialize a smaller negative queue, then fill the queue to its set length in the first few updates, and then update normally. According to experiments, the model achieves the highest results when the negative queue size set to 512 and the smaller initial queue size set to 128.

According to the experiments of MoCo, the increase of queue length improves the model performance. However, as shown in Table 7, increasing the queue length with a fixed batch size decreases our model performance, which is not consistent with the observation in MoCo. We speculate that this may be due to that NLP models updating faster, and thus larger queue lengths store too much outdated feature information, which is detrimental to the performance of the model. Combined with the observed effect of batch size, we further conjecture that the effect of the negative sample queue on model performance is controlled by the model

Initial	Queue Size				
Size	128	256	512	1024	4096
w.o. init.	76.40	76.19	75.38	**76.63**	50.17
init. 1/4 queue	75.92	76.34	**77.30**	76.20	**50.42**
init. 1/2 queue	76.16	**76.39**	76.94	76.57	38.74
init. all (normal)	**76.87**	75.81	76.29	76.45	45.80

Table 7: Correlation performance of initializing different proportion of negative queue with different negative queue size.

Corr.	0∼ 512	256∼ 768	512∼ 1024	Without 256∼768	All
Avg.	76.10	**77.02**	75.71	76.18	76.86

Table 8: The impact of negative samples at different locations in the queue on the model performance.

history information contained in the negative sample in the queue. See Appendix A.9 and A.10 for more results of the effect of randomization size and queue length.

Since the queue is first-in-first-out, to test the hypothesis above, we sliced the negative sample queue and use different parts of the queue to participate in loss calculation. Here, we set the negative queue length to 1024, the initial queue size to 128, and the batch size to 256. Thus, 256 negative samples will be push into the queue for each iteration. We take $0 \sim 512$, $256 \sim 768$, $512 \sim 1024$, a concatenated of slice $0 \sim 256$ and $768 \sim 1024$, and all negative sample queues respectively for testing. The experiment results are shown in Table 8.

The experiments show that the model performs best when using the middle part of the queue. So we find that the increase in queue length affects the model performance not only because of the increased number of negative samples, but more because it provides historical information within a certain range.

5.7 Maximum Traceable Distance Metric

To testify there are historical information in negative sample queue influencing the model performance, we define a Maximum Traceable Distance Metric d_{trace} to help explore the phenomenon.

$$d_{trace} = \frac{1}{1-\eta} + \frac{queue\_size}{batch\_size} \tag{4}$$

The η refers to the decay weight of EMA. The d_{trace} calculates the update steps between the current online branch and the oldest negative samples in the queue. The first term of the formula represents the traceable distance between target and

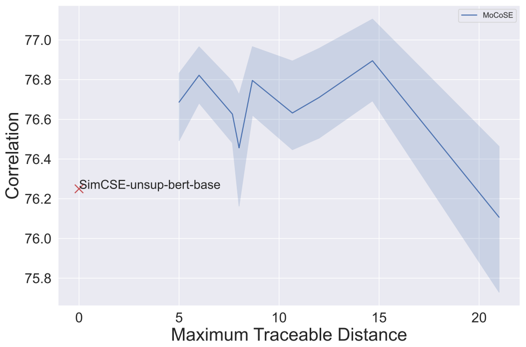

Figure 2: The relationship between traceable distance and model correlation.

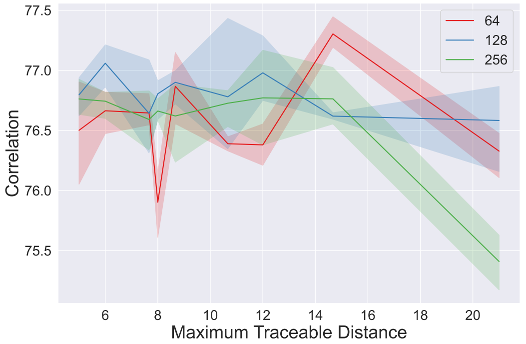

Figure 3: The batch size does not invalidate the traceable distance. The traceable distance needs to be maintained within a reasonable range even for different batch sizes. This explains why increasing the batch size only does not improve the performance, because increasing the batch size only can cause the distance changes into unsuitable regions.

online branch due to the EMA update mechanism. The second term represents the traceable distance between the negative samples in the queue and the current target branch due to the queue's first-in-first-out mechanism. The longer traceable distance, the wider the temporal range of the historical information contained in the queue. We obtained different value of traceable distance by jointly adjust the decay weight, queue size, and batch size. As shown in Figure 2 and Figure 3, the best result of BERT base is obtained with d_{trace} is set around 14.67. The best result of BERT large shows the similar phenomenon, see Appendix A.11 for details. This further demonstrates that in text contrastive learning, the historical information used should be not too old and not too new, and the appropriate traceable distance between branches is also important. Some derivations about eq.4 can be found in Appendix A.12.

However, for an image contrast learning model, like MoCo, experimental results suggests that longer queue size increases the performance. We believe that this is due to the phenomenon of unique anisotropy (Zhang et al., 2020b) of text that causes such differences. The text is influenced by the word frequency producing the phenomenon of anisotropy with uneven distribution, which is different from the near-uniform distribution of pixel points of image data. Such a phenomenon affects the computation of the cosine similarity (Wang and Isola, 2020), and the loss of InfoNCE that we use depends on it, which affects the performance of the model through the accumulation of learning steps. To test such a hypothesis, we use alignment and uniformity to measure the distribution of the representations in space and monitor the corresponding values of alignment and uniformity for different MTDs. As shown in the Figure 4, it can be found that a proper MTD allows the alignment and uniformity of the model to reflects an optimal combination. The change in MTD is reflected in the performance of uniformity and alignment of the learned text embedding, and the increase and decrease of MTD is a considering result of uniformity and alignment moving away from their optimal combination region.

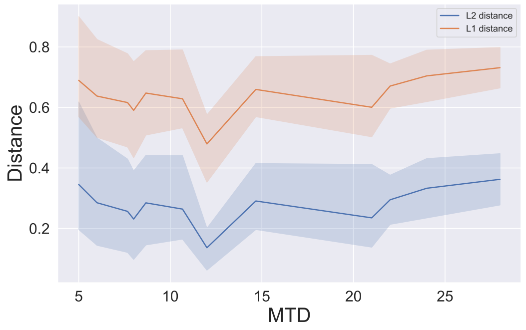

Figure 4: L1 and L2 distances of learned embedding's uniformity and alignment with a fixed point changes along with MTD.

6 Conclusion

In this study, we propose MoCoSE, it applies the MoCo-style contrastive learning model to the empirical study of sentence embedding. We conducted experiments to study every detail of the model to provide some experiences for text contrastive learning. We further delve into the application of the negative sample queue to text contrastive learning and propose a maximum traceable distance metric to explain the relation between the queue size and model performance.

A Appendix

A.1 Experiment Settings

We train our MoCoSE model using a single NVIDIA RTX3090 GPUs. Our training system runs Microsoft Windows 10 with CUDA toolkit 11.1. We use Python 3.8 and PyTorch version v1.8. We build the model with Transformers 4.4.2 (Wolf et al., 2020) and Datasets 1.8.0 (Lhoest et al., 2021) from Huggingface. We preprocess the training data according to the SimCSE to directly load the stored data in training. We compute the uniformity and alignment metrics of embedding on the STS-B dataset according to the method proposed by Wang (Wang and Isola, 2020). The STS-B dataset is also preprocessed. We use the **nlpaug** toolkit in our data augmentation experiments. For synonym replace, we use '$ContextualWordEmbsAug$' function with 'roberta-base' as parameter. For typo, we use '$SpellingAug$' and back translation we use '$BackTranslationAug$' with parameter 'facebook/wmt19-en-de' and paraphrase we use '$ContextualWordEmbsForSentenceAug$' with parameter 'xlnet-base-cased'. All the parameter listing here is default value given by official.

A.2 Symmetric Two-branch Structure

We remove the online branch predictor and set the EMA decay weight to 0, i.e., make the structure and weights of the two branches identical. As shown in Figure 5, it is clear that the model is collapsing at this point. And we find that the model always works best at the very beginning, i.e., training instead hurts the performance of the model. In addition, as the training proceeds, the correlation coefficient of the model approaches 0, i.e., the prediction results have no correlation with the actual labeling. At this point, it is clear that a collapse of the model is observed. We observed such a result for several runs, so we adopted a strategy of double branching with different structures plus EMA momentum updates in our design. Subsequent experiments demonstrated that this allowed the model to avoid from collapsing.

Figure 5: Experiment on a symmetric two-branch structure with EMA decay weight set to 0.

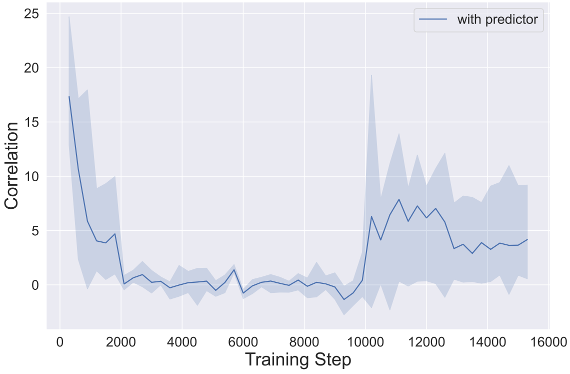

Figure 6: Experiment after adding predictor on the online branch with EMA decay weight set to 0.

We add predictor to the online branch and set the EMA decay weight to 0. We find that the model also appears to collapse and has a dramatic oscillation in the late stage of training, as shown in Figure 6.

A.3 Pseudo-Code for Training MoCoSE

The PyTorch style pseudo-code for training MoCoSE with the negative sample queue is shown in Algorithm 1.

A.4 Distribution of Singular Values

Similar to SimCSE, we plot the distribution of singular values of MoCoSE sentence embeddings with SimCSE and BERT for comparison. As illustrated in Figure 7, our method is able to alleviate the rapid decline of singular values compared to other methods, making the curve smoother, i.e., our model is able to make the sentence embedding more isotropic.

Algorithm 1: Momentum **Co**ntrastive **S**entence **E**mbedding

```
Input:
$\mathcal{D}$ : Training data set ;
$\mathcal{Q}$ : Negative Sample Queue;
$E_a$ : Embedding with random data augmentation;
$\theta_o, \theta_t$ : weights of online branch and target branch;
Optimizer : Adam optimizer
$K, K_s$: Queue size, Queue size at initialisation;
$\eta$ : ema decay ema and ema scheduling strategy;
$\tau$ Temperature parameters
Output: MoCoSE model $\theta_o$
Initializing the queue $\mathcal{Q}$ with size $K_s$;
foreach $\mathcal{B} \in \mathcal{D}$ do
    $v_o, v_t \leftarrow E_a(\mathcal{B}), E_a(\mathcal{B})$ // Using data Augmentation to generate different views
    $z_o \leftarrow \theta_o(v_o)$ // $(N, d)$, $N$ is batch size, $d$ is dimension of sentence embedding
    $z_t \leftarrow \theta_t(v_t)$
    $l_{z_o,z_t,\mathcal{Q}} \leftarrow -\log \frac{\exp(z_o \cdot z_t/\tau)}{\exp(z_o \cdot z_t/\tau)+\sum_{x\in\mathcal{Q}} \exp(z_o \cdot x/\tau)}$ // compute contrastive loss using $InFoNCE$
    optimizer($l_{z_o,z_t,\mathcal{Q}}, \theta_o$) // Update only the parameters of the online branch according to the loss gradient;
    $\theta_t \leftarrow \eta * \theta_t + (1-\eta) * \theta_o$ // Update the parameters of the target branch using $EMA$
    enqueue($\mathcal{Q}, v_t$) // Update the negative sample queue $\mathcal{Q}$
    dequeue($\mathcal{Q}$)
return $\theta_o$
```

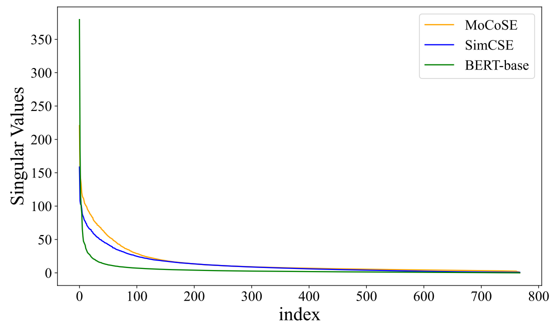

Figure 7: Singular value distributions of sentence embedding matrix from sentences in STS-B.

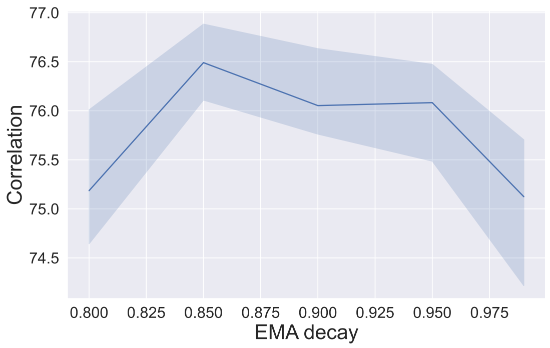

Figure 8: Effect of EMA decay weight on model performance.

A.5 Experiment Details of EMA Hyperparameters

The details of the impact caused by the EMA parameter are shown in the Figure 8. We perform this experiment with all parameters held constant except for the EMA decay weight.

A.6 Details of Different Data Augmentations

We use only dropout as a baseline for the results of data augmentations. Then, we combine dropout with other data augmentation methods and study their effects on model performance. The results are shown in Figure 9.

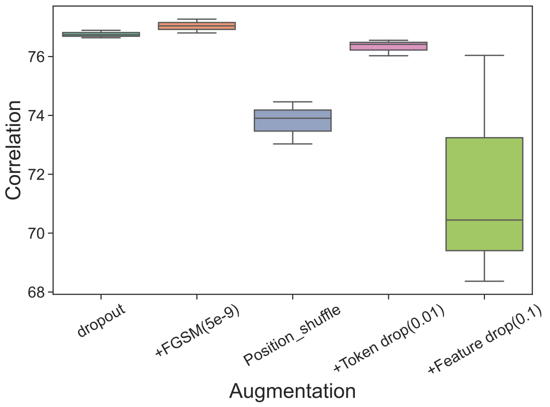

Figure 9: Impact of four additional data enhancements with dropout combinations on the model.

A.7 Experiment Details of FGSM

We test the effect of the intensity of FGSM on the model performance. We keep the other hyperparameters fixed, vary the FGSM parameters (1e-9, 5e-9, 1e-8, 5e-8). As seen in Table 9, the average results of the model are optimal when the FGSM parameter is 5e-9.

Epsilon	1e-9	**5e-9**	1e-8	5e-8	No
Avg.	75.61	**76.64**	75.39	76.62	76.26

Table 9: Different parameters of FGSM in data augmentation affect the model results.

A.8 Dimension of Sentence Embedding

In both BERT-whitening (Su et al., 2021) and MoCo (He et al., 2020), it is mentioned that the dimension of embedding can have some impact on the performance of the model. Therefore, we also changed the dimension of sentence embedding in MoCoSE and trained the model several times to observe the impact of the embedding dimension. Because of the queue structure of MoCoSE, we need to keep the dimension of negative examples consistent while changing the dimension of sentence embedding. As shown in the Figure 10, when the dimension of Embedding is low, this causes considerable damage to the performance of the model; while when the dimension rises to certain range, the performance of the model stays steady.

A.9 Details of Random Initial Queue Size

We test the influence of random initialization size of the negative queue on the model performance when queue length and batch size are fixed. As seen in Figure 11, random initialization does have some impact on the model performance.

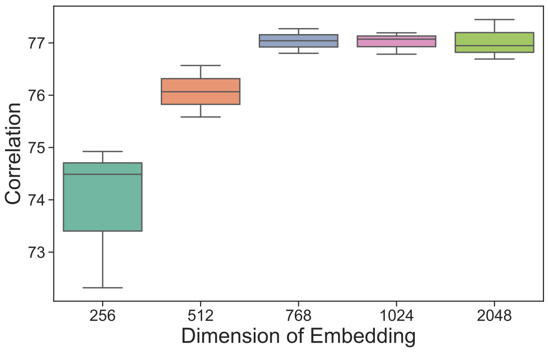

Figure 10: Impact of dimensions of the sentence embedding.

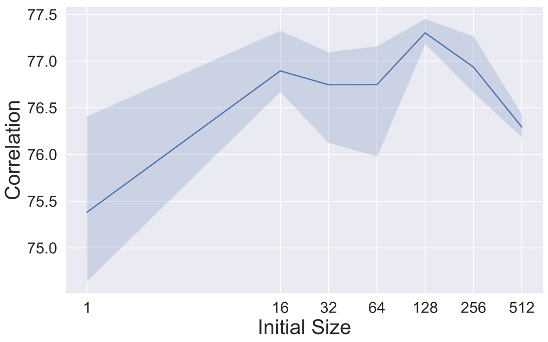

Figure 11: The effect of the initial queue size on the model results when the queue length is 512 and the batch size is 64.

A.10 Queue Size and Initial Size

We explored the effect of different combinations of initial queue sizes and queue length on the model performance. The detailed experiment results are shown in Figure 12. It can be found that model performance rely deeply on initialization queue size. Yet, too large queue size will make the model extremely unstable. This is quite different from the observation of negative sample queue in image contrastive learning.

A.11 Maximum Traceable Distance in BERT-large

We also train mocose with different batch size and queue size on BERT-large. As shown in Figure 13, we observe the best model performance in MoCoSE-BERT-large within the appropriate Maximum Traceable Distance range (around 22). Once again, this suggests that even on BERT-large, the longer queue sizes do not improve the model performance indefinitely. Which also implies that the

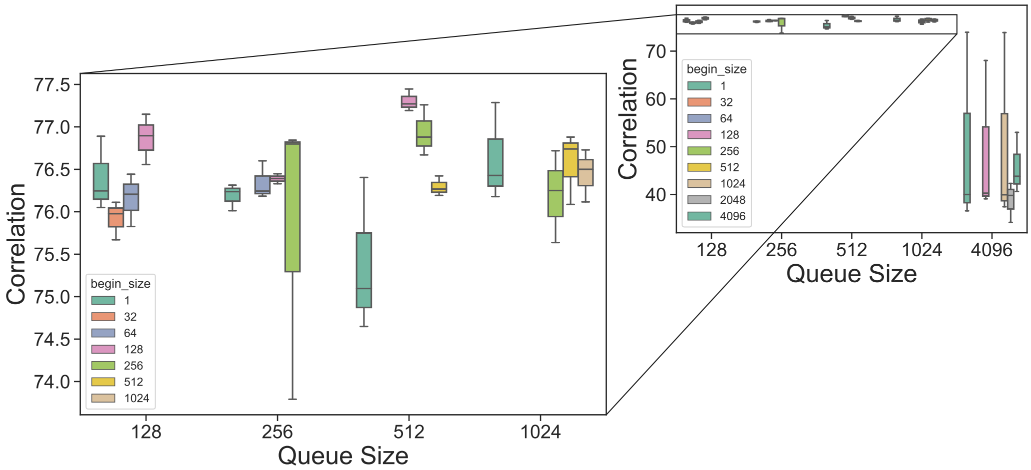

Figure 12: The impact of different initial negative sample queue sizes for different initial sizes on model performance. (left):Zoomed view. (right):Overview with different negative queue size. Results of different initial size under same queue size.

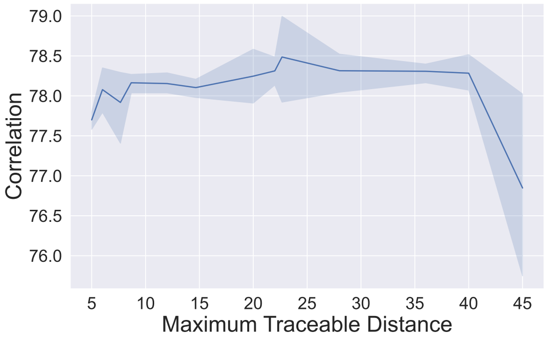

Figure 13: The relationship between MTD and correlation of MoCoSE-BERT-large. It can be seen that even at large model, peaks occur within a certain MTD range.

history information contained in the negative sample queue needs to be kept within a certain range on BERT-large as well.

A.12 Proof of Maximum Traceable Distance

Here, we prove the first term of the formula for Maximum Traceable Distance. Due to the EMA update mechanism, the weight of target branch is a weighted sum of the online weight in update history. The first term of Maximum Traceable Distance calculate the weighted sum of the historical update steps given a certain EMA decay weight η. From the principle of EMA mechanism, we can get the following equation.

$$\mathcal{S}_n = \sum_{i=0}^{k} (1-\eta) \cdot \eta^i \cdot (i+1) \tag{5}$$

$\mathcal{S}_n$ represents the update steps between online and target branch due to the EMA mechanism. Since EMA represents the weighted sum, we need to ask for $\mathcal{S}_n$ to get the weighted sum.

We can calculate $\mathcal{S}_n$ as:

$$\mathcal{S}_n = (-1) * \eta^{k+1} * (k+1) - \frac{\left(1-\eta^{k+1}\right)}{(\eta-1)} \tag{6}$$

As k tends to infinity, the limit for $\mathcal{S}_n$ can be calculated as following:

$$\lim_{k\to\infty} \mathcal{S}_n = \lim_{k\to\infty} \left[(-1) * \eta^{k+1} * (k+1) - \frac{\left(1-\eta^{k+1}\right)}{(\eta-1)} \right] \tag{7}$$

It is obvious to see that the limit of the equation 7 consists of two parts, so we calculate the limit of these two parts first.

$$\lim_{k\to\infty} (-1) * \eta^{k+1} * (k+1) \overset{\eta \leq 1}{=} 0 \tag{8}$$

The limit of the first part can be calculated as 0. Next, we calculate the limit of the second part.

$$\lim_{k\to\infty} \frac{\left(1-\eta^{k+1}\right)}{(\eta-1)} \overset{\eta \leq 1}{=} \frac{1}{1-\eta} \tag{9}$$

We calculate the limit of the second part as $\frac{1}{1-\eta}$. Since the limits of both parts exist, we can obtain the limit of $\mathcal{S}_n$ by the law of limit operations.

$$\begin{aligned}
&\lim_{k\to\infty} \mathcal{S}_n \\

Abstract

Language models are increasingly becoming popular in AI-powered scientific IR systems. This paper evaluates popular scientific language models in handling (i) *short-query texts* and (ii) *textual neighbors*. Our experiments showcase the inability to retrieve relevant documents for a short-query text even under the most relaxed conditions. Additionally, we leverage textual neighbors, generated by small perturbations to the original text, to demonstrate that not all perturbations lead to close neighbors in the embedding space. Further, an exhaustive categorization yields several classes of orthographically and semantically related, partially related and completely unrelated neighbors. Retrieval performance turns out to be more influenced by the surface form rather than the semantics of the text.

1 Introduction

Representation learning methods have drastically evolved large scientific volume exploration strategies. The popular applications include summarization, construction of mentor-mentee network (Ke et al., 2021), recommendation (Ostendorff et al., 2020; Cohan et al., 2020; Das et al., 2020; Hope et al., 2021), QA over scientific documents (Su et al., 2020), and verification of scientific claims (Wadden et al., 2020). The growing community's interest has led to the development of several scientific document embedding models such as OAG-BERT (Liu et al., 2021), SPECTER (Cohan et al., 2020), SciBERT (Beltagy et al., 2019), and BioBERT (Lee et al., 2020) over the past five years. OAG-BERT has been deployed in the Aminer production system. Given similar possibilities of future deployments of scientific document embeddings models in the existing scholarly systems, it is crucial to evaluate and identify limitations robustly. However, we do not find any existing work that critically analyzes the scientific language models to the best of our knowledge.

To motivate the reader, we present a simple experiment. Queries *'document vector'* and *'document vectors'* fetch no common candidates among first page results on Google Scholar and Semantic Scholar (candidates in Appendix A). This illustrates the extremely brittle nature of such systems to minor alterations in query text, leading to completely different search outcomes. To motivate further, we experiment with textual queries encoded by the popular SciBERT model. A perturbed text *'documen vector'* (relevant in AI) is closer to the Biomedical term *'Virus vector'* in the embedding space. Similar observations were found for many other queries. As scholarly search and recommendation systems are complex systems and their detailed algorithms are not publicly available, we analyze the behavior of scientific language models, which are (or will be) presumably an integral component of each of these systems. Motivated by the usage of perturbed inputs to stress test ML systems in interpretability analysis, we propose to use *'textual neighbors'* to analyze how they are represented in the embedding space of scientific LMs. Unlike previous works (Ribeiro et al., 2020; Rychalska et al., 2019), which analyze the effect of perturbations on downstream task-specific models, we focus on analyzing the embeddings which are originally inputs to such downstream models. With the explosion of perturbation techniques for various kinds of robustness and interpretability analysis, it is difficult to generalize the insights gathered from perturbation experiments. We propose a classification schema based on orthography and semantics, to organize the perturbation strategies.

The distribution of various types of textual neighbors in a training corpus is non-uniform. Specifically, the low frequency of textual neighbors results in non-optimized representations, wherein semantically similar neighbors might end up distant in the space. These non-optimal representations have a cascading effect on the downstream task-specific

Findings of the Association for Computational Linguistics: ACL 2022, pages 3153 - 3173
May 22-27, 2022

models. In this work, we analyze whether all textual neighbors of input X are also X's neighbors in the embedding space. Further, we also study if their presence in the embedding space can negatively impact downstream applications dependent on similarity-based document retrieval. Our main contributions are:

1. We introduce (in Section 3) five textual neighbor categories based on orthography and semantics. We further construct a non-exhaustive list of thirty-two textual neighbor types and organize them into these five categories to analyze the behavior of scientific LMs on manipulated text.
2. We conduct (in Section 5) robust experiments to showcase the limitations of scientific LMs under a short-text query retrieval scheme.
3. We analyze (in Section 6) embeddings of textual neighbors and their placement in the embedding space of three scientific LMs, namely SciBERT, SPECTER, and OAG-BERT. Our experiments highlight the capability and limitations of different models in representing different categories of textual neighbors.

2 Related Works

Several works utilize Textual Neighbors to interpret decisions of classifiers (Ribeiro et al., 2016; Gardner et al., 2020), test linguistic capabilities of NLP models (Ribeiro et al., 2020), measure progress in language generation (Gehrmann et al., 2021), and generate semantically equivalent adversarial examples (Ribeiro et al., 2018). Similar to these works, we use textual neighbors of scientific papers to analyze the behavior of scientific LMs. MacAvaney et al. (2020) analyze the behavior of neural IR models by proposing test strategies: constructing test samples by controlling specific measures (e.g., term frequency, document length), and by manipulating text (e.g., removing stops, shuffling words). This is closest to our work, as we also employ text manipulation to analyze the behavior of scientific language models using a simple Alternative-Self Retrieval scheme (Section 4). However, our focus is not evaluation of retrieval-augmented models and we only use a relaxed document retrieval pipeline in our evaluation to analyze the behavior of scientific LMs trained on diverse domains, in encoding scientific documents. We organize the textual neighbors into categories which capture different capabilities of LMs. We also show that it is crucial to evaluate models on dissimilar texts rather than just semantically similar textual neighbors. Ours is a first work in analyzing the properties of scientific LMs for different inputs and can be utilized by future works to design and evaluate future scientific LMs. Due to space limitations, we present the detailed discussion on scientific LMs in Appendix C.

3 Short Queries and Textual Neighbors

In this paper, we experiment with short queries to fetch relevant scientific documents. The term '*short*' signifies a query length comparable to the length of research titles. The candidates are constructed from either title (T) or title and abstract (T+A) text. We, further, make small alterations to the candidate text to construct *'textual neighbors'*. The textual neighbors can be syntactically, semantically, or structurally similar to the candidate text. Unlike previous works that explore textual neighbors to analyze and stress test complex models (Q&A, Sentiment, NLI, NER (Rychalska et al., 2019)), we experiment directly with representation learning models and analyze the placement of textual neighbors in their embedding space. While semantically similar neighbors are frequently used in previous works (Ribeiro et al., 2018); we also explore *semantically dissimilar* textual neighbors to analyze scientific language models. While an LM is expected to represent semantically similar texts with high similarity, some orthographically similar but semantically dissimilar texts can have highly similar embeddings, which is undesirable behavior. Note that we restrict the current query set to titles for two main reasons: (i) most real-world search queries are shorter in length, and (ii) flat keyword-based search lacks intent and can lead to erroneous conclusions.

Textual neighbors have a similar word form or similar meaning. We observe that Textual neighbors possess the following properties based on two aspects: (i) Orthography (surface-level information content of text in terms of characters, words, and sentences), and (ii) Semantics. These two aspects are integral for a pair of texts to be textual neighbors. The properties of these aspects are:

1. **Orthography**: Orthographic-neighbors are generated by making small surface-level transformations to the input. Based on the textual content, neighbors can be generated by:
   (a) ***Lossy Perturbation (LO)***: 'Lossy' behavior indicates that the information

O-S	Neighbor Code	Form
LL-PS	T_ARot	Title → Preserve Abs → Rotate
LL-PS	T_AShuff	Title → Preserve Abs → Shuffle
LL-PS	T_ASortAsc	Title → Preserve Abs → Sort Ascending
LL-PS	T_ASortDesc	Title → Preserve Abs → Sort Descending
LO-PS	T_ADelRand	Title → Preserve Abs → Random word deletion 30%
LO-PS	T_ADelADJ	Title → Preserve Abs → Delete all ADJs
LO-DS	T_ADelNN	Title → Preserve Abs → Delete all NNs
LO-PS	T_ADelVB	Title → Preserve Abs → Delete all Verbs
LO-PS	T_ADelADV	Title → Preserve Abs → Delete all ADVs
LO-PS	T_ADelPR	Title → Preserve Abs → Delete all PRs
LO-HS	T_ADelDT	Title → Preserve Abs → Delete all DTs
LO-PS	T_ADelNum	Title → Preserve Abs → Delete all Numbers
LO-DS	T_ADelNNPH	Title → Preserve Abs → Delete all NN Phrases
LO-PS	T_ADelTopNNPH	Title → Preserve Abs → Delete top 50% NPs
LO-HS	TDelADJ_A	Title → Delete all ADJs Abs → Preserve
LO-HS	TDelNN_A	Title → Delete all NNs Abs → Preserve
LO-HS	TDelVB_A	Title → Delete all VBs Abs → Preserve
LO-HS	TDelDT_A	Title → Delete all DTs Abs → Preserve
LO-DS	TDelNN	Title → Delete all NNs Abs → Delete
LO-PS	T_ADelQ1	Title → Preserve Abs → Delete quantile 1
LO-PS	T_ADelQ2	Title → Preserve Abs → Delete quantile 2
LO-PS	T_ADelQ3	Title → Preserve Abs → Delete quantile 3
LL-HS	TNNU_A	Title → Uppercase NNs Abs → Preserve
LL-HS	TNonNNU_A	Title → Uppercase non NNs Abs → Preserve
LL-HS	T_ANNU	Title → Preserve Abs → Uppercase NNs
LL-HS	T_ANonNNU	Title → Preserve Abs → Uppercase non NNs
LO-PS	T_A_DelNNChar	Title → Delete chars from NNs Abs → Delete chars from NNs
LO-HS	TRepNNT_A	Title → Add a NN from title Abs → Preserve
LO-HS	TRepNNA_A	Title → Add a NN from abs Abs → Preserve
LO-DS	T_ADelNonNNs	Title → Preserve Abs → Delete all non NNs
LO-DS	T_ARepADJ	Title → Preserve Abs → Replace ADJs with antonyms
LL-HS	T_A_WS	Randomly replace 50% whitespace chars with 2-5 whitespace chars in the title & abstract

Table 1: Neighbor code is in format Txx_Ayy_zz, where xx and yy denote the perturbation to the paper title (T) and the abstract (A) respectively. zz denotes perturbation to both T and A. Missing T or A denotes that the corresponding input field is deleted completely.

   from the original text is lost, either due to addition or deletion of textual content. E.g., random deletion of 2–3 characters from a word.

   (b) ***Lossless Perturbation (LL)***: 'Lossless' behavior indicates that the original information content is unaltered. E.g., shuffling sentences of a paragraph.

2. **Semantics**: Textual neighbors can either be semantically similar or not. While semantic categories are subjective, we try to define them objectively:

   (a) ***Dissimilar (DS)***: Semantically dissimilar neighbors are generated by deletion of nouns (NNs) or noun phrases (NPs), or by changing the directionality of text such as replacing adjectives (ADJs) with antonyms.

   (b) ***Partially Similar (PS)***: Partially similar neighbors are constructed by sentence level modifications such as sentences scrambling (while preserving the word order in each sentence), word deletion of non-NNs (or NPs), or character deletion in words (including NNs) such that the textual neighbor preserves at least 70% of the words in the original text.

   (c) ***Highly Similar (HS)***: Highly similar neighbors are constructed by (i) non-word-semantic changes such as changing the case of words or altering the whitespace characters, (ii) word deletions or additions such that the textual neighbor preserves at least 90% of the words in the original text. Note that deletion of NNs only from the title while preserving the abstract will qualify to be the *HS* category.

Since SPECTER and OAG-BERT utilize paper titles and abstracts to learn embeddings, we generate textual neighbors by altering texts of these two input fields. We present 32 textual neighbor types in Table 1. Each of these 32 neighbor types is categorized into one of the five categories: LO-HS, LO-PS, LO-DS, LL-HS, and LL-PS. We exclude the LL-DS category (e.g., scrambling all words in the text) as it is infrequent and less probable to occur in a real-world setting. Examples of the textual neighbors are presented in Appendix B (Table 7).

4 Experiment Design

The Alternative-Self Retrieval: We propose an embarrassingly simple binary retrieval scheme

Arxiv-QBIO	QB	Neurons and Cognition	6,903
Arxiv-ECON	ECO	Econometrics, General & Theoretical Economics	4,542

Table 2: Dataset Statistics

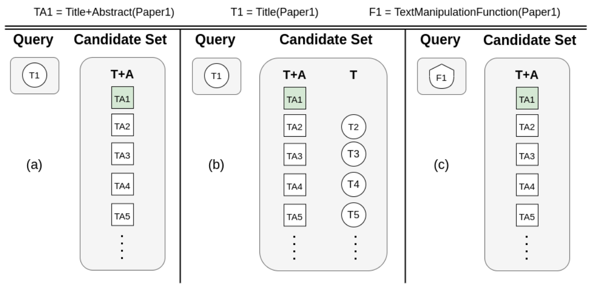

Figure 1: Alternative-Self Retrieval schemes for (a) Sec. 5 Task I, (b) Sec. 5 Task II, and (c) Sec. 6.2. Green represents the relevant candidate document for the query. The query is a subset of the relevant candidate document in schemes (a) and (b), and a textual neighbor of the relevant candidate in scheme (c).

which contains only one relevant document in the candidate set. Alternative-Self Retrieval refers to the characteristic that the query is an altered version of the relevant candidate document. E.g., the candidate documents are the embeddings of paper title and abstract (henceforth T+A) and the query is embedding of title. We present a schematic of three Alternative-Self Retrieval schemes in Figure 1. The retrieval is simple and we measure performance with accommodating metrics discussed in this section further. Our purpose is to analyze scientific LM embeddings under the most relaxed conditions.

The Datasets: We evaluate the scientific LMs on seven datasets (statistics in Table 2) to understand their effectiveness in encoding documents from diverse research fields. Each dataset contains the titles and abstracts of papers. We curate the ACL Anthology dataset[1] and the ICLR dataset from OpenReview[2]. To control the size of the ACL Anthology dataset, we exclude papers from workshops and non-ACL venues. We also curate five datasets from arXiv for the domains Mathematics (MT), High Energy Physics (HEP), Quantitative Biology (QB), Economics (ECO), and Computer Science (CS). We make available our code and dataset for public access[3].

The Notations: $\mathcal{D}$ is the set of seven datasets described in Table 2. $\mathcal{X}$ is the set of original input texts to the scientific LMs consisting of the paper title (T) and the abstract (A). For d $\in \mathcal{D}$, $\mathcal{X} = \{x_j : x_j =$ (T+A)(p), where (T+A)$(p) =$ concat(title(p), abstract(p), $\forall$ paper $p \in$ d$\}$. f represents the type of textual neighbor (represented by the neighbor code presented in Table 1). $\mathcal{Q}$ and $\mathcal{R}$ are the query and candidate set for the IR task.

Evaluation Metrics: We report performance scores on the following retrieval metrics:

Mean Reciprocal Rank (MRR): All our tasks use binary relevance of documents to compute MRR.

T100: It represents the percentage of queries which retrieve the one and only relevant document among the top-100 documents.

NNk_Ret: % of queries in textual neighbor category whose k nearest neighbors (k-NN) retrieve the original document.

AOP-10: Average overlap percentage among 10-NN of x and y, where x = T+A(x_j) and y = $f(x_j)$. f is a text manipulation function, represented by the textual neighbor codes presented in Table 1.

5 Analysing Embeddings for Scientific Document Titles and Abstracts

In this section, we experiment with the inputs to the scientific language models. Due to free availability and ease of parsing paper title and abstract, majority scientific LMs learn embeddings from the title and the abstract of the paper. However, multiple downstream applications such as document search involve short queries (often keywords). We present two Alternative-Self retrieval experiments to compare the embeddings of paper title (T) with the embeddings of paper titles and abstract (T+A). In both experiments, $|\mathcal{Q}|$ = 1000 queries for each dataset.

Task I: Querying titles against original candidate documents In this Alternative-Self Retrieval setup, given a query q constructed only from the paper title, the system recommends relevant candidate document embeddings constructed from title and abstract both (T+A). This setting is similar to querying in a scientific literature search engine as the search queries are usually short. The

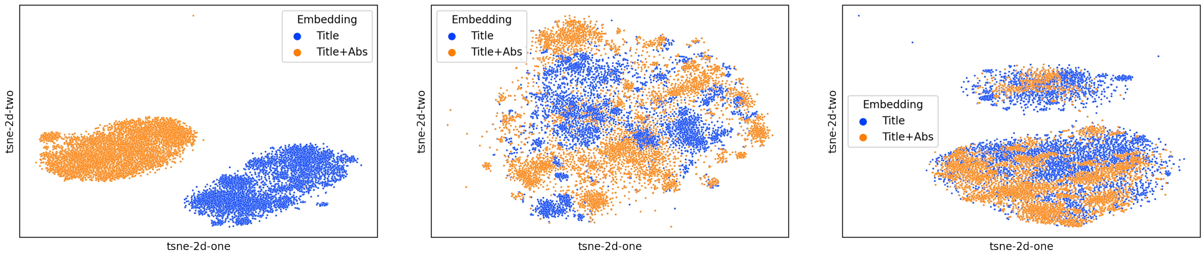
Table 3: For both Task I and Task II, SPECTER consistently performs the best on all datasets. For Task II, drop in MRR and T100 scores for SPECTER is significant in comparison to Task I.



(a) SciBERT (b) SPECTER (c) OAG-BERT

Figure 2: t-SNE plots for T and T+A embeddings for the ICLR dataset. Completely non-overlapping embeddings for T and T+A by SciBERT model highlight differences in encoding texts of varying lengths.

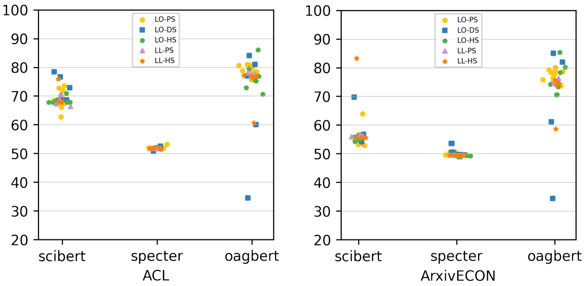


Figure 3: Percentage of pair of documents for each Textual Neighbor whose similarity is greater than the average similarity. OAG-BERT has high inter similarity ($>$ 50%), i.e. more than 50% document pairs have cosine similarity greater than average similarity.

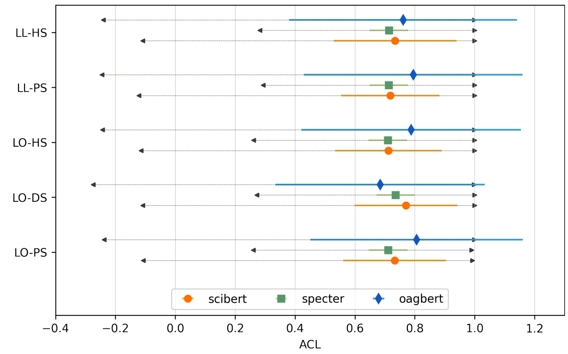

Figure 4: Inter Similarity of Textual Neighbor Vectors. Bold lines represent the μ and the σ of pairwise similarities. Arrow heads represent min and max values. Pairwise similarities are spread out in a broad range for OAG-BERT, suggesting vectors for textual neighbors are more spread out in the vector space.

motivation behind this experiment is to analyse the similarity among the T and the T+A embedding of a paper (Figure 1(a)). The experiment details are:
Query: $\mathcal{Q} = \{q_j \colon x_j \in \mathcal{X}, f = \mathrm{T}, q_j = f(x_j)\}$
Candidate Documents: $\mathcal{R} = \{x_k \colon x_k \in \mathcal{X}\}$
Task: For $q_j \in \mathcal{Q}$, rank the candidates based on cosine similarity.
Evaluation: MRR and T100. For each q_j, there is only one relevant document in the candidate set which is the corresponding T+A embedding.
We present the results for various models on different domains in Table 3. The results suggest that SciBERT performs poorly for all domains. OAG-BERT on an average ranks the original document in the range 5-7th position. However, we also observe that even in the best case, only 33% queries retrieve the original document in the top-100 retrieved candidates. SPECTER, on the other hand performs consistently better than both SciBERT and OAG-BERT. The MRR score suggests that on average, the original document is ranked in the top-2 documents, also has a good T100 score across all domains. However, for around 10% of the queries in the Arxiv-MATH, Arxiv-HEP, and ICLR datasets, SPECTER does

not rank the original relevant document in the top-100 retrieved candidates.

Task II: Introducing all Titles in the Candidate Set To increase the complexity of the previous task, we add all the title embeddings (T) in the candidate set (Figure 1(b)). We test if the T embeddings are more similar to other titles, or to their corresponding T+A embeddings.

Query: $\mathcal{Q} = \{q_j\colon x_j \in \mathcal{X}, f = \mathrm{T}, q_j{=}f(x_j)\}$

Candidate Documents: For query q_j, the candidate set $\mathcal{R}_j$ is defined as,

$\mathcal{R}_j{=}\{f(x_i) : x_i \in \mathcal{X}, f = \mathrm{T}, i \neq j\} \bigcup \{x_k\colon x_k \in \mathcal{X}\}$

The task and evaluation metrics are same as Task I. Extremely poor values for SciBERT (Table 3) lead us to examine the vector space of embeddings presented in Figure 2 (t-SNE plots for T and T+A embeddings), revealing that T and T+A embeddings form two non overlapping clusters. Even though the title text is a subset of T+A, SciBERT embeddings are significantly different, suggesting that input length influences SciBERT. This highlights the issue in retrieval for varying length query and candidates. We present the t-SNE plots for other datasets in the Appendix D.

SPECTER still performs the best, but a significant drop in MRR and T100 suggests that both T and T+A embeddings tightly cluster together in partially overlapping small groups (can be verified from Figure 2). However, comparable T100 for OAG-BERT to the previous experiment suggests that the model does not falter when the input text length is small. Ideally, we expect T and T+A embeddings to overlap, indicating that the embeddings of the same paper are closer. The pretraining of these models could be the reason for such distribution of T and T+A embeddings. SciBERT is trained on sentences from full text of research papers, leading to different representations for short (T) and longer (T+A) texts. As SPECTER and OAG-BERT are trained on title and abstract fields both, such non-overlapping behavior is not observed.

6 Analysing Scientific LMs with Textual Neighbors

In the previous section, we experimented with different input fields (T vs T+A). In this section, we experiment with the 32 textual neighbors classes (which alter different input fields: T, A, or T+A). We present our results for the following experiments for the five broad categories: LL-HS, LL-PS, LL-DS, LO-HS, and LO-DS. Due to space constraints, we present plots for selective datasets for each of the experiment in the paper. The rest of the plots are presented in Appendix E.

6.1 Distribution of Textual Neighbors in the Embedding Space

We measure how textual neighbor embeddings are distributed in the embedding space in each dataset when encoded by the SciBERT, SPECTER, and OAG-BERT model. For each textual neighbor class listed in Table 1, we compute pairwise similarities among all input pairs. A plot of the similarity values for different textual neighbor categories is presented in Figure 4 (additional plots in Appendix E.2). It can be observed that the pairwise similarities among documents are spread out in a significantly broader range for OAG-BERT than SciBERT and SPECTER on all datasets. The average similarity for all datasets by all models is above 0.5. We do not observe any significant difference in the average similarity for different textual neighbor classes. Interestingly, for the SPECTER model, the minimum similarity is greater than zero for all datasets across all neighbor categories. Document pair similarity via OAG-BERT embeddings have a low average similarity for the LO-DS category.

We present the percentage of pair of documents for each Textual Neighbor whose similarity is greater than the average similarity in Figure 3 (additional plots in Appendix E.2). OAG-BERT shows high inter similarity (greater than 50%) for majority of textual neighbors suggesting that more than 50% document pairs have a cosine similarity greater than average similarity. For SPECTER vectors, all types of textual neighbors have around 50% documents pairs having a similarity greater than mean similarity. However, extremely high values of percentage of document pairs having similarity greater than average similarity for the SciBERT model on the ACL dataset, and the OAG-BERT on almost all dataset suggests that majority of the documents in the embedding space are represented compactly for all textual neighbor categories.

6.2 Similarity of Textual Neighbors with Original Documents

Let $\mathcal{F} = \{f^1, f^2, ..., f^n\}$ be the set of textual neighbor functions described in Table 1. We query different types of textual neighbor classes against the documents embeddings (T+A). We compute the

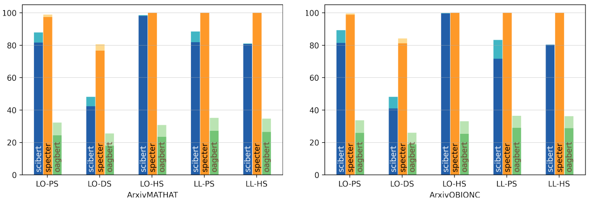

Figure 5: The bottom and the stacked bars represent NN1_Ret and NN10_Ret respectively. Results suggest that SciBERT embeddings for textual neighbors of scientific text are the most optimal.

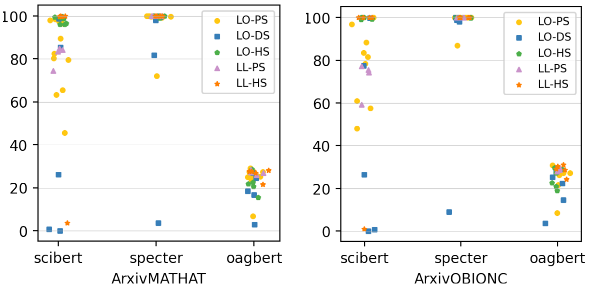

Figure 6: Distribution of NN1_Ret for each textual neighbor category. SciBERT embeddings preserve the hierarchy of NN1_Ret, i.e. PS categories (LO-PS and LL-PS) have lower values than HS categories (LO-HS and LL-HS).

percentage of queries that successfully rank the original document in the top-1 and top-10 ranked list. We expect *HS* and *PS* categories to rank the original document higher in the rank list, and *DS* to rank it lower. If any of the textual neighbor classes or categories don't show the expected behavior, it can be asserted that the LM is brittle in representing the specific type of textual neighbor.

Query: $\mathcal{Q} = \bigcup_{f\in\mathcal{F}} \mathcal{Q}_f = \bigcup_{f\in\mathcal{F}} \{q_j\colon x_j \in \mathcal{X}, q_j{=}f(x_j)\}$

Candidate Documents: $\mathcal{R} = \{x_k\colon x_k \in \mathcal{X}\}$

Task: For $q_j \in \mathcal{Q}$, retrieve the most similar documents based on cosine similarity.

Evaluation: NN1_Ret and NN1_10. There is only one relevant document in the candidate set for each q_j, which is the corresponding T+A embeddings.

We present the results in Figure 5. SciBERT and OAG-BERT for the LO-DS category show less than 50% NN10_Ret, which is desirable as LO-DS neighbors are semantically dissimilar, and hence should not be neighbors in the embedding space. SciBERT shows improvement via NN10_Ret over NN1_Ret for *PS* categories. High NN1_Ret for *HS* categories indicates SciBERT successfully encodes highly similar texts closer than partially similar texts. OAG-BERT performs poorly for both metrics, indicating that it doesn't encode textual

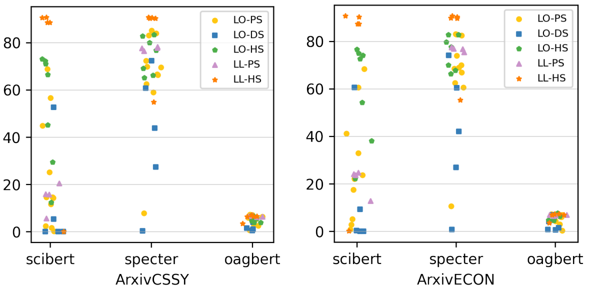

Figure 7: AOP-10 distribution of all categories of textual neighbors. SciBERT performs poorly for LL-PS (consists of neighbors that scramble abstract sentences). If we ignore LO-DS category, SPECTER embeddings perform decently overall.

neighbors optimally. SPECTER embeddings perform poorly on the LO-DS category. They however achieve the maximum values showing no difference between LO vs LL, or HS vs PS categories.

To analyse the high values for SPECTER, we present the individual NN1_Ret for each of the 32 textual neighbor classes in Figure 6 and observe only two classes 'TDelNN' and 'T_A_DelNNChar' which lead to less than 90% NN1_Ret. Unlike SPECTER and OAG-BERT, SciBERT preserve the hierarchy, with *Highly Similar* classes ranked higher than *Partially Similar* classes. An interesting case with SciBERT embeddings is that the T_A_WS neighbor class belonging to the LL-HS category, has a low NN1_Ret value across all datasets, suggesting that the SciBERT model is extremely brittle to white space character perturbations (because of the constraint on sequence length). Another breaking point for the SciBERT is the textual neighbor class T_ARepADJ (replacing adjectives with antonyms) of LO-DS category, which shows high values (around 80%) for NN1_Ret which is undesirable. We observe that among the three specific LO-PS categories 'T_ADelQ1', 'T_ADelQ2', and 'T_ADelQ3', SciBERT performs worst for the 'T_ADelQ3', indicating that the last quantile of the abstract contains relevant information encoded by SciBERT. OAG-BERT shows a reverse trend to SPECTER by achieving low values for all neighbors classes indicating brittleness to text manipulation.

6.3 Overlap amongst Nearest Neighbors

We compute the overlap amongst the nearest neighbors of each textual neighbor class and the original document embeddings. We randomly sample a query set of 2000 queries for each textual neighbor

Table 4: AOP-10 values for different categories. The best results for LO-DS category are from OAG-BERT (OB), however that is because the model performs poorly on all categories of textual neighbors. Similarly, best results for the rest four categories are from SPECTER (SP), following which it also has a high overlap percentage for the LO-DS category. SciBERT (SB) embeddings perform the best for HS and DS but falter on PS semantic categories.

class (and their corresponding T+A embedding) and compute nearest neighbor (NN) overlap for these. In this task, we are interested in evaluating if NN-based retrieval retrieves the same documents for a textual neighbor class and T+A embedding.
Query: $\mathcal{Q} = \mathcal{Q}_f \cup \mathcal{Q}_{T+A}$
$\mathcal{Q}_f = \{q_j\text{: } x_j \in \mathcal{X}_{2000},\, q_j = f(x_j)\}$
$\mathcal{Q}_{T+A} = \{q_j\text{: } x_j \in \mathcal{X}_{2000},\, q_j = T + A(x_j)\}$
Candidate Documents: $\mathcal{R} = \{q_j\text{: } x_j \in \mathcal{X},\, q_j{=}f(x_j)\} \cup \{q_j\text{: } x_j \in \mathcal{X},\, f = T + A,\, q_j{=}f(x_j)\}$
Task: For each pair of $q_j, q_k \in \mathcal{Q}$, such that $q_j \in \mathcal{Q}_f$ and $q_k \in \mathcal{Q}_{T_A}$, compute the overlap among ten nearest neighbors (NN-10) of q_j and q_k.
Evaluation: AOP-10.
We present the results arranged by Textual Neighbor categories in Table 4. The individual AOP-10 distribution of all categories of textual neighbors is presented in Figure 7. While overall results look good for SPECTER, it should be noted that SPECTER performs poorly for embedding LO-DS textual neighbors indicating that it has a shallow understanding of semantics. AOP-10 values for SPECTER show a positive trend: LL-HS $>$ LO-HS and LL-HS $>$ LL-PS. SciBERT performs decently for the *HS* category, but its performance drops for the *PS* categories. OAG-BERT has the lowest AOP-10 for all textual neighbor categories. When put in perspective against the previous NN1_Ret and NN10_Ret, we believe that SciBERT performs decently in encoding the HS and PS neighbors closer to the original T+A embedding. However, low value of AOP-10 for SciBERT for PS neighbors reflects that while the PS neighbors are closer to the original document in comparison to others, the original document has other nearest neighbors than the PS neighbor.

We present a matrix to summarize the capability of the models in Table 5 in encoding the five textual neighbor categories. The five categories arranged in increasing order of semantic similarity are: LL-HS $\geq$ LO-HS $>$ LL-PS $>$ LO-PS $>$ LO-DS. We use heuristic-based values to define optimality. For each of the five categories, we define AOP-20 thresholds to classify if the textual neighbor representations for the corresponding are optimal or not. It is expected that AOP-20 values for semantic categories should be in order: HS $>$ PS $>$ DS. AOP-20 values for orthographic categories should follow: LL $>$ LO.

	LL-HS	LO-HS	LL-PS	LO-PS	LO-DS
Threshold	> 75	> 70	$50 < \text{AOP-20} < 70$		< 20
SciBERT	**75.04**	59.62	22.6	26.28	14.35
SPECTER	**86.77**	**77.55**	80.93	**69.03**	41.32
OAG-BERT	6.84	6.24	7.31	5.95	**3.17**

Table 5: Capability of the models in encoding textual neighbor categories optimally in the embedding space. Gray cells represent optimal representations for each model based on AOP-20.

7 Conclusion

We propose five categories of textual neighbors to organize the increasing number of textual neighbor types: LL-HS, LO-HS, LL-PS, LO-PS, and LO-DS. We evaluate SciBERT, SPECTER, and OAG-BERT models on thirty-two textual neighbor classes organized into the previous five categories. We show that evaluation of language models on 'Semantically Dissimilar' texts is also important rather than just evaluation on 'Semantically Similar' texts. We show that the SciBERT model is highly sensitive to the input length. SPECTER embeddings for all types of textual neighbors are highly similar irrespective of whether the textual neighbor is semantically dissimilar or not. SPECTER embeddings show sensitivity to the presence of specific keywords. Lastly, OAG-BERT embeddings of all categories of textual neighbors are highly dissimilar to the original title and abstract (T+A) embeddings. We believe that our insights could be used to develop better pretraining strategies for scientific document language models and also to evaluate other language models. One example for MLM (or replaced token identification) could be utilizing a weighted-penalty based loss, i.e. partially similar tokens if predicted should be penalized less in comparison to the prediction of unrelated (or dissimilar) tokens. Additionally, these insights could also be utilised by several systems that use these scientific document language models to incorporate informed strategies in downstream systems such as recommendation systems.

Table 6: Candidate documents retrieved for queries ‘document vector’ and ‘document vectors’.

B Textual Neighbors

We present examples for textual neighbors in Table 7. We use NLTK for preprocessing text and constructing textual neighbors.

C Summary of Scientific LMs

We discuss some popular scientific document language models which leverage the transformer architecture.

SciBERT (Beltagy et al., 2019) is also a BERT model trained on large amounts of scientific data. It is trained on a random sample of 1.14M papers from the Semantic Scholar Corpus. The training corpus consists of 18% papers from the computer science domain and 82% from the broad biomedical domain. Full texts of the papers are used for training.

SPECTER (Cohan et al., 2020) uses citation-informed Transformers to generate general-purpose vector representations of scientific documents. Unlike traditional models, they also leverage inter-document relatedness to learn general purpose embeddings that are effective across a variety of downstream tasks without task-specific fine-tuning. SPECTER leverages citations as a signal for document-relatedness and formulate this into a triplet-loss pre-training objective. SPECTER achieves state-of-the-art results on six out of seven document-level tasks for scientific literature in the SCIDOCS (Cohan et al., 2020) benchmark suite.

OAG-BERT (Liu et al., 2021) jointly model texts (title and abstract of the paper) and heterogeneous academic entities (authors, research field, venues, and affiliations) to learn representations for a scientific document. The architecture is similar to BERT, however the authors employ multiple techniques to learn entity embeddings. To distinguish different textual and academic entities use entity type embeddings to indicate the entity type. They design an entity aware 2D-positional encoding to indicate the inter-entity and the intra-entity sequence order. It also proposes span-aware entity masking to preserve the sequential relationship between the entity's tokens.

BioBERT (Lee et al., 2020) is a BERT model pre-trained on large-scale biomedical corpora. BioBERT model is initialized with BERT cite weights and then pre-trained on PubMed abstracts and PMC full-text articles.

Succeeding the BioBERT model, several models have been trained exclusively for Biomedical texts such as ClinicalBERT (Huang et al., 2019), MIMIC-BERT (Si et al., 2019), PubMedBERT (Gu et al., 2020), and BioMegatron (Shin et al., 2020) to list a few. However, in this work, we focus on general purpose scientific language models that have been trained on scientific documents from diverse research fields.

We summarize the details of the SciBERT, SPECTER, and the OAG-BERT model in Table 8.

C.1 Non Transformer-based Models

Majority of Non Transformer based models utilise the Paragraph Vector (Le and Mikolov, 2014) technique to learn vectors for the textual content. Citation networks are utilised to learn similar embeddings for related papers. Paper2Vec (Ganguly and Pudi, 2017) learns embeddings by applying DeepWalk (Perozzi et al., 2014) on an augmented citation network of papers. Apart from connecting cited papers, the augmented network also connects k nearest neighbors (from textual embeddings generated using Paragraph Vector (Le and Mikolov, 2014)). Paper2Vec (Tian and Zhuo, 2017) learns distributed vertex embeddings from matrix factorization on the weighted context definition of nodes. Following a similar technique as Paper2Vec (Ganguly and Pudi, 2017), VOPRec (Vector Representation Learning of Papers with Text Information and Structural Identity for Recommendation) (Kong et al., 2021) learns embeddings from the text using Paragraph Vector (Le and Mikolov, 2014) and the citation network using Struc2Vec (Ribeiro et al., 2017).

Zhu et al. (2019) present a method to learn scholar paper embeddings (Represent Anything from Scholar Papers) from different scholar entities such as title, authors, publication venue, and citations. It trains the model by trying to maximize the likelihood of references of a paper. It uses an encoder-decoder framework to learn representations from title words, author names, publication venue, and publication year. The proposed method can generate representations for papers even if the references are missing as that information is already encoded in the entities during the training.

As the pretrained models or code for none of the Non Transformer-based models is publicly available, we skip their evaluation in this work.

D Analysing Embeddings for Scientific Document Titles and Abstracts

We present the t-SNE plots for the Task II in Figure 8. The embedding space contains vectors for titles and the T+A embeddings.

D.1 Normalized Embeddings

Timkey and van Schijndel (2021) indicate that cosine similarity is dominated by few rouge dimensions in embeddings. We repeat Task I with: (i) L2-normalized embeddings, and (ii) standardization procedure by Timkey and van Schijndel (2021). While L2-normalization leads to an incremental improvement, standardization leads to improvement only for SciBERT and SPECTER models. We present the results of **Task I** (Section 5) with normalized embeddings in Table 9.

E Analysing Scientific LMs with Textual Neighbors

We present the plots for each of the seven datasets for the experiments with textual neighbors in the following sections.

E.1 Distribution of Textual Neighbors in the Embedding Space

We present the plot for inter similarity of textual neighbor vectors in Figure 9, which depicts the maximum, minimum, mean and standard deviation of all pairs of documents for the five neighbor categories. Next, we present the percentage of document pairs for each of the 32 textual neighbor classes, whose similarity is greater than the average similarity for that particular class in Figure 10.

E.2 Similarity of Textual Neighbors with Original Documents

Figure 11 presents the NN1_Ret and NN10_Ret for each of the datasets for the five textual neighbor

categories in the stacked bar format (NN10_Ret stacked onto NN1_Ret values). It can be observed that for all datasets, SPECTER achieves extremely high (> 95%) NN1_Ret values for four (LO-PS, LO-HS, LL-PS, and LL-HS) out of five classes, and hence NN10_Ret does not significantly improve the retrieval. SciBERT values though less in comparison to SPECTER, show a nice trend

Table 9: L2 normalization leads to an incremental improvement in performance. Standardization leads to improvement for SciBERT and SPECTER models, but the same effect is not observed for OAG-BERT embeddings.

where NN10_Ret does not improve the retrieval significantly for *HS* categories (LO-HS and LL-HS), however it does improve retrieval recall for *PS* categories (LO-PS and LL-PS). OAG-BERT performs poorly with all categories achieving NN10_Ret values less than 40%. We present in Figure 12, the NN1_Ret for each of the 32 textual neighbor classes. A close inspection reveals an interesting case for SciBERT, which has extremely low NN1_Ret values ($< 10\%$) for one of the LL-HS category, T_A_WS whih replaces 50% whitespace characters randomly with 2-5 whitespaces.

E.3 Overlap amongst Nearest Neighbors

AOP-10 is the average overlap percentage among the 10-NN (10 nearest neighbors) of the original document embeddings (T+A) and the textual neighbor embeddings. AOP-10 distribution of the 32 textual neighbor classes is presented in Figure 13. Low overlap percentage for OAG-BERT suggests that the model falters when presented with textual neighbors and does not represent textual neighbors in the neighborhood of the original document embeddings in the embedding space.

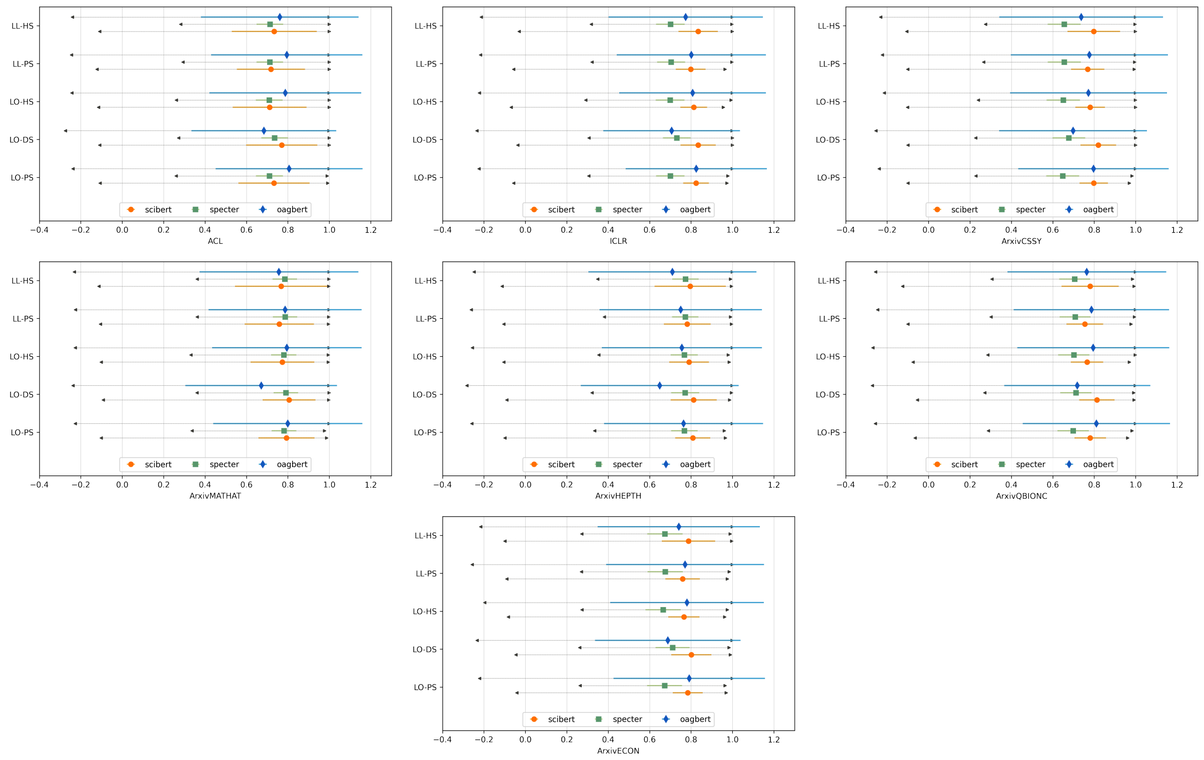

Figure 9: Inter Similarity of Textual Neighbor Vectors. The pairwise similarities among documents are spread out in a significantly broader range for OAG-BERT than SciBERT and SPECTER, suggesting that OAG-BERT vectors for different textual neighbors are more spread out in the vector space.

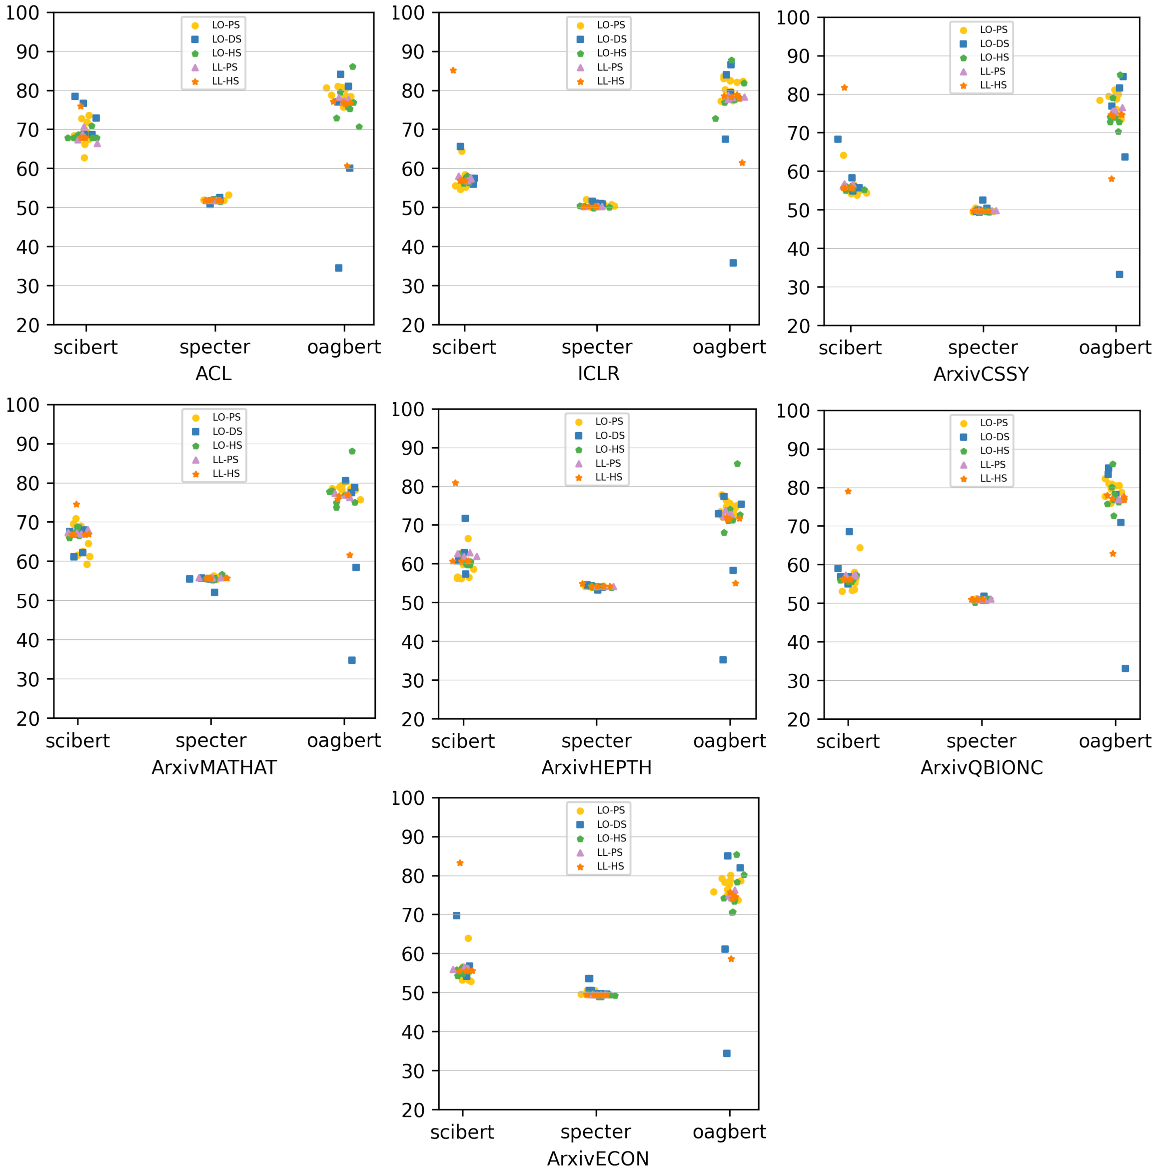

Figure 10: Percentage of pair of documents for each Textual Neighbor whose similarity is greater than the average similarity. OAG-BERT shows high inter similarity (greater than 50%) among all textual neighbors suggesting that more than 50% document pairs have a cosine similarity greater than average similarity.

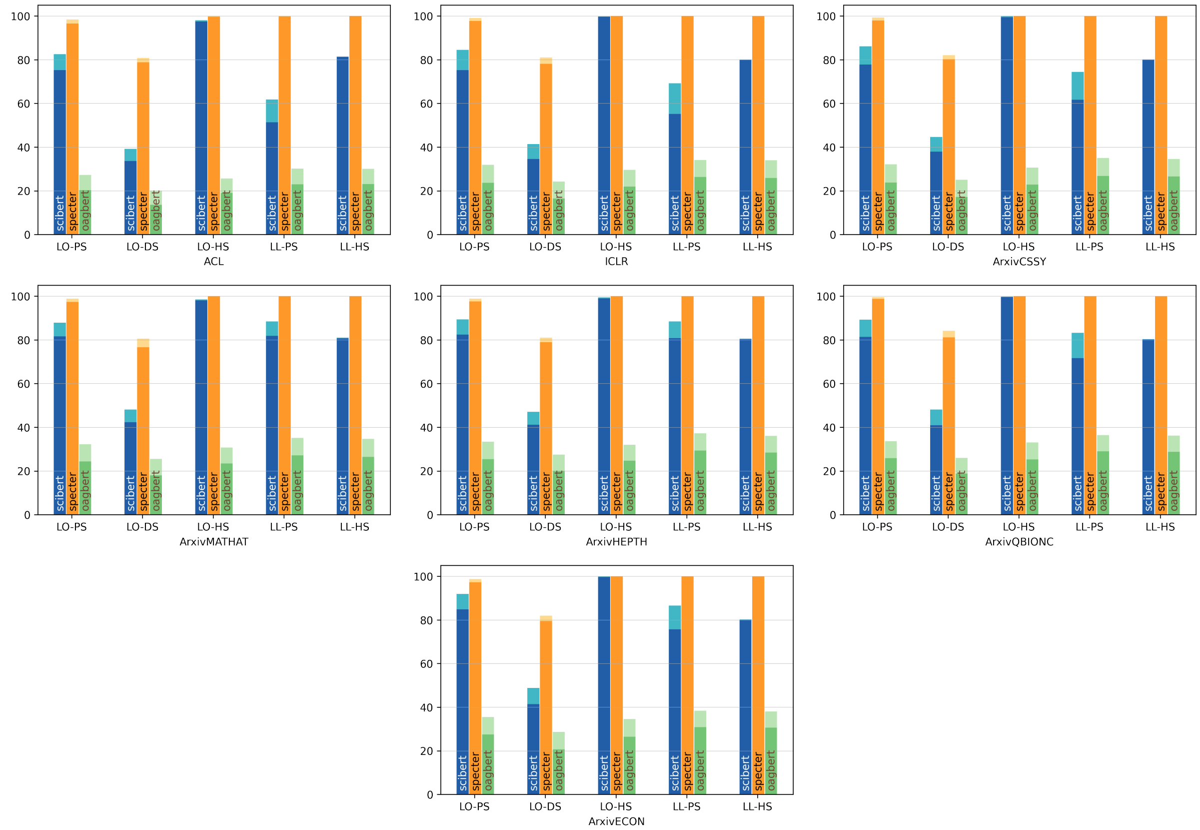

Figure 11: Stacked bars representing the percentage of documents of each textual neighbor category which retrieve the original document in the top-1 nearest neighbor and the top-10 nearest neighbor respectively. Results suggest that SciBERT embeddings for textual neighbors of scientific text are the most optimal.

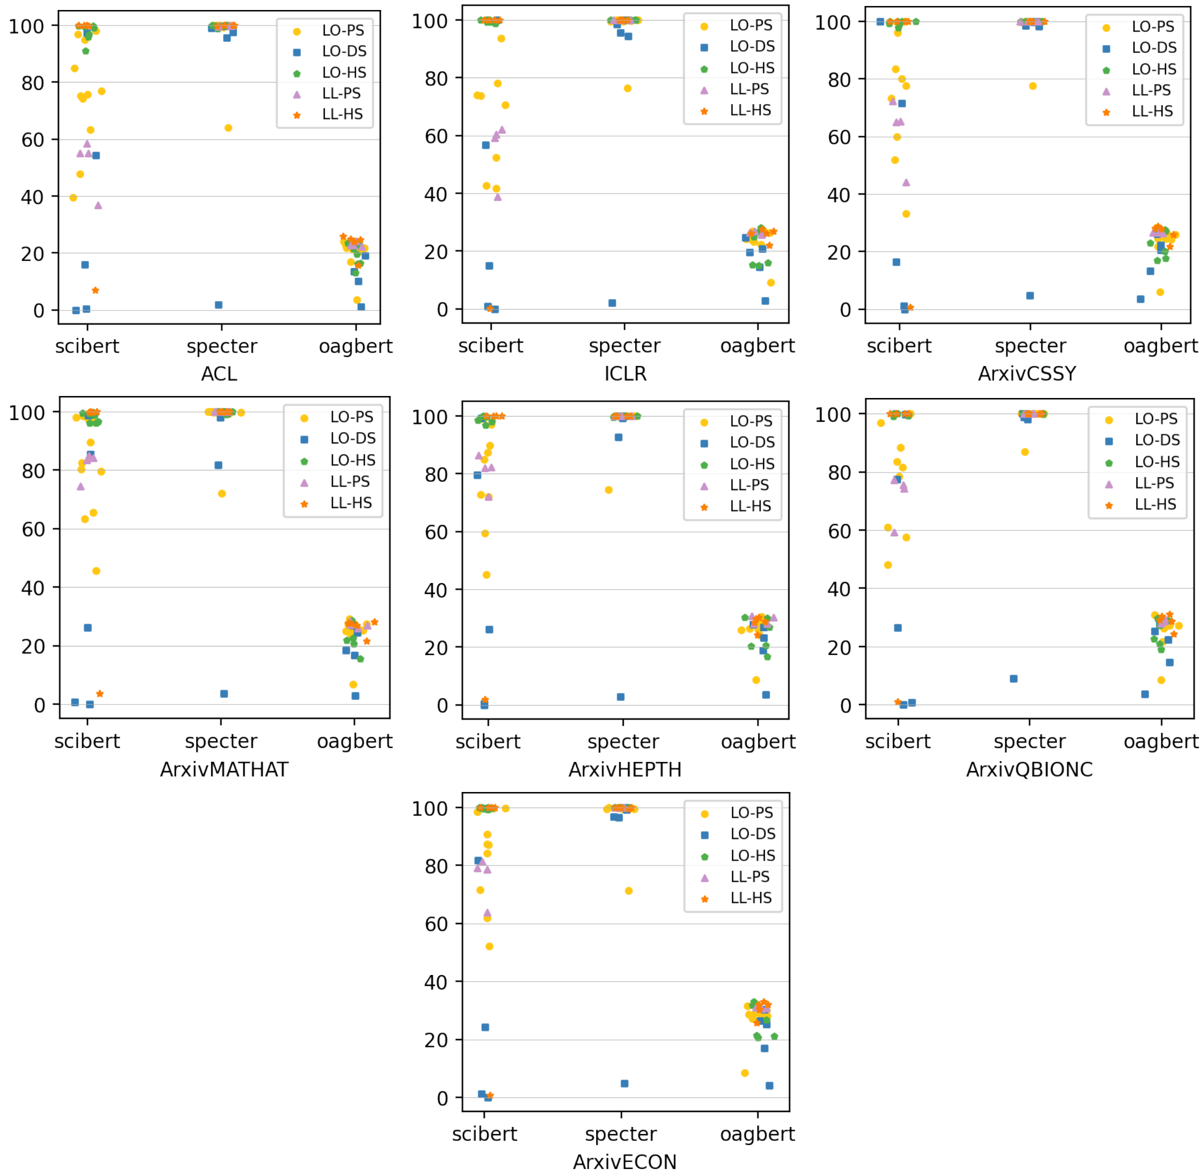

Figure 12: Distribution of NN1_Ret for each textual neighbor category. It can be observed that SciBERT embeddings preserve the hierarchy of NN1_Ret, i.e. Partially Similar categories (LO-PS and LL-PS) have lower values than Highly Similar categories (LO-HS and LL-HS).

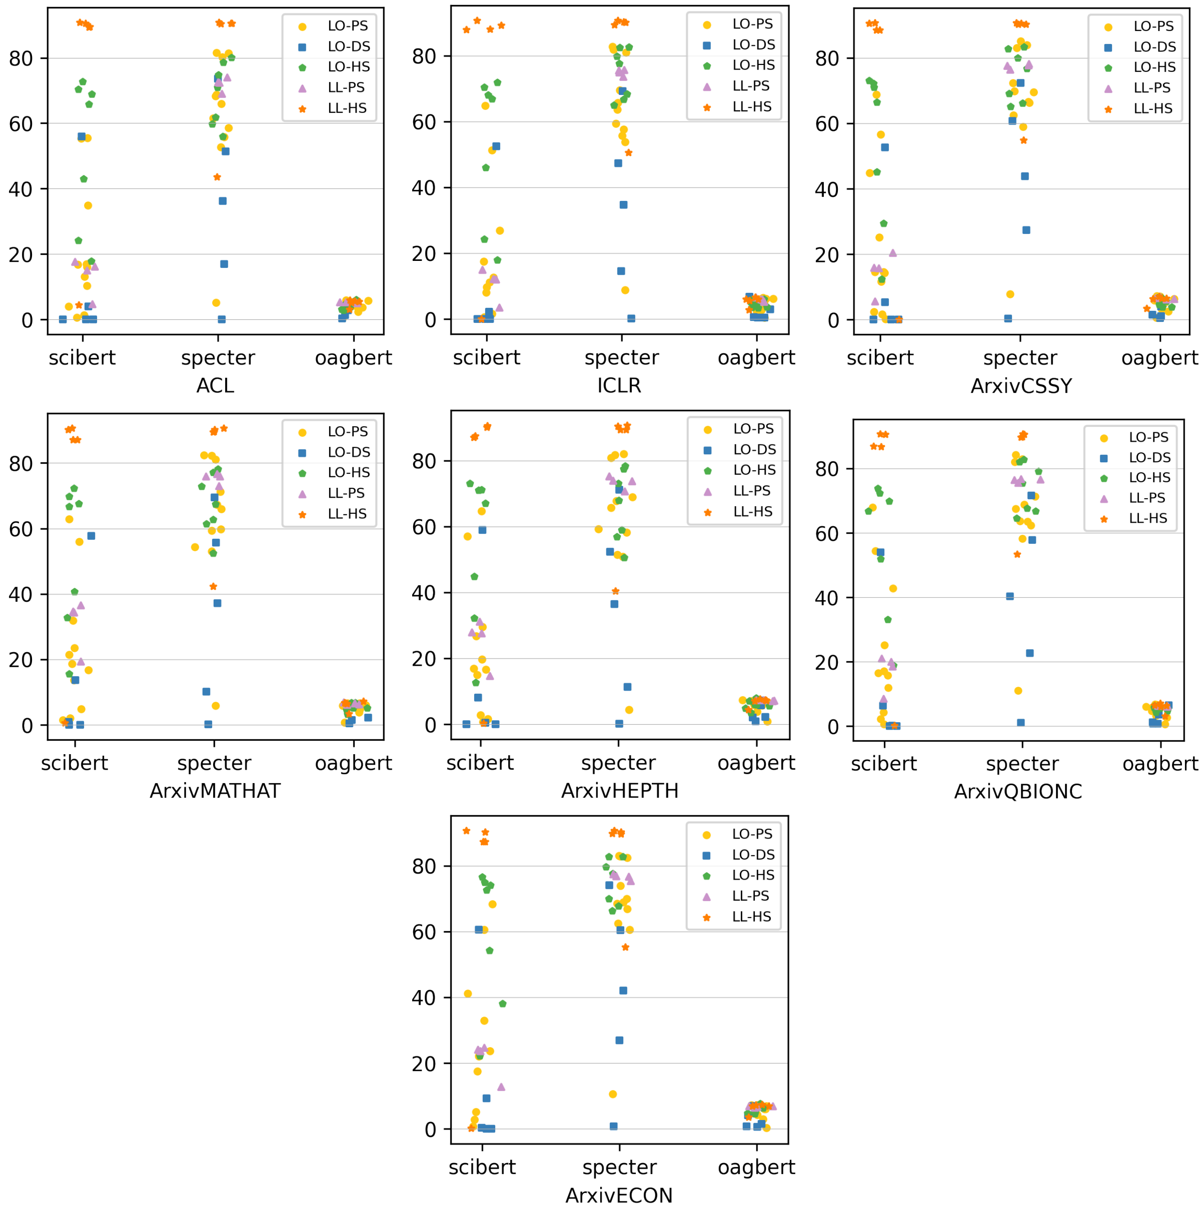

Figure 13: AOP-10 distribution of all categories of textual neighbors. It can be observed that SciBERT performs poorly for the LL-PS category (involves neighbors that scramble sentences such as arranging randomly, or arranging in increasing or decreasing order of sentence length). For the rest of the categories, SciBERT embeddings show desirable order of AOP-10 values, e.g. LL-HS > LO-HS. SPECTER values have high AOP-10, which is desirable, except for the LO-DS category.

Fusing Heterogeneous Factors with Triaffine Mechanism for Nested Named Entity Recognition

Abstract

Nested entities are observed in many domains due to their compositionality, which cannot be easily recognized by the widely-used sequence labeling framework. A natural solution is to treat the task as a span classification problem. To learn better span representation and increase classification performance, it is crucial to effectively integrate heterogeneous factors including inside tokens, boundaries, labels, and related spans which could be contributing to nested entities recognition. To fuse these heterogeneous factors, we propose a novel triaffine mechanism including triaffine attention and scoring. Triaffine attention uses boundaries and labels as queries and uses inside tokens and related spans as keys and values for span representations. Triaffine scoring interacts with boundaries and span representations for classification. Experiments show that our proposed method outperforms previous span-based methods, achieves the state-of-the-art F_1 scores on nested NER datasets GENIA and KBP2017, and shows comparable results on ACE2004 and ACE2005.

1 Introduction

Named entity recognition (NER) is a fundamental natural language processing task that extracts entities from texts. Flat NER has been well studied and is usually viewed as a sequence labeling problem (Lample et al., 2016). However, nested entities also widely exist in real-world applications due to their multi-granularity semantic meaning (Alex et al., 2007; Yuan et al., 2020), which cannot be solved by the sequence labeling framework since tokens have multiple labels (Finkel and Manning, 2009).

Various paradigms for nested NER have been proposed in recent years. A representative direction is the span-based approach that learns deep representation for every possible span and then classifies it to the corresponding type (Zheng et al., 2019; Xia et al., 2019; Wadden et al., 2019; Tan et al., 2020; Wang et al., 2020; Yu et al., 2020). By leveraging the large-scale pretrained language model, several works show that the simple model structure for span representation and classification can achieve satisfactory results (Luan et al., 2019; Zhong and Chen, 2021). However, we still believe that explicit modeling of some relevant features will further benefit the span representation and classification under the complex nested setting. Taking Figure 1 as an example, we claim that the following factors are critical for recognizing whether a span is an entity. (1) **Tokens**: It is obvious that tokens of the given span contribute to the recognition. (2) **Boundaries**: We emphasize boundaries (or boundary tokens) because they are special tokens with rich semantics. Works with simple structure may just produce the span representation based on the concatenation or biaffine transformation of boundary representation (Yu et al., 2020; Fu et al., 2021). Some other works take boundary detection as additional supervision for better representation learning (Zheng et al., 2019; Tan et al., 2020). More importantly, a unilateral boundary cannot determine the entity type since it can exist in multiple entities with different labels (e.g., "*NF*", "*B*", and "*cells*") under the nested setting. (3) **Labels**: As mentioned above, tokens could belong to entities with different labels. Therefore, we propose that the model should learn label-aware span representation to take into consideration of the different

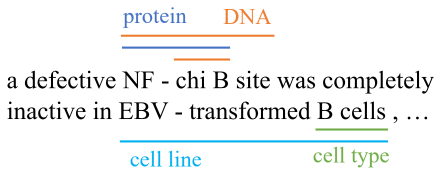

Figure 1: An example sentence with nested entities from the GENIA dataset.

Findings of the Association for Computational Linguistics: ACL 2022, pages 3174 - 3186
May 22-27, 2022

token contributions at the label level.[1] For example, "*NF*" may contribute more to "protein" type when classifying the span "*NF - chi B*", as well as "*chi B*" and "*site*" contribute more to "DNA" type when classifying the span "*NF - chi B site*". (4) **Related spans**: Interactions among spans are important in nested entities (Luo and Zhao, 2020; Wang et al., 2020; Fu et al., 2021). The insider and outsider entities may hint at each other's types. For example, entities inside "*EBV-transformed B cells*" have more possibilities to be cell-related entities. Interactions can also help the non-entity span like "*transformed B cells*" to validate its partialness by looking at outer entity "*EBV - transformed B cells*".

Although some of the factors may have been explored in previous works, to the best of our knowledge, it is the first work to fuse all these heterogeneous factors into a unified network. As the traditional additive, multiplicative attention, or biaffine transformation cannot interact with such multiple heterogeneous factors simultaneously, we propose a novel triaffine mechanism as the tensor multiplication with three rank-1 tensors (vectors) and a rank-3 tensor, which makes it possible to jointly consider high-order interactions among multiple factors. Specifically, our method follows the pipeline of span representation learning and classification. At the stage of span representation learning, we apply the triaffine attention to aggregate the label-wise span representations by considering boundaries and labels as queries as well as inside tokens as keys and values. Then, a similar triaffine attention is applied to produce the label-wise cross-span representations by querying boundaries and labels with related spans. At the stage of span classification, we fuse the span representations and boundaries for label-wise classification with a triaffine score function. In practice, we add an auxiliary object function to classify spans without the cross-span interaction, which benefits learning robust span representation and can be used as a span filter to speed up both training and inference without performance degradation.

We conduct experiments on four nested NER datasets: ACE2004, ACE2005, GENIA, and KBP2017. Our model achieves 88.56, 88.83, 81.23, and 87.27 scores in terms of F_1, respectively. Using the BERT encoder, our model outperforms state-of-the-art methods on GENIA and KBP2017 and shows comparable performances on ACE2004 and ACE2005 with the latest generative methods. Ablation studies show the effectiveness of each factor and the superiority of the triaffine mechanism.

Our contributions are summarized as [2]:

- We propose that heterogeneous factors (i.e., tokens, boundaries, labels, related spans) should be taken into consideration in the span-based methods for nested NER.
- We propose a span-based method with a novel triaffine mechanism including triaffine attention and scoring to fuse the above-mentioned heterogeneous factors for span representations and classification.
- Experiments show that our proposed method performs better than existing span-based methods and achieves state-of-the-arts performances on GENIA and KBP17.

2 Related Work

2.1 Nested NER

Nested NER approaches do not have a unified paradigm. Here we mainly focus on span-based methods since they are close to our work.

The span-based methods are one of the most mainstream ways for the nested NER. With the development of pre-training, it is easy to obtain the span representation by the concatenation of boundary representation (Luan et al., 2019; Zhong and Chen, 2021) or the aggregated representation of tokens (Zheng et al., 2019; Wadden et al., 2019), and then follow a linear layer (Xia et al., 2019) or biaffine transformation (Yu et al., 2020) for classification. Several works improve the span-based methods with additional features or supervision. Zheng et al. (2019); Tan et al. (2020) point out the importance of boundaries and therefore introduce the boundary detection task. Wang et al. (2020) propose Pyramid to allow interactions between spans from different layers. Fu et al. (2021) adopt TreeCRF to model interactions between nested spans. Compared with previous methods, our method can jointly fuse multiple heterogeneous factors with the proposed triaffine mechanism.

Other methods for nested NER vary greatly. Earlier research on nested NER is rule-based (Zhang et al., 2004). Lu and Roth (2015); Katiyar and

---

[1] Label is the perdition object that we cannot touch in representation learning. Here, leveraging label information only means we need label-aware representation learning.

[2] Codes and models are available at `https://github.com/GanjinZero/Triaffine-nested-ner`.

Cardie (2018); Wang and Lu (2018) leverage the hypergraph to represent all possible nested structures, which needs to be carefully designed to avoid spurious structures and structural ambiguities. Wang et al. (2018); Fisher and Vlachos (2019) predict the transition actions to construct nested entities. Lin et al. (2019) propose an anchor-based method to recognize entities. There are other works that recognize entities in a generative fashion (Yan et al., 2021; Shen et al., 2021; Tan et al., 2021). Generally, it is not a unified framework for nested NER, and we model it with a span-based method since it is most straightforward.

2.2 Affine Transformations in NLP

Dozat and Manning (2017) introduce the biaffine transformation in the dependency parsing task for arc classification. Later, it is widely used in many tasks that need to model bilateral representations (Li et al., 2019; Yu et al., 2020). The triaffine transformation is further introduced to extend biaffine transformation for high-order interaction in the field of dependency parsing (Wang et al., 2019; Zhang et al., 2020) and semantic role labeling (Li et al., 2020b). Except for the similar formula of vectors' interactions, the motivation and the use of triaffine are different in our paper. Firstly, they only model the homogeneous features such as three tokens, but our triaffine transformation can model heterogeneous factors including labels, boundaries, and related spans. Secondly, they usually leverage triaffine transformation to obtain log potentials for CRFs, but we apply it for span representation and classification.

3 Approach

Figure 2 shows an overview of our method. We will first introduce the triaffine transformations, which lie in the heart of our model to fuse heterogeneous factors. Then, we will introduce our model including triaffine attention and triaffine scoring based on the proposed triaffine transformations.

3.1 Deep Triaffine Transformation

We define the deep triaffine transformation with vectors $\mathbf{u}, \mathbf{v}, \mathbf{w} \in \mathbb{R}^d$ and a tensor $\mathcal{W} \in \mathbb{R}^{d+1} \times \mathbb{R}^d \times \mathbb{R}^{d+1}$ which outputs a scalar by applying distinct MLP (multi-layer perceptron) transformations on input vectors and calculating tensor vector multiplications. A constant 1 is concatenated with inputs to retain the biaffine transformation.

$$\mathbf{u}' = \begin{bmatrix} \mathrm{MLP_a}(\mathbf{u}) \\ 1 \end{bmatrix}, \mathbf{v}' = \begin{bmatrix} \mathrm{MLP_c}(\mathbf{v}) \\ 1 \end{bmatrix} \quad (1)$$

$$\mathbf{w}' = \mathrm{MLP_b}(\mathbf{w}) \quad (2)$$

$$\mathrm{TriAff}(\mathbf{u}, \mathbf{v}, \mathbf{w}, \mathcal{W}) = \mathcal{W} \times_1 \mathbf{u}' \times_2 \mathbf{w}' \times_3 \mathbf{v}' \quad (3)$$

where $\times_n$ is the mode-n tensor vector multiplication and $\mathrm{MLP_t}$ is a t-layer MLP (0-layer MLP is equal to identify function). The tensor $\mathcal{W}$ is initialized using $\mathcal{N}(0, \sigma^2)$. In our approach, we use boundary representations as $\mathbf{u}$ and $\mathbf{v}$. Inside tokens or span representations are used as $\mathbf{w}$. We denote the tensors in the triaffine attention as $\{\mathcal{W}_r\}$ and triaffine scoring as $\{\mathcal{V}_r\}$, which decouples attention weights and scores for different labels.

3.2 Text Encoding

We follow Ju et al. (2018); Shen et al. (2021); Tan et al. (2021) to encode the text. For text $X = [x_1, x_2, ..., x_N]$ with N tokens, we first generate the contextual embedding $\mathbf{x}_i^c$ with the pre-trained language model,

$$\mathbf{x}_1^c, \mathbf{x}_2^c, ..., \mathbf{x}_N^c = \mathrm{PLM}(x_1, x_2, ..., x_N) \quad (4)$$

Then, we concatenate $\mathbf{x}_i^c$ with word embedding $\mathbf{x}_i^w$, part-of-speech embedding $\mathbf{x}_i^p$ and character embedding $\mathbf{x}_i^{ch}$, and feed the concatenated embedding $\mathbf{x}_i$ into a BiLSTM (Hochreiter and Schmidhuber, 1997) to obtain the token representations $\{\mathbf{h}_i\}$.

3.3 Triaffine Attention for Span Representations

To fuse heterogeneous factors for better span representation, we propose a triaffine attention mechanism shown in Figure 3a. To interact tokens with labels and boundaries, we learn the label-wise span representation $\mathbf{h}_{i,j,r}$ with the triaffine attention $\alpha_{i,j,k,r}$ for the span (i, j):

$$s_{i,j,k,r} = \mathrm{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_k, \mathcal{W}_r) \quad (5)$$

$$\alpha_{i,j,k,r} = \frac{\exp(s_{i,j,k,r})}{\sum_{k'=i}^{j} \exp(s_{i,j,k',r})} \quad (6)$$

$$\mathbf{h}_{i,j,r} = \sum_{k=i}^{j} \alpha_{i,j,k,r} \mathrm{MLP}(\mathbf{h}_k) \quad (7)$$

Boundary representations ($\mathbf{h}_i$, $\mathbf{h}_j$) and the label-wise parameters ($\mathcal{W}_r$) can be viewed as attention queries, and tokens ($\mathbf{h}_k$) can be viewed as keys

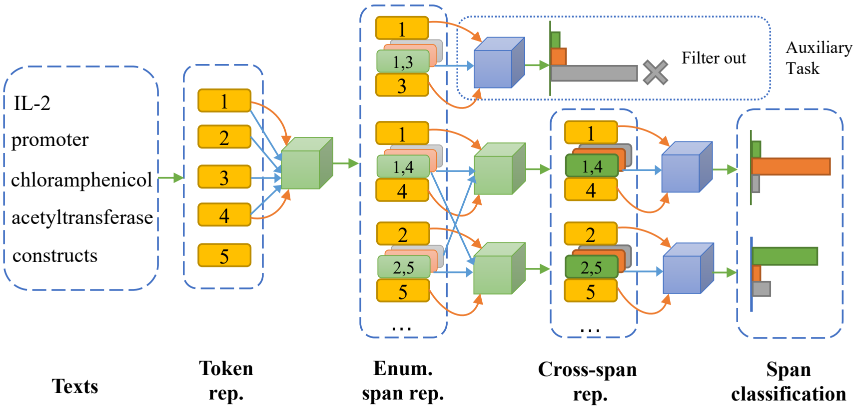

Figure 2: The architecture of our method. Green cubes indicate triaffine attention. Blue cubes indicate triaffine scoring. Orange arrows mean boundary information. Blue arrows mean inside tokens or related spans information. For each span, we have head and tail representations in yellow and label-wise span representations in different colors. The grey color indicates None class.

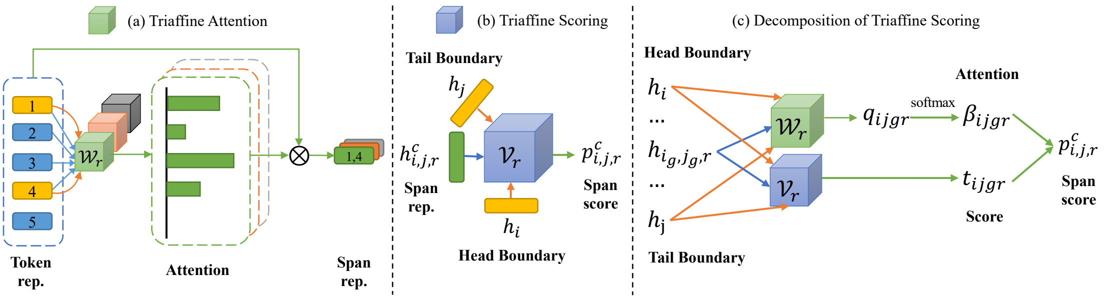

Figure 3: Visualization of triaffine attention, triaffine scoring, and the decomposition of triaffine scoring.

and values. Compared with the general attention framework (additive or multiplicative attention), our triaffine attention permits all high-order interactions between heterogeneous queries and keys.

3.4 Triaffine Attention for Cross-span Representations

Motivated by the span-level interactions in the nested setting, we fuse related spans information into cross-span representations. We view the boundaries of the span and labels as attention queries, related spans (containing the span itself) as attention keys and values to obtain cross-span representations. Similar to the Equation 7, we obtain label-wise cross-span representations $\mathbf{h}^c_{i,j,r}$ for the span (i, j) based on triaffine attention $\beta_{i,j,g,r}$.

$$q_{i,j,g,r} = \text{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_{i_g,j_g,r}, \mathcal{W}_r) \tag{8}$$

$$\beta_{i,j,g,r} = \frac{\exp(q_{i,j,g,r})}{\sum_{g'} \exp(q_{i,j,g',r})} \tag{9}$$

$$\mathbf{h}^c_{i,j,r} = \sum_g \beta_{i,j,g,r} \text{MLP}(\mathbf{h}_{i_g,j_g,r}) \tag{10}$$

where $\{(i_g, j_g)\}$ are the related spans. One can treat all enumerated spans as related spans, and we will introduce how we select them in Section 3.6.

3.5 Triaffine Scoring for Span Classification

To classify the entity type of the span, we calculate label-wise scores based on cross-span representations. Since boundary information has been proved effective in previous works (Yu et al., 2020; Fu et al., 2021), we leverage the boundaries information and cross-span representations for span classification via triaffine scoring. Specifically, we estimate the log probabilities $p^c_{i,j,r}$ of the span (i, j) for label r using boundaries $\mathbf{h}_i$, $\mathbf{h}_j$ and cross-span representations $\mathbf{h}^c_{i,j,r}$.

$$p^c_{i,j,r} = \text{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}^c_{i,j,r}, \mathcal{V}_r) \tag{11}$$

Since $\mathbf{h}^c_{i,j,r}$ are composed by $\mathbf{h}_{i_g,j_g,r}$, we can decompose Equation 11 into following if and only if the layer of MLP transformation on $\mathbf{h}^c_{i,j,r}$ is 0:

$$t_{i,j,g,r} = \text{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_{i_g,j_g,r}, \mathcal{V}_r) \tag{12}$$

$$p^c_{i,j,r} = \sum_g \beta_{i,j,g,r} t_{i,j,g,r} \tag{13}$$

Figure 3b and 3c show the mechanism of triaffine scoring and the decomposition. We also apply the similar decomposition functions in the auxiliary span classification task, which applies the triaffine scoring on boundary representations and intermediate span representations $\mathbf{h}_{i,j,r}$ to estimate log probabilities $p_{i,j,r}$ as intermediate predictions.

3.6 Training and Inference

In practice, it is expensive and non-informative to consider interactions between all spans. Therefore, we propose an auxiliary task to classify spans with intermediate span representations. Then, we can rank all spans based on the maximum of log probabilities (except None) from the intermediate predictions $p_{i,j} = \max_{r=1}^{R} p_{i,j,r}$, and retain top-$m$ spans $\{(i_l, j_l)\}_{l=1}^{m}$ as candidates. We calculate cross-span representations $\mathbf{h}^c_{i_l,j_l,r}$ for retained spans by considering the full interactions among them, and estimate the classification logits $p^c_{i_l,j_l,r}$. Thus, we have two groups of predictions in our model $\{p_{i,j,r}\}_{1\le i\le j\le N}$ and $\{p^c_{i_l,j_l,r}\}_{1\le l\le m}$. $\{p_{i,j,r}\}$ are calculated for every possible span, and $\{p^c_{i_l,j_l,r}\}$ are calculated only on top-m spans.

In the training phase, we jointly minimize two groups of cross-entropy losses:

$$\mathcal{L}_{aux} = -\frac{2}{N(N+1)} \sum_{i,j} \log \frac{\exp(p_{i,j,r_{ij}})}{\sum_r \exp(p_{i,j,r})} \tag{14}$$

$$\mathcal{L}_{main} = -\frac{1}{m} \sum_{1\le l\le m} \log \frac{\exp(p^c_{i_l,j_l,r_{i_l,j_l}})}{\sum_r \exp(p^c_{i_l,j_l,r})} \tag{15}$$

$$\mathcal{L} = \mu_{aux}\mathcal{L}_{aux} + \mathcal{L}_{main} \tag{16}$$

where r_{ij} is the label of span (i, j).

In both the training and inference phase, $\{p_{i,j,r}\}$ are used to select spans with high possibilities based on the supervision from $\mathcal{L}_{aux}$. We inference the labels of selected spans using $\{p^c_{i_l,j_l,r}\}$ by assigning label $\tilde{r}_{i_l,j_l} = \arg_r \max p^c_{i_l,j_l,r}$, and we assign None class for others.

4 Experiments

4.1 Datasets

We conduct our experiments on the ACE2004[3], ACE2005[4] (Doddington et al., 2004), GENIA (Kim et al., 2003) and KBP2017[5] (Ji et al., 2017) datasets. To fairly compare with previous works, we follow the same dataset split with Lu and Roth (2015) for ACE2004 and ACE2005 and use the split from Lin et al. (2019) for GENIA and KBP2017 datasets. The statistics of all datasets are listed in Table 1. Following previous work, we measure the results using span-level precision, recall, and F_1 scores.

4.2 Implementation Details

We use `BERT-large-cased` (Devlin et al., 2019) and `albert-xxlarge-v2` (Lan et al., 2020) as the contextual embedding, `fastText` (Bojanowski et al., 2017) as the word embedding in ACE2004, ACE2005 and KBP2017 dataset. We use `BioBERT-v1.1` (Lee et al., 2020) and `BioWordVec` (Zhang et al., 2019) as the contextual and word embedding in the GENIA dataset respectively. We truncate the input texts with context at length 192. The part-of-speech embeddings are initialized with dimension 50. The char embeddings are generated by a one-layer BiLSTM with hidden size 50. The two-layers BiLSTM with a hidden size of 1,024 is used for the token representations. For triaffine transformations, we use $d = 256$ for the ACE2004, ACE2005, and KBP2017 dataset, and $d = 320$ for the GENIA dataset, respectively. We set μ_{aux} to 1.0, and select $m = 30$ in both training and inference. We use AdamW (Loshchilov and Hutter, 2019) to optimize our models with a linear learning rate decay. Detailed training parameters are presented in Appendix A.

4.3 Baselines

DYGIE (Luan et al., 2019) uses multi-task learning to extract entities, relations, and coreferences.
MGNER (Xia et al., 2019) uses a detector to find span candidates and a classifier for categorization.
BENSC (Tan et al., 2020) trains the boundary detection and span classification tasks jointly.
TreeCRF (Fu et al., 2021) views entities as nodes in a constituency tree and decodes them with a Masked Inside algorithm.
Biaffine (Yu et al., 2020) classifies spans by a biaffine function between boundary representations.
Pyramid (Wang et al., 2020) designs pyramid layer and inverse pyramid layer to decode nested entities.

We also report the results of models with other paradigms, including hypergraph-based methods (Wang and Lu, 2018), transition-based methods (Fisher and Vlachos, 2019), generative methods (Yan et al., 2021; Tan et al., 2021; Shen et al., 2021), and so on. We do not compare to BERT-MRC (Li

et al., 2020a) since they use additional resources as queries. DYGIE++ (Wadden et al., 2019) and PURE (Zhong and Chen, 2021) use different splits of the ACE datasets which are not comparable.

4.4 Results

We compare our method with baseline methods in Table 2 for the ACE2004, ACE2005, and GENIA datasets and Table 3 for the KBP2017 dataset, respectively. With BERT as the encoder, our model achieves 87.40, 86.82, 81.23, and 85.05 scores in terms of F_1, outperforming all other span-based methods such as BENSC, Pyramid, TreeCRF, and Biaffine (+0.70 on ACE2004, +1.42 on ACE2005, +0.73 on GENIA). Compared with methods in other paradigms, our model also achieves the state-of-the-art results on the GENIA (+0.69 vs. Locate and Label) and KBP2017 dataset (+1.00 vs. Locate and Label) and shows comparable performances on ACE2004 (-0.01 vs. Locate and Label) and ACE2005 (-0.23 vs. Sequence to Set). With a stronger encoder ALBERT, our model achieves 88.56, 88.83, and 87.27 scores in terms of F_1 on ACE2004, ACE2005, and KBP2017 respectively, which exceeds all existing baselines including the Pyramid model with ALBERT (+0.82 on ACE2004, +2.49 on ACE2005) and the previous state-of-the-art method on KBP2017 dataset (+3.22 vs. Locate and Label).

4.5 Ablation Study

Considering we leverage multiple factors in multiple parts of the model, we design the following ablation settings to validate the effectiveness of each factor and the proposed triaffine mechanism.

	Setting							Datasets	
	Span Representation			Span Classification				ACE2004	GENIA
Setting	Label	Boundary	Function	Boundary	Attention	Cross	Function	F_1	
(a)	×	×	×	√	×	×	bi.	86.71	78.97
(b)	√	√	tri.	×	√	×	lin.	87.36	80.50
(c)	×	√	tri.	√	√	×	tri.	87.17	80.49
(d)	√	×	lin.	√	√	×	tri.	87.14	80.50
(e)	√	√	lin.	√	√	×	tri.	87.35	80.63
(f)	√	√	tri.	√	√	×	lin.	87.49	80.70
(g)	√	√	tri.	√	√	×	tri.	87.54	80.84
(h)	√	√	tri.	√	√	√	tri.	**87.82**	**81.23**

Table 4: Ablation tests on ACE2004 development set and GENIA test set. Cross means using cross attention for span classification. Lin. means linear transformation, bi. means biaffine transformation, and tri. means triaffine transformation.

(a) To show the effectiveness of triaffine mechanism, we use a baseline biaffine model with the combination of boundary representations:

$$p_{i,j,r} = \begin{bmatrix} \mathbf{h}_i \\ 1 \end{bmatrix}^T \mathbf{V}_r \begin{bmatrix} \mathbf{h}_j \\ 1 \end{bmatrix} \tag{17}$$

(b) To show the effectiveness of boundaries in scoring, we remove boundaries factor from scoring:

$$p_{i,j,r} = \mathbf{V}_r \mathbf{h}_{i,j,r} + \mathbf{b}_r \tag{18}$$

(c) To show the effectiveness of labels in representation, we remove label factor in attention:

$$s_{i,j,k,r} = \mathrm{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_k, \mathcal{W}) \tag{19}$$

(d) To show the effectiveness of boundaries in representation, we remove boundaries factor in attention:

$$s_{i,j,k,r} = s_{k,r} = \mathbf{q}_r \cdot \mathbf{h}_k \tag{20}$$

(e) To show the effectiveness of the triaffine mechanism in representations, we replace triaffine attention with linear attention:

$$s_{i,j,k,r} = \mathbf{W}_r(\mathbf{h}_i \parallel \mathbf{h}_j \parallel \mathbf{h}_k) + \mathbf{c}_r \tag{21}$$

(f) To show the effectiveness of triaffine scoring, we replace triaffine scoring to linear scoring:

$$p_{i,j,r} = \mathbf{V}_r(\mathbf{h}_i \parallel \mathbf{h}_j \parallel \mathbf{h}_{i,j,r}) + \mathbf{b}_r \tag{22}$$

(g) To show the effectiveness of cross-span interactions, we use our partial model with intermediate predictions (model (a)-(g) use $p_{i,j,r}$).
(h) Our full model (i.e, use $p^c_{i_l,j_l,r}$ as predictions).

Table 4 shows the results of ablation studies on ACE2004 and GENIA datasets. We use `BERT-large-cased` as the backbone encoder on ACE2004 and `BioBERT-v1.1` on GENIA, respectively. By comparing (a) with (g), we observe significant performances drop (-0.87 on ACE2004, -1.87 on GENIA), which indicates that our proposed triaffine mechanism with multiple heterogeneous factors performs better than the biaffine baseline. Comparing (b) with (g), we find that the boundary information contributes to span classification. Comparing (c) and (d) with (g) supports that either label or boundary in the triaffine attention improves the performance. The setting (g) performs better than (e) and (f), which shows the superiority of the triaffine transformation over the linear function. We observe that (h) performs better than (g) (+0.28 on ACE2004, +0.39 on GENIA), proving the strength of triaffine attention with interactions among related spans. The above studies support that our proposed triaffine mechanism with associated heterogeneous factors is effective for span representation and classification.

4.6 Discussion

We compare the F_1 scores of GENIA between triaffine model (g) and biaffine model (a) grouped by entity lengths in Figure 4. In all columns, the F_1 score of our method is better than the baseline. Furthermore, the right columns show that the F_1 score of the baseline gradually decreases with the incremental entity lengths. However, our method based on the triaffine mechanism with heterogeneous factors takes advantage of the interaction from boundaries and related spans, which keeps consistent results and outperforms the baseline.

The results grouped by flat or nested entities are shown in Table 6. Our method has consistent improvements than the baseline, especially for the nested setting. Based on the above observations, our method is good at solving long entities that are

Span	Type	$p_{i,j,r}$ Probability	Rank	Type	$p^c_{i,j,r}$ Probability
... [Cisco]$_{\text{ORG}}$'s been slammed, but once [they]$_{\text{ORG}}$'re exposed to [the rest of [the trading population]$_{\text{PER}}$]$_{\text{PER}}$ ...

40 enhancer	None	0.99	6	None	1.00

Table 5: Case study on ACE2004 and GENIA dataset. Colored brackets indicate the boundaries and semantic types of entities in true labels. "cl" and "ct" is the abbreviation of *cell line* and *cell type*, respectively.

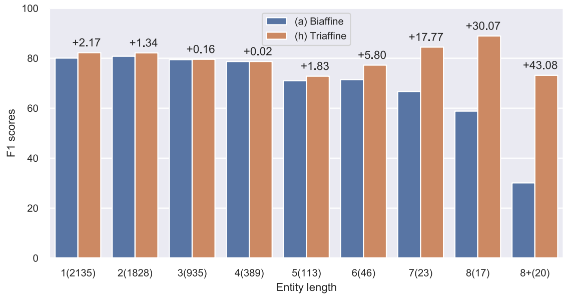

Figure 4: Comparison between triaffine and biaffine models on GENIA with different lengths of entities. Entity counts are in the parentheses.

	ACE2004 Flat (1,422)	ACE2004 Nested (1,092)	GENIA Flat (4,307)	GENIA Nested (1,199)
(a)	88.51	84.19	80.09	74.23
(h)	89.54	85.45	82.18	77.24
Δ	+1.03	+1.26	+2.09	+ 3.01

Table 6: Comparison between triaffine and biaffine models on ACE2004 and GENIA grouped by flat or nested entities. Entity counts are in the parentheses.

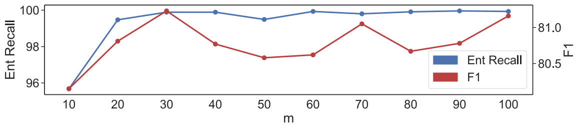

Figure 5: Recall for entity spans and F_1 scores with different numbers of candidate spans in GENIA dataset.

more likely to be nested, which supports our model is built upon the characteristics of nested NER.

At the stage of cross-span interactions, we only select top-m spans in practice. In Figure 5, we analyze the number m in two aspects. Firstly, we check the recall of entity spans. We observe that taking top-30 spans achieves a recall of 99.89, which means it covers almost all entities. As the maximum number of entities is 25, we believe it is enough to select top-30 spans. Secondly, we check the model performance. With top-30 spans, the model achieves 81.23 scores in terms of F_1 and there is no obvious performance improvement with more candidates. Based on two above observations, we choose $m = 30$, which can well balance the performance and efficiency.

Finally, we test the efficiency of the decomposition. Compared with the naive triaffine scoring that takes 638.1ms (509.4ms in GPU + 128.7ms in CPU), the decomposed triaffine scoring takes 432.7ms (330.5ms in GPU + 102.2ms in CPU) for 10 iterations, which leads to approximately 32% speedup (details are shown in Appendix B).

4.7 Case Study

To analyze the effect of fusing information from related spans with the cross-span interaction, we show two examples from ACE2004 and GENIA datasets in Table 5. In the first example, the model first predicts "*the trading population*" as "GPE", however, it revises to "PER" correctly by considering span interactions with the outer span "*the rest of the trading population*". In the second example, it first predicts "*MnlI-AluI*" as "protein". By interacting with surrounding entities "*MnlI-AluI fragment*", the model corrects its label to None.

5 Conclusion

In this paper, we propose a span-based method for nested NER. Heterogeneous factors including tokens, boundaries, labels, and related spans are introduced to improve span classification with a novel triaffine mechanism. Experiments show our method outperforms all span-based methods and achieves state-of-the-art performance on four nested NER datasets. Ablation studies show the introduced heterogeneous factors and triaffine mechanism are helpful for nested setting. Despite that large-scale pretrained language models have shown consistent improvement over many NLP tasks, we argue that the well-designed features and model structures are still useful for complex tasks like nested NER. Furthermore, although we only verify our triaffine mechanism in nested NER, we believe it can also be useful in tasks requiring high order interactions like parsing and semantic role labeling.

A Reproducibility Checklist

We set seeds of *torch*, *torch.cuda*, *numpy*, and *random* in Python to ensure reproducibility. We use a grid search to find the best hyperparameters depending on development set performances. We search contextual embedding learning rate among {1e-5,3e-5}. If the contextual embedding learning rate is 1e-5, we use static embedding learning rate and task learning rate as 1e-4 and 1e-5. If the contextual embedding learning rate is 3e-5, we use static embedding learning rate and task learning rate as 5e-4 and 3e-5. We search batch size among {8,48,72}. We search MLP dropout ratio among {0.1,0.2}. The final hyperparameters we used for four datasets are listed in Table 7 and Table 8.

B The Decomposition of Triaffine Scoring

We introduce the decomposition of triaffine scoring in calculating $p_{i,j,r}$ and $p^c_{i,j,r}$.

The naive calculation procedure of $p_{i,j,r}$ is:

$$s_{i,j,k,r} = \mathrm{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_k, \mathcal{W}_r) \tag{23}$$

$$\alpha_{i,j,k,r} = \frac{\exp(s_{i,j,k,r})}{\sum_{k'=i}^{j} \exp(s_{i,j,k',r})} \tag{24}$$

$$\mathbf{h}_{i,j,r} = \sum_{k=i}^{j} \alpha_{i,j,k,r} \mathrm{MLP}(\mathbf{h}_k) \tag{25}$$

$$p_{i,j,r} = \mathrm{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_{i,j,r}, \mathcal{V}_r) \tag{26}$$

For our proposed decomposition of $p_{i,j,r}$, we first calculate $\alpha_{i,j,k,r}$ as equations 23 and 24. And we calculate:

$$o_{i,j,k,r} = \mathrm{TriAff}(\mathbf{h}_i, \mathbf{h}_j, \mathbf{h}_k, \mathcal{V}_r) \tag{27}$$

$$p_{i,j,r} = \sum_{k=i}^{j} \alpha_{i,j,k,r} o_{i,j,k,r} \tag{28}$$

The main difference between naive calculation and decomposition calculation is between Equation 26 and Equation 27.

We suppose our batch size as B, sequence count as N, output dimensions of MLP layers as d, the count of spans for calculating cross span representations as m, and label count as R (including None class). The shapes of tensors $[\mathbf{h}_i]$, $[\mathbf{h}_j]$, $[\mathbf{h}_k]$ are $B \times N \times d$. The shape of tensor $[\mathbf{h}_{i,j,r}]$ is $B \times N \times N \times R \times d$.

We benchmark the performances of Equation 26 and Equation 27 in PyTorch for 10 iterations. We use the same hyper-parameters and devices as our main experiments. We levearge opt_einsum[6] to calculate triaffine transformations in both equations.

Table 9 shows the time usage comparison between Equation 26 and Equation 27. Equation 26 uses 309.7ms (300.5ms in GPU + 9.2ms in CPU) and Equation 27 uses 150.1ms (145.6ms in GPU + 4.4ms in CPU). The larger tensor size and higher rank of $[\mathbf{h}_{i,j,r}]$ results in slower calculations of *aten::bmm*, *aten::copy_* and *aten::permute* in Equation 26. The time usage differences are clearly dominated by the function *aten::copy_*, which is optimized by our decomposition.

We also compare the time usage between the naive triaffine scoring and the decomposed triaffine scoring in Table 9. The naive triaffine scoring takes 638.1ms (509.4ms in GPU + 128.7ms in CPU), and the decomposed triaffine scoring takes 432.7ms (330.5ms in GPU + 102.2ms in CPU) for 10 iterations, which leads to approximately 32% speedup. The GPU time usages are reasonable since they both need to calculate two triaffine transformations. The CPU time usages increase for both naive and decomposition triaffine scoring. Additional CPU time usages come from function *aten::einsum*, *aten::permute*, and *aten::reshape*, and the naive calculation increases more due to slower *aten::einsum*. Overall, the decomposition triaffine scoring uses less time on both GPU and CPU than the naive triaffine scoring.

Futhermore, we also test the time usage of $p^c_{i,j,r}$ using two calculation procedures. We find using the decomposition triaffine scoring still has about 6% speed up (naive:125.8ms in GPU + 15.0ms in CPU vs. decomposition:115.5ms in GPU + 16.8ms in CPU) regardless the relatively small size of $\mathbf{h}^c_{i,j,r}$ (The shape of tensor $[\mathbf{h}^c_{i,j,r}]$ is $B \times m \times R \times d$).

Abstract

Vision-Language Pre-training (VLP) has achieved impressive performance on various cross-modal downstream tasks. However, most existing methods can only learn from aligned image-caption data and rely heavily on expensive regional features, which greatly limits their scalability and performance. In this paper, we propose an end-to-end unified-modal pre-training framework, namely UNIMO-2, for joint learning on both aligned image-caption data and unaligned image-only and text-only corpus. We build a unified Transformer model to jointly learn visual representations, textual representations and semantic alignment between images and texts. In particular, we propose to conduct grounded learning on both images and texts via a sharing grounded space, which helps bridge unaligned images and texts, and align the visual and textual semantic spaces on different types of corpora. The experiments show that our grounded learning method can improve textual and visual semantic alignment for improving performance on various cross-modal tasks. Moreover, benefiting from effective joint modeling of different types of corpora, our model also achieves impressive performance on single-modal visual and textual tasks. Our code and models are public at the UNIMO project page `https://unimo-ptm.github.io/`.

1 Introduction

Large-scale pre-training has drawn much attention in the community of Computer Vision (CV), Natural Language Processing (NLP) and Multi-Modal (MM) due to its strong capability of generalization and efficient usage of large-scale data. However, in the existing literature, the work on vision, language and vision-language representation learning are mostly studied separately with different training data sources. In the vision domain, pre-training on large-scale image corpus such as ImageNet (Deng et al., 2009), OpenImages (Kuznetsova et al., 2020) and JFT-300M (Dosovitskiy et al., 2020) has proven to be critical for learning transferring visual representation for various downstream tasks. In NLP, pre-training on easily-accessible unannotated text corpora greatly improves the capabilities of language understanding and generation (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019). Pre-training has also become the de-facto approach in vision-language modeling (Lu et al., 2019; Chen et al., 2020c; Li et al., 2020, 2019a; Yu et al., 2020). However, existing VLP methods require a massive amount of aligned image-text pairs which are costly to collect and hard to scale up. The large volumes of image corpus in CV and text corpus in NLP cannot be effectively utilized. Thus, the scalability and performance upper limit of existing VLP methods are largely restricted. As they only learn joint vision-language representations on image-text pairs, they are also difficult to be effectively adapted to visual and textual tasks (Li et al., 2021b; Lin et al., 2020).

To address the limitations, we propose a new end-to-end unified-modal pre-training framework, namely UNIMO-2, for joint learning on various types of corpora, including images, texts, and image-caption pairs. Specifically, we build a unified Transformer model to jointly learn visual representations, textual representations, and cross-modal alignment from the three types of corpora. Both the visual and textual representations are learned end-to-end from raw images and textual sentences. Combining a large number of unaligned images and texts is not only expected to improve the performance of joint vision-language tasks, but also improve the scalability of adapting to single-modal visual and textual tasks. However, it is challenging to bridge unaligned images and texts and effectively align the visual and textual semantic spaces on different types of corpora.

Only a few works have attempted to bridge

Findings of the Association for Computational Linguistics: ACL 2022, pages 3187 - 3201

unaligned images and texts by leveraging object tags from an pre-trained object detector as "anchor points" (Li et al., 2021a,b). However, they all rely heavily on expensive object-centric visual feature extraction, thus facing the problems of limited visual expressive power and computation inefficiency. In this paper, in order to bridge the unpaired image and text corpora and align the visual and textual semantic spaces end-to-end, we propose to conduct grounded learning on images, texts, and image-text pairs via a sharing grounded space. Specifically, we introduce a grounded dictionary shared by images and texts, which represents vision-language grounded semantics. To learn the grounded dictionary, we apply vector quantization on both visual and textual representations to group image patches and text tokens with similar semantics into grounded tokens. Furthermore, we design a Grounded Transformer architecture to let the visual and textual information exchanged by the grounded tokens, which not only facilitates grounded dictionary learning, but also improves cross-modal alignment. Our grounded learning method can help bridge the textual and visual semantic spaces on unpaired image and text corpora to improve cross-modal fusion on different types of corpora.

We evaluate UNIMO-2 on a variety of representative vision-language understanding and generation tasks, including image/text retrieval, visual question answering, visual reasoning and image caption. On all these tasks, UNIMO-2 obtains obvious improvements compared to the baselines that only learn on aligned image-caption data or without our grounded learning component. Moreover, we also evaluate our model on single-modal textual tasks such as natural language inference and visual tasks such as image classification (Deng et al., 2009). The results show that our model has also achieved very impressive performance on these tasks, which proves the strong scalability and adaptability of our model.

UNIMO-2 has the following advantages compared with previous methods:

- UNIMO-2 can jointly learn from both aligned and unaligned image and text corpora end-to-end, effectively alleviating the limitations of corpus, and learning more generalized visual and textual representations on large volumes of different types of corpus.
- Benefiting from utilizing different types of corpora, UNIMO-2 has better scalability for different types of tasks, including both cross-modal tasks and single-modal tasks.
- Our grounded learning method can help align textual and visual semantic spaces more effectively, thereby greatly improving the performance of various cross-modal tasks. In particular, the performance of zero-shot image/text retrieval even outperforms CLIP pre-trained on an order of magnitude larger pair corpus.

2 Related Work

Vision-Language Pre-training Recent years have witnessed rapid progress in vision-and-language pretraining (VLP) (Li et al., 2019b; Lu et al., 2019; Chen et al., 2020c; Li et al., 2019a, 2020; Yu et al., 2020). Most existing mainstream VLP models adopt a two-stage training method, which firstly extracts region-based visual features using a pre-trained object detection model, and then combines the derived object-centric region features of images and text embeddings as the input of Transformer (Vaswani et al., 2017) for cross-modal pre-training. These methods rely heavily on an off-the-shelf object detector like Faster R-CNN (Ren et al., 2016) typically pretrained on the Visual Genome dataset (Anderson et al., 2018). As the visual representation is not optimized towards a more generic cross-modal understanding and extracting region features with an object detection model is so time-consuming, they face the problems of limited visual expressive power and computation inefficiency, which makes them less scalable.

Some recent work has also explored VLP without object detection modules (Xu et al., 2021; Kim et al., 2021; Huang et al., 2021; Wang et al., 2021). They either utilize grid features from pretrained CNNs or patch features following ViT (Dosovitskiy et al., 2020), however they only use limited image-caption pairs for cross-modal pretraining and thus their scalability and performance are limited. Only a few works have explored utilizing unaligned images and texts for vision-language pre-training, including our previous work UNIMO (Li et al., 2021b) and U-VisualBERT (Li et al., 2021a). However, they all rely on pre-extraction of region-based visual features or object tags by time-consuming object detection. How to bridge unpaired visual and textual corpora end-to-end without using object detection remains challenging.

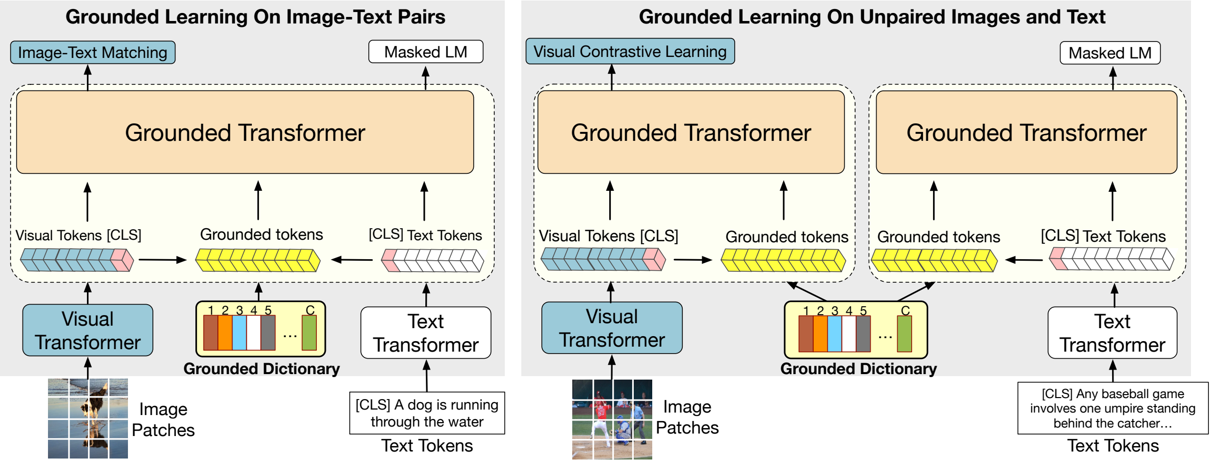

Figure 1: Illustration of our UNIMO-2 framework. The left part shows the architecture of learning on image-text pairs, which produces grounded tokens based on the sharing semantics in images and texts. The right part shows the architecture of learning on unpaired images and texts, which produces grounded tokens from image representations or text representations, respectively. As they share the same grounded dictionary, the grounded tokens act as "anchor points" to bridge the gap between images and texts.

Grounded Learning Language grounding is an active field aiming at enriching textual representations with visual information, which has been shown to improve performance on a variety of core NLP tasks (Bruni et al., 2014; Baroni, 2016; Kiela, 2017). Kiela et al. (2018) investigate grounded sentence representations by training a sentence encoder to predict the image features of a given caption. Tan and Bansal (2020) propose a vokenization method that maps language tokens to their related images. These works all enrich the language representation with visual information by learning a projection of text representations to corresponding images (Chrupała et al., 2015). Recently, Huang et al. (2021) propose an end-to-end VLP method that aggregates visual features from a CNN encoder into visual tokens with a visual dictionary. Liu et al. (2021) propose to improve cross-modal retrieval tasks by incorporating a shared discretized embedding space, which is utilized to compute matching scores between different modalities to complement the representations from individual encoders. These works all rely on image-text pairs to learn cross-modal representations and only focus on joint vision-language tasks. By contrast, our work for the first time proposes to jointly model both aligned and unaligned images and texts by end-to-end learning a shared grounded semantic space, which can improve modality alignment between both aligned and unaligned images and texts.

3 Approach

The overall architecture of our model is shown in Figure 1. UNIMO-2 is an end-to-end framework, which consists of a trainable Transformer-based visual encoder, a Transformer-based text encoder, a grounded dictionary (GD) embedding module, and a multi-layer Grounded Transformer for modality fusion. The visual encoder takes an image as input by splitting it into small sizes of patches, and produces the high-level visual representations for all patches, similar to ViT (Dosovitskiy et al., 2020). The text encoder encodes textual tokens to produce high-level token representations. Based on the high-level representations of patches and tokens, we design a GD embedding module to group similar vision-language representations into grounded tokens with a shared grounded dictionary. The Grounded Transformer is further adopted to fuse features from vision and language modalities through interacting with the common grounded tokens. UNIMO-2 can be end-to-end pre-trained by joint Masked Language Modeling (MLM) on text, Image-Text Matching (ITM) on image-text pairs and Visual Contrastive Learning (VCL) on images. UNIMO-2 can also be easily adapted to various tasks including visual, textual and cross-modal tasks.

3.1 End-to-End Grounded Learning

Human acquire much of their knowledge through grounded learning – visual concepts can be acquired through language, and language acquisition emerges through visual interaction (Jones et al., 1991; Perfetti, 1998; Fincher-Kiefer, 2001; Andrews et al., 2009; Riordan and Jones, 2011). Inspired by this type of grounded learning, we propose to learn a sharing semantic space (i.e. grounded space) between images and texts to better align fine-grained visual and textual semantics. Specifically, based on the high-level visual representations of patches $V = \{v_1, \ldots, v_M\}$ and textual representations of tokens $T = \{t_1, \ldots, t_N\}$, we introduce a grounded dictionary to group similar visual and textual representations into the same grounded token. The grounded features not only help align the visual and textual semantics in aligned image-caption data, but also act as "anchor points" to help bridge the unaligned images and texts, as shown in Figure 1.

Grounded Dictionary Learning We define a grounded dictionary (GD) as a matrix $G \in \mathbb{R}^{C \times D}$ which contains C embedding vectors with D-dim. The embedding vector for the j^{th} grounded token is denoted as $g_j \in \mathbb{R}^D, j \in 1, 2, \ldots, C$. Vector Quantization (VQ) is widely used to group continuous embeddings into groups of discrete latent variables (Oord et al., 2017; Liu et al., 2021; Huang et al., 2021). For example, each patch or token can be mapped to a grounded token by finding its nearest neighbor in the GD, as in Oord et al. (2017).

Most existing VLP methods implicitly assume that there is a one-to-one correspondence hypothesis between the visual and textual modalities of image-text pairs. However, this hypothesis does not hold in reality as most image-text pairs on the Web are noisy or only have weak correlation. To tackle this issue, instead of mapping each patch or token representation to a grounded token, we only detect the most significant sharing semantics between image and text. We propose to find the top-K most significant grounded tokens for both the textual and visual input. Specifically, let x_{ij} denotes the similarity between embedding vectors of visual token v_i and grounded token g_j, which is computed by:

$$x_{ij} = \sigma(\eta * v_i^T g_j) \tag{1}$$

where σ denotes the $sigmoid$ function, and η denotes a learnable temperature parameter. Similarly, y_{kj} denotes the similarity between embedding vectors of textual token t_k and grounded token g_j.

For image-text pairs, the accumulated score of the grounded token g_j is computed as:

$$s_j = \sum_{i=1}^{M} x_{ij} + \sum_{k=1}^{N} y_{kj} \tag{2}$$

We obtain the top-K most significant grounded tokens with the largest accumulated scores: $g_1, \ldots, g_K = Top_K\{s_1, \ldots, s_C\}$, where K is a hyper-parameter. Note that, if we set $K = M + N$, then it is similar that each patch or token is mapped to a grounded token, which will increase the computation cost and introduce noisy information into the grounded learning process. So, we set K much smaller than $M + N$ to obtain the most significant and sharing grounded tokens, which can help align fine-grained visual and textual representations while eliminating the noisy or unrelated information in image-text pairs. For unpaired images or text, the accumulated score of each grounded token g_j is $s_j = \sum_{i=1}^{M} x_{ij}$ or $s_j = \sum_{k=1}^{N} y_{kj}$, and the top-$K$ grounded tokens can be obtained similarly.

The grounded dictionary is randomly initialized, and further updated end-to-end while pre-training. As the Top_K function is non-differentiable, we import a *grounding loss* to help learn the grounded dictionary. Specifically, we propose a revised form of the Vector Quantisation (VQ) algorithm (Oord et al., 2017), which uses the l_2 error to move the embedding vectors g_i towards the mapped patch or token representations, as shown in the first term of Equation 3. For simplicity, here we take image input as an example. Since the volume of the embedding space is dimensionless, it can grow arbitrarily if the embeddings g_i do not train as fast as the visual and textual encoder parameters. To make sure the encoder commits to an embedding and its output does not grow, we add a commitment loss, the second term in Equation 3. Thus, the total grounding loss becomes:

$$\begin{aligned}\mathcal{L}_{GD} = &\sum_{i=1}^{M} \|sg(v_i) - \sum_j \frac{x_{ij}}{\sum_k x_{ik}} g_j\|_2^2 \\ &+ \beta \sum_{j=1}^{K} \|sg(g_j) - \sum_i \frac{x_{ij}}{s_j} v_i\|_2^2\end{aligned} \tag{3}$$

where $sg(.)$ denotes the stop-gradient operator that is defined as identity at forward computation time and has zero partial derivatives, and β denotes a weight parameter.

The grounded dictionary faces a cold-start problem for unpaired images and texts. So we apply

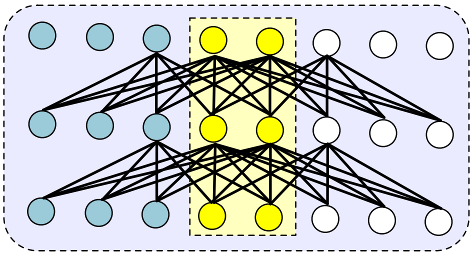

Figure 2: The self-attention architecture of Grounded Transformer. Cross-modal information is exchanged through the grounded tokens.

curriculum learning on different types of corpora. Specifically, we first only train on image-text pairs for 20 epoches to obtain a usable grounded embedding space, then further train on all three types of corpus to help bridge unpaired images and texts. To show what the GD has learned, we have visualized some grounded tokens in Appendix A.

Grounded Transformer After obtaining the grounded tokens, we append them with the visual tokens and textual tokens as input to our Grounded Transformer for cross-modal fusion. Specifically, we propose to bridge visual and textual representations by grounded tokens. As shown in Figure 2, the cross-modal information can only be exchanged by grounded tokens, which also push the grounded tokens to capture the most significant sharing semantics between images and texts. In this way, our model is more robust on weak correlation image-text pairs by modeling cross-modal interaction through common grounded tokens. Furthermore, the novel self-attention architecture can improve the computation efficiency compared to the standard pairwise self-attention mechanism.

For unpaired images and texts, the Grounded Transformer also models the fusion of visual tokens or textual tokens with the grounded tokens. As the grounded dictionary captures common visual and textual semantics, it also helps learn cross-modal representations on unpaired images and texts.

3.2 Pre-training On Different Corpus

Based on the outputs of the Grounded Transformer, we adopt Masked Language Modeling (MLM) and Image-Text Matching (ITM) pre-training tasks on image-text pairs. Furthermore, we also apply MLM on text corpus and Visual Constrastive Learning (VCL) on images.

Masked Language Modeling We iteratively sample spans of text until totally 15% tokens have been selected. We sample the span length from a geometric distribution $l \sim Geo(p)$, where p is set as 0.2, similar to SpanBERT (Joshi et al., 2020). All tokens in the selected spans are replaced with either a special [MASK] token, a random token or the original token with probability 80%, 10% and 10%, respectively. The goal is to predict these masked tokens based on their surrounding context and all visual features. The MLM task is also applied on text-only corpus, which predicts masked tokens only based on the surrounding tokens.

Image-Text Matching To enhance the cross-modal matching, we adopt ITM task for pre-training as in previous works (Chen et al., 2020c). We apply a binary classifier on the concatenated embedding features of the "[CLS]" token in text and the "[CLS]" token in image by Grounded Transformer to predict whether the input image and text are matched or not.

Visual Contrastive Learning UNIMO-2 learns representations on unpaired images by maximizing agreement between differently augmented views of the same image while minimizing similarities between different images via a contrastive loss in the latent space, similar to SimCLR (Chen et al., 2020a). We apply stochastic data argumentation module that transforms an image randomly resulted in two corelated views as a positive pair, and random images in the same minibatch as negative pairs. We combine augmentations of random cropping, random rotating and random color distortion followed by resizing back to the original size.

3.3 Transferring To Different Tasks

Our model can be effectively finetuned on different types of tasks, including cross-modal tasks, visual tasks and textual tasks. For cross-modal tasks, the model architecture is the same as the pre-training architecture on image-text pairs, as shown in the left part of Figure 1. Grounded tokens are produced based on both the visual and textual representations to facilitate cross-modal understanding and generation. For visual tasks, the model architecture is the same as the pre-training architecture on images, as shown in the middle part of Figure 1. Grounded tokens are obtained based on the visual representations from the Visual Transformer. As the grounded tokens contain sharing semantics between images and texts, UNIMO-2 can learn language-grounded image representations for visual tasks. Similarly, for textual tasks the model architecture is the same as the pre-training architecture on text, as shown in the right part of Figure 1. Grounded tokens are obtained based on the textual representations from the Text Transformer. Also, the sharing grounded space helps learn grounded text representations to facilitate textual tasks.

4 Experimental Settings

Pretraining Dataset Our pre-training datasets consist of three types: text corpus, image corpus and image-text pairs. The text corpus includes two large-scale corpora: BookWiki and OpenWebText, which are part of the training dataset of RoBERTa (Liu et al., 2019). The image corpus are images without textual descriptions, including a subset of OpenImages (Krasin et al., 2017) and ImageNet-21k (Deng et al., 2009). Each image in these datasets contains a textual label. The image-text pairs are composed of four existing multi-modal datasets: COCO (Lin et al., 2014), Visual Genome (VG) (Krishna et al., 2017), Conceptual Captions (CC) (Sharma et al., 2018) and SBU Captions (Ordonez et al., 2011), which have also been widely used in previous VLP models. The detail statistics are shown in the appendix. We also transform the label of each image to a sentence by prompts (e.g. “a photo of [label]”) to create pseudo image-text pairs from the OpenImages and ImageNet-21k datasets for pretraining.

Implementation Detail UNIMO-2 consists of 12 layers of Visual Transformer, 12 layers of Text Transformer, and 12 layers of Grounded Transformer. The Visual Transformer is initialized by ViT-B/16. The Text Transformer and Grounded Transformer are both initialized by RoBERTa-Base. The maximum sequence length of text tokens are set as 512. An Adam optimizer with initial learning rate 5e-5 and a learning rate linear decay schedule is utilized.

For the visual encoder, our model receives the raw image $\mathbf{x} \in \mathbb{R}^{H \times W \times C}$ and maps it into flattened $1D$ sequence of patches $\mathbf{x}_p \in \mathbb{R}^{\frac{HW}{P^2} \times D}$ as input for the transformer, where D is the fixed hidden size of the transformer layers and P is the patch size. During pretraining, we utilize the 224×224 resolution with a fixed patch size of 16×16, resulting in a patch sequence of length 14×14 as visual tokens. During fine-tuning, we increase the image resolution to 384×384 and interpolate the positional encoding of image patches following (Dosovitskiy et al., 2020). For the grounded embedding module, the grounded dictionary size C is set as 2048, and the number of grounded tokens K during pre-training and finetuning are both set as 100 that is much smaller than the max number of patches and tokens for pre-training (i.e. 709) and finetuning (i.e. 1089). We set $\beta = 0.25$ in all our experiments and the results did not vary obviously for values ranging from 0.1 to 1.0. We have compared different grounding settings in detail in Appendix A.

Finetuning Tasks To show the scalability of our model, we fine-tune it on three types of downstream tasks: (1) joint vision-language cross-modal tasks, (2) visual tasks, and (3) textual tasks. The cross-modal tasks include: visual question answering (VQA) on the VQA v2.0 dataset (Goyal et al., 2017), image caption on the Microsoft COCO Captions dataset (Chen et al., 2015), visual entailment on the SNLI-VE dataset (Xie et al., 2019) and image-text retrieval on Flickr30k datasets (Young et al., 2014). The visual tasks include image classification on the ImageNet-1k dataset (Krizhevsky et al., 2012). The textual tasks include sentiment classification on the SST-2 dataset (Socher et al., 2013), natural language inference on the MNLI dataset (Williams et al., 2018), linguistic acceptability analysis on the CoLA dataset (Warstadt et al., 2019) and semantic similarity analysis on the STS-B dataset (Cer et al., 2017). The detail statistics of the datasets and hyper-parameter settings for the above tasks are described in Appendix B.

5 Results and Analysis

We compare UNIMO-2 to a variety of state-of-the-art models on cross-modal, visual and textual tasks.

5.1 Cross-Modal Tasks

The evaluation results on the joint vision-language cross-modal tasks are shown in Table 1. We compare with most of the existed VLP models, including regional feature-based models ViLBERT (Lu et al., 2019), UNITER (Chen et al., 2020c), Oscar (Li et al., 2020), Villa (Gan et al., 2020) and UNIMO (Li et al., 2021b), and end-to-end models ViLT (Kim et al., 2021), E2E-VLP (Xu et al., 2021), SOHO (Huang et al., 2021) and CLIP (Radford et al., 2021).The results show that UNIMO-2 achieves the best results against most benchmarks, outperforming both the base and large sizes of other

Table 1: Evaluation results on cross-modal tasks. ZS denotes zero-shot performance. IR and TR represents image-retrieval and text-retrieval, respectively. B@4 and C denotes metrics of BLUE4 and CIDEr, respectively. "Our Baseline" is similar to UNIMO-2, except that the grounded embedding module in UNIMO-2 is removed. It is trained on the same corpus and experimental settings with UNIMO-2.

Model	Acc@1 Zero-Shot	 Finetuned
SimCLRv2 (Chen et al., 2020b)	-	80.5
CLIP-ViT(B/16)	**68.6**	80.2
Our Baseline	58.2	80.7
UNIMO-2	66.3	**80.8**

Table 2: Evaluation results on visual tasks, compared to state-of-the-art representation learning methods. We report both the zero-shot and finetuned top-1 accuracy on ImageNet-1k. The finetuned result of CLIP-ViT is linear probe performance.

VLP models. Particularly, UNIMO-2 achieves very good performance on the task of zero-shot image/text retrieval, even outperforming CLIP (Radford et al., 2021) that pre-trained on an order of magnitude larger corpus. The results demonstrate that UNIMO-2 can obtain better cross-modal representations based on joint end-to-end grounded learning on different types of corpus.

Furthermore, the performance of "Our Baseline" that just removes the grounded embedding module in UNIMO-2 drop obviously on all tasks, which demonstrates the effectiveness of our grounded learning method for cross-modal alignment. Especially, on the zero-shot image retrieval and text retrieval tasks, UNIMO-2 obtains 7.59 R@1 and 9.66 R@1 absolute gains compared to "Our Baseline". The results demonstrate that our grounded learning method can help align the visual and textual semantic space on different types of corpora to obtain more effective cross-modal representations.

Model	SST-2 Acc	MNLI Acc-(m/mm)	CoLA Mat	STS-B Per

UNIMO-2	94.7	**87.5/87.5**	62.1	**91.2**

Table 3: Evaluation results on textual tasks. Mat and Per denote Matthews correlation coefficient and Pearson correlation coefficient, respectively. All the results are evaluated on the dev set.

5.2 Visual Tasks

UNIMO-2 can also be effectively adapted to visual tasks such as image classification. As UNIMO-2 learns effective cross-modal representations, it can classify images without finetuning. Specifically, the target labels of images can be transformed into pseudo image descriptions, such as "a photo of [label]". Then the zero-shot image-to-text retrieval method can be used to obtain the label for each image, similar to CLIP (Radford et al., 2021). Both the zero-shot and finetuned performance is compared to several state-of-the-art representation learning methods. The results in Table 2 show that UNIMO-2 can achieve comparable performance with CLIP that pretrained on billions of image-text pairs, on both the zero-shot and supervised settings. Moreover, UNIMO-2 obviously outperforms

	Model	ZS-IR R@1	ZS-TR R@1	IR R@1	TR R@1	COCO Caption B@4 / C	ZS-ImageNet Acc@1	MNLI m/mm

Table 4: Ablation study on the effectiveness of our unified end-to-end grounded learning architecture.

"Our Baseline" on the zero-shot setting, achieving 8.1 Acc@1 absolute gains. The results demonstrate that UNIMO-2 also learns generalized visual representations through unified-modal learning on different types of corpora.

5.3 Textual Tasks

To show the effectiveness of UNIMO-2 on textual tasks, we further compare with both VLP models including UNITER, VilBERT and UNIMO, and pre-trained language models including BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and UniLM (Dong et al., 2019). The comparison results in Table 3 demonstrate that UNIMO-2 achieves much better performance than existing VLP models including UNITER and VilBERT, and achieves comparable performance than existed PLMs such as RoBERTa. UNIMO-2 also outperforms "Our Baseline" on all textual tasks.

The above results demonstrate the adaptability and scalability of our unified end-to-end VLP architecture for joint learning on both aligned and unaligned images and texts. In all, UNIMO-2 not only achieves excellent performance on cross-modal tasks, but also performs very well on visual and textual tasks, which validates the superiority of our unified-modal learning architecture.

5.4 Analysis

Effectiveness of Grounded Learning We further validate the effectiveness of our grounded learning component by ablation study. "w/o GD (P)" denotes removing the grounded learning component during both pre-training and inference in order to validate its effectiveness for unified learning on different types of corpus. "w/o GD (I)" denotes keeping the grounded learning component during pre-training, but removing it during inference, in order to validate the effectiveness of the grounded representations to downstream tasks. "1-to-1 Map" denotes mapping each patch or token to a grounded token by finding its nearest neighbor in the grounded dictionary, similar to the vector quantization method in (Oord et al., 2017). We compare their performance on three types of tasks, as shown in the top part of Table 4. The results demonstrate that our grounded learning (GD) method is essential to the end-to-end joint learning from different types of corpus, which can help bridge unaligned images and texts and improve vision-language semantic alignment. The learned grounded representations is also critical to both the cross-modal and single-modal downstream tasks. We further validate the effectiveness of our Grounded Transformer by replacing it with a traditional Transformer, denoted as "w/o G.T.". The results show that the performance of cross-modal tasks drop obviously compared to UNIMO-2, which demonstrate the effectiveness of our Grounded Transformer architecture.

Effectiveness of Unaligned Images and Texts To further validate the effectiveness of unaligned images and texts to cross-modal learning, we compare the performance of UNIMO-2 on different pre-training datasets. Specifically, we compare the performance of UNIMO-2 by either removing the text cropus (i.e. "w/o Text"), the image corpus (i.e. "w/o Images") or removing them both (i.e. "w/o Both"). The comparison results are shown in the bottom part of Table 4, which show that either removing text corpus or image corpus will consistently reduce the performance of all three types of tasks, including cross-modal, visual and textual tasks. It is worth noting that the performance of the image/text retrieval tasks drop obviously when either removing the text-only cropus or image-only corpus, which demonstrate that unaligned corpus is also useful to cross-modal tasks. UNIMO-2 can effectively leverage unaligned images and texts to improve cross-modal learning.

6 Conclusion

In this work, we propose UNIMO-2, an end-to-end unified-modal pre-training framework that can learn from both aligned and unaligned image and text corpora. Our proposed grounded learning method can help bridge unpaired images and texts and align the textual and visual semantic spaces more effectively. Benefiting from effectively utilizing different types of corpora, UNIMO-2 has better scalability for different types of tasks. Experiments show that UNIMO-2 greatly improves the performance of various cross-modal tasks and also achieves very impressive performance on visual and textual tasks. The results also show that it is promising to further uniformly improve the performance of cross-modal, visual and textual tasks by utilizing larger scales of unpaired images and texts.

A Grounded Learning Analysis

Visualization of Grounded Dictionary To show the semantics of the grounded dictionary learned by UNIMO-2, we visualize the image patches and textual tokens that are grouped in each grounded token. We map each patch or token into a grounded token with which has the largest similarity between their representations by Equation 1. For each grounded token, the patches and tokens that have the largest similarity scores are selected and visualized. Several examples are shown in Figure 3, which demonstrate that each grounded token captures meaningful and consistent vision-language grounded semantics.

Parameter Analysis In all our experiments, we utilize the default grounding settings that the grounded dictionary (GD) size C is set as 2048 and the number of grounded tokens K is set as 100. We further compare different grounding settings to explore the properties of the grounded semantic space for cross-modal learning. Specifically, we validate the performance of grounded learning with different grounded dictionary (GD) size C from $\{1024, 2048, 4096, 8192\}$ and different number of grounded tokens K from $\{10, 20, 50, 100\}$. When comparing different GD size C, we set K as 100. We also keep $C = 2048$ when comparing different settings of K. Furthermore, we also compare our method with the simplest Vector Quantization (VQ) method that maps each visual or textual token to a grounded token by finding its nearest neighbor in the grounded dictionary, namely "1-to-1 map". The number of grounded tokens for "1-to-1 map" is depended on the total number of image patches and textual tokens, which is 709 (i.e. 197 + 512) during pre-training and 1089 (i.e. 577 + 512) during finetuning.

For time efficiency, we only pre-train UNIMO-2 on the corpus of image-text pairs for 10 epoches under the above settings, and then compare their performance on two representative cross-modal tasks, including zero-shot image/text retrieval and image caption, to validate their effectiveness on cross-modal alignment. The comparison results are shown in Table 5, which demonstrate that our grounded learning method achieves better performance on the two representative cross-modal tasks when the GD size C is set as 4096 or the number of grounded tokens K is set as 50. Too large C will increase the difficulty of learning while too small C may restrict the volume of grounded semantic space. Similarly, too small K will lose sharing semantics between images and texts while too large K will introduce noisy information. Although different settings have different behavior, the performance of our grounded learning method is relatively stable. In particular, the "1-to-1 map" method achieves much worse results than our grounded learning method under different settings, which validates the effectiveness of our grounded learning method on cross-modal alignment. Furthermore, our grounded learning method is much more efficient in computation than "1-to-1 map" as the number of grounded tokens is much smaller, which largely reduce the sequence length during cross-modal fusion.

B Experimental Settings

Pretraining Datasets The pre-training datasets consist of text corpus, image collections and image-text pairs. The detail statistics of them are shown in Table 6.

Finetuning Tasks The multi-modal finetuning tasks include:

- **VQA** requires the model to answer natural language questions by selecting the correct answer from a multi-choice list based on an image. We conduct experiments on the widely-used VQA v2.0 dataset (Goyal et al., 2017), which is built based on the COCO (Chen et al., 2015) images. Similar to previous work, both training and validation sets are used for training for the results on both the test-std and test-dev splits.

- **Image Caption** requires the model to generate a natural language description of an image. We report our results on the Microsoft COCO Captions dataset (Chen et al., 2015). Following Karpathy's (Karpathy and Fei-Fei, 2015) split, the dataset contains 113.2k/5k/5k images for train/val/test splits respectively.

- **Visual Entailment (SNLI-VE)** is evaluated on the SLNI-VE dataset (Xie et al., 2019) which was derived from Flickr30K images and Stanford Natural Language Inference (SNLI) dataset. The task is to determine the logical relationship (i.e., "Entailment", "Neutral" and "Contradiction") between a natural language statement and an image.

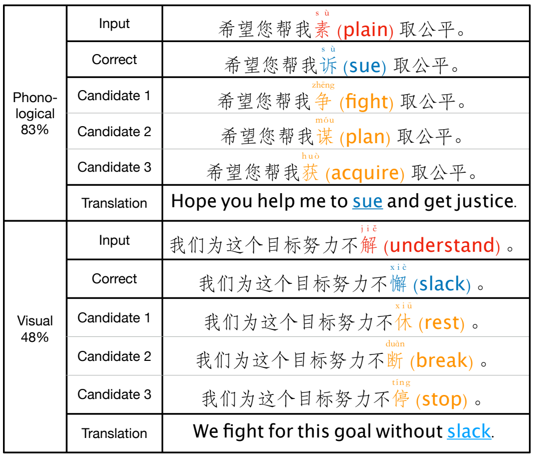
Abstract

Chinese Spell Checking (CSC) aims to detect and correct Chinese spelling errors, which are mainly caused by the phonological or visual similarity. Recently, pre-trained language models (PLMs) promote the progress of CSC task. However, there exists a gap between the learned knowledge of PLMs and the goal of CSC task. PLMs focus on the semantics in text and tend to correct the erroneous characters to semantically proper or commonly used ones, but these aren't the ground-truth corrections. To address this issue, we propose an **E**rror-driven **CO**ntrastive **P**robability **O**ptimization (ECOPO) framework for CSC task. ECOPO refines the knowledge representations of PLMs, and guides the model to avoid predicting these common characters through an error-driven way. Particularly, ECOPO is model-agnostic and it can be combined with existing CSC methods to achieve better performance. Extensive experiments and detailed analyses on SIGHAN datasets demonstrate that ECOPO is simple yet effective.

1 Introduction

Chinese Spell Checking (CSC) aims to detect and correct spelling errors in Chinese texts (Wu et al., 2013a). It is a crucial research field for various NLP downstream applications, such as Optical Character Recognition (Afli et al., 2016), search query correction (Gao et al., 2010) and essay scoring (Dong and Zhang, 2016). However, CSC is also very challenging because it mainly suffers from confusing characters, such as phonologically and visually similar characters (Liu et al., 2010; Zhang et al., 2020). As illustrated in Figure 1, "素(sù, plain)" and "诉(sù, sue)" are confusing characters for each other due to the shared pronunciation "sù".



Phono-logical 83%	Input	sù 希望您帮我素 (plain) 取公平。
	Correct	sù 希望您帮我诉 (sue) 取公平。
	Candidate 1	zhēng 希望您帮我争 (fight) 取公平。
	Candidate 2	móu 希望您帮我谋 (plan) 取公平。
	Candidate 3	huò 希望您帮我获 (acquire) 取公平。
	Translation	Hope you help me to sue and get justice.
Visual 48%	Input	jiě 我们为这个目标努力不解 (understand)。
	Correct	xiè 我们为这个目标努力不懈 (slack)。
	Candidate 1	xiū 我们为这个目标努力不休 (rest)。
	Candidate 2	duàn 我们为这个目标努力不断 (break)。
	Candidate 3	tíng 我们为这个目标努力不停 (stop)。
	Translation	We fight for this goal without slack.

Figure 1: Examples of Chinese spelling errors. Previous research (Liu et al., 2021) shows that 83% of errors belong to phonological error and 48% belong to visual error. We give the characters with their pronunciation and translation. We mark the input confusing/golden/common candidate characters in red/blue/orange. The characters in "Candidate" sentences are all predicted by fine-tuned BERT.

Recently, pre-trained language models (PLMs) such as BERT (Devlin et al., 2019) have been utilized in the CSC task and became mainstream solutions (Zhang et al., 2020; Cheng et al., 2020). However, there exists a significant gap between the learned knowledge of PLMs and the goal of CSC task. PLMs provide informative representations from the perspective of semantics, but if only considering the semantics in CSC, there are multiple appropriate characters as the correction. Without the constraints of phonological and visual similarities, PLMs easily predict semantically proper or common characters due to the masking strategy in the pre-training procedure.

Figure 1 presents two predictions of BERT to better understand the gap mentioned before. The first example is caused by the misuse of "素(sù, plain)" and "诉(sù, sue)". An ideal CSC model should pay attention to the pronunciation information "sù"

May 22-27, 2022

and output the golden character "诉(sue)" as a correction for the input confusing character. However, as pre-trained on general corpora, BERT tend to predict semantically proper characters, such as "争(zhēng, fight)", "谋(móu, plan)" and "获(huò, acquire)". These characters are also from more commonly used phrases. In the second example, BERT also overlooks the visual similarity between "解(jiě, understand)" and "懈(xiè, slack)", resulting in wrong correction.

To alleviate this gap, we propose to empower the PLMs to avoid predicting the above-mentioned common characters by optimizing the knowledge representation of PLMs. Intuitively, if we guide the model to not make the same mistakes it would prone to make before, the model performance should be improved. Hence, the mistakes that the model has ever made can be utilized as constraints on the knowledge representation of the model. In other words, we exploit the past mistakes that the model may make to further enhance the model itself, this is the meaning of our title, "the past mistake is the future wisdom".

Motivated by the above intuition, we propose the **E**rror-driven **CO**ntrastive **P**robability **O**ptimization (ECOPO), a simple yet effective training framework which aims to refine the knowledge representation of models for CSC. The ECOPO consists of two stages: (1) *Negative samples selection*. Based on the model's prediction probabilities for different characters, we select the common characters with high probability as negative samples. The golden character is directly regard as the positive sample. (2) *Contrastive probability optimization*. After obtaining the positive and negative samples, we train the model by Contrastive Probability Optimization (CPO) objective which aims to optimize the prediction probabilities for different characters. Through this optimization process, we can finally narrow the gap between the pre-trained knowledge of PLMs and the goal of CSC. Additionally, ECOPO has no strict restrictions on the model to be optimized, so it can further improve the performance of various existing CSC models.

In summary, our contributions are in three folds: (1) We firstly observe and focus on the negative impact of the gap between the knowledge of PLMs and the goal of CSC. (2) We propose model-agnostic ECOPO framework, which can teach the models to grow and progress with their own past mistakes. (3) We conduct extensive experiments and detailed analyses on SIGHAN benchmarks and achieve state-of-the-art performance.

2 Related Work

2.1 Chinese Spell Checking

Early works in CSC mainly focus on designing heuristic rules to detect different kinds of errors (Chang et al., 2015; Chu and Lin, 2015). Most of these methods rely on solid linguistic knowledge and manually designed features, and thus do not have the generalization performance required for large-scale application. Next, various traditional machine learning algorithms, such as Conditional Random Field (CRF) and Hidden Markov Model (HMM), are applied in CSC (Wang and Liao, 2015; Zhang et al., 2015). Then, deep learning-based models have gradually become the mainstream of CSC in recent years (Wang et al., 2021a; Guo et al., 2021; Zhang et al., 2021).

Wang et al. (2018) utilize a BiLSTM trained on an automatically generated dataset to convert CSC to sequence labeling problem. Hong et al. (2019) propose to generate and curtail the candidate characters through a BERT-based denoising autoencoder. The Soft-Masked BERT model (Zhang et al., 2020) uses two separate networks for detection and correction. Then SpellGCN (Cheng et al., 2020) uses GCN (Kipf and Welling, 2017) to fuse character embedding with similar pronunciation and shape, explicitly modeling the relationship between characters. PLOME (Liu et al., 2021) is proposed to be a task-specific pre-trained language model for CSC, which designs a confusion set based masking strategy and introduces various external knowledge. Additionally, REALISE (Xu et al., 2021) verifies that the multimodal knowledge can be leveraged to improve CSC performance.

2.2 Contrastive Learning

The main motivation of contrastive learning is to attract the positive samples and repulse the negative samples in a certain space (Hadsell et al., 2006; Chen et al., 2020; Khosla et al., 2020). Existing contrastive learning models in NLP are mainly focusing on the *language representation space* (e.g, word/sentence/semantic representations) (Iter et al., 2020; Gao et al., 2021; Wang et al., 2021b). Different from them, our proposed method directly optimizes the model's *probability space* for different characters through selected positive/negative samples and their original predicted probability.

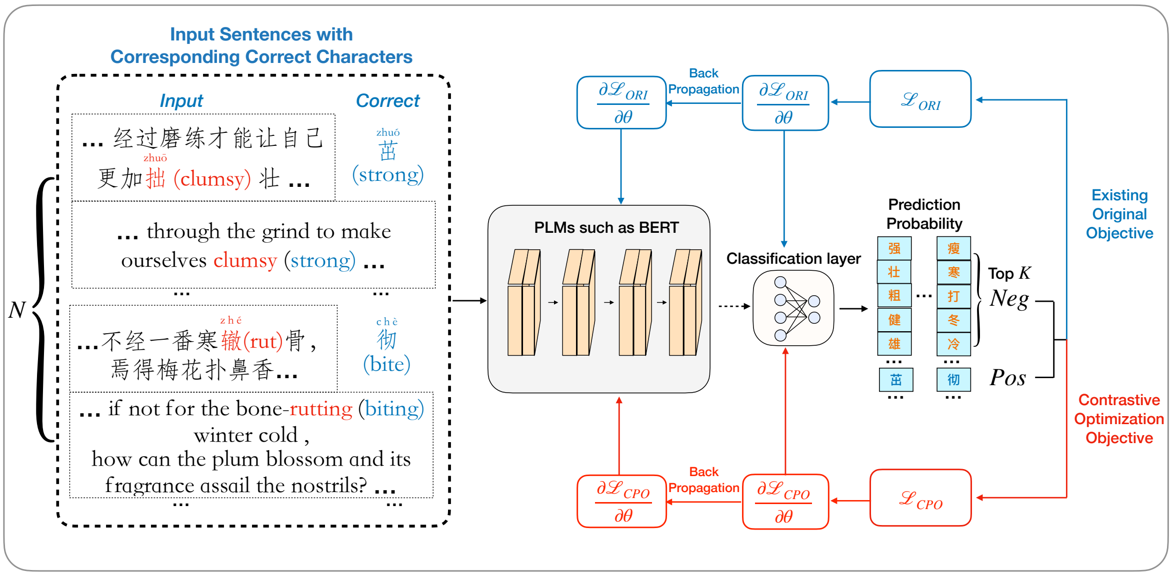

Figure 2: Overview of ECOPO framework. We select negative samples according to the original prediction probability of PLMs (e.g, for the position of "拙", PLMs predicts the Top 5 characters as "强", "壮", "粗", "健", and "雄".), then optimize the PLMs with the contrastive optimization objective and traditional original objective.

3 Methodology

In this section, we introduce the proposed ECOPO in details, as illustrated in Figure 2. ECOPO aims to refine the knowledge representation of PLMs to narrow the gap between it and the essential of CSC task. As mentioned in Section 1, with the model before our optimization process, we select the mistakes generated by this model itself to be the negative samples. Then through the Contrastive Probability Optimization objective, we maximize the prediction probabilities of the model for correct answers and minimize the prediction probabilities of the model for negative samples. In this error-driven way, the original prediction probabilities of the model are refined, improving the performance of the model on the CSC task. *Therefore, the model will grow and progress after making mistakes again and again, just as humans do.* Note that the proposed ECOPO is a model-agnostic framework, we can choose different PLMs or CSC models to be optimized in practice for better performance.

3.1 Observation and Intuition

To present our approach more clearly, we first describe our observation, and then give our explanation of the observation and intuition.

The key observation that ECOPO builds on is that PLMs such as BERT cannot focus well on the confusing characters that need to be paid more attention in the CSC task, as illustrated in Figure 1. We think that this gap comes mainly from the general corpora and the training paradigm used in the pre-training of language models. Taking the BERT as an example, its pre-training corpus is mainly from the text in Wikipedia, which has a very low proportion of contexts containing confusing characters, as verfied in Section 4.6. Additionally, Devlin et al. (2019) randomly choose 15% of tokens in the entire corpus to be masked by a fixed token "[MASK]" and then recover them. This masking-recovering strategy makes the knowledge acquired by PLMs in pre-training process discontinuous in the CSC task (Liu et al., 2021). Because the size of confusing characters will be lower in the 15% of characters that are randomly selected.

In fact, there also exists the same challenge when humans correct spelling errors. When only given the context of input sentence without seeing the misspelling, they tend to associate the common character rather than the confusing character with the context. Therefore, humans or models would wrongly predict common characters. *Intuitively, if the model can be optimized with common characters through an error-driven way, then the model can certainly be further enhanced, just as humans get progress from the mistakes they have made.*

3.2 Stage 1: Negative Samples Selection

We define the negative samples in CSC as those common characters that be incorrectly assigned high prediction probability by PLMs before our optimization process. According to our observation, negative samples that can form common collocations or phrases with the context tend to be assigned higher probability than the golden character, leading the model to make wrong corrections. Therefore, we use a simple strategy based on the prediction probability to select the negative samples which we utilize in the next stage.

Specifically, we use PLMs such as BERT to predict the original character for each input token based on the output of the last transformer layer. The prediction probability of the i-th token x_i in a sentence X is defined as:

$$p\left(y_i=j \mid X\right)=\operatorname{softmax}\left(\boldsymbol{W} \boldsymbol{h}_{\boldsymbol{i}}+\boldsymbol{b}\right)[j], \quad (1)$$

where $p\left(y_i=j \mid X\right)$ means the conditional probability that the i-th token x_i is predicted as the j-th character in the vocabulary of PLMs, $\boldsymbol{W} \in \boldsymbol{R}^{vocab \times hidden}$ and $\boldsymbol{b} \in \boldsymbol{R}^{vocab}$ are learnable parameters, $vocab$ is the size of vocabulary and the $hidden$ is the size of hidden state, $\boldsymbol{h}_{\boldsymbol{i}} \in \boldsymbol{R}^{hidden}$ is hidden state output of PLMs for the i-th token x_i.

Based on the original prediction probability, if the model makes wrong correction for the input character, we will select negative samples for the input character. The negative samples set Neg is selected from the candidate set T as:

$$T=\{t \mid t \in V \ \ and \ \ t \neq t^{+}\}, \quad (2)$$

$$Neg=\underset{T^{\prime} \subset T,\left|T^{\prime}\right|=K}{\arg \max } \sum_{t^{-} \in T^{\prime}} p\left(y_i=t^{-} \mid X\right), \quad (3)$$

where t^- and t^+ mean the negative and positive samples, respectively. The negative samples t^- are selected from those tokens whose prediction probability is in the Top K of the vocabulary V, and the best value of K is selected empirically. It is worth noting that the training process is supervised in the CSC task, so we can regard the golden character as the positive sample t^+.

3.3 Stage 2: Contrastive Probability Optimization

After obtaining the positive/negative samples and their corresponding prediction probability, we train the model by Contrastive Probability Optimization (CPO) objective which is defined as:

$$\begin{aligned}\mathcal{L}_{CPO}=-\frac{1}{N} \sum_{i=1}^{N} \frac{1}{K} \sum_{k=1}^{K}\{p\left(y_i=t^{+} \mid X\right) \\ -p\left(y_i=t_k^{-} \mid X\right)\},\end{aligned} \quad (4)$$

where N is the batch size, K is the selected negative samples size, t_k^- is the k-th negative sample in Neg. The CPO objective aims to teach the model to increase the prediction probability for positive sample (i.e., confusing character) and decrease the prediction probabilities for negative samples (i.e., common characters) by the maximum likelihood of the difference between the original probabilities for positive and negative samples.

To preserve the generalization performance of the model, we train both the existing original objective $\mathcal{L}_{ORI}$ and the CPO objective $\mathcal{L}_{CPO}$. The overall objective is defined as:

$$\mathcal{L}=\lambda_1 \mathcal{L}_{ORI}+\lambda_2 \mathcal{L}_{CPO}, \quad (5)$$

where λ_1 and λ_2 are weighting factors for two objectives. We use cross-entropy loss function as the $\mathcal{L}_{ORI}$ for BERT in our experiments. The training pseudo-code of ECOPO is shown in Appendix A.1. As described in Equation 5, we can replace the $\mathcal{L}_{ORI}$ with other models' training objectives, so ECOPO is model-agnostic and it can be easily used in other PLMs or previous CSC methods to achieve further improvements.

Most previous works use $\operatorname{softmax}$ and $\operatorname{cross-entropy}$ functions to train CSC models. But why just using $\operatorname{softmax}$ is not enough and using CPO is necessary? **Theoretically**: (1) *Their motivations are different*, $\operatorname{softmax}$ is to normalize the PLMs' logits into a probability distribution, but CPO aims to refine the knowledge representation of PLMs in the probability space. (2) *Their scopes are different*, $\operatorname{softmax}$ relies on all logits output by models for weighted calculation, this global weighting mechanism makes it not have good local attention. However, CPO can pay attention to a part of really difficult samples that models would often make mistakes through the negative samples selection stage. (3) *Their results are different*, through the $\operatorname{softmax}$ operation, we finally obtain a probability distribution that is softer than the original logits. But the CPO we proposed can eventually change the order of the original prediction probability, directing the model to assign higher probability to positive sample and lower probabilities to negative samples. Therefore, our work can be regarded as a great complement to the traditional $\operatorname{softmax} + \operatorname{cross-entropy}$ training paradigm. **Empirically**, we conducted in-depth analyses in Sections 4.5.1- 4.5.3.

4 Experiments

In this section, we introduce the details of experiments and main results we obtained. Then we conduct detailed analyses and discussions to verify the effectiveness of our method.

4.1 Datasets

Training Data We use the same training data by following previous works (Zhang et al., 2020; Liu et al., 2021; Xu et al., 2021), including the training samples from SIGHAN13 (Wu et al., 2013b), SIGHAN14 (Yu et al., 2014), SIGHAN15 (Tseng et al., 2015) and the pseudo training samples (size of 271K, we denote this part of samples as Wang271K in our paper) automatically generated by OCR-based and ASR-based methods (Wang et al., 2018).

Test Data To ensure the fairness, we use the exact same test data as the baseline methods, from the test datasets of SIGHAN13/14/15. Noted that the text of original SIGHAN datasets is in the Traditional Chinese, we pre-process these original datasets to the Simplified Chinese using the OpenCC[1]. This data conversion procedure has been widely used in previous works (Wang et al., 2019; Cheng et al., 2020; Zhang et al., 2020). The detailed statistic of the training/test data we use in our experiments is presented in Appendix A.2.

4.2 Baseline Methods

To evaluate the performance of ECOPO, we select several advanced strong baseline methods: **BERT** (Devlin et al., 2019) is directly fine-tuned on the training data. **Hybrid** (Wang et al., 2018) casts CSC into sequence labeling problem and implements BiLSTM model. **FASpell** (Hong et al., 2019) consists of a denoising autoencoder and a decoder. **Soft-Masked BERT** (Zhang et al., 2020) consists of a detection network and a correction network. **SpellGCN** (Cheng et al., 2020) integrates the confusion set to the correction model through GCNs. **PLOME** (Liu et al., 2021) is a task-specific PLM which jointly learns how to understand language and correct spelling errors. **REALISE** (Xu et al., 2021) is a multimodel model which captures and mixes the semantic, phonetic and graphic information to improve CSC performance. REALISE is the previous state-of-the-art method on SIGHAN13/14/15 datasets.

4.3 Experimental Setup

In terms of evaluation granularity, there are two levels of metrics, namely character/sentence-level. Obviously, the sentence-level metric is stricter than the character-level metric because there may be multiple wrong characters in a sentence. One sentence sample is considered to be correct only when all the wrong characters in it are detected and corrected successfully. Therefore, we report the sentence-level metrics for evaluation, which are widely used in previous works (Li et al., 2021; Huang et al., 2021; Xu et al., 2021).

Specifically, the metrics we report include Accuracy, Precision, Recall and F1 score for detection and correction levels. At the detection level, all locations of wrong characters in a sentence should be identical successfully. At the correction level, the model must not only detect but also correct all the erroneous characters with the gold standard.

Other implementation details and hyper-parameters choices are presented in Appendix A.3.

4.4 Experimental Results

From Table 1, we can observe that:

1. The ECOPO (BERT) performs better than BERT on all test sets and evaluation metrics. Specifically, ECOPO (BERT) achieves significant improvement on SIGHAN15, and outperforms the previous state-of-the-art models with a very thin model, while REALISE and PLOME are two complex models with some auxiliary modules. Note that ECOPO (BERT) only consists of a BERT encoder.

2. From the results on the SIGHAN14 test set, we can see that the performance improvement of ECOPO (BERT) based on BERT is not as large as on the other two test sets, but still effective. Additionally, due to the model-agnostic advantage of ECOPO, it can be simply combined with other previous state-of-the-art models such as REALISE and get further enhancement, which are presented in the rows of REALISE and ECOPO (REALISE).

3. Considering the impact of external knowledge, several previous works exploit various additional information to improve performance. For example, FASpell and SpellGCN introduce character similarity to CSC, REALISE and PLOME propose to leverage multimodal

Table 1: The performance of ECOPO and all baseline methods. Note that all baseline results are directly from other published paper. ECOPO (model-X) means that we perform ECOPO framework on model-X. We underline the previous state-of-the-art performance for convenient comparison. "$\uparrow$" indicates that the corresponding baseline method receives a further performance improvement after optimization by ECOPO.

knowledge such as phonetic and graphic information. Unlike the aforementioned models, ECOPO (BERT) achieves competitive performance without any additional knowledge and optimizing only based on the mistakes that the original BERT itself has made.

4. To verify the model-agnostic characteristic of ECOPO, we choose two other models including Soft-Masked BERT and REALISE to be optimized. Practically, we train the combined model with the joint objective, as described in Equation 5. From the results of Table 1, we can see that ECOPO's improvement is stable and significant over the three models.

4.5 Analysis and Discussion

4.5.1 Statistics of Different Characters

To further empirically explain why the method we proposed is effective, we conduct sufficient statistical experiments, as shown in Table 2. We apply different methods to the SIGHAN13/14/15 datasets, and carry out statistical analyses on their wrong correction samples. Note that if a character co-occurs with the character before or after the error position more than 1,000 times in wiki2019zh[2], we regard it as a common character.

From Table 2, we can see that when only $\mathrm{softmax}$ is used, most of the failures of the model are because it incorrectly assigns higher prediction probabilities to common characters, which reflects the gap between the pre-trained knowledge of PLMs and the goal of CSC. When we run ECOPO or only CPO, the model does pay more attention to the less common but more confusing characters. Our proposed CPO indeed effectively change the model's predictions for different types of characters. Thus, CPO refines the knowledge representation of PLMs for CSC and narrow the gap between PLMs and CSC, but $\mathrm{softmax}$ does not.

---

[2] The general pre-training corpus which is from Wikipedia dump (as of February 7, 2019) and contains one million pages.

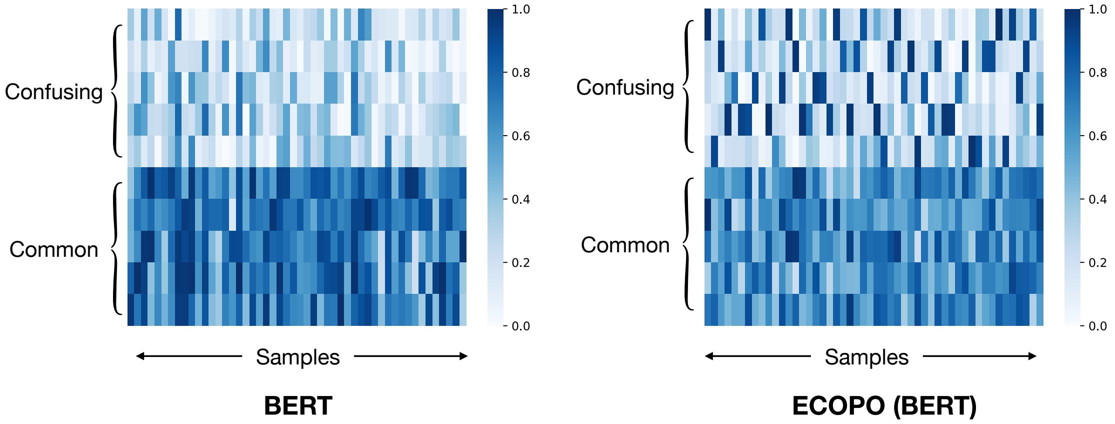

Figure 3: Heat map visualization of probability. The darker the blue, the higher the model's prediction probability for a particular character (vertical axis) given the input of samples containing misspelled characters (horizontal axis). The selected samples are from SIGHAN15, and the original BERT would make wrong corrections for them.

Dataset	Method	Common	Confusing
SIGHAN13	softmax	172 (76%)	54 (24%)
	CPO	108 (54%)	92 (46%)
	ECOPO	100 (52%)	93 (48%)
SIGHAN14	softmax	208 (77%)	62 (23%)
	CPO	159 (61%)	101 (39%)
	ECOPO	152 (59%)	106 (41%)
SIGHAN15	softmax	171 (82%)	38 (18%)
	CPO	72 (41%)	103 (59%)
	ECOPO	68 (40%)	101 (60%)

Table 2: Statistical results on different types of characters. The statistical samples are the all wrong correction samples of different methods.

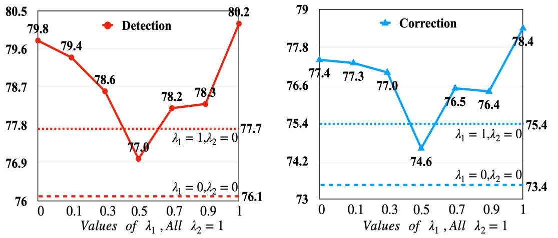
4.5.2 Visualization of Common/Confusing Character Probability

The key objective of ECOPO is to optimize the prediction probability of the PLMs for two different kinds of characters, i.e., **common characters** which original PLMs would be more inclined and **confusing characters** which CSC task should pay more attention to. Therefore, we visualize the probability optimization effect of ECOPO in this part of experiment. Specifically, we apply BERT and ECOPO (BERT) to predict the character which should appear at the position of the misspelled character based on its context. We select the Top-5 characters co-occurring with the context of the misspelled character as the common characters, and 5 confusing characters from the widely used confusion set (Wu et al., 2013b). Note that we ensure that the common and confusing characters selected are not duplicated, and the golden character must be in the selected 5 confusing characters. Then we visualize the prediction probabilities of common/confusing characters as a heat map.

Figure 3 shows the prediction probability distributions of BERT and ECOPO (BERT) for the common/confusing characters. By comparison, we can see that BERT assigns higher probability to common characters than confusing characters, and ECOPO (BERT) focuses more on confusing characters which are similar to the golden character. This difference in BERT before and after ECOPO's optimization is consistent with our study motivation and design objective. We can see that ECOPO does refine the knowledge representation and prediction probability of BERT for different characters.

4.5.3 Effects of Weighting Factors λ_1, λ_2

Firstly, from Figure 4, we can see that no matter how the values of λ_1, λ_2 change, ECOPO (BERT) always has improvement compared to the baseline BERT, which reflects the general effectiveness of our proposed method. We also can find that whether only using $\mathcal{L}_{ORI}$ ($\lambda_1 = 1$, $\lambda_2 = 0$) or $\mathcal{L}_{CPO}$ ($\lambda_1 = 0$, $\lambda_2 = 1$) for training, there is an improvement compared to the baseline model. Besides, only using $\mathcal{L}_{CPO}$ has a greater improvement than only using $\mathcal{L}_{ORI}$, which illustrates the advantage of our proposed CPO over $\mathrm{softmax}$. Furthermore, when λ_2 is fixed to 1, as λ_1 increases, the model performance shows a trend of first decreasing and then increasing. From this phenomenon, we suspect that the widely used $\mathcal{L}_{ORI}$ in previous works has a certain regularization effect on the



(a) Detection performance (b) Correction performance

Figure 4: The F1 results on SIGHAN15, using different combinations of λ_1, λ_2 in Equation 5 in ECOPO (BERT). When $\lambda_1 = 0, \lambda_2 = 0$, it is equivalent to the baseline BERT.

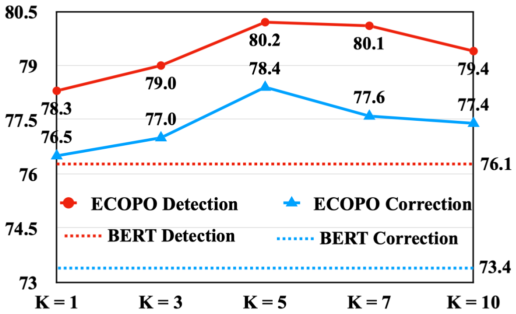


Figure 5: The F1 results on SIGHAN15, using different values of K in Equation 3 in ECOPO (BERT). The dotted lines represent the baseline BERT's performance.

probability space of the model. Also for this reason, only using $\mathcal{L}_{ORI}$ has improvements compared to the baseline. Additionally, the regularization effect of $\mathcal{L}_{ORI}$ is good for the process of $\mathcal{L}_{CPO}$ optimizing the probability representation, and can help model avoid over-fitting. Therefore, in practice, we chose the combination that perform best in SIGHAN13/14/15, namely $\lambda_1 = 1, \lambda_2 = 1$.

4.5.4 Effects of Negative Samples Size K

As different amounts of negative samples can affect ECOPO's performance, it is essential to study the impact of negative samples size K in Equation 3.

Figure 5 illustrates the performance change from the perspective of detection and correction. We find that when the value of K reaches a certain value (e.g., $K > 5$), the overall performance of the model (F1 score) does not improve anymore. This is because ECOPO optimizes the model based on the probability representation, when the value of K becomes very large, the predicted probabilities of samples become so small that they have almost no effect on the probability optimization of the positive sample. Therefore, choosing an appropriate K value is critical to the performance improvement of ECOPO, although ECOPO has significant improvement based on BERT at all values of K.

Input:	与其自暴自气 (弃) 不如往好处想。 It's better to think for the good than to be angry (give up).
BERT:	[己(own), 大(big), 利(benefit)]
ECOPO:	[弃(give up), 尊(respect), 强(strong)]
Input:	我努力打败数不进 (尽)的风雨。 I try to beat the enter (endless) storms.
BERT:	[起(raise), 上(up), 得(get)]
ECOPO:	[尽(endless), 得(get), 完(end)]

Table 3: Examples of spelling errors and corresponding output (Top 3 candidates) of original BERT and ECOPO (BERT). We mark the input confusing/golden/wrong correction characters in red/blue/orange.

4.6 Case Study for Probability Optimization

Table 3 shows the comparisons between the correction results of BERT and ECOPO (BERT). In the first examples, the output of BERT such as "己", "大" and "利" all can form a correct Chinese phrase with "自", but they cause a semantic incoherence for the whole sentence. The statistics of the general pre-training corpus wiki2019zh show that "自己" co-occurs 136,318 times and "自弃" co-occurs 119 times, which verifies the intuition about common/confusing characters described in Section 3.1. In the second example as well, the output of BERT can be formed with "数不" as reasonable phrases. From the two examples, we can see that ECOPO does guide the BERT to accurately predict the ideal confusing characters by the highest probability and make the right corrections. Such experimental results are in line with our work's core motivation.

5 Conclusion

In this paper, we introduce to promote CSC by narrowing the gap between the knowledge of PLMs and the goal of CSC. We propose the ECOPO, a simple yet effective training framework that aims to perform an error-driven optimization for the PLMs based on their original probability representation. Extensive experiments and empirical results show the competitive performance of our method. In the future, we will study how to automatically measure the quality of negative samples to further enhance our method. Additionally, applying our core idea to other tasks will be an interesting direction.

A Appendices

A.1 Pseudo-code of ECOPO

Figure 6 shows the Pytorch-style pseudo-code for the ECOPO. As described in Section 3, our proposed ECOPO consists of two stages, namely Negative Samples Selection and Contrastive Probability Optimization. It is worthy noting that in the pseudo-code, we only show the process of calculating the loss of one training sample.

```
# vocab_prob : the prediction probability for all characters in vocabulary
# pos_idx    : the index of positive sample (golden character) in vocabulary
# K          : the selected negative samples amount

# Negative Samples Selection
pos_prob = vocab_prob[pos_idx]
neg_prob = torch.topk(vocab_prob, K)[0]
neg_idx = torch.topk(vocab_prob, K)[1].tolist()

# Contrastive Probability Optimization Objective
loss_list = []
for x in range(0, K):
   if neg_idx[x] != pos_idx:
       loss_list.append(pos_prob - neg_prob[x])
loss = - torch.stack(loss_list).mean()
```

Figure 6: Pseudo-code of our practical implementation.

A.2 Datasets Details

Table 4 shows the detailed statistics of our used datasets. We report the number of sentences in the datasets (#Sent), the average sentence length of the datasets (Avg.Length), and the number of misspellings the datasets contains (#Errors).

Training Data	#Sent	Avg. Length	#Errors

Table 4: Statistics of the datasets that we use in experiments. All the training data are merged to train the models in our experiments. The test sets are used separately to evaluate performance.

A.3 Implementation Details

All the source code of our experiments is implemented using Pytorch (Paszke et al., 2019) based on the Huggingface's implementation of Transformer library[3] (Wolf et al., 2020). The architecture of the BERT encoder we use in the related models is same as the $BERT_{BASE}$ model, which has 12 transformers layers with 12 attention heads and its hidden state size is 768. We initialize the BERT encoder with the weights of Chinese BERT-wwm model (Cui et al., 2020). We train ECOPO with the AdamW (Loshchilov and Hutter, 2018) optimizer for 10 epochs. The training batch size N is set to 64 and the evaluation batch size is set to 50. The negative samples size K is set to 5 by default. The weighting factors λ_1, λ_2 are both set to 1. In all our experiments, when λ_1 is equal to 1, it means that we use a fine-tuned BERT on the training set as the initialization model to continue the corresponding training process under different loss functions. The initial learning rate is set to 5e-5. We set the maximum sentence length to 128. The model is trained with learning rate warming up and linear decay.

It is worth noting that the annotation quality of SIGHAN13 test dataset is relatively poor. As we have observed and mentioned in (Cheng et al., 2020; Xu et al., 2021), quite lots of the mixed usage of auxiliary (such as "的", "地", and "得") don't have correct annotations. Therefore, the evaluation metrics we use may not accurately reflect the real model performance on SIGHAN13. To alleviate this problem, there are two main solutions in previous works. Cheng et al. (2020) propose to continue fine-tuning well-trained models on the SIGHAN13 training dataset before testing, which we think will suffer from the over-fitting problem. Therefore, we follow the post-processing method proposed in (Xu et al., 2021) and don't consider all the detected and corrected mixed auxiliary. This approach does not compromise the fairness of the evaluation process and can better reflect the model performance.

Abstract

Multimodal pre-training with text, layout, and image has achieved SOTA performance for visually rich document understanding tasks recently, which demonstrates the great potential for joint learning across different modalities. However, the existed research work has focused only on the English domain while neglecting the importance of multilingual generalization. In this paper, we introduce a human-annotated multilingual form understanding benchmark dataset named **XFUND**, which includes form understanding samples in 7 languages (Chinese, Japanese, Spanish, French, Italian, German, Portuguese). Meanwhile, we present LayoutXLM, a multimodal pre-trained model for multilingual document understanding, which aims to bridge the language barriers for visually rich document understanding. Experimental results show that the LayoutXLM model has significantly outperformed the existing SOTA cross-lingual pre-trained models on the XFUND dataset. The XFUND dataset and pre-trained LayoutXLM models have been publicly available at `https://aka.ms/layoutxlm`.

1 Introduction

Recently, multimodal pre-training for visually rich document understanding (VRDU) has achieved new SOTA performance on several public benchmarks (Xu et al., 2021, 2020), including form understanding (Jaume et al., 2019), receipt understanding (Park et al., 2019), complex layout understanding (Stanisławek et al., 2021), document image classification (Harley et al., 2015) and document VQA task (Mathew et al., 2021), due to the advantage that text, layout and image information is jointly learned end-to-end in a single framework. However, since most evaluation benchmarks focus on English VRDs, it is hard to explore the performance of a document understanding system on VRDs in other languages. Simply translating these documents automatically with machine translation services might help, but it is often not satisfactory due to the poor translation quality on document images (Afli and Way, 2016). Therefore, it is vital to explore the multilingual generalization ability of multimodal pre-training for VRDU tasks.

Multilingual pre-trained models such as mBERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019), XLM-RoBERTa (Conneau et al., 2020), mBART (Liu et al., 2020), and the recent InfoXLM (Chi et al., 2021) and mT5 (Xue et al., 2021) have pushed many SOTA results on cross-lingual natural language understanding tasks by pre-training the Transformer models on different languages. These models have successfully bridged the language barriers in a number of cross-lingual transfer benchmarks such as XNLI (Conneau et al., 2018) and XTREME (Hu et al., 2020). Although a large amount of multilingual text data has been used in these cross-lingual pre-trained models, text-only multilingual models cannot be easily used in the VRDU tasks because they are usually fragile in analyzing the documents due to the format/layout diversity of documents in different countries, and even different regions in the same country. Hence, to accurately understand these visually rich documents in different languages, it is crucial to pre-train the multilingual models in a multimodal framework. Meanwhile, it is vital to provide a human-labeled benchmark to further facilitate multilingual document understanding.

To this end, we introduce a human-annotated multilingual form understanding benchmark dataset named **XFUND**, which contains 7 languages, including Chinese, Japanese, Spanish, French, Italian, German, Portuguese. In addition to the fully annotated data, we propose two subtasks

May 22-27, 2022

with three different settings. The two subtasks are semantic entity recognition and relation extraction. And we introduce three different settings to explore the multilingual and complex layout generalization ability: (1) Language-specific fine-tuning follows the typical paradigm of fine-tuning and testing on the same language. (2) Zero-transfer learning means that the model is trained on English data only and then evaluated on each target language. (3) Multitask fine-tuning requires the model to be trained on data from all languages and then evaluated on each target language. These different settings evaluate not only the multilingual representation for each languages but also the cross-lingual generalization across tasks.

Moreover, we also present a multimodal pre-trained model for multilingual VRDU tasks, aka LayoutXLM, which is a multilingual extension of the recent LayoutLMv2 model (Xu et al., 2021). To evaluate the multilingual generalization ability of this framework, we use the pre-training objectives of LayoutLMv2, including Masked Visual-Language Model (MVLM), Image-Text Matching (ITM), and Image-Text Alignment (ITA). In addition, we pre-train the model with the IIT-CDIP dataset (Lewis et al., 2006) as well as a great number of publicly available digital-born multilingual PDF files from the internet, which helps the LayoutXLM model to learn from real-world documents. In this way, the model obtains textual and visual signals from a variety of document templates/layouts/formats in different languages, thereby taking advantage of the local invariance property from both textual, visual and linguistic perspectives. Experiment results show that the pre-trained LayoutXLM outperforms several SOTA cross-lingual pre-trained models(Conneau et al., 2020; Chi et al., 2021) on the XFUND benchmark dataset, which also demonstrates the potential of the multimodal pre-training strategy for multilingual document understanding.

The contributions of this paper are summarized as follows:

- We introduce XFUND, a multilingual form understanding benchmark dataset that includes human-labeled forms with key-value pairs in 7 languages (Chinese, Japanese, Spanish, French, Italian, German, Portuguese).

- We propose LayoutXLM, a multimodal pre-trained model for multilingual document understanding, which is trained with large-scale real-world scanned/digital-born documents.

- LayoutXLM has outperformed other SOTA multilingual baseline models on the XFUND dataset, which demonstrates the great potential for the multimodal pre-training for the multilingual VRDU task. The pre-trained LayoutXLM model and the XFUND dataset have been publicly available.

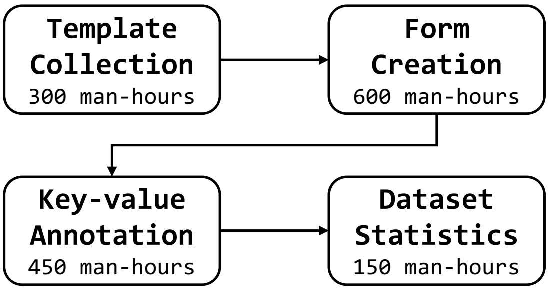

Figure 1: The illustration of corpus construction.

2 XFUND

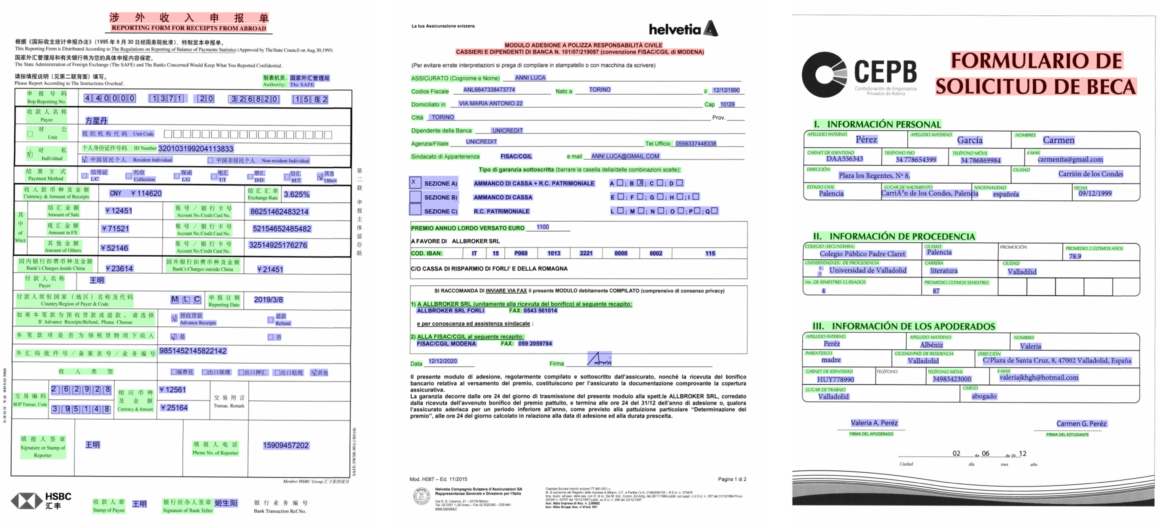
As illustrated in Figure 1, we develop our XFUND dataset in four steps including §2.1 Template Collection, §2.2 Form Creation, §2.3 Key-value Annotation, and §2.4 Data Finalization and Statistics, spending around 1,500 hours of human labor in total. Further details of ethic consideration are presented in §A Ethical Consideration.

2.1 Template Collection

Forms are usually used to collect information in different business scenarios. To avoid the privacy and sensitive information issue with real-world documents, we collect the documents publicly available on the internet and remove the content within the documents while only keeping the templates to fill in synthetic information manually. We collect form templates in 7 languages from the internet.

2.2 Form Creation

With the collected form templates, the human annotators manually fill synthetic information into these templates following corresponding requirements. Each template is allowed to be used only once, which means each form is different from the others. Besides, since the FUNSD (Jaume et al., 2019) documents contain both digitally filled-out forms and handwritten forms, we also ask annotators to fill in the forms by typing or handwriting. The completed



(a) Chinese (b) Italian (c) Spanish

Figure 2: Three sampled forms from the XFUND benchmark dataset (Chinese and Italian), where red denotes the headers, green denotes the keys and blue denotes the values.

forms are finally scanned into document images for further OCR processing and key-value labeling.

2.3 Key-value Annotation

Key-value pairs are also annotated by human annotators. Equipped with the synthetic forms, we use Microsoft Read API[1] to generate OCR tokens with bounding boxes. With an in-house GUI annotation tool, annotators are shown the original document images and the bounding boxes visualization of all OCR tokens. The annotators are asked to group the discrete tokens into entities and assign pre-defined labels to the entities. Also, if two entities are related, they are linked together as a key-value pair.

2.4 Data Finalization and Statistics

We design testing scripts to filter and check the annotated files and ask specific annotators for ethic checking. Cases with detected issues will be sent to the data annotation pipeline again for new valid labels.

Finally, the XFUND benchmark includes 7 languages with 1,393 fully annotated forms, where sampled documents are shown in Figure 2. Each language includes 199 forms, where the training set includes 149 forms, and the test set includes 50 forms. Detailed information is shown in Table 1.

2.5 Task Definition

Key-value extraction is one of the most critical tasks in form understanding. Inspired by FUNSD (Jaume et al., 2019), we define this task with two sub-tasks, which are semantic entity recognition and relation extraction.

Semantic Entity Recognition Given a visually rich document $\mathcal{D}$, we acquire discrete token set $t = \{t_0, t_1, ..., t_n\}$, where each token $t_i = (w, (x_0, y_0, x_1, y_1))$ consists of a word w and its bounding box coordinates (x_0, y_0, x_1, y_1).

---

[1] `https://docs.microsoft.com/en-us/azure/cognitive-services/computer-vision/overview-ocr`

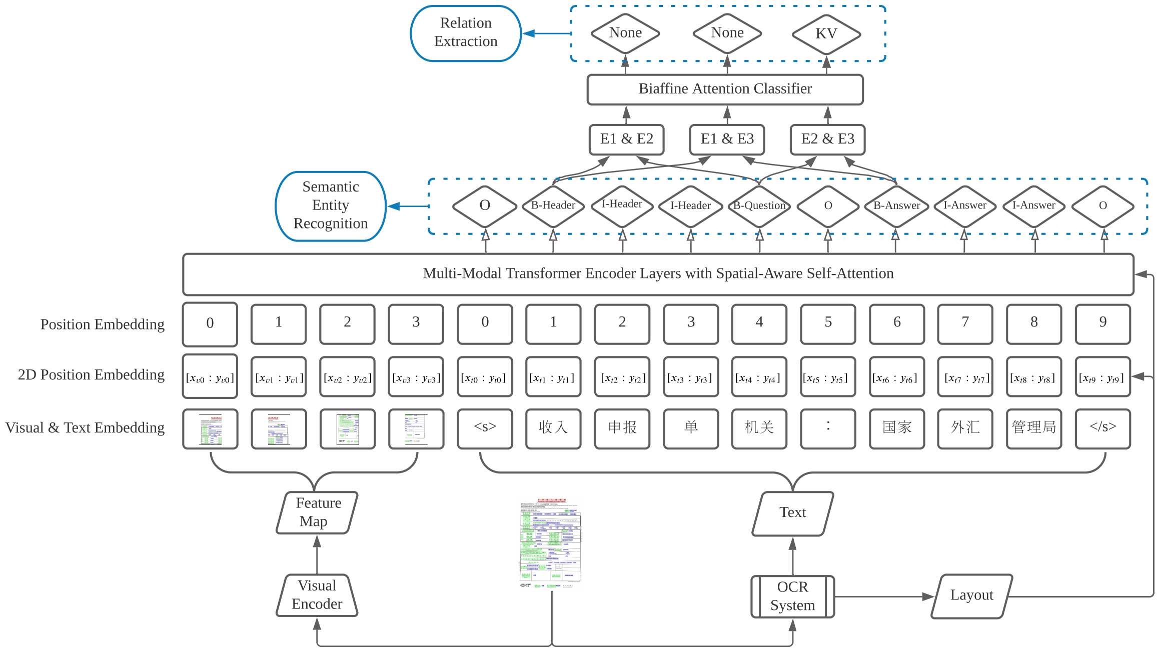

Figure 3: Architecture of the LayoutXLM Model, where the semantic entity recognition and relation extraction tasks are also demonstrated.

$\mathcal{C} = \{c_0, c_1, .., c_m\}$ is the semantic entity labels where the tokens are classified into. Semantic entity recognition is the task of extracting semantic entities and classifying them into given entity types. In other words, we intend to find a function $F_{SER} : (\mathcal{D}, \mathcal{C}) \rightarrow \mathcal{E}$, where $\mathcal{E}$ is the predicted semantic entity set:

$$\mathcal{E} = \{(\{t_0^0, ..., t_0^{n_0}\}, c_0), ..., (\{t_k^0, ..., t_k^{n_k}\}, c_k)\}$$

Relation Extraction Equipped with the document $\mathcal{D}$ and the semantic entity label set $\mathcal{C}$, relation extraction aims to predict the relation between any two predicted semantic entities. Defining $\mathcal{R} = \{r_0, r_1, .., r_m\}$ as the semantic relation labels, we intend to find a function $F_{RE} : (\mathcal{D}, \mathcal{C}, \mathcal{R}, \mathcal{E}) \rightarrow \mathcal{L}$, where $\mathcal{L}$ is the predicted semantic relation set:

$$\mathcal{L} = \{(head_0, tail_0, r_0), ..., (head_k, tail_k, r_k)\}$$

where $head_i$ and $tail_i$ are two semantic entities. In this work, we mainly focus on the key-value relation extraction.

3 LayoutXLM

In this section, we present a powerful baseline model LayoutXLM and introduce its model architecture, pre-training objectives, and pre-training dataset. We follow the LayoutLMv2 (Xu et al., 2021) architecture and transfer the model to large-scale multilingual document datasets.

3.1 Model Architecture

Similar to the LayoutLMv2 framework, we built the LayoutXLM model with a multimodal Transformer architecture. The framework is shown in Figure 3. The model accepts information from three different modalities, including text, layout, and image, which are encoded respectively with text embedding, layout embedding, and visual embedding layers. The text and image embeddings are concatenated, then plus the layout embedding to get the input embedding. The input embeddings are encoded by a multimodal Transformer with the spatial-ware self-attention mechanism. Finally, the output contextual representation can be utilized for the following task-specific layers. For brevity, we refer to (Xu et al., 2021) for further details on architecture.

3.2 Pre-training

The pre-training objectives of LayoutLMv2 have shown effectiveness in modeling visually rich documents. Therefore, we naturally adapt this pre-training framework to multilingual document pre-training. Following the idea of cross-modal alignment, our pre-training framework for document understanding contains three pre-training objectives, which are Multilingual Masked Visual-Language Modeling (text-layout alignment), Text-Image Alignment (fine-grained text-image alignment), and Text-Image Matching (coarse-grained text-image alignment).

Multilingual Masked Visual-Language Modeling The Masked Visual-Language Modeling (MVLM) is originally proposed in the vanilla LayoutLM and also used in LayoutLMv2, aiming to model the rich text in visually rich documents. In this pre-training objective, the model is required to predict the masked text token based on its remaining text context and whole layout clues. Similar to the LayoutLM/LayoutLMv2, we train the LayoutXLM with the Multilingual Masked Visual-Language Modeling objective (MMVLM).

In LayoutLM/LayoutLMv2, an English word is treated as the basic unit, and its layout information is obtained by extracting the bounding box of each word with OCR tools, then subtokens of each word share the same layout information. However, for LayoutXLM, this strategy is not applicable because the definition of the linguistic unit is different from language to language. To prevent the language-specific pre-processing, we decide to obtain the character-level bounding boxes. After the tokenization using SentencePiece with a unigram language model, we calculate the bounding box of each token by merging the bounding boxes of all characters it contains. In this way, we can efficiently unify the multilingual multimodal inputs.

Text-Image Alignment The Text-Image Alignment (TIA) task is designed to help the model capture the fine-grained alignment relationship between text and image. We randomly select some text lines and then cover their corresponding image regions on the document image. The model needs to predict a binary label for each token based on whether it is covered or not.

Text-Image Matching For Text-Image Matching (TIM), we aim to align the high-level semantic representation between text and image. To this end, we require the model to predict whether the text and image come from the same document page.

3.3 Pre-training Data

The LayoutXLM model is pre-trained with documents in 53 languages. In this section, we briefly describe the pipeline for preparing the large-scale multilingual document collection.

Data Collection To collect a large-scale multilingual visually rich document collection, we download and process publicly available multilingual digital-born PDF documents following the principles and policies of Common Crawl[2]. Using digital-born PDF documents can benefit the collecting and pre-processing steps. On the one hand, we do not have to identify scanned documents among the natural images. On the other hand, we can directly extract accurate text with corresponding layout information with off-the-shelf PDF parsers and save time for running expensive OCR tools.

Pre-processing The pre-processing step is needed to clean the dataset since the raw multilingual PDFs are often noisy. We use an open-source PDF parser called PyMuPDF[3] to extract text, layout, and document images from PDF documents. After PDF parsing, we discard the documents with less than 200 characters. We use the language detector from the FastText (Joulin et al., 2017) library and split data per language. Following CCNet (Wenzek et al., 2020), we classify the document as the language if the language score is higher than 0.5. Otherwise, unclear PDF files with a language score of less than 0.5 are discarded.

Data Sampling After splitting the data per language, we use the same sampling probability $p_l \propto (n_l/n)^\alpha$ as XLM (Conneau and Lample, 2019) to sample the batches from different languages, where n_l is the document counts per language and n denotes the total number. Following InfoXLM (Chi et al., 2021), we use $\alpha = 0.7$ for LayoutXLM to make a reasonable compromise between performance on high- and low-resource languages. Finally, we follow this distribution and sample a multilingual document dataset with 22 million visually rich documents. In addition, we also sample 8 million scanned English documents from the IIT-CDIP dataset so that we totally use 30 million documents to pre-train the LayoutXLM, where the model can benefit from the visual information of both scanned and digital-born document images.

4 Key-value Extraction with PLMs

In this section, we present a simple yet efficient baseline framework based on pre-trained language

---

[2] `https://commoncrawl.org`

[3] `https://github.com/pymupdf/PyMuPDF`

models (PLMs) for our two sub-tasks. Equipped with this framework, we integrate two existing popular cross-lingual pre-trained language models, XLM-RoBERTa and InfoXLM, and our proposed LayoutXLM as the pre-trained language model backbones.

In this framework, given a visually rich document $\mathcal{D}$, we will pass discrete token set $\mathbf{T} = \{t_0, t_1, ..., t_n\}$ into these backbone models to obtain the contextual representation of each tokens $\mathbf{H} = \{\mathbf{h_0}, \mathbf{h_1}, ..., \mathbf{h_n}\}$. For different tasks, the representations will be processed with different modules to predict the required labels.

4.1 Semantic Entity Recognition

For this task, we simply follow the typical sequence labeling paradigm with BIO labeling format and build task-specific feed-forward network layers ($\texttt{FFN}^{SER}$) over the output of backbone models.

$$\mathbf{h}_i^{SER} = \texttt{FFN}^{SER}(\mathbf{h}_i)$$

4.2 Relation Extraction

For the relation extraction task, we first incrementally construct the set of relation candidates by producing all possible pairs of given semantic entities. For each pair, the representation of the head entity $\mathbf{h}_i^{head}$ or tail entity $\mathbf{h}_j^{tail}$ is the concatenation of the first token vector in each entity and the entity type embedding $\mathbf{e}^{head}$/$\mathbf{e}^{tail}$ obtained with a specific type embedding layer. After respectively projected by two feed-forward network layers, the representations of head and tail are fed into a biaffine classifier consisting of trainable weights $\mathbf{U}$, $\mathbf{W}$, and $\mathbf{b}$.

$$\begin{aligned}
\mathbf{h}_i^{head} &= \texttt{FFN}^{head}([\mathbf{h}_i; \mathbf{e}^{head}]) \\
\mathbf{h}_j^{tail} &= \texttt{FFN}^{tail}([\mathbf{h}_j; \mathbf{e}^{tail}]) \\
\mathbf{h}_{i,j}^{relation} &= \mathbf{h}_i^{head}\mathbf{U}\mathbf{h}_j^{tail} + \mathbf{W}(\mathbf{h}_i^{head} \circ \mathbf{h}_j^{tail}) + \mathbf{b}
\end{aligned}$$

5 Experiments

5.1 Settings

Cross-lingual Evaluation Besides the experiments of typical language-specific fine-tuning, we also design two additional settings to demonstrate the ability to transfer knowledge among different languages, which are zero-shot transfer learning and multitask fine-tuning. Specifically, (1) language-specific fine-tuning refers to the typical fine-tuning paradigm of fine-tuning on language X and testing on language X. (2) Zero-shot transfer learning means the models are trained on English data only and then evaluated on each target language. (3) Multitask fine-tuning requires the model to train on data in all languages. We evaluate models in these three settings over two sub-tasks in XFUND: semantic entity recognition and relation extraction, and compare LayoutXLM to two cross-lingual language models: XLM-R and InfoXLM.

Pre-training LayoutXLM Following the original LayoutLMv2 recipe, we train LayoutXLM models with two model sizes. For the LayoutXLM$_{\text{BASE}}$ model, we use a 12-layer Transformer encoder with 12 heads and set the hidden size to $d = 768$. For the LayoutXLM$_{\text{LARGE}}$ model, we increase the layer number to 24 with 16 heads and hidden size to $d = 1,024$. ResNeXt101-FPN is used as a visual backbone in both models. Finally, the number of parameters in these two models are approximately 345M and 625M. During the pre-training stage, we first initialize the Transformer encoder along with text embeddings from InfoXLM and initialize the visual embedding layer with a Mask-RCNN model trained on PubLayNet. The rest of the parameters are initialized randomly. Our models are trained with 64 Nvidia V100 GPUs with batch size of 1,024 for 150k training steps.

Fine-tuning on XFUND For a fair comparison, we train all models with the basic hyper-parameter settings and slightly adapt them to make sure every optimization has well converged. For the semantic entity recognition task, we train for 1,000 steps with batch size of 16. For the relation extraction task, we train for 3,000 steps with batch size of 8. We use the linear decay with a learning rate of 5e-5 and warm-up ratio of 0.1.

5.2 Results

We evaluate the LayoutXLM model on language-specific fine-tuning tasks, and the results are shown in Table 2. Compared with the pre-trained models such as XLM-R and InfoXLM, the LayoutXLM LARGE model achieves the highest F1 scores in both SER and RE tasks. The significant improvement shows LayoutXLM's capability to transfer knowledge obtained from pre-training to downstream tasks, which further confirms the effectiveness of our multilingual pre-training framework.

For the cross-lingual zero-shot transfer, we present the evaluation results in Table 3. Although the models are only fine-tuned on FUNSD dataset (in English), it can still transfer the knowledge to

different languages. In addition, it is observed that the LayoutXLM model significantly outperforms the other text-based models. This verifies that LayoutXLM can capture the common layout invariance among languages and transfer to others.

Finally, Table 4 shows the evaluation results on the multitask learning. In this setting, the pre-trained LayoutXLM model is fine-tuned with all 8 languages simultaneously and evaluated on each specific language, in order to investigate whether improvements can be obtained by multilingual fine-tuning. We observe that the multitask learning further improves the model performance compared to the language-specific fine-tuning, which also confirms that document understanding can benefit from the layout invariance among different languages.

6 Related Work

Multimodal Pre-training Multimodal pre-training has become popular in recent years due to its successful applications in vision-language representation learning. Lu et al. (2019) proposed ViLBERT for learning task-agnostic joint representations of image content and natural language by extending the popular BERT architecture to a multimodal two-stream model. Su et al. (2020) proposed VL-BERT that adopts the Transformer model as the backbone, and extends it to take both visual and linguistic embedded features as input. Li et al. (2020a) propose VisualBERT consists of a stack of Transformer layers that implicitly align elements of an input text and regions in an associated input image with self-attention. Chen et al. (2020) introduced UNITER that learns through large-scale pre-training over four image-text datasets (COCO, Visual Genome, Conceptual Captions, and SBU Captions), which can power heterogeneous downstream V+L tasks with joint multimodal embeddings. Li et al. (2020b) proposed a new learning method Oscar (Object-Semantics Aligned Pre-training), which uses object tags

detected in images as anchor points to significantly ease the learning of alignments. Inspired by these vision-language pre-trained models, we would like to introduce the vision-language pre-training into the document intelligence area, where the text, layout, and image information can be jointly learned to benefit the VRDU tasks.

Multilingual Pre-training Multilingual pre-trained models have pushed many SOTA results on cross-lingual natural language understanding tasks by pre-training the Transformer models on different languages. These models have successfully bridged the language barriers in many cross-lingual transfer benchmarks such as XNLI (Conneau et al., 2018) and XTREME (Hu et al., 2020). Devlin et al. (2019) introduced a new language representation model called BERT and extend to a multilingual version called mBERT, which is designed to pre-train deep bidirectional representations from the unlabeled text by jointly conditioning on both left and right context in all layers. As a result, the pre-trained BERT model can be fine-tuned with just one additional output layer to create SOTA models for a wide range of tasks. Conneau and Lample (2019) proposed two methods to learn cross-lingual language models (XLMs): one unsupervised that only relies on monolingual data, and one supervised that leverages parallel data with a new cross-lingual language model objective. Conneau et al. (2020) proposed to train a Transformer-based masked language model on 100 languages, using more than two terabytes of filtered CommonCrawl data, which significantly outperforms mBERT on a variety of cross-lingual benchmarks. Recently, Chi et al. (2021) formulated cross-lingual language model pre-training as maximizing mutual information between multilingual-multi-granularity texts. The unified view helps to better understand the existing methods for learning cross-lingual representations, and the information-theoretic framework inspires to propose a pre-training task based on contrastive learning. Liu et al. (2020) presented mBART – a sequence-to-sequence denoising auto-encoder pre-trained on large-scale monolingual corpora in many languages using the BART objective. Xue et al. (2021) introduced mT5, a multilingual variant of T5 that was pre-trained on a new Common Crawl-based dataset covering 101 languages. The pre-trained LayoutXLM model is built on the multilingual textual models as the initialization, which benefits the VRDU tasks in different languages worldwide.

7 Conclusion

In this paper, we introduce the multilingual form understanding benchmark XFUND, which includes key-value labeled forms in 7 languages. Meanwhile, we present LayoutXLM, a multimodal pre-trained model for multilingual visually rich document understanding. We make XFUND and LayoutXLM publicly available to advance the document understanding research. For future research, we will further enlarge the multilingual training data to cover more languages as well as more document layouts and templates. In addition, as there are a great number of business documents with the same content but in different languages, we will also investigate how to leverage the contrastive learning of parallel documents for the multilingual pre-training.

A Ethical Consideration

The ethical implications of research are always an important consideration for us. While pursuing better model performance and high quality datasets, we respect the intellectual property rights of data resources, the privacy and rights of data sources, and strive to avoid potential harm to vulnerable populations.

When crawling the documents needed to build the XFUND dataset and LayoutXLM pre-training data, we strictly follow each site's robots exclusion standard [4] to ensure we are allowed to collect data. We also manually excluded websites with privacy concerns, keeping only those pages that we had permission to edit and republish according to the permission rules.

For the data used to build XFUND, we first removed all content and kept only the template, thus removing the maximum amount of sensitive content. On this basis, annotators filled in the templates using synthetic data that does not involve sensitive personal information of annotators, thus ensuring the privacy and rights of annotators. Then, we manually reviewed the templates to prevent potential privacy violations and harm to vulnerable populations. Any data that does not meet the specifications will be completely deleted.

Abstract

Grammatical Error Correction (GEC) aims to automatically detect and correct grammatical errors. In this aspect, dominant models are trained by one-iteration learning while performing multiple iterations of corrections during inference. Previous studies mainly focus on the data augmentation approach to combat the exposure bias, which suffers from two drawbacks. First, they simply mix additionally-constructed training instances and original ones to train models, which fails to help models be explicitly aware of the procedure of gradual corrections. Second, they ignore the interdependence between different types of corrections. In this paper, we propose a *Type-Driven Multi-Turn Corrections* approach for GEC. Using this approach, from each training instance, we additionally construct multiple training instances, each of which involves the correction of a specific type of errors. Then, we use these additionally-constructed training instances and the original one to train the model in turn. By doing so, our model is trained to not only correct errors progressively, but also exploit the interdependence between different types of errors for better performance. Experimental results and in-depth analysis show that our approach significantly benefits the model training. Particularly, our enhanced model achieves state-of-the-art single-model performance on English GEC benchmarks. We release our code at `https://github.com/DeepLearnXMU/TMTC`.

1 Introduction

Grammatical Error Correction (GEC) aims at automatically detecting and correcting grammatical (and other related) errors in a text. It attracts much attention due to its practical applications in writing assistant (Napoles et al., 2017b; Ghufron and Rosyida, 2018), speech recognition systems (Karat et al., 1999; Wang et al., 2020; Kubis et al., 2020) etc. Inspired by the success of neural machine translation (NMT), some models adopt the same paradigm, namely NMT-based models. They have been quite successful, especially with data augmentation approach (Boyd, 2018; Ge et al., 2018; Xu et al., 2019; Grundkiewicz et al., 2019; Wang and Zheng, 2020; Takahashi et al., 2020). However, these models have been blamed for their inefficiency during inference (Chen et al., 2020; Sun et al., 2021). To tackle this issue, many researchers resort to the sequence-to-label (Seq2Label) formulation, achieving comparable or better performance with efficiency (Malmi et al., 2019; Awasthi et al., 2019; Stahlberg and Kumar, 2020; Omelianchuk et al., 2020).

Despite their success, both NMT-based and Seq2Label models are trained by one-iteration learning, while correcting errors for multiple iterations during inference. As a consequence, they suffer from exposure bias and exhibit performance degrade (Ge et al., 2018; Lichtarge et al., 2019; Zhao and Wang, 2020; Parnow et al., 2021). To deal with this issue, Ge et al. (2018) propose to generate fluency-boost pseudo instances as additional training data. Besides, Parnow et al. (2021) dynamically augment training data by introducing the predicted sentences with high error probabilities.

However, the above-mentioned approaches construct pseudo data based on a GEC model or an error-generation model, which extremely depends on the performance of these models. Thus, the error distribution of pseudo data is biased and lacks diversity and practicality. Moreover, they simply mix original and pseudo data to train models, which are unable to learn correcting errors progressively. Furthermore, they ignore the interdependence between different types of errors, which intuitively plays an important role on GEC. Taking Table 1 as example, correcting "*little*" with "*few*" or "*job*" with "*jobs*"

Erroneous Sentence: *In my country there are* ***little job*** *because the economy is very bad .*
Reference Sentence: *In my country there are* ***few jobs*** *because the economy is very bad .*

Table 1: An example for the interdependence between corrections. Please note that whichever error is corrected first, the other error can be corrected more easily.

first can help the other error be better corrected. Therefore, we believe that how to construct and exploit pseudo data with editing-action corrections for GEC is still a problem worthy of in-depth study.

In this paper, we first conduct quantitative experiments to investigate the performance improvements of GEC model with providing different types of error corrections. Experimental results show that corrections of appending or replacing words first indeed benefit the corrections of other errors. Furthermore, we propose a **T**ype-Driven **M**ulti-**T**urn **C**orrections (TMTC) approach for GEC. Concretely, by correcting a certain type of errors with others unchanged, we construct an intermediate sentence for each training instance and pair it with its raw erroneous sentence and reference sentence respectively, forming two additional training instances. During the model training, using the former instance, we firstly guide the model to learn correcting the corresponding type of errors. Then, using the latter instance, we teach the model to correct other types of errors with the help of previous corrections. Overall, contributions of our work are three-fold:

- Through quantitative experiments, we investigate the interdependence between different types of corrections, with the finding that corrections of appending or replacing words significantly benefit correcting other errors.
- We propose a TMTC approach for GEC. To the best of our knowledge, our work is the first attempt to explore the interdependence between different types of errors for GEC.
- We conduct experiments and in-depth analysis to investigate the effectiveness of our proposed approach. Experimental results show that our enhanced model achieves the state-of-the-art performance.

2 Related Work

Generally, there are two categories of models in GEC: Transformer-dominant NMT-based models (Boyd, 2018; Ge et al., 2018; Xu et al., 2019; Grundkiewicz et al., 2019; Wang and Zheng, 2020; Takahashi et al., 2020) and GECToR-leading Seq2Label models (Malmi et al., 2019; Awasthi et al., 2019; Stahlberg and Kumar, 2020; Omelianchuk et al., 2020). The former models consider GEC as a machine translation task, where the model is fed with the erroneous sentence and then output the corrected sentence token by token. By comparison, Seq2Label models are able to correct grammatical errors more efficiently and even better. Among them, the GECToR models (Omelianchuk et al., 2020) obtain remarkable performance. Typically, they adopt a pre-trained language model as the encoder to learn word-level representations and utilize a softmax-based classifier to predict designed editing-action labels.

Since GEC models may fail to completely correct a sentence through just one-iteration inference, some researchers resort to data augmentation that has been widely used in other NLP studies (Song et al., 2020; Xu et al., 2020). For instance, Ge et al. (2018) propose to let the GEC model infer iteratively and design a fluency boost learning approach. Specifically, they establish new erroneous-reference sentence pairs by pairing predicted less fluent sentences with their reference sentences during training. Likewise, to solve the mismatches between training and inference of Seq2Label models, Parnow et al. (2021) apply a confidence-based method to construct additional training data by pairing low-confidence sentences with reference sentences. Note that these two methods also involve constructing pseudo data using sentences with partial errors. However, ours is still different from them in two aspects. First, these two methods simply mix their pseudo data with original data to still train models in a one-iteration learning manner. By contrast, we decompose the one-iteration corrections into multiple turns, so as to make the model aware of gradual corrections. Second, these two methods ignore the interdependence between different types of errors, which is exploited by our proposed approach to enhance the model.

3 Background

In this work, we choose GECToR (Omelianchuk et al., 2020) as our basic GEC model due to its efficiency and competitive performance. Typically, it considers the GEC task as a sequence-to-label task, where the candidate editing-action la-

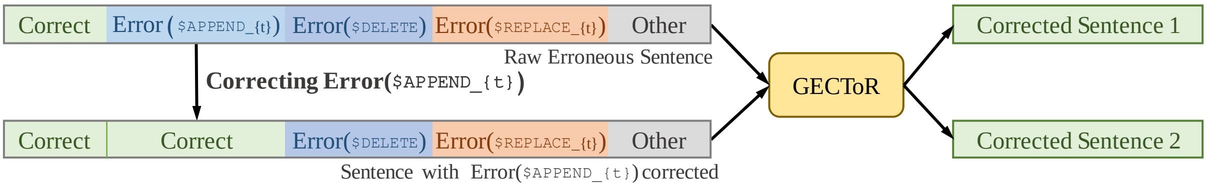

Figure 1: The procedure of our quantitative experiments. Each sentence is composed of five parts as illustrated, where Error(`ACTION` *label*) denote the erroneous words that can be corrected via corresponding editing-action label. We only correct one type of errors and compare the prediction results of other types of errors.

bels mainly include `$KEEP` (to keep the current word unchanged), `$DELETE` (to delete the current word), `$APPEND_{t}` (to append the word t after the current word), `$REPLACE_{t}` (to replace the current word with the word t) and some elaborate g-transformation labels (Omelianchuk et al., 2020) performing task-specific operations, such as `$TRANSFORM_CASE_LOWER` and `$TRANSFORM_CASE_CAPITAL` (to change the case of the current word).

On the whole, the GECToR model is composed of an encoder based on pre-trained language model and two linear classifiers: one for grammatical error detection (GED) and the other for GEC. The encoder reads the erroneous sentence $X_e{=}x_1, x_2, ..., x_N$ and represent words with hidden states $\{h_i\}_{i=1}^{N}$, which are fed into classifiers to predict the binary label sequence $Y{=}y_1, y_2, ..., y_N$ for GED and the editing-action label sequence $T{=}t_1, t_2, ..., t_N$ for GEC, respectively. Formally, the losses of two classifiers can be formulated as

$$L_d = -\sum_{i=1}^{N} \mathrm{log} p(y_i|X_e, \theta), \qquad (1)$$

$$L_c = -\sum_{i=1}^{N} \mathrm{log} p(t_i|X_e, \theta), \qquad (2)$$

where θ denotes model parameters. Usually, the GECToR model is trained to optimize the sum of two losses: $L{=}L_d{+}L_c$.

It is worth noting that the GECToR model is trained to correct all errors in a one-iteration manner, while correcting errors in a multiple-iteration way during inference (at most 5 iterations). Besides, there are three stages involved during the training of the GECToR model, as shown in Table 2.

4 Effect of the Interdependence between Different Types of Corrections

In this section, we conduct several groups of quantitative experiments to explore the interdependence between corrections.

Dataset	#Instance	Stage
PIE-synthetic (Awasthi et al., 2019)	9,000,000	I
Lang-8 (Tajiri et al., 2012)	947,344	II
NUCLE (Dahlmeier et al., 2013)	56,958	II
FCE (Yannakoudakis et al., 2011)	34,490	II
W&I+LOCNESS (Bryant et al., 2019)	34,304	II, III

Table 2: GECToR is trained on PIE-synthetic dataset for pre-training at Stage I. Then, it is fine-tuned on Lang-8, NUCLE, FCE, W&I+LOCNESS at Stage II. At Stage III, the final fine-tuning is conducted on W&I+LOCNESS.

We first train the GECToR model on *Stage II Only* for efficiency. All training settings are the same to published parameters.[1] Afterwards, we use the model to conduct corrections on the BEA-2019 (W&I+LOCNESS) dev set and CoNLL-2014 test set (Ng et al., 2014) and their variants with some errors corrected manually. For simplicity, we only consider the three most frequent editing-action labels: `$APPEND_{t}`, `$DELETE` and `$REPLACE_{t}`.

Figure 1 shows the procedure of quantitative experiments. Specifically, we separate each raw erroneous sentence into five parts: correct words, erroneous words that can be corrected by `$APPEND_{t}`/`$DELETE`/`$REPLACE_{t}`, and words with other types of errors. If we want to investigate the influence of `$APPEND_{t}`, we first select the data containing `$APPEND_{t}` labels and denote them as D(`APPEND`). Then we manually correct all the errors which should be corrected by `$APPEND_{t}` labels, obtaining the new subset D(`APPEND`✓). Afterwards, we use our model to correct erroneous sentences of subsets D(`APPEND`) and D(`APPEND`✓) for just one iteration, and finally we only evaluate and compare the model performance on the predictions of

Table 3: Results of our quantitative experiments. D(`ACTION`) denotes a subset consisting of instances with `ACTION` label. D(`ACTION`✓) denotes another version of D(`ACTION`), where corresponding errors have been manually corrected.

`$DELETE` and `$REPLACE_{t}`. For example, by comparing the model performance with respect to the `$DELETE` label, we can draw the conclusion that appending some words first could help the model to achieve better predictions on `$DELETE` .

Likewise, we conduct experiments with respect to `$DELETE` and `$REPLACE_{t}` labels. Besides, we evaluate the performance for each type of labels on the raw dataset without any constraints. Experimental results of the RoBERTa-based GECToR model (Liu et al., 2019) are listed in Table 3. We can observe that the consistent performance improvements occur on both the W&I+LOCNESS dev set and the CoNLL-2014 test set, no matter which type of errors are corrected first. Moreover, it is surprising that if replacing words or appending words are conducted beforehand, the model performance is significantly improved on correcting other types of errors. Meanwhile, deleting words does not benefit others compared with other two kinds of corrections.

We also notice that the model improvements are positively associated with the number of manual corrections on the BEA-2019 dev set. However, the performance improvements on the CoNLL-2014 test set is not closely related to the number of manual corrections. Thus, we can conclude that the interdependence between different types of corrections indeed plays a more important role than the number of corrections on performance improvements. Having witnessed these experimental results, we can arrive at the following two conclusions:

- GEC models can better deal with errors when some types of errors have been corrected.
- Corrections of appending words or replacing words help the model correct other types of errors more than deleting words.

Please note that we also conduct experiments using the XLNet-based GECToR model (Yang et al., 2019). Similar trend can be observed from experimental results reported in Appendix §A.1.

5 Our Approach

In this section, we introduce our proposed Type-Driven Multi-Turn Corrections (TMTC) approach in detail. As concluded above, correcting certain types of errors first benefits correcting others, thus, we decompose one-iteration corrections of each training instance into multi-turn corrections, so as to make the trained model to learn performing corrections progressively.

The key step of our approach is to construct an intermediate sentence for each training instance. Formally, each training instance is a sentence pair (X_e, X_c) consisting an erroneous sentence X_e and a reference sentence X_c. To construct its intermediate sentence X', we randomly select partial grammatical errors and correct them manually while keeping others unchanged. Then, X' is paired with X_e and X_c to generate two new pairs: (X_e, X') and (X', X_c), respectively. Figure 2 illustrates an example of constructing two additional training instances from a sentence pair. In this example, for

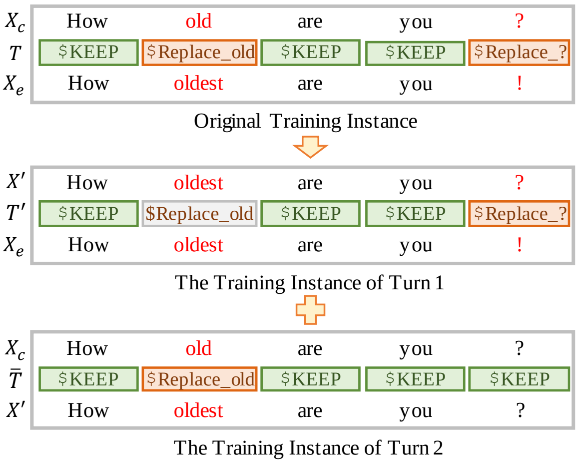

Figure 2: The procedure illustration of constructing additional training instances. Here, we construct an intermediate sentence X', which is paired with the raw erroneous sentence X_e and reference sentence X_c to form two additional training instances (X_e, X') and (X', X_c), respectively. Red squares mean labels correcting errors, while green ones mean the labels to keeping the current word unchanged. Losses of gray squares will be omitted in the first turn.

the erroneous sentence with two grammatical errors "*oldest*" and "*!*", we correct "*!*" by "*?*" manually to form the semi-corrected sentence "*How oldest are you ?*". It should be noted that our constructed training instances are derived from the original training corpus, and thus their grammatical errors are also human-making.

Based on the above findings mentioned in Section §4, we apply our approach to design three training strategies: **`APPEND`-first**, **`DELETE`-first** and **`REPLACE`-first**. Here, the `ACTION`-first strategy means that the model is trained to learn `ACTION` corrections in the first turn and then the others in the second turn. For example, when using the `DELETE`-first strategy, we keep the errors with "`$DELETE`" as target labels unchanged during the constructions of intermediate sentences. Using additionally-constructed training instances involving these sentences, the trained model will be encouraged to focus on performing corrections first via `$DELETE`. Table 4 lists the numbers of additionally-constructed training instances using these strategies. According to our findings concluded in Section §4, the models trained using `APPEND`-first and `REPLACE`-first strategies should perform better.

Using our approach, we adopt different objectives to successively train our model. Specifically, we define the following training objectives $L_c^{(1)}$ and $L_c^{(2)}$ in the first and second turns, respectively:

Strategy	#Additional Instance
`RANDOM`	367,814
`APPEND`-first	311,348
`DELETE`-first	326,100
`REPLACE`-first	296,683

Table 4: Numbers of additionally-constructed training instances. We also explore the training strategy that randomly corrects partial errors first. For convenience, we name this training strategy as `RANDOM`.

$$L_c^{(1)} = -\sum_{i=1}^{N} \mathbb{1}(t_i' = t_i) \cdot \log p(t_i'|X_e, \theta), \quad (3)$$

$$L_c^{(2)} = -\sum_{i=1}^{\bar{N}} \log p(\bar{t}_i|X', \theta), \quad (4)$$

where $\{t_i'\}_{i=1}^{N}$ and $\{\bar{t}_i\}_{i=1}^{\bar{N}}$ are the editing-action label sequences of additionally-constructed training instances (X_e, X') and (X', X_c) respectively.

Notably, there remain some grammatical errors within intermediate sentences which not be learned by the model in the first turn. Therefore, we omit the incorrect supervisal signals in the definition of $L_c^{(1)}$ via an indicator function $\mathbb{1}(*)$, which is used to shield the effect of incorrect losses. However, because our additionally-constructed training instances contain less grammatical errors compared with original ones, which causes the trained model to correct less errors. To address this defect, we still use the original training instances to continuously train model in the third turn.

Formally, we finally, we use all training instances to continuously train our model with the following objective L'=$L_c^{(1)}$+$L_c^{(2)}$+L. Our experimental results presented in Section §6 show that our additionally-constructed training instances and original ones are complementary to each other.

6 Experiment

6.1 Setup

To ensure fair comparison, we train the GECToR models using the same training datasets and parameters as (Omelianchuk et al., 2020), and then evaluate them on the BEA-2019 (W&I+LOCNESS) dev, test set and the CoNLL-2014 test set. The details of the training data are listed in Table 2. Following (Omelianchuk et al., 2020), we conduct

Table 6: Results of models at the dataset setting of Three Stages of Training.

experiments in two dataset settings: Stage II Only and Three Stages of Training. Notably, in the latter setting, we only apply our approach at Stage II and Stage III for efficiency. Finally, we evaluate the model performance in terms of official ERRANT (Bryant et al., 2017) and M^2 scorer (Dahlmeier and Ng, 2012) respectively.

6.2 Main Results and Analysis

Stage II Only. In this setting, we compare the performance of GECToR with or without applying our approach[2].

Results are presented on Table 5. Notably, the results are consistent with our findings in Section §4. That is, since correcting some types of errors benefit the corrections of other errors, all models trained with our approach significantly perform better than their corresponding baselines. Moreover, the GECToR models trained by the `APPEND`-first or `REPLACE`-first strategies are superior to models trained by `DELETE`-first or `RANDOM`, echoing the conclusions mentioned in Section §4.

Three Stages of Training. In this setting, we compare our enhanced models with more baselines under the setting of the single model, including the most related work, Dual-boost (Ge et al., 2018), GECToR(GST) (Parnow et al., 2021) and the current best NMT-based model SAD(12+2) (Sun et al., 2021).

As reported in Table 6, we obtain the similar results to Stage II Only. Our approach promotes models to obtain desirable improvements, where the `APPEND`-first and `REPLACE`-first strategies perform better. Overall, the GECToR models trained by our approach are comparable or even better than SAD(12+2). Particularly, when ensembling our

---

[2] Please note that previous studies do not provide the performance of other baselines under the setting of Stage II Only.

Table 8: Ablation study. Our model is based on RoBERTa and trained using `APPEND`-first. The $\mathbb{1}(*)$ is the indicator function mentioned in Equation 3.

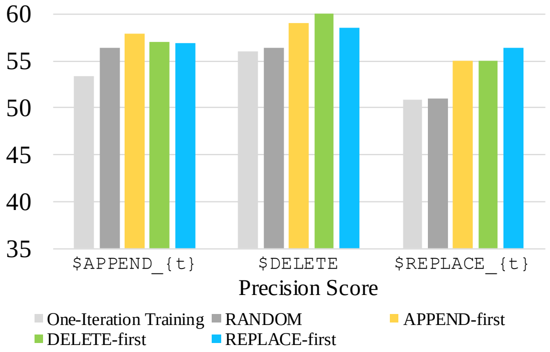

Figure 3: Label predictions of the RoBERTa-based model on the BEA-2019 dev set in the first iteration of prediction.

enhanced models with competitive GEC models, we obtain 77.93 $F_{0.5}$, achieving SOTA score on the BEA-2019 test set.

Moreover, we find that our approach allows the trained models to correct more cautiously. That is, the trained models tend to perform less but more precise corrections, compared with the basic GECToR models. One of underlying reasons is that our additionally-constructed training instances contain more `$KEEP` labels especially in the second turn, which makes the label predictions of the model biased.

6.3 Ablation Study

Then, we conduct more experiments to investigate the effectiveness of various details on our proposed approach.

All experimental results are provided in Table 8. Results of lines 3-5 (“w/o turn 1”, “w/o turn 2”, “w/o original”) demonstrate that our additionally-constructed training instances are complementary to original ones. In addition, we also directly mix the additionally-constructed training instances and the original ones to train a GECToR model. However, such a training strategy does not promote the model to learn much better, showing the advantage of gradual learning error corrections. Finally, as mentioned in Section §5, some grammatical errors should not be learned within intermediate sentence. Here, we also report the performance of the GECToR model without omitting incorrect supervisal signals. As shown in the line 7 (“w/o $\mathbb{1}(*)$”) of Table 8, the lower recall values indicate these incorrect `$KEEP` labels make the model to infer more conservatively.

6.4 Analysis

Correction Trend. Here, we use the models trained under different strategies to not only evaluate the one-iteration performance with respect to our investigated three types of labels, but also conduct quantitative experiments again. By doing so, we can investigate if our approach indeed guides the model to correct some types of error first.

Table 9: Results of more fine-grained strategies. We conduct experiments by the model trained at Stage II Only based on RoBERTa.

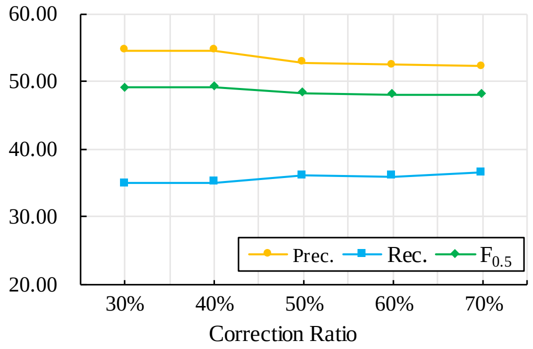

Figure 4: The precision, recall and $F_{0.5}$ values with respect to different correction ratios.

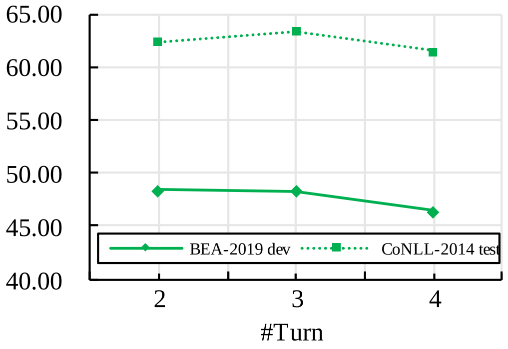

Figure 5: The $F_{0.5}$ scores of GECToR(`RANDOM`) with more turns of corrections.

As shown in Figure 3, we find our strategies indeed guide model to correct corresponding errors more precisely in the first iteration. Meanwhile, the less but more precise predictions occur again with respect to corresponding labels. For example, when only considering the model performance with respect to `$APPEND_{t}`, we observe that the model trained by `APPEND`-first obtains the highest precision score.

More importantly, back to Table 7, the phenomenon that correcting some types of errors benefits the others is highlighted. It indicates that our approach indeed allows the trained model to capture the interdependence between different types of corrections.

Effect of Correction Ratio. As described in Section §5, the correction ratio is an important hyper-parameter that determines the numbers of manual corrections. Thus, we try different correction ratio values to investigate its effect on our approach. Figure 4 shows the performance of the trained model with varying correction ratios. Apparently, with the correction ratio increasing, the precision score drops and recall score rises. By contrast, the overall $F_{0.5}$ scores are always steady.

Effect of More Turns of Corrections. The above experimental results show that decomposing the conventional one-iteration training of into the two-turn training is useful to improve model training. A natural problem arises: can the trained model be further improved if we use more turns of training?

To answer this question, we use the model trained by the `RANDOM` strategy to conduct experiments. Specifically, we decompose the one-iteration corrections into K turns of corrections, where we construct intermediate sentence by accumulatively correct $\frac{1}{K}$ errors during each turn of corrections. From Figure 5, we can observe that more turns of corrections do not benefit our models over two-turn corrections under the `RANDOM` strategy while with more training cost.

Also, we conduct experiments using more fine-grained strategies. For example, we can design a training strategy: after learning corrections of `$APPEND_{t}`, the model learns to correct errors of `$REPLACE_{t}` and then to correct others. For convenience, we name this strategy as `APP+REP+DEL`, where APP, REP and DEL are abbreviations of `$APPEND_{t}`, `$REPLACE_{t}` and `$DELETE`, respectively. As illustrated in Table 9, all models trained by our approach obtain slightly better performance when introducing more iterations of corrections. However, they require almost 1.5x training time compared with our standard TMTC approach.

7 Conclusion

In this paper, we have firstly conducted quantitative experiments to explore the interdependence between different types of corrections, with the finding that performing some types of corrections such as appending or replacing words first help models to correct other errors. Futhermore, we propose a Type-Driven Multi-Turn Corrections (TMTC) approach for GEC, which allows the trained model to be not only explicitly aware of the progressive corrections, but also exploit the interdependence between different types of corrections. Extensive experiments show that our enhanced model is able to obtain comparable or better performance compared with the SOTA GEC model.

In the future, we plan to apply bidirectional decoding (Zhang et al., 2018; Su et al., 2019; Zhang et al., 2019) to further improve our approach. Besides, inspired by the recent syntax-aware research (Li et al., 2021), we will explore the interdependence between corrections from other perspectives for GEC such as syntax.

A Appendix

A.1 Quantitative Experiments on XLNet

We also conduct quantitative experiments described in Section §4 using model trained based on XLNet. The overall results are closely similar to Table 3, which indicates that our findings and conclusions are not specific to a certain model or a certain dataset, but common among realistic human-making datasets.

A.2 Evaluation on JFLEG

Suggested by reviewers, we evaluate our approach on the JFLEG (Napoles et al., 2017a) dataset which focus on fluency. As shown in Table 11 and Table 12, models trained by our approach obtain higher GLEU (Heilman et al., 2014) compared with baselines, which demonstrate the effectiveness of decomposing one-iteration correction into multiple turns. However, editing-action based interdependence seems not very beneficial from the view of fluency.

Abstract

Commonsense reasoning (CSR) requires models to be equipped with general world knowledge. While CSR is a language-agnostic process, most comprehensive knowledge sources are restricted to a small number of languages, especially English. Thus, it remains unclear how to effectively conduct multilingual commonsense reasoning (XCSR) for various languages. In this work, we propose to use English as a pivot language, utilizing English knowledge sources for our our commonsense reasoning framework via a translate-retrieve-translate (TRT) strategy. For multilingual commonsense questions and answer candidates, we collect related knowledge via translation and retrieval from the knowledge in the source language. The retrieved knowledge is then translated into the target language and integrated into a pre-trained multilingual language model via visible knowledge attention. Then we utilize a diverse of four English knowledge sources to provide more comprehensive coverage of knowledge in different formats. Extensive results on the XCSR benchmark demonstrate that TRT with external knowledge can significantly improve multilingual commonsense reasoning in both zero-shot and translate-train settings, consistently outperforming the state-of-the-art by more than 3% on the multilingual commonsense reasoning benchmark X-CSQA and X-CODAH.

1 Introduction

Commonsense reasoning (CSR) is one of the key challenges in natural language understanding. It requires a model to integrate world knowledge into language modeling to produce answers. A large number of tasks have been proposed to evaluate commonsense reasoning in English, such as COPA (Roemmele et al., 2011a) and CSQA (Talmor et al., 2019).

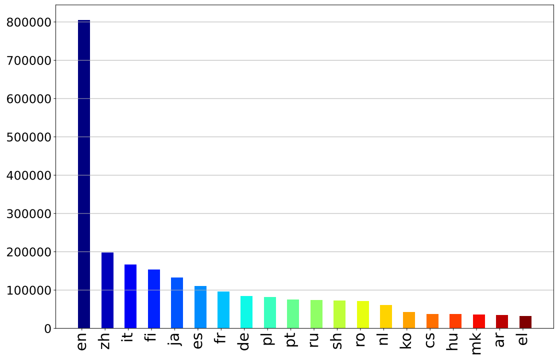

Figure 1: Number of total definitions per language. The statistics are generated from Wiktionary 2021-10-01 dump. There are 55 languages with 10,000 or more definitions and we list top 20 languages by the definition count here.

Most recently, multilingual commonsense reasoning (XCSR) extends a model's commonsense capability beyond language barriers and has begun to draw attention from the community. A number of multilingual datasets have emerged for this challenging task, for example, X-CSQA (Lin et al., 2021), X-CODAH (Lin et al., 2021), XCOPA (Ponti et al., 2020).

To solve commonsense reasoning tasks, it is essential to fuse human created knowledge into pre-trained language models (PLM) (Lin et al., 2019; Feng et al., 2020; Yu et al., 2020; Xu et al., 2021b). For example, DEKCOR (Xu et al., 2021b) integrates knowledge from ConceptNet (Speer et al., 2017) and Wiktionary [1] into the ALBERT model (Lan et al., 2020) for commonsense question answering. However, most existing knowledge sources are crafted in a few popular languages, especially English. For example, Figure 1 shows the number of total definitions in English is much greater than any other language based on the statistics from a recent 2021-10-01 dump of Wiktionary. Thus, it remains an open question how to tackle XCSR with a lack of curated knowledge in the

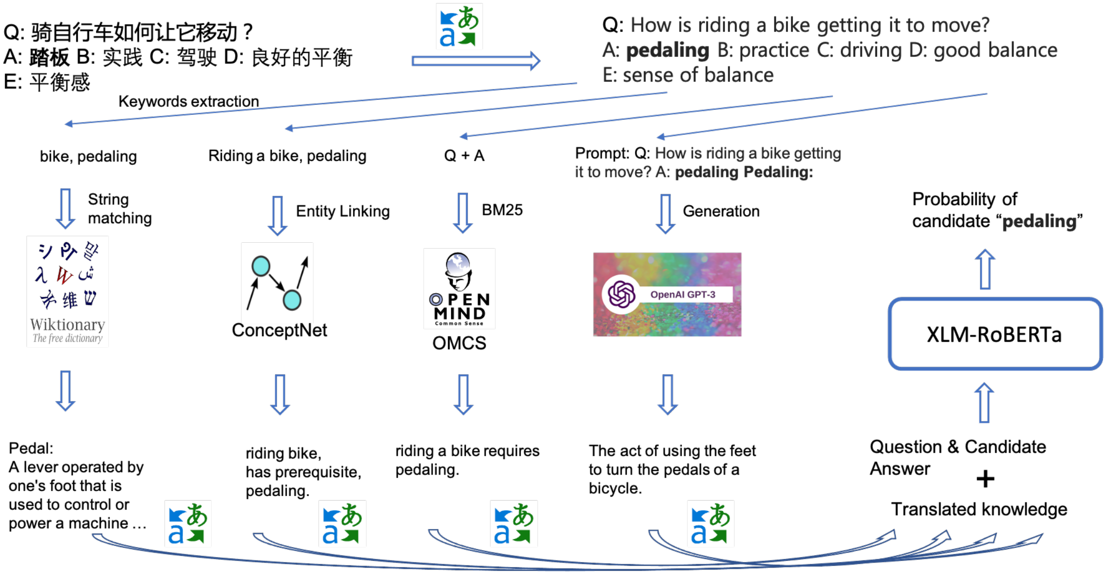

Figure 2: An overview of our framework for multilingual commonsense reasoning. Given the question and candidate answers in the target language (Chinese), we first translate it into English, then retrieve related knowledge from four English knowledge sources and translate the retrieved knowledge back into the target language. The retrieved knowledge, along with question and candidate answer, are fed into the multilingual pretrained language model for answer prediction.

target language.

In this paper, we propose a translate-retrieve-translate (TRT) solution to utilize English knowledge sources for XCSR. Specifically, given a commonsense reasoning question (possibly concatenated with a candidate answer) in the target language, we first translate it into English. Next, we retrieve related knowledge from English knowledge sources. The retrieved knowledge is then translated back into the target language. Finally, the knowledge is integrated into a multilingual language model via an visible knowledge attention mechanism to answer the question.

Another contribution of our work is that the utilization of a diverse set of knowledge sources to provide a more comprehensive coverage of knowledge in different formats. Specifically, we utilize unstructured text corpus (Open Mind Common Sense (Singh, 2002)), structural knowledge graph (ConceptNet (Speer et al., 2017)), dictionary (Wiktionary) and large-scale language model (GPT-3 (Brown et al., 2020)). Given an input query, we utilize information retrieval, entity linking, and model inference to obtain knowledge from the corresponding sources.

We conduct extensive evaluation of our model on the multilingual commonsense reasoning benchmark X-CSQA and X-CODAH (Lin et al., 2021). The results demonstrate the effectiveness of our proposed translate-retrieve-translate solution with multiple knowledge sources. For example, in the zero-shot transfer setting, TRT with Wiktionary can improve 1.9 and 2.7 points over the baselines. For translate-train setting, TRT with Wiktionary and OMCS outperform 1.6 and 1.0 over the baselines. Compared with previous state-of-the-art results on the XCSR leaderboard, TRT improve them by more than 3 points.

We summarize the main contributions of this work as follows. (i) We propose a translate-retrieve-translate (TRT) solution to utilize English knowledge sources for multilingual commonsense reasoning. (ii) We comprehensively explore four knowledge sources in different formats and demonstrate their utility on a pair of XCSR benchmarks (X-CSQA, X-CODAH). (iii) We achieve the state-of-the-art results on the on XCSR leaderboard, outperforming the previous best methods by more than 3.3 points.

2 Related Work

Multilingual Commonsense Reasoning Evaluating the commonsense reasoning abilities of trained models has been explored through a variety of tasks and problem settings. An early work in this space was the Winograd scheme challenge (Levesque et al., 2012), where the goal is to disambiguate the reference of a pronoun (Levesque

Knowledge Source	Knowledge Format	Query Format	Retrieved Knowledge	Retrieval Method
Wiktionary	Dictionary	Content Word	Definition	String Matching
ConceptNet	Entity-Relation Triplets	Entity Pair	Entity-Relation Triplet	Entity linking
OMCS	Text in Sentences	Sentences	Sentences	BM25
GPT-3	Parameters	Unstructured Text	Unstructured Text	Conditional Generation

Table 1: Different knowledge resources for retrieval. OMCS is short for Open Mind Common Sense (Singh, 2002). Wiktionary is a multilingual, web-based dictionary from https://www.wiktionary.org/. ConceptNet (Speer et al., 2017) is a freely-available multlingual knowledge graph. GPT-3 (Brown et al., 2020) is a large scale pre-trained language model.

et al., 2012). Another early work is COPA (Roemmele et al., 2011b), where the goal is to select cause or result for a premise. Later on, researchers have constructed larger scale datasets, such as SWAG (**?**), CODAH (Chen et al., 2019), and CommonsenseQA (Talmor et al., 2019), for commonsense knowledge learning. Recently, commonsense reasoning tasks have been extended to multilingual setting, such as X-CSQA (Lin et al., 2021), X-CODAH (Lin et al., 2021), XCOPA (Ponti et al., 2020). In paper, we focus on training models to learn commonsense knowledge in multiple languages.

External Knowledge Fusion Knowledge bases are an important external data source to help models learn the ability of commonsense reasoning. A wide range of knowledge resources, such as ConceptNet (Speer et al., 2017), Wikipedia, Freebase (Pellissier Tanon et al., 2016), and some KBs in domain (Fader et al., 2011), can be fused into the model. LoBue and Yates (2011) explored how commonsense knowledge involved in recognizing textual entailments. Guan et al. (2020) utilize commonsense knowledge to generate reasonable stories. Bi et al. (2019) incorporate external Knowledge into question answering. Xu et al. (2021b) fuse the ConceptNet (Speer et al., 2017) and Wikionary into the model for solving CommonsenseQA. In this paper, we will follow this direction and explore how to leverage different knowledge sources for multiligual commonsense reasoning.

Multilingual Language Model Large scale multilingual pretrained language models (MPLM) (Devlin et al., 2019; Lample and Conneau, 2019; Conneau et al., 2020) have always been the most important backbone for solving multilingual tasks including commensense reasoning tasks. Knowledge bases have also been integrated into the pretraining process (Kassner et al., 2021a; Jiang et al., 2021). As shown in (Kassner et al., 2021a), there exist multilingual knowledge base. But they still lack the components or contexts to explicitly integrate knowledge and commonsense. And Lin et al. (2021) builds a commonsense probing dataset to improve the pre-trained MPLM for commonsense reasoning beyond English. Our work is orthogonal to these pre-trained methods and focus on fusing knowledge during finetuning.

GPT-3 Prompt learning Large scale pretrained language models like GPT-3 (Brown et al., 2020) have shown tremendous success on few-shot learning. There exists a large body of work on prompting to leverage the implicit knowledge from it (Li and Liang, 2021; Liu et al., 2021; Wei et al., 2021). In this work, we focus on leveraging GPT-3 to generate three diverse knowledge formats and then fusing them into fine-tuning stage.

3 Approach

In this section, we first formalize the multilingual commonsense reasoning (XCSR) task (Section 3.1). Then we describe more details about our commonsense knowledge resources (Section 3.2). Next, we introduce our proposed translate-retrieve-translate (TRT) solution to obtain the multilingual knowledge (Section 3.3). Finally, we introduce how to fuse the obtained knowledge into multilingual pretrained language models by employing the visible attention mechanism (Section 3.4). An overview of our framework is illustrated in Figure 2.

3.1 Problem Formulation

We denote a language by $l \in L$, where $L = \{en, fr, de, zh, \cdots\}$. Given a commonsense question q^l in the target language l, the goal is to choose the correct answer from N candidates $\{c_1^l, c_2^l, \cdots, c_N^l\}$. We assume there are one or more external knowledge sources to provide world knowledge in various formats for commonsense reasoning. Each time the model retrieves

Dataset	Knowledge Source	Prompt
X-CODAH	Wiktionary	<Q> \n hedge: A thicket of bushes or other shrubbery, especially one planted as a fence between two portions of land.
	ConceptNet	<Q> \n hedge capable of fence house
	OMCS	<Q> \n he is a man.
X-CSQA	Wiktionary	<Q> \n pedalling: A lever operated by one's foot that is used to control or power a machine or mechanism, such as a bicycle or piano.
	ConceptNet	<Q> \n riding bike has prerequisite pedalling.
	OMCS	<Q> \n riding a bike requires pedalling.

Table 2: A GPT-3 prompt example with knowledge sources from Wiktionary, ConceptNet and OMCS. <Q> are short for the query "A man is using a pair of hedge trimmers on trees. He is talking to the camera as he goes." and "Q: How is riding a bike getting it to move? A: pedalling" for X-CODAH and X-CSQA datastes respectively.

knowledge from these sources using the question-candidate pair as query, i.e., $p^l = [q^l, c^l_i]$.

3.2 Commonsense Knowledge

External sources of commonsense knowledge are critical to the performance of a commonsense reasoning (CSR) model. Previous methods for CSR primarily integrate knowledge from one or two sources (Xu et al., 2021b). In this work, we conduct comprehensive experiments by leveraging commonsense knowledge from four different resources: unstructured text corpus (Open Mind Common Sense), knowledge graph (KG) (ConceptNet), dictionary (Wiktionary), and pre-trained language model (PLM) (GPT-3). Open Mind Common Sense (OMCS) (Singh, 2002) is a large commonsense knowledge base which has accumulated millions of facts from the contributions of many thousands of people across the Web. ConceptNet (Speer et al., 2017) is a freely-available semantic network, originated from OMCS. Wiktionary is a multilingual web-based project to create a free content dictionary and provides the definitions for all the words. GPT-3 (Brown et al., 2020) is a large-scale pre-trained language model which can be induced to generate knowledge for some queries (Liu et al., 2022). These knowledge resources are saved in quite diverse formats as the analysis shown in Table 1. To retrieve the knowledge, we will consider different query formats and retrieval methods in the next section.

3.3 Knowledge Retrieval

Most large-scale knowledge sources in either academia or industry are crafted in a few popular languages, especially in English (see Figure 1 as an example). To obtain knowledge for low-resource languages, we propose a translate-retrieve-translate (TRT) solution. In detail, we first use a machine translation tool to translate the query in all languages into English. Then, we can retrieve knowledge from English knowledge sources using the translated query. The retrieved knowledge can be then translated back into the original target language for model training.

As a knowledge source usually contains vast amounts of information, we need to retrieve and leverage only the related knowledge for a given query p^l. Next we introduce the details of knowledge retrieval for four knowledge sources.

Word definition retrieval from Wiktionary Every word has its own definition but not all of them are delivering knowledge for commonsense reasoning. In this work, we mainly focus on retrieving the content words, such as nouns, verbs, and adjectives, and the words harder to understand by multilingual language models. In detail, after part-of-speech tagging of the sequence, we select the nouns, verbs and adjectives as the candidate words. Then, we mask one word at a time and compute its masked language model (MLM) probability by pre-trained multilingual language model, XLM-RoBERTa (Conneau et al., 2020). We select top-N words with lowest MLM probability for dictionary retrieval. If the original word is not in Wiktionary, we try to find its lemmazied form. The first definition entry in Wiktionary is the retrieved knowledge.

Structured knowledge retrieval from ConceptNet A knowledge graph can provide relation information between entities. We enumerate pairs of candidate words from the input sequence and check whether there exists a relation between them in the knowledge graph ConceptNet. If so, we retrieve the corresponding triplet as the external knowledge.

Unstructured text retrieval from OMCS Open Mind Common Sense (OMCS) consists of knowledge in natural language description. We first build a search index [2] for all the sentences in OMCS. Then, whenever a new query comes, we retrieve the highest ranked sentence based on BM25 as the external knowledge text.

Knowledge Generation with GPT-3 Previous research shows that large-scale PLM contains rich knowledge implicitly (Roberts et al., 2020; Kassner et al., 2021b). Thus, we use one of the largest PLM, GPT-3 (Brown et al., 2020), to generate related knowledge given the query. As GPT-3 requires a prompt with input and output examples, we feed it with a few examples with a query and the knowledge in designated format. Table 2 lists an example with above three knowledge formats for X-CODAH and X-CSQA. For example, given the word ‘pedalling‘” and its definition “A lever operated by one’s foot that is used to control or powera machine or mechanism, such as a bicycle or piano.” along with the query “ How is riding a bike getting it to move?”, GPT-3 will generate its version of definition of a word it thinks important in the input query. For the prompt that is not in English, we translate the English prompt into the target language.

3.4 Fusing Knowledge into Multilingual Language Model

Given the question answer pair $p^l = [q^l, c_i^l]$, we use the retrieval techniques to collect K pieces of retrieved knowledge text: $S = [s_1, \cdots, s_K]$.

The most intuitive way is to concatenate them with p^l as input to the multilingual pre-trained language model (XPLM) for answer generation, i.e., the input would be $I =$ [CLS] q^l c_i^l [SEP] s_1 [SEP] $\cdots$ s_K [SEP].

However, this simple way may divert the original meaning of p^l because of the introduced noise by appending S, as pointed out by Liu et al. (2020); Xu et al. (2021a). To remedy this issue, we adopt the visibility matrix (Liu et al., 2020; Xu et al., 2021a) to limit the impact of knowledge set S on the original question-candidate pair p_l. Specifically, in each transformer layer of XPLM, an attention mask matrix M is added to the self-attention weights before softmax.

Suppose t_j and t_k are the j-th and k-th tokens from the input I. We set M_{jk} to zero to allow attention from t_j to t_k, and set M_{jk} to $-\infty$ to forbid attention. M_{jk} is set to zero if: i) both tokens belong to the input p_l, or ii) both tokens belong to the same knowledge s_i, or iii) t_j is the token at the start position of linked word in p_l and t_k is from its correspond knowledge text. More formally, the mask matrix M is

$$M_{jk} = \begin{cases} 0 & t_j, t_k \in p^l \\ 0 & t_j, t_k \in s_i \\ 0 & t_j \in p^l, t_k \in s_i \\ -\infty & \text{otherwise} \end{cases} \tag{1}$$

For model training, let $z_0 \in R^d$, the `[CLS]` hidden state from the last layer, denotes the representation of encoding the question, candidate, and the corresponding retrieved knowledge. d is the dimension of the output vector of the encoder. Then we calculate the prediction score $\hat{y}_i$ for each candidate c_i^l with one linear layer, $\hat{y}_i = W_o z_0$, where $W_o \in R^{1*d}$, followed by a softmax normalization upon all candidates, $\hat{y} = softmax([\hat{y}_i, \cdots, \hat{y}_N])$, where N is the number of candidate for each question. The final loss function is the standard cross-entropy loss.

Dataset	X-CSQA	X-CODAH
Task Format	QA	Scene Completion
#Languages	16	16
#Options	5	4
#train	8888	8476
#dev	1000	300
#test	1074	1000

Table 3: Statistics of the two datasets in the multilingual commonsense reasoning benchmark XCSR (Lin et al., 2021).

4 Experiments

In this section, we perform extensive experiments to explore the aforementioned TRT solution with four knowledge sources on the multilingual commonsense reasoning benchmark XCSR (Lin et al., 2021).

4.1 Datasets

Table 3 lists the statistics for the two datasets in XCSR. They are collected from CSQA (Talmor et al., 2019) and CODAH (Chen et al., 2019) by translating into another 15 languages other than English with online commercial services such as DeepL Pro Translate. (i) X-CSQA (Lin et al., 2021) for commonsense question answering: given

Table 4: Overall test results on the multilingual commonsense reasoning benchmark XCSR. Results of mBERT (Devlin et al., 2019), XLMR-B, XLMR-L (Conneau et al., 2020), MCP(XLMR-L) (Lin et al., 2021) for X-CSQA and X-CODAH are from XCSR leaderboard (Lin et al., 2021). We submit the test prediction with the best dev result in table 5 to the XCSR leaderboard for evaluation. Leaderboard: https://inklab.usc.edu//XCSR/leaderboard

the human authored question that describes the relation between concepts from ConceptNet (Speer et al., 2017), the model needs to choose the answer from five concepts. All of the data in English are from original CSQA datset. (ii) X-CODAH (Lin et al., 2021) for Scene Completion: given a prompt question and the subject of the subsequence sentence, the model needs to choose from four candidate complements that can be consistent with question in commonsense. Part of the training data and all validation data comes from original CODAH. They also include 7k SWAG validation examples as additional training data.

4.2 Baselines

For X-CODAH and X-CSQA datasets, we mainly compare with the previous state-of-the-art MCP (XLMR-L) (Lin et al., 2021) as well as other three multilingual pretrained langauge models: mBERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020) base and large models. For MCP (XLMR-L), they first create a multilingual parallel dataset MickeyCorpus from OMCS which has 561k sentences in 11 languages. Then based on XLM-RoBERTa large model, they first fine-tune on the reformated multiple-choice question answering dataset MickeyCorpus (Lin et al., 2021) and further fine-tune on the final datasets X-CODAH and X-CSQA.

4.3 Implementation Details

We use Microsoft Machine Translator [3] for all translations, including translating the given query, the retrieved knowledge and English training data to other 15 languages. We will release these translations for academic usage. For Wiktionary, we use the dump of Wiktionary which includes 999,614 definitions. We empirically obtaining 6 words definitions from Wiktionary for X-CODAH (see Figure 3 (a)) and use the provided question concept and answer as two candidate words for X-CSQA. For ConceptNet, we use ConceptNet version 5.7.0 [4]. For GPT-3, we use the curie [5] model.

Our model implementation is based on HuggingFace's Transformers Library (Wolf et al., 2020). We conduct all experiments on 8 Nvidia V100-32GB GPU cards. We follow the configurations in XCSR to pretrain the MCP model based on XLM RoBERTa large except that the maximum sequence length is 256 and batch size is 32. The accuracy of the resulting MCP checkpoint on its dev set is 87.4. We then initialize with this checkpoint for further fine-tuning with the extracted knowledge from different knowledge sources. During fine-tuning, we set the training epochs, batch size and gradient accumulation steps as 10, 4 and 2 respectively. The total batch size here is 64 by "*batch size per device × # GPUs × # gradient accumulation steps*". For hyper-parameter search, we sweep over the learning rates $\in \{1e-5, 3e-5, 5e-5, 3e-6, 5e-6\}$ and report the maximum results.

4.4 Experimental Results

Results on test set Table 4 summarizes our results on the hidden test set from XCSR leaderboard. TRT outperforms all previous works by a significant margin on both datasets, achieving the average score of 59.8/63.7 with an absolute improvement of 3.3/3.6 over previous state-of-the-art MCP(XLMR-L). For some high-resource languages, like Ger-

57.9	59.1	58.2	58.4

Table 6: Zero shot results with GPT-3 in different knowledge formats on X-CODAH. G-Wikt., G-Cpnt. and G-OMCS. are short for using GPT-3 to generate definition, triple and sentence as the knowledge format in Wiktionary, ConceptNet and OMCS.

man (de), we observe larger gain with 4.6 points improvement on X-CSQA. For low-resource languages, like Swedish, there are even larger gains with 7.7 and 7.9 improvements on X-CSQA and X-CODAH.

Effectiveness of different knowledge sources Table 5 list the detailed comparisons among different knowledge sources in both zero-shot and translate-train settings. We observe the following findings from these results: (i) Knowledge can be helpful for multilingual commonsense reasoning in both zero-shot and translate-train setting. For example, in the zero-shot setting, TRT with Wiktionary improve 2.7 and 1.9 points over the MCP (XLMR-L) baseline on X-CODAH and X-CSQA. In translate-train setting, there are 1.0 and 1.6 improvements for each dataset. (ii) Wiktionary helps the most among all knowledge sources in both settings, except that OMCS performs slightly better than Wiktionary on X-CODAH in the translate setting. We hypothesize that the difficulty of understanding hardness words can be mitigated by incorporating additional knowledge as context. (iii) The generated knowledge from GPT-3 can also improve over the baseline, without leveraging machine translation and explicit knowledge, which demonstrates the rich implicit knowledge in GPT-3. For example, for X-CODAH dataset, GPT-3 can outperform the baseline about 1.2 point. However, there still exist the gap between GPT-3 and designated knowledge format. We leave this one as future work to bridge the gap.

Effectiveness of GPT-3 generation in different knowledge formats As GPT-3 requires the prompt with input and output examples, we feed it with a few examples with a query and the knowledge in three designated formats from Wiktionary, ConceptNet and OMCS on X-CODAH. Table 6 shows the zero-shot results with different generated knowledge from GPT-3. We observe that G-Wikt. outperforms the baseline MCP (XLMR-L) 1.2 points while G-Cpnt. and G-OMCS don't show significant improvements. This demonstrates GPT-3 does exist implicit knowledge in its parameters. But the generated knowledge from GPT-3 is still less helpful than the same knowledge format from the explicit Wiktionary which indicates the potential improvement with the language model. To further look at the generated knowledge, Table 7 lists five examples for G-Wikt., G-Cpnt, and G-OMCS respectively. We can see that most of them make sense and especially the quality of generated knowledge from G-Wikt. looks good. These also

Question	G-Wikt.	G-Cpnt.	G-OMCS
Swat officers sweep the space with rifle lights. Someone climbs backward through the narrow vent hole.	sweep: To clean by means of a stroking motion of a broom or brush.	sweep has context card games.	vent-hole is a synonym of vent.
A boy is running across a field wearing a green shirt. He smiles because his shirt is bright green.	shirt: A piece of clothing worn by men and women.	field defined as same shape as ribbon	The boy is wearing a green shirt.
The dog stands to catch the Frisbee the leans on the man. The dog jumps into the man's arms.	lean: To rest on something.	dog defined as animal	The dog jumps into the man's arms.
We see a colorful and playful title screen. We then see people in a room and outdoors at a fancy party.	fancy: Showy or pretentious.	title screen defined as same shape as ribbon	The title screen is colorful and playful.
Someone glares at the stick then at someone. Someone leans the stick against the bed.	glare: To direct a look of anger or hatred at someone.	glare similar to look	The stick is leaning against the bed.

Table 7: GPT-3 generation examples in different knowledge format. G-Wikt., G-Cpnt. and G-OMCS are short for the GPT-3 generated knowledge with prompts from Wiktionary, ConceptNet and OMCS.

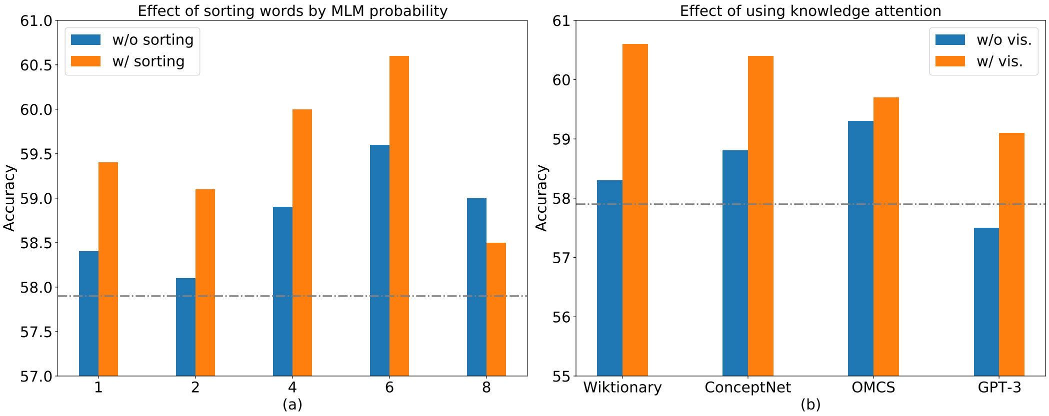

Figure 3: Effects of the number of word definitions and the visible knowledge attention mechanism on X-CODAH dataset. Figure (a) shows the performance can be improved by selecting the hardness words and increasing the number of definitions from 1 to 6. Figure (b) shows visible knowledge attention can be helpful on a variety of knowledge sources. The dashed lines in figure (a) and (b) represent the baseline result.

explain the larger improvement with G-Wikt. than G-Cpnt. and G-OMCS.

Effectiveness of sorting definitions by MLM probability In Section 3.3, we introduce using masked language model (MLM) to select the top-N hardness words with the lowest probability. Here we perform an ablation study by comparing this strategy (w/ sorting) with randomly choosing the words (w/o sorting). As shown in Figure 3 (a), sorting by MLM probability can outperform the random selecting, especially with a smaller number of words, achieving the best performance with 6 words definitions. However, there is no much difference when we use eight definitions.

Effectiveness of knowledge attention In Section 3.4, we mention that simply appending knowledge as additional context can be noise to some tasks like X-CODAH, a scene completion tasks, which may divert the original semantic meaning. Therefore, here we compare the model performance between full attention (w/o vis.) and visible knowledge attention (w/ vis.) on all investigated knowledge sources (Wiktionary, ConceptNet, OMCS and GPT-3). As shown in Figure 3 (b), visible knowledge attention can consistently outperform full attention on all knowledge sources. For example, there are 2.3 and 1.6 points improvement between them when integrating from Wiktionary and GPT-3.

5 Conclusion

In this work, we first present the translate-retrieve-translate (TRT) strategy for multilingual commonsense reasoning that collects related knowledge via translation and then retrieval from the knowledge sources. Then we conduct extensive experiments by utilizing a diverse of four English knowledge sources, including Wiktionary, ConceptNet, OMCS and GPT-3. By using TRT with different knowledge sources, we achieve state-of-the-art results on XCSR leaderboard which demonstrates the effectiveness of our proposed methods. Future work includes more effective ways to incorporate the diverse knowledge sources into pre-training and fine-tuning stage for commonsense reasoning.

Abstract

Prior studies use one attention mechanism to improve contextual semantic representation learning for implicit discourse relation recognition (IDRR). However, diverse relation senses may benefit from different attention mechanisms. We also argue that some linguistic relation in between two words can be further exploited for IDRR. This paper proposes a *Multi-Attentive Neural Fusion* (MANF) model to encode and fuse both *semantic connection* and *linguistic evidence* for IDRR. In MANF, we design a *Dual Attention Network* (DAN) to learn and fuse two kinds of attentive representation for arguments as its semantic connection. We also propose an *Offset Matrix Network* (OMN) to encode the linguistic relations of word-pairs as linguistic evidence. Our MANF model achieves the state-of-the-art results on the PDTB 3.0 corpus.

1 Introduction

Implicit Discourse Relation Recognition (IDRR) is to detect and classify some latent relation in between a pair of text segments (called arguments) without an explicit connective word. It is of great importance for many downstream Natural Language Processing (NLP) applications, such as question answering (Liakata et al., 2013), machine translation (Guzmán et al., 2014), information extraction (Xiang and Wang, 2019), sentiment analysis (Wang and Wang, 2020), and etc. However, due to the absence of an explicit connective word, inferring discourse relations from the contextual semantics of arguments is still a challenging task.

Conventional machine learning based methods usually train a relation classifier by using many handmade features to capture lexical, syntactic regularity and contextual information of arguments, which is time-consuming and labor-intensive (Pitler et al., 2009, 2008). Deep learning based methods design diverse neural networks to automatic learn the contextual semantic representation of each argument, such as the Shallow Conventional Neural Network (SCNN) (Zhang et al., 2015), Tree-like Long Short-Term Memory (Tree-LSTM) (Rutherford et al., 2017), and BiLSTM-CNN framework (Guo et al., 2019). Although these neural networks can autonomously learn a kind of deeper contextual semantics of arguments, they do not differentiate arguments' words in the representation learning.

Recently, some attention mechanisms have been employed in neural networks to unequally treat words in representation learning. For example, the *self-attention* computes the local contextual importance of each word in one argument, which generally prioritizes *content words* for better learning substantive meaning of an argument (Zhou et al., 2016). The *interactive attention* weights each word in one argument according to its interaction with the representation of another argument, which usually focuses on the rhetorical device of two arguments, like prioritizing some *function words* with little substantive meaning but potentially indicating the connection of two arguments (Liu and Li, 2016; Guo et al., 2018).

Both kinds of attention mechanisms have been proven effective for IDRR, as each can well exploit either content semantics or rhetorical devices of an argument pair. We regard these contextual semantic information derived from argument content as a kind of *semantic connection* for relation recognition. However, the IDRR task normally needs to recognize diverse senses of relations, while different senses may benefit from different attentions. To enjoy both advantages, we propose to learn two kinds of argument representation, each based on one attention mechanism. They are next fused to encode an argument pair as the semantic connection for relation recognition in this paper.

Besides semantic connection, we argue that a

Findings of the Association for Computational Linguistics: ACL 2022, pages 3247 - 3257
May 22-27, 2022

kind of *linguistic evidence* can be obtained from word distributed representation for relation recognition. Indeed, many pre-trained language models, like the word2vec (Mikolov et al., 2013) and BERT (Devlin et al., 2019), are learned from a large amount of unlabeled text by encoding the linguistic regularities and patterns in an unsupervised way. As a word embedding contains inherent meaning of the word, it can be used to infer some linguistic relation in between two words by linear translation. This motivates us to encode such linguistic relations of word-pairs as linguistic evidence.

In this paper, we propose a *Multi-Attentive Neural Fusion* (MANF) model to encode and fuse both semantic connection and linguistic evidence for the IDRR task. The MANF model contains two modules. One is a *Dual Attention Network* (DAN) : It builds upon a BiLSTM to first encode a self-attentive representation and an inter-attentive representation for each argument. To adapt to different relation senses, we next use a fusion gate to integrate the two representations into the semantic connection representation. Another is an *Offset Matrix Network* (OMN): It first computes the offset between word embeddings of a word-pair that contains one word from the first argument and another word from the second argument. Upon the offset matrix, we next design an offset attention layer and a multilayer perceptron to encode the linguistic evidence representation. Finally, we design another fusion gate to integrate both semantic connection and linguistic evidence representation for relation recognition. Our MANF Model achieve the state-of-the-art results on the PDTB 3.0 corpus. Our main contributions are as follows:

- Propose a MANF model to encode and fuse semantic connection and linguistic evidence for the IDRR task.
- Propose a DAN to enjoy both self-attention and interactive attention for semantic connection encoding.
- Propose an OMN to encode word-pairs' offsets as linguistic evidence.
- Provide a new baseline result for the IDRR task on the PDTB 3.0 corpus.

2 The Multi-Attentive Neural Fusion Model

Fig. 1 illustrates our MANF model, including the DAN, the OMN, and a hierarchical fusion mechanism.

2.1 Dual Attention Network

Our DAN is built upon a BiLSTM or BERT to encode a self-attentive representation and an inter-attentive representation for each argument, which are next fused to output the semantic connection representation for an argument pair. We note that a BiLSTM has been widely used to capture word contextual semantics for its good sequential encoding capability. In our experiments, we also replace the word2ve by a fine-tuned BERT for comparison.

The DAN model is illustrated in the left part of Fig. 1, which consists of a BiLSTM layer, a dual attention layer, and a fusion gate layer. We use pre-trained word2vec word embeddings $\mathbf{x} \in \mathbb{R}^{d_w}$ to input the BiLSTM. An argument pair $(Arg_1; Arg_2)$ can be denoted by:

$$Arg_1 : [\mathbf{x}_1^1, \mathbf{x}_2^1, \ldots, \mathbf{x}_{L_1}^1]; \tag{1}$$

$$Arg_2 : [\mathbf{x}_1^2, \mathbf{x}_2^2, \ldots, \mathbf{x}_{L_2}^2], \tag{2}$$

where $\mathbf{x}_i^1$ and $\mathbf{x}_j^2$ represents the i-th word embedding in the 1st argument and the j-th word embedding in the 2nd argument respectively, and d_w the word embedding dimension.

BiLSTM layer: After the BiLSTM, we obtain two hidden states $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ for each word in one argument from the forward and backward sequence respectively, which are concatenated to obtain an intermediate state $\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i, \overleftarrow{\mathbf{h}}_i]$. We use a matrix $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_L]$ to denote an argument encoding after the BiLSTM, where $\mathbf{h}_i \in \mathbb{R}^{2d_h}$, $\mathbf{H} \in \mathbb{R}^{L \times 2d_h}$, d_h is the dimension of hidden state.

Dual attention layer: To enjoy both advantages of self-attention and interactive attention, we propose a dual attention mechanism to encode an argument pair. For self-attention, the representation of each argument $\mathbf{r_s}$ is formed by weighted sum of intermediate state vectors produced by BiLSTM (Zhou et al., 2016):

$$\boldsymbol{\alpha}_s = softmax(\mathbf{w}_s^\mathsf{T}\mathbf{H}), \tag{3}$$

$$\mathbf{r}_s = \mathbf{H}\boldsymbol{\alpha}_s^\mathsf{T}, \tag{4}$$

where $\boldsymbol{\alpha}_s \in \mathbb{R}^L$ is the self-attention weight vector of an argument computed by local contextual importance of each word, $\mathbf{w}_s$ a learnable parameter vector.

For interactive attention, we use the representation of one argument to weight each word in another argument (Ma et al., 2017; Meng et al., 2016). We sum up the intermediate states $\mathbf{h_i}$ to obtain an intermediate argument representation, i.e.,

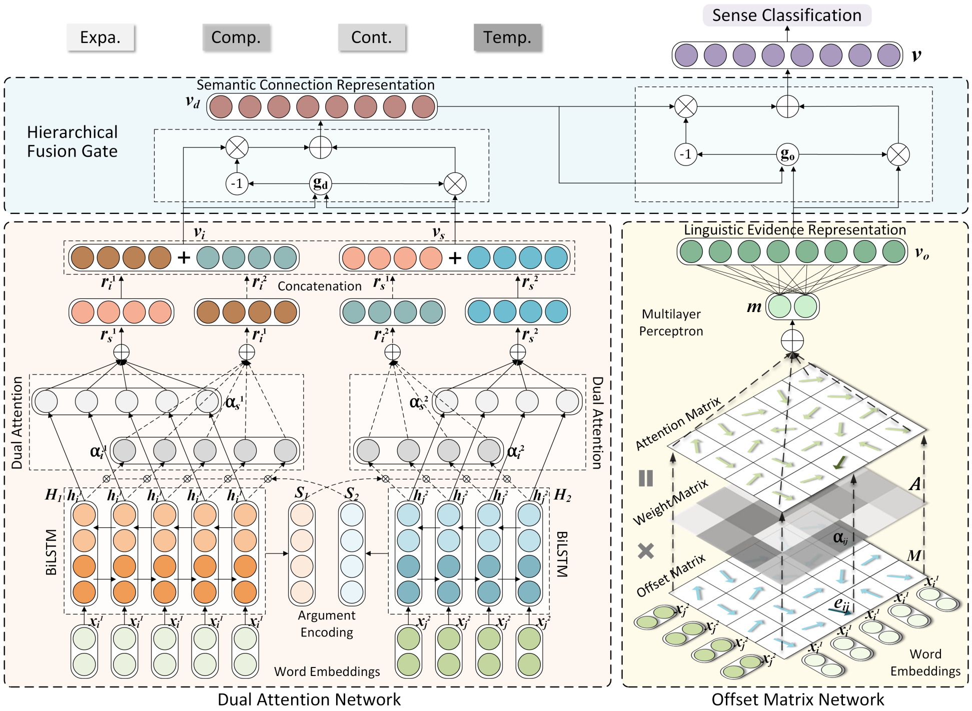

Figure 1: Illustration of our multi-attentive neural fusion model.

$\mathbf{S} = \sum_{i=1}^{L} \mathbf{h}_i$. The weight vector $\boldsymbol{\alpha}_i \in \mathbb{R}^L$ is computed by taking inner product between $\mathbf{S}$ and $\mathbf{H}$ cross two arguments, and followed by a softmax function as follows:

$$\boldsymbol{\alpha}_i^1 = softmax(\mathbf{H}_1 \mathbf{S}_2^\top) \tag{5}$$

$$\boldsymbol{\alpha}_i^2 = softmax(\mathbf{H}_2 \mathbf{S}_1^\top) \tag{6}$$

Finally, we weighted sum the intermediate state vectors with corresponding weight vector to form the interactive attention representation $\mathbf{r}_i$ for each argument:

$$\mathbf{r}_i^1 = \mathbf{H}_1 (\boldsymbol{\alpha}_i^1)^\top, \quad \mathbf{r}_i^2 = \mathbf{H}_2 (\boldsymbol{\alpha}_i^2)^\top. \tag{7}$$

Fusion gate layer: Considering the importance of the two attentions not always the same for different relation sense classification, we use a fusion gate to integrate their representations. First, we concatenate the representation of Arg_1 and Arg_2 to model their discourse relation as $\mathbf{v}_s = [\mathbf{r}_s^1, \mathbf{r}_s^2]$ and $\mathbf{v}_i = [\mathbf{r}_i^1, \mathbf{r}_i^2]$, where $\mathbf{v}_s, \mathbf{v}_i \in \mathbb{R}^{4d_h}$. The transition functions of fusion gate layer are computed as follows:

$$\mathbf{g}_d = sigmoid(\mathbf{W}_d \mathbf{v}_s + \mathbf{U}_d \mathbf{v}_i + \mathbf{b}_d), \tag{8}$$

$$\mathbf{v}_d = \mathbf{g}_d \odot \mathbf{v}_s + (1 - \mathbf{g}_d) \odot \mathbf{v}_i, \tag{9}$$

where $\mathbf{W}_d \in \mathbb{R}^{4d_h \times 4d_h}$, $\mathbf{U}_d \in \mathbb{R}^{4d_h \times 4d_h}$ and $\mathbf{b}_d \in \mathbb{R}^{4d_h}$ are learnable parameters and $\odot$ donates the element-wise product of vectors.

With the fusion gate, our DAN adaptively assigns different importance to self-attention and interactive attention, and outputs $\mathbf{v}_d \in \mathbb{R}^{4d_h}$ as the semantic connection vector for an argument pair.

2.2 Offset Matrix Network

We propose an OMN to encode the linguistic evidence representation based on the offsets of pretrained word embeddings, as shown in the right part of Fig. 1. First, we compute the offset between word embeddings of a word-pair that contains one word from the first argument and another word from the second argument. Then all the word-pair offsets of an argument pair compose an offset matrix $\mathbf{M} \in \mathbb{R}^{L_1 \times L_2 \times d_h}$, where $\mathbf{e}_{ij} \in \mathbb{R}^{d_h}$ is the offset vector between the i-th word in the 1st argument and the j-th word in the 2nd argument.

Considering that each word-pair in the offset matrix may have different contribution to the relation classification, we assign a weight score $\boldsymbol{\alpha}_{ij}$ to every offset vectors, and the weight scores are compute as follows:

$$\mathbf{A} = softmax(\mathbf{w}_o^\top \mathbf{M}), \tag{10}$$

where $\mathbf{A} \in \mathbb{R}^{L_1 \times L_2}$ is the weight matrix, $\mathbf{w}_o$ is a learnable parameter vector. We compute a word-pair interaction vector $\mathbf{m} \in \mathbb{R}^{d_h}$ as the weighted sum of all word-pair offset vectors:

$$\mathbf{m} = \sum_{i=1}^{L_1} \sum_{j=1}^{L_2} \mathbf{e}_{ij} \boldsymbol{\alpha}_{ij} \tag{11}$$

Next, we input $\mathbf{m}$ into a multilayer perceptron (MLP) followed by a tanh activation function to output the linguistic evidence vector $\mathbf{v}_o \in \mathbb{R}^{4d_h}$ for an argument pair:

$$\mathbf{v}_o = \tanh(\mathbf{W}_o \mathbf{m} + \mathbf{b}_o), \tag{12}$$

where $\mathbf{W}_o \in \mathbb{R}^{d_h \times 4d_h}$ and $\mathbf{b}_o \in \mathbb{R}^{4d_h}$ are learnable parameters.

2.3 Implicit Discourse Relation Classification

After obtaining the semantic connection vector $\mathbf{v}_d$ and the linguistic evidence vector $\mathbf{v}_o$, we also argue that they may have different importance for diverse relation sense classification. So we use another fusion gate to integrate the two kinds of representation vectors and obtain the final representation $\mathbf{v} \in \mathbb{R}^{4d_h}$ of an argument pair for relation classification. The transition functions are:

$$\mathbf{g}_o = sigmoid(\mathbf{W}_f \mathbf{v}_d + \mathbf{U}_f \mathbf{v}_o + \mathbf{b}_f), \tag{13}$$

$$\mathbf{v} = \mathbf{g}_o \odot \mathbf{v}_d + (1 - \mathbf{g}_o) \odot \mathbf{v}_o, \tag{14}$$

where $\mathbf{W}_f$, $\mathbf{U}_f \in \mathbb{R}^{4d_h \times 4d_h}$ and $\mathbf{b}_f \in \mathbb{R}^{4d_h}$ are learnable parameters.

The classifier is a fully connected layer with softmax to transform the final argument pair representation $\mathbf{v}$ to a probability distribution $\hat{\mathbf{y}} \in \mathbb{R}^n$ for predicting the discourse relation sense:

$$\hat{\mathbf{y}} = softmax(\mathbf{W}_c \mathbf{v} + \mathbf{b}_c),$$

where $\mathbf{W}_c \in \mathbb{R}^{4d_h \times n}$, $\mathbf{b}_c \in \mathbb{R}^n$ are learnable parameterss.

For model training, we adopt the cross entropy loss as the cost function:

$$J(\theta) = -\frac{1}{K} \sum_{k=1}^{K} \mathbf{y}^{(k)} \log(\hat{\mathbf{y}}^{(k)}) + \lambda \|\theta\|^2, \tag{15}$$

where $\mathbf{y}^{(k)}$ and $\hat{\mathbf{y}}^{(k)}$ are the gold label and predicted label of the k-th training instance respectively. λ and θ are the regularization hyper-parameters. We use the Adam optimizer and combine dropout with $L2$ regularization for model training.

Relation	Train	Dev.	Test

Table 1: Statistics of implicit discourse relation instances in PDTB 3.0 with four top-level relation senses.

3 Experiment Setting

3.1 The PDTB 3.0 Dataset

We conduct experiments on the latest version 3.0 of Penn Discourse TreeBank (PDTB) corpus, which was released on March 2019 and updated on February 2020. Following the conventional data splitting in PDTB 2.0, we use sections 2-20 as the training set, sections 21-22 as the testing set and 0-1 as the development set (Ji and Eisenstein, 2015). Our experiments are conducted on the four top-level classes of relation sense as the existing studies, including Comparison, Contingency, Expansion and Temporal. The statistics of implicit discourse relation instances in the PDTB 3.0 corpus are summarized in Table 1. More details about PDTB 3.0 are provided in the supplementary material.

3.2 Competitors

- **NNMA** (Liu and Li, 2016) combines two arguments' representation for stacked interactive attentions.
- **ANN** (Lan et al., 2017) applies interactive attention into a multi-task learning framework.
- **IPAL** (Ruan et al., 2020) propagates self-attention into interactive attention by a cross-coupled network.
- **DAGRN** (Chen et al., 2016b) encodes word-pair interactions by a neural tensor network.

3.3 Parameter Setting

We obtain the pre-trained word embeddings from the 300-dimensional English word2vec model ($d_w = 300$) provided by Google [1] and the 768-dimensional English BERT model ($d_w = 768$) provided by HuggingFace [2]. From our statistics, 99.46% of arguments do not exceed 50 words in PDTB3.0. So we set the maximum length of argument to 50 ($L = 50$). For the word2vec model, we set the mini-batch size to 32 and the

---

[1] code.google.com/archive/p/word2vec

[2] huggingface.co/bert-base-uncased

initial learning rate to 5e-4; while for the BERT model, the mini-batch size and initial learning rate is 16 and 1e-5. The trainable parameters are randomly initialized from normal distributions, and the dropout rate is set to 0.2 in the fusion gates and 0.5 in the MLP. We release the code at: https://github.com/HustMinsLab/MANF.

4 Result and Analysis

4.1 Overall Result

We implement four-way classification and binary classification (i.e. one-versus-others) on the PDTB 3.0, in which macro F_1 score and accuracy (Acc) are used for four-way classification and F_1 score is used for binary classification.

Table 2 compares the overall performance between our MANF and the competitors. In four-way classification, our MANF achieves significant improvements over competitors in terms of both macro F_1 and Acc. In binary-classification, ours also achieves the best performance in three relation sense classification, while the second with a small F_1 gap to that of NNMA in the Temporal sense classification.

We note that the first three competitors are neural models mainly for learning argument representation from contextual semantic connections; While the DAGRN is a neural model for learning representation from word linguistic evidences. The first observation is that the DARGN cannot outperform the first three competitors, though the performance gaps are not obvious. This might suggest that latent semantic connections learned from sequential contexts play the main role in relation recognition. This, however, is not unexpected. A relation is usually used for linking the meanings of two arguments, i.e., semantic connections, no matter with or without an explicit connective.

The second observation is that in the first three competitors, the ANN cannot outperform either NNMA or IPAL, not even once in all the performance metrics. We note that although they all employ attention mechanisms in learning semantic connection, the ANN applies a straightforward interactive attention to learn argument representation; While the NNMA designs a sophisticated mechanism for stacking multiple levels of attentions, and the IPAL employs a kind of sequential attention mechanism, i.e., interactive attention after self-attention.

Finally, we attribute the outstanding performance of our MANF model to its fusion of two attentions for learning semantic connection, as well as its exploitation of word linguistic evidence. This will be further analyzed in our ablation studies.

4.2 Ablation Study

Linguistic Evidence: We have argued that the inherent meaning of a word, other than its contextual semantics, can be exploited as a kind of linguistic evidence between two arguments for relation classification. To this end, we have designed the OMN module with the pre-trained word embeddings as its input. This input choice is from such considerations: A pre-trained word embedding is normally learned from a huge corpus containing materials from diverse backgrounds [3], which not only could capture some polysemous property for one word, but also could encode some linguistic regularity and pattern in between words from different contexts. While such properties might be compromised, if we input the OMN with the contextual semantic encodings.

To verify our arguments, we design two variants for the input of the OMN module. (1) **Shared**: It replaces the input of pre-trained $\mathbf{x}_i^1$ ($\mathbf{x}_j^2$) by the hidden state $\mathbf{h}_i^1$ ($\mathbf{h}_j^2$) of the respective BiLSTM in the DAN module. That is, two modules share the same BiLSTM for encoding word contextual semantics. (2) **Parallel**: We adopt additional BiLSM networks with their hidden states to replace pre-trained word embeddings. That is, two modules adopt parallel BiLSTM networks.

Table 3 presents the results of the three input choices for the OMN module. The better performance of using pre-trained word embedding can support our arguments. Although a BiLSTM network is well capable of encoding a word contextual semantics for its sequential processing mechanism, our design objective is to exploit the inherent meaning of a word to capture linguistic evidence for an argument pair. This is particular evident in the binary classification of Comparison and Temporal relation sense for its larger improvements. So using the pre-trained word embedding is a wise choice.

Module ablation study: To examine the effectiveness of different modules, we design the following ablation study.

---

[3] The word2vec was trained from the Google News dataset containing 100 billion words from diverse domain articles. The BERT was trained from the BookCorpus consisting of 11,038 books and English Wikipedia containing over six million articles.

Model	Four-way Classification		Binary Classification (F1)			
	F1	Acc	Expa.	Comp.	Cont.	Temp.
NNMA (EMNLP, 2016)	46.13%	57.67%	65.10%	29.15%	63.33%	**41.03%**
ANN (EMNLP, 2017)	47.29%	57.06%	64.03%	30.10%	60.91%	33.71%
IPAL (COLING, 2020)	49.45%	58.01%	64.28%	30.37%	61.95%	34.74%
DAGRN (ACL, 2016)	45.11%	57.33%	64.71%	27.34%	62.56%	38.91%
Our MANF	**53.14%**	**60.45%**	**67.82%**	**34.16%**	**65.48%**	40.22%

Table 2: Overall result of comparison models for implicit discourse relation classification.

Four-way Classification

Method	Pre-trained	Shared	Parallel
F1	**53.14** %	50.41%	51.54%
Acc	60.45%	58.82%	**60.85%**

Binary Classification (F1)

Method	Pre-trained	Shared	Parallel
Expa.	**67.82%**	67.13%	67.47%
Comp.	**34.16%**	31.43 %	30.48%
Cont.	**65.48%**	63.06%	64.93%
Temp.	**40.22%**	38.83%	38.36%

Table 3: Ablation study for linguistic evidence by using different word encodings as the OMN input.

- **BiLSTM (B)** is the building block of DAN, without two attentions and word-pair offsets.
- **B+SelfAtt** is a subpart of DAN, with only self-attention, but without interactive attention and word-pair offsets.
- **B+InterAtt** is a subpart of DAN, with only interactive attention, but without self-attention and word-pair offsets.
- **B+DualAtt (DAN)** is only the DAN module, with two attentions, but without word-pair offsets.
- **WordPair (OMN)** is only the OMN module, without argument representation for semantic connection.
- **B+WordPair** combines the OMN with a BiLSTM for encoding semantic connection but without any attention.
- **B+DualAtt+WordPair** is our MANF model.

Table 4 presents the results of our module ablation study. Among the first four models without using word-pair offsets, we first observe that the bare BiLSTM cannot outperform those employing attention(s) to differentiate words in argument representation learning. On the other hand, the B+DualAtt achieves better performance compared with the B+SelfAtt and B+InterAtt each using only one kind of attention, except a slight gap of Acc in the four-way classification. This indicates that our fusion of both attention mechanisms is an effective approach to augment semantic connection learning for an argument pair.

We also observe that the WordPair(OMN) only exploiting word-pair offsets performs the worst among all models. This, however, is not unexpected, as it totally ignores an argument semantics as well as latent semantic connection between arguments. On the other hand, the B+WordPair model, fusing linguistic evidence with semantic connection even learned by a bare BiLSTM without any attention, can greatly improve the performance of WordPair(OMN). The B+WordPair model can even achieve the best or the second best in some cases. This again validates our arguments of encoding and fusing both semantic connection and linguistic evidence to improve relation recognition.

Table 5 presents experiments using fine-tuned BERT to replace the word2vec based BiLSTM for semantic connection encoding. In contrast, the OMN module uses the BERT without fine-tuning to exploit linguistic evidence. The first three ablation modules correspond to the BiLSTM (B), B+DualAtt (DAN) and B+WordPair, respectively. We can observe that the BERT+DualAtt and BERT+WordPair models achieve better performance than the baseline BERT model. This further confirms the necessity of fusing both attention mechanisms and exploiting linguistic evidence. Finally, our MANF model yields substantial improvements overall ablation modules, and the outstanding performance approves our arguments and design objectives.

4.3 Case Study

We use case study to visualize and compare different attention mechanisms. Fig. 2 visualizes the word weight obtained by self-attention and interactive attention for four cases of different relation senses. We observe that the two attentions assign different weights to different words. In particular, the interactive attention seems to mainly focus on

Model	Four-way Classification		Binary Classification (F1)			
	F1	Acc	Expa.	Comp.	Cont.	Temp.

Table 5: Experiment results with the fine-tuned BERT language model.

one word with a very high weight in each argument, which is generally a kind of function word, such as the "*in*", "*back*" in the Temporal case, "*His*", "*and*" in Contingency case, and "*I*" in Comparison case. Such function words may be regarded as serving a kind of rhetorical devices for some common linguistic regularities and patterns.

On the other hand, the self-attention tends to assign several words in one argument with similar yet non-ignorable weights, which are often kinds of content words, such as "*slithered*", "*and*", "*slipped*" in the Expansion case. Such a few of content words might be more important to capture the contextual semantics of an argument, which can be next exploited for encoding semantic connection between two arguments. Such functionality differences of the two attentions indeed have motivated us to try a fusion mechaism, so as for each to excel in relation recognition of different senses.

Fig. 3 visualizes the weight matrix of word-pair offsets in the OMN module but with different input. It can be observed that using pre-trained word embeddings can help emphasizing the word-pair "*don't-did*" probably for their generally containing fewer contextual information. On the other hand, the other two using word contextual encoding pay attentions to word-pairs much similar to those words in the self-attention and interactive attention, such as "*I-I*", "*I-think*", "*I-don't*". As word contextual encoding has already been exploited in the DAN module, we argue that using pre-trained word embeddings for word-pair offsets could complete argument representation learning from another view of common linguistic evidence.

5 Related Work

The IDRR task is usually approached as a classification problem, and the key is the argument representation.

Machine learning approaches, like using a *Naive Bayes*, *Support Vector Machine* (SVM) classifier, have designed various features to capture lexical, syntactic regularity and contextual information as argument representation (Pitler et al., 2008; Lin et al., 2009; Pitler et al., 2009; Louis et al., 2010). However, manually crafting features is not only time-consuming and labor-intensive, but also suffers from data sparsity problem due to the use of one-hot feature encoding.

Deep learning models have prevailed for their capabilities of automatic learning argument representation (Zhang et al., 2015; Rutherford et al., 2017). For example, the SCNN model (Zhang et al., 2015) obtains each argument representation via a single convolution layer, and the concatenation of two arguments' representations is used for relation classification. Rutherford et al. (Rutherford et al., 2017) employ a LSTM network to capture word contextual semantics for argument representation. Some hybrid models have attempted to combine CNN, LSTM, graph convolutional networks and etc. for more sophisticated argument representa-

tion (Guo et al., 2019; Xu et al., 2019; Zhang et al., 2021). These approaches, however, have ignored the fact that different words may contribute differently in argument representation learning.

Attention mechanisms can guide a neural model to unequally encode each word according to its contextual importance for argument representation (Zhou et al., 2016; Bai and Zhao, 2018; Liu and Li, 2016; Guo et al., 2018, 2020). For example, Zhou et al. (Zhou et al., 2016) apply self-attention to weight a word according to its similarity to its belonging argument. Guo et al. (Guo et al., 2018, 2020) adopt an interactive attention to differentiae words in one argument, where a word is weighted according to the similarity between its encoding and another argument representation. Liu and Li (Liu and Li, 2016) design a multi-level attention to repeatedly compute word importance in a hierarchical way. Ruan et al. (Ruan et al., 2020) propose a pipeline workflow to apply interactive attention after self-attention.

Word pair features have been exploited in machine learning and deep learning approaches for argument representation (Blair-Goldensohn et al., 2007; Biran and McKeown, 2013; Zhou et al., 2013; Chen et al., 2016a,b). For example, Biran and McKeown (Biran and McKeown, 2013) compute the appearance probabilities of aggregated word pairs to train a logistic regression classifier. Chen et al. (Chen et al., 2016b) construct a relevance score word-pair interaction matrix based on a bilinear model (Jenatton et al., 2012) and a single layer neural model (Collobert and Weston, 2008).

The proposed MANF model is a deep neural model, employing a hierarchical fusion mechanism to fuse two kinds of attentive word encodings as well as word pair offset encodings in argument representation learning.

6 Concluding Remarks

In this paper, we argue that implicit relation recognition can benefit from both semantic connection and linguistic evidence between arguments. Motivated from such considerations, we have designed the MANF model to encode and fuse them for the IDRR task. The MANF model consists a DAN module to fuse both self-attentive and inter-attentive contextual semantics for learning representation of semantic connection, and a OMN module to attentively encode word-pair offsets for learning representation of linguistic evidence. Both kinds of representations are finally fused for relation recognition. Experiments on the latest PDTB 3.0 corpus have validated our design objectives for the new benchmark performance established by our MANF model.

This paper has employed the pre-trained word embeddings trained by the word2vec and BERT; While other pre-training models shall also be adopted and tested in our future work. The performance differences of recognizing different relation senses also motivate to further investigate other advanced fusion mechanisms.

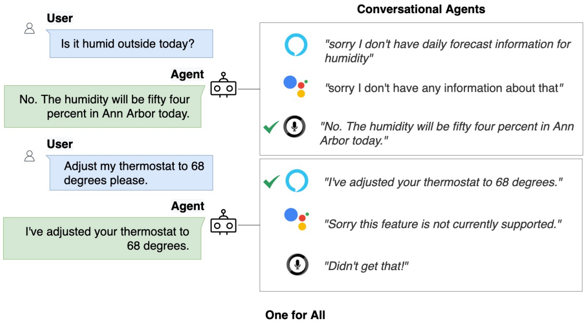
Abstract

The increasing volume of commercially available conversational agents (CAs) on the market has resulted in users being burdened with learning and adopting multiple agents to accomplish their tasks. Though prior work has explored supporting a multitude of domains within the design of a single agent, the interaction experience suffers due to the large action space of desired capabilities. To address these problems, we introduce a new task BBAI: **B**lack-**B**ox **A**gent **I**ntegration, focusing on combining the capabilities of multiple black-box CAs at scale. We explore two techniques: *question agent pairing* and *question response pairing* aimed at resolving this task. Leveraging these techniques, we design One For All (OFA), a scalable system that provides a unified interface to interact with multiple CAs. Additionally, we introduce MARS: **M**ulti **A**gent **R**esponse **S**election, a new encoder model for question response pairing that jointly encodes user question and agent response pairs. We demonstrate that OFA is able to automatically and accurately integrate an ensemble of commercially available CAs spanning disparate domains. Specifically, using the MARS encoder we achieve the highest accuracy on our BBAI task, outperforming strong baselines.

1 Introduction



Is it humid outside today?

No. The humidity will be fifty four percent in Ann Arbor today.

"sorry I don't have daily forecast information for humidity"

"sorry I don't have any information about that"

✓ "No. The humidity will be fifty four percent in Ann Arbor today."

Adjust my thermostat to 68 degrees please.

I've adjusted your thermostat to 68 degrees.

✓ "I've adjusted your thermostat to 68 degrees."

"Sorry this feature is not currently supported."

"Didn't get that!"

Figure 1: An example interaction using One For All which integrates multiple production black-box agents into a unified experience.

Influenced by the popularity of intelligent conversational agents (CAs), such as Apple Siri and Amazon Alexa, the conversational AI market is growing at an increasingly rapid pace and is projected to reach a valuation of US $13.9 billion by 2025 (Market and Markets, 2020). These CAs have already begun to show great promise when deployed in domain-specific areas such as driver assistance (Lin et al., 2018), home automation (Luria et al., 2017), and food ordering (Frangoul, 2018) with platforms such as Pandora and Facebook today hosting more than 300,000 of these agents (Chaves and Gerosa, 2018; Nealon, 2018).

Most CAs are designed to be specialized in a single or set of specific domains. As such, users are required to interact with multiple agents in order to complete their tasks and answer their queries as shown in figure 1. For example, a user may use an agent such as Amazon Alexa for online shopping but engage with Google Assistant for daily news updates. Additionally, a given agent may be more proficient at a specific domain over another i.e A finance CA is better suited to answer finance questions. As a result, users are taxed with the burden of learning and adopting multiple agents leading to an increase in the cognitive load of interacting with agents, further discouraging the proliferation of their usage (Dubiel et al., 2020; Novick et al., 2018; Saltsman et al., 2019). This is escalated further as the number of conversational agents deployed into the market continues to increase. Therefore, the need arises for unifying multiple independent CAs through one conversational interface. This need has manifested in the commercial conversational AI industry with initiatives such as the Amazon Voice Interoperability Initiative (Amazon, 2019) which aims to create voice-enabled products that contain multiple, distinct, interoperable intelligent assistants on a single device. However, this interaction

is still manual, requiring the user to orchestrate which agent is initiated. In addition, while it is possible to have distinct agents in a single device, users prefer interacting with a single agent over multiple (Chaves and Gerosa, 2018).

Prior work has explored in part combining the strengths of multiple agents in one system but they rely on direct access to the design and implementation details of the to-be-integrated agents. Subramaniam et al. (2018) and Cercas Curry et al. (2018) direct incoming user questions to a specific agent based on the candidate agents' internal knowledge graph and NLU architectures, respectively. However, in practice, the majority of the publicly available CAs are "black boxes" where their inner-workings contain highly-protected IP that is not accessible to the public. Additionally, Cercas Curry et al. (2018) facilitates their bot selection with a manual heuristic preference order that requires intimate knowledge of the agents to construct, and additional effort to maintain, thus not scaling well for the adaption of existing agents and introduction of new agents. Therefore, the task of integrating multiple production black-box CAs with a unified interface remains an open problem.

In order to explore this problem, we introduce the task BBAI: **B**lack-**B**ox **A**gent **I**ntegration that focuses on integrating multiple black-boxes CAs. We propose two techniques to tackle black-box multi-agent integration: (1) Question agent pairing and (2) Question response pairing. Intuitively, these two approaches can be viewed as a query-to-agent classification problem in contrast to that of a response selection problem. This formulation allows us to facilitate multi-agent integration whilst operating within the black-box constraints of the agents. Using these techniques we develop *One For All*, a novel conversational system that accurately and automatically unifies a set of black-box CAs spanning disparate domains. Additionally, we introduce MARS: **M**ulti **A**gent **R**esponse **S**election, a new encoder model for question response pairing that jointly encodes user question and agent response pairs. We evaluate these techniques on a suite of 19 publicly available agents consisting of Amazon Alexa[1], Google Assistant[2], SoundHound Houndify[3], Ford Adasa (Lin et al., 2018) and many more.

Specifically, this paper makes the following contributions:

- Formulation of the BBAI task that focuses on the challenge of integrating disparate black-box conversational agents into one experience. We construct a new dataset for this task, comprising of examples from a suite of 19 commercially deployed conversational agents. We publish our model and datasets. [4]

- We design *One For All*, a novel conversational system that accurately and automatically unifies a set of black-box CAs and introduce the MARS encoder model that outperforms strong state-of-art classification and ranking model baselines on our BBAI task.

- We conduct a thorough evaluation of various agent integration approaches showing that our MARS encoder outperforms strong baselines. We show that by facilitating the integration of multiple agents we can alleviate the need for users to adopt multiple agents whilst facilitating the improvement and growth of agents over time.

2 BBAI: Black-Box Agent Integration Task Formulation

Building a unified interface for production agents spanning different domains presents several key challenges. First, most commercially available CAs are black-boxes, providing little to no information on their inner workings. Any approach for agent integration must operate without relying on the internals of any given agent. Second, these conversational agents are constantly improved upon and expanded with new capabilities. The agent integration approaches need to be flexible and adaptive to these changes with relative ease. Given these constraints we assume the existence of the following information sources for the agent integration task:

1. User query/utterance: The question that the user asks the agent.

2. Agent skill representation: A textual representation that denotes what each agent is capable of. This can be in the form of example queries or a description of that agent.

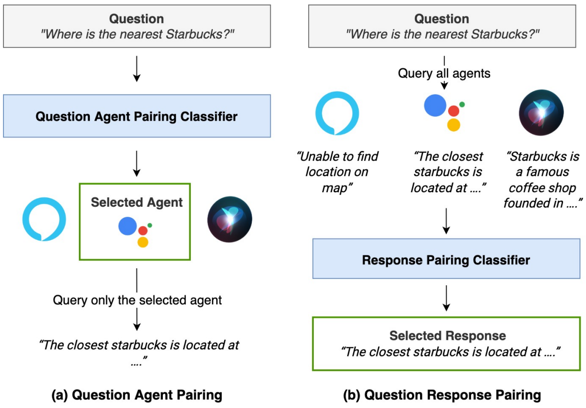

Figure 2: Overview of our proposed black-box agent integration techniques. In QA Pairing, the goal is to select the correct agent using information about the agent's capabilities. In QR Pairing, the goal is to select the correct agent response.

3. Agent response: Each agent's response to the query asked.

Using this information we formulate the task of agent integration as given a query Q, a set of agents $A = \{a_1, a_2, \ldots, a_n\}$ and a set of agent responses $R = \{r_1, r_2, ..., r_n\}$ to query Q, determine the question-agent-response pair (Q, A_i, R_i) that resolves the query Q. Further, given the information available, we can taxonomize our approach into two techniques: (1) Question agent pairing where we preemptively select the agent for the query and (2) Question response pairing where we evaluate the set of returned responses as depicted in Figure 2.

2.1 Question Agent Pairing

As shown in Figure 2, the goal of question agent pairing is, given a query Q and a set of agents $A = \{a_1, a_2, \ldots, a_n\}$, determine the question-agent pair (Q, A_i) that resolves the query Q. At its core, this can be viewed as a classification problem where the model learns the respective capabilities of each independent agent in order to predict which agent to use for a given question.

2.2 Question Response Pairing

As shown in Figure 2, the goal of question response pairing is, given a query Q and a set of agent responses $R = \{r_1, r_2, ..., r_n\}$, determine the question-response pair (Q, R_i) such that R_i resolves the query Q.

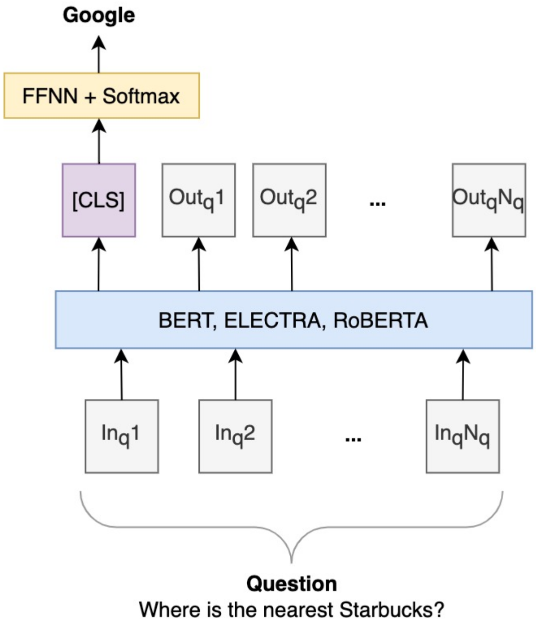

Figure 3: The transformer-based classification models in the OFA system. The models are trained on question agent pairs and tasked to predict an agent to route the given query to.

3 The One For All System

In this section, we present the design of One For All (OFA), a scalable system that integrates multiple black-box CAs with a unified interface. We explain the various approaches implemented in One For All, detailing their inputs, outputs and training methodology.

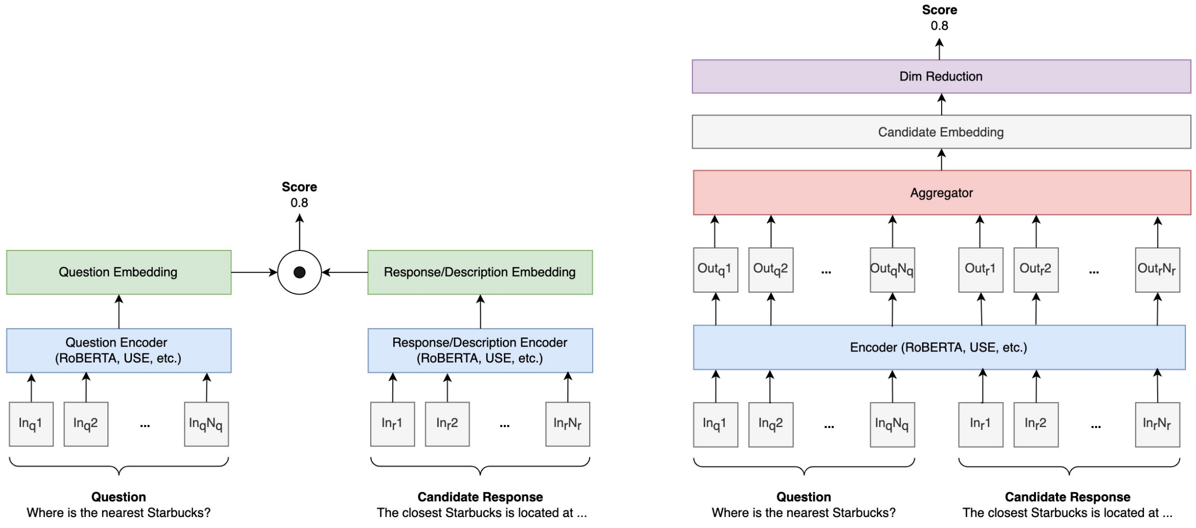
3.1 Question Agent Pairing

In order to predict the best agent for a given query, knowledge of each agent's individual skill-set is required. However, as described in the task formulation in Section 2, the internal details of the agents are unavailable. Everyday users of these agents have no insight into the internal specifics of these agents. However, they are able to use these agents to accomplish tasks by building a mental model of each agents' respective capabilities through usage over time. We draw inspiration from this to determine the information we can use to represent an agent's skills without access to its internals.

3.1.1 Agent Skills Representation

Following the learning patterns described above, we model an agent's skill-set in two distinct ways:

(1) Query examples: Similar to building knowledge overtime via agent interaction, an agents'



(a) Bi-Encoder for Response and Description Ranking

(b) MARS Encoder for Question Response Ranking

Figure 4: Overview of OFA approaches. (a) Bi-Encoder which is used for both QA and QR pairing encodes the question and candidate response/description separately and computes a ranking score via a dot product calculation. (b) Our MARS encoder jointly encodes the question and response into a single transformer and performs self-attention between the question and candidate response. To score a response we reduce the candidate embedding from a vector to a scalar score between 0...1 (Humeau et al., 2020).

query examples allows the model to learn what type of queries each agent is capable of resolving. For example, questions such as *“Where is the nearest gas station?"* and *"Direct me to Starbucks please"* will be amongst the query examples for a *“Directions"* agent.

(2) Agent descriptions:. These are textual summaries of an agent's capabilities. For example, a bank releases a new CA for its customers to use instead of having to visit the bank. Accompanied with this agent will be a semi-formal description of what this agent is capable of doing. This information is often publicly available in the agent's marketing materials.

Using these query examples and agent descriptions, we explore approaches for determining the agent best to resolve a given query. We describe in more detail the dataset collection process in Section 4.

Question agent pairing using query examples QA pairing using query examples seeks to explore how best we can facilitate agent orchestration in a data constrained environment where only a few examples of the questions the agents can answer are present. This is similar to the use of text examples for the training of an intent classifier but at the agent level instead. Therefore, we treat this as a multi-label classification problem where a given query Q is mapped to a set of agents A. e.g Q: *‘locate me some good places in Kentucky that serve sushi‘* maps to the set of agents A: [“Alexa”, "Google"] indicating that this query can be correctly answered by the agents Alexa and Google. Specifically, as shown in Figure 3, we build a multi-label classifier on top of state-of-the-art transformer models, BERT (Devlin et al., 2019), RoBerta (Liu et al., 2019) and Electra (Clark et al., 2020) to predict an agent A given a query Q.

Question agent pairing using agent descriptions While query examples are useful for understanding the capabilities of a given agent, they may not be readily available. When a new agent is introduced, users are unsure of the exact questions this agent can answer but they would typically have access to an explanation of its capabilities. As an alternative, we explore the use of such a description of the agents. For this task, we assume a textual description of an agent's capabilities, e.g. "Our productivity bot helps you stay productive and organized. From sleep timers and alarms to reminders, calendar management, and email ....".

In order to map a given query Q to an agent A described by description D_i, we treat this as a semantic similarity task. The intuition behind this is that for a given query Q the agent that is capable of answering a given question is likely to feature an agent description semantically similar to the question. We explore a suite of pre-trained and fine-tuned language models focusing on ranking the relevance of given description D_i to a query Q. Additionally, given the length of descriptions and the range of capabilities that may be described within a single description, we split the full description at the sentence level and use each sentence to represent a single skill S_i belonging to agent A. With this variation, the question-description similarity score is calculated as the $\max_i SemSim(Q, S_i)$.

For our BBAI task we consider the following state-of-art semantic retrieval-based approaches whose utility map well to our problem domain:

BM25 This classic method measures keyword similarity and uses it to estimate the relevance of documents to a given search query (Robertson and Zaragoza, 2009). We encode the collection of agent descriptions and return the agent whose description is most relevant to the given query.

Universal Sentence Encoder (Cer et al., 2018) A sentence encoding model for encoding sentences into high dimensional vectors. We use the transformer model[5] for our experiment. As shown in part (a) of Figure 4, we encode the user query and the agent description and compute the dot product as a ranking score.

Roberta + STS (Reimers and Gurevych, 2019) We fine-tune Roberta-base on the STS benchmark dataset and use this model to encode our agent descriptions and user query. We compute the cosine similarity between the two vectors to compute a ranking score for each description as shown in Figure 4.

3.2 Question Response Pairing

Contrary to question agent pairing which selects the agent beforehand, question response pairing assumes that we provide each agent in the ensemble the opportunity to respond to the query Q and focus on selecting the best response from the set of returned responses. As such, we treat this as a response ranking problem of determining which question-response pair (Q, R_i) best answers the query Q. Prior work has shown strong performance on sentence pairing tasks such as this through the use of sentence encoders and language model fine-tuning (Henderson et al., 2019; Humeau et al., 2020; Reimers and Gurevych, 2019). We explore the use of these architectures in the domain of response selection with the goal of learning representations for correct question answering from diverse conversational agents.

BM25 Similar to our use of BM25 for question agent pairing we use it to rank each of our question response pairs.

USE and USE QA (Yang et al., 2019) We apply the USE model from our agent pairing task to rank agent responses. In addition, we consider USE QA, an extended version of the USE architecture specifically designed for question-answer retrieval applications. We use the Bi-Encoder architecture as shown in Figure 4 (a).

Roberta + STS We fine-tune Roberta-base on the STS benchmark dataset and use it to encode our question response pairs using the bi-encoder architecture in figure 4.

MARS encoder Pre-existing sentence pairing scoring models are tuned to score sentence pairs deemed semantically similar. However, in the case of conversational systems, an agent's response can be semantically similar but still incorrect. e.g Q: "What is the weather in Santa Clara today?", R: "Weather information is currently unavailable". These two sentences are semantically similar but the response does not resolve the query. In the MARS encoder, we focus on learning representation beyond similarity by also incorporating the correctness of agent responses. Using the cross-encoder architecture (Humeau et al., 2020; Reimers and Gurevych, 2019) shown in part (b) of Figure 4, we train a question response pair scoring model for the task of ranking responses to a given query Q generated by conversational agents. We concatenate both the input question and response performing full self-attention on the entire input sequence. By passing both the question and agent response through a single transformer, the agent response is able to attend to the user query and produce a more input sensitive representation of the question response embedding. Using the generated question response embedding vector we then convert it to a scalar score $S(Q, R_i)$ between 0..1 via a linear layer. Our training objective is to minimize the Cross-Entropy loss between the correct agent responses and the negative agent responses to the query Q.

Question	Agent Response			
	Alexa	Google	Houndify	Adasa
At how many miles will I run out of gas	"here's something I found on the web according to freakonomics.com previously when cars got 8 to 12 miles ...."	"on the website post Dash gazette.com they say some popular car models can make it between 30 and 50 miles ....",	Didn't get that!	"With your current fuel economy of 28 MPG, you should be able to cover about 532 miles with the fuel you have."
Is it gonna be warm Friday in Alhambra?	"here's something I found on the web according to Wikipedia. Org Cobra is one of the 100 selected cities in India which will be developed ...."	"No, it won't be hot Friday in Alhambra, California. Expect a high of 21 and a low of 6.",	"There will be a high of seventy degrees in Alhambra on Friday November twenty-seventh."	"Out of scope!"

Table 1: Sample question agent responses from the One For All dataset. Responses highlighted in green represent agent responses voted as correct by crowd workers.

4 Dataset Construction

For the task of BBAI, we construct a new dataset focusing on making it representative of real-world conversational agents at scale and covering a broad range of domains.

Using Amazon Mechanical Turk and scenario/paraphrasing-based prompts (Kang et al., 2018; Larson et al., 2019), we crowd-sourced utterances across a range of agent skills/capabilities. These skills were extracted from public information sources describing each of the agents, in addition to observing their capabilities. Our dataset is comprised of utterances across 37 broad domain categories. These include domains such as *Weather, Flight Information, Directions, Automobile*, etc. Crowd workers were paid \$0.12 for 5 utterances. These submitted utterances were then vetted by hand to ensure quality. Using the curated utterances, we then generated question responses by querying each agent to gather its response to the utterance.

In order to generate ground truth samples on which of the question-response pairs (Q, R_i) correctly resolves the query Q we launched a crowd-sourcing task asking workers to indicate the candidate responses that best answer the question shown. Five workers were assigned to each response selection task and majority voting (>2) was used to label the gold responses. As such for each query Q and the set of responses R we were able to gather the necessary question-agent pairs (Q, A_i) and question-response pairs (Q, R_i) needed to evaluate our approaches.

Agent Descriptions We gather our agent descriptions by scraping the contents of each of the agent's public product pages and their built-in feature documentation web pages. We then manually clean, reformat and merge this data into a single document per agent. For our experiment, we focus only on extracting descriptions related to the built-in features of our agents.

Overall our dataset contains 5550 utterances with 19 question-response pairs per question (one from each of the 19 agents), 105,450 in total. The utterances are split into 3700 utterances (100 per domain) for the training set and 1850 (50 per domain) for the test set. The train and test sets respectively contain 2399 and 1186 utterances with at least one positive question-response pair. In the remaining examples, none of the agents were able to achieve annotator agreement (>= 3). A sample dataset example is shown in table 1 with responses from 4 of the 19 agents.

5 Results and Discussion

In this section we present and analyze the results of our experiments, detailing our insights and discussing the implications of each of our techniques.

Evaluation task: Similar to standard information retrieval evaluation measures, we denote accuracy as the metric *precision@1* and use it to evaluate both our question agent and question response pairing approaches. For question agent pairing this metric denotes: Given a set of N agents to the given query, whether the agent selected ultimately resolves the query successfully. For question response pairing it denotes: Given a set of N responses to the given query, whether the top-scoring response resolves the query successfully. For this evaluation, we test on examples with at least one valid agent response.

5.1 Question agent pairing

The results are summarized in tables 2 and 3. We find that for the QA pairing Roberta yields the best result with an accuracy of 69% in selecting the correct agent and 61.8% when scaled to 19

			Agent Breakdown			
	Method	**Accuracy (n=4)**	**Alexa**	**Google**	**Houndify**	**Adasa**
Question Agent Pairing (QA Labels)	Bert	68.31	37.98	**40.93**	18.49	2.6
	Electra	67.86	35.28	**42.01**	20.11	2.6
	Roberta	**69.03**	34.92	**41.56**	20.65	2.87
Question Agent Pairing (Descriptions)	BM25	27.91	13.91	10.95	17.33	**57.81**
	USE	**47.84**	13.20	28.82	**52.42**	5.56
	Roberta+STS	39.40	18.94	22.35	**51.35**	7.36
Response Selection	BM25	51.07	28.64	24.69	14.81	**31.86**
	USE	72.89	**34.20**	27.65	22.98	15.17
	USE QA	75.49	**41.65**	36.45	17.95	3.95
	Roberta+STS	69.83	18.94	22.35	**51.35**	7.36
	MARS	**79.70**	37.34	**43.9**	15.71	3.05
Individual Agents	Alexa	49.37	-	-	-	-
	Google	**51.79**	-	-	-	-
	Houndify	34.82	-	-	-	-
	Adasa	4.12	-	-	-	-

Table 2: Performance breakdown of QA and QR approaches on our BBAI task when using our 4 largest agents Alexa, Google, Houndify and Adasa. **Note:** n = number of agents.

Method		**Accuracy (n=19)**	**Agents**
Question Agent Pairing (QA Labels)	Bert	59.10	Alexa, Google
	Electra	52.86	Houndify, Adasa
	Roberta	**61.88**	Recipe agent
Question Agent Pairing (Descriptions)	BM25	23.69	Dictionary agent
	USE	**43.59**	Task Manager
	Roberta+STS	36.67	Hotel agent, Stock agent
Response Selection	BM25	59.94	Math agent, Sports agent
	USE	64.42	Wikipedia agent
	USE QA	71.66	Mobile Account agent
	Roberta+STS	56.82	Banking agent
	MARS	**83.55**	Coffee shop agent
Individual Agents	Alexa	44.09	Event Search agent
	Google	**48.06**	Jokes agent
	Houndify	32.04	Reminders agent
	Adasa	3.45	Covid-19 agent

Table 3: Performance breakdown of QA and QR approaches on our BBAI task on all 19 commercial agents we show that the MARS encoder is able to scale and leverage the capabilities of new agents added to the ensemble without diminishing performance compared to other approaches.

Evaluation Performance per Domain (n=19)			
Domain	**MARS (QR)**	**USE (QA)**	**Roberta (QA)**
Weather	0.88	0.45	0.67
Directions	0.78	0.29	0.44
Auto	1.00	0.79	0.82
Restaurant Suggestion	0.79	0.5	0.68
Travel Suggestion	0.97	0.33	0.57
Time	0.81	0.54	0.76
Flight Info	0.83	0.61	0.7
Date	0.82	0.47	0.56

Table 4: Further breakdown of the best-performing approaches per technique on a subset of 8 out of the 37 domains. We find that our MARS encoder generalizes well across the various agent domains.

agents. Similarly, we see that we can achieve fair performance in extreme data-scarce environments when using simple agent descriptions compared to that of query agent examples, with USE achieving 47.8% accuracy. Using agent descriptions offers greater flexibility in facilitating the improvement of agents over time compared to query examples since it only requires an update to the agent description. However, it still falls short when compared to using a single agent like Google or Alexa. Also, while consistent in learning to recognize the domain a given agent may be performant in, QA approaches fall short in a few cases:

(1) Agent overlap - This is when a given domains' coverage is split between various agents. e.g The model learns that both Alexa & Google have proficiency in handling some weather queries but it remains unclear about which one is best suited for the current query at hand.

(2) Query variation - While an agent's examples or descriptions may allude to proficiency in a given domain, it may still fail when asked certain query variations. e.g Figure 1 shows a case where Alexa is capable of handling weather queries but fails when a condition like humidity is asked for. Another example is when a similar question is asked in a different or more complex way. Both Houndify & Alexa are known to be proficient at answering age-related questions but for questions like *"How old I will be on September 28, 1995, if I was born on March 29, 1967?"*, Alexa is unable to answer as opposed to Houndify.

These cases are further highlighted when inspecting QA pairing performance at the domain level in table 4. We find that the QA approaches struggle with domains such as *"travel suggestion"* and *"Directions"* which are heavily split in coverage and more diverse in their variation.

5.2 Question response pairing

In overall performance we find that our MARS encoder outperforms strong baselines, achieving 83.55% accuracy on the BBAI task. We note that our MARS encoder outperforms the best single performing agent (Google Assistant) by 32%. This shows the utility and power of OFA in not only alleviating the need for users to learn and adopt multiple agents but also validating that multiple agents working collectively can achieve significantly more than single agents working in isolation.

When inspecting the performance of MARS at the domain level we see in Table 4 that it is able to maintain its high performance across the varying domains unlike the QA approaches. This advantage comes from the ability to select an agent at the response level allowing the system to catch cases in which an agent once deemed proficient fails or another agent improves.

5.3 Agent pairing vs Response pairing

We now describe the trade-offs between agent pairing and response pairing. Question response pairing greatly outperforms agent pairing in terms of accuracy, given that it is privy to the final responses from each of the agents. However, in practice, this comes with additional networking, compute, and latency costs from having to send the query to each of the agents and await their response. Given that the querying of agents is done in parallel, the latency cost is equal to that of the slowest agent. Question response pairing also better supports agent adaptation. With response pairing, a system can seamlessly add or remove an agent without diminishing the experience as shown by MARS in table 3. In addition, as conversational agents are upgraded to offer a more diverse feature-set such as new domain support or improved responses, they can instantly be integrated into a response pairing approach.

5.4 Scalability

We evaluate our approaches on a suite of 19 commercially deployed agents spanning 37 broad domain categories. As shown in table 2 we examine performance when using the 4 largest agents in terms of domain support and popularity (Alexa, Google Assistant, Houndify and Ford Adasa) showing improvement upon single-agent use in both QA and QR approaches. When scaled up to 19 agents, MARS encoder improves even further by leveraging the new capabilities of the additional agents and is the only approach that does not decrease in performance as the number of agents and domains scale. This improvement is due to the input sensitive representations that the MARS encoder is able to learn by encoding both the question and response in a single transformer.

Cross-encoding vs Bi-encoding For pairwise sentence scoring tasks such as response selection which compare question response pairs, it is important to be mindful of the trade-offs between cross encoder based models such as MARS in figure 4 (b) and bi-encoder models such as USE in 4 (a). Cross-encoders perform full self-attention over the pairwise input of the question and response, thus, producing an encoding representative of the combined input. This typically leads to much more performative models, especially in pairwise scoring tasks such as ours. However, given that this encoding isn't independent of the question for each question response pair, it is necessary to produce an encoding for each question label pair. Bi-encoders on the other hand perform self-attention over the question response pairs separately, map them to a dense vector space, and score them using an appropriate distance metric. With this separation, bi-encoders are able to index the question and compare these representations for each response resulting in faster prediction times when the numbers of candidate responses to a given question scales. Given the nature of our BBAI task which focuses on the scoring of responses to a singular question as opposed to a clustering task which requires an encoding for every pairwise combination across a set of sentences, cross-encoder based architectures remain a viable option even at the production scale for our use case.

6 Related Work

Ensemble approaches to solving complex tasks in the context of NLP are widely used (Deng and Platt, 2014; Araque et al., 2017). In dialogue systems, recent attempts at ensemble approaches and multi-agent architectures include Cercas Curry et al. (2018) and Subramaniam et al. (2018). AlanaV2 (Cercas Curry et al., 2018) demonstrated an ensemble architecture of multiple bots using a combination of rule-based machine learning systems built to support topic-based conversations across domains. It was built to be an open domain bot supporting topic-based conversations. Specifically, AlanaV2's architecture utilizes a variety of ontologies and NLU pipelines that draw information from a variety of web sources such as Reddit. However, its agent selection approach is guided by a simple priority bot list. Subramaniam et al. (Subramaniam et al., 2018) describe their conversational framework that employs an *Orchestrator Bot* to understand the user query and direct them to a domain-specific bot that handles subsequent dialogue. In our work, we expand up the multi-agent goal by focusing on the integration of black-box conversational agents at scale.

6.1 Response Selection

This is the task of selecting the most appropriate response given context from a pool of candidates. It is a central component of information retrieval applications and has become a focal point in the evaluation of dialogue systems. (Sato et al., 2020; Henderson et al., 2019; Wang et al., 2020). Prior work has shown strong performance on sentence pairing tasks through the use of sentence encoders and language model fine-tuning (Henderson et al., 2019; Humeau et al., 2020; Reimers and Gurevych, 2019). In our work, we explore the task of response selection using it as one of the bases for integrating black-box conversation agents.

7 Conclusion

The rapid proliferation of conversational agents calls for a unified approach to interacting with multiple CAs. The key challenge of building such an interface lie in that most commercial CAs are black-boxes with hidden internals. This paper introduces BBAI a new task of agent integration that focuses on unifying black-boxes CAs across varying domains. We explore two task techniques, question agent pairing and question response pairing and present One For All, a scalable system that unifies multiple black-box CAs with a centralized user interface. Using a combination of commercially available conversational agents, we evaluate a variety of approaches to multi-agent integration through One For All. Our MARS encoder achieves 83.5% accuracy on BBAI and outperforms the best single agent configuration by over 32%. These results demonstrate the power of One For All which can leverage state-of-the-art NLU approaches to enable multiple agents to collectively achieve more than any single conversational agent in isolation eliminating the need for users to learn and adopt multiple agents.

This work opens up a wide range of potential future work involving the design of systems geared towards facilitating more advanced multi-agent interaction. We foresee a system with even greater response selection performance as the NLP community continues to produce more state-of-the-art language models with even greater contextual knowledge of the world. Extensions of this work can include examining not only the integration of agents but the interoperability by facilitating the passing of shared conversation knowledge across agents especially in multi-turn conversational scenarios across multiple agents.

Abstract

We present two simple modifications for word-level perturbation: Word Replacement considering Length (WR-L) and Compositional Word Replacement (CWR). In conventional word replacement, a word in an input is replaced with a word sampled from the entire vocabulary, regardless of the length and context of the target word. WR-L considers the length of a target word by sampling words from the Poisson distribution. CWR considers the compositional candidates by restricting the source of sampling to related words that appear in subword regularization. Experimental results showed that the combination of WR-L and CWR improved the performance of text classification and machine translation.

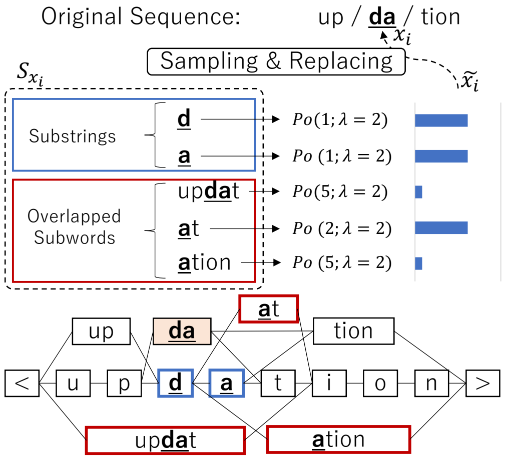

Figure 1: Outline of replacing the word “da” in “up/da/tion” using our method, CWR-L.

1 Introduction

Word-level perturbation is a well-known technique used NLP (Zhang and Yang, 2018; Takase and Kiyono, 2021). For example, word replacement (WR) (Bengio et al., 2015; Zhang and LeCun, 2015) randomly replaces words in the input sequence with words sampled from a vocabulary. The conventional WR uses a uniform distribution for sampling. Although a simple method, it is as effective as complex methods, such as adversarial perturbations (Takase and Kiyono, 2021). However, the conventional WR frequently replaces original words with unrelated words. If the probability of replacement (hyperparameter) is set to be large, a perturbed input sequence would be drastically different from the original one, which would significantly affect performance. Thus, it is important to search for an appropriate hyperparameter.

Subword regularization (SR) (Kudo, 2018; Hiraoka et al., 2019; Provilkov et al., 2020) is another effective method for word-level perturbation. We used different tokenizations sampled from a pretrained language model in each training epoch with the SR. As this method focuses only on tokenization, unrelated words are not used. However, sampling tokenization takes a longer time owing to its complex procedure for managing various tokenization candidates. In addition, the improvement achieved by SR is sometimes unimpressive in comparison with WR; however, it requires a considerable amount of time.

In this study, we propose two approaches to compromise between WR and SR. Our method restricts candidates in WR to related words in terms of (1) word length and (2) tokenization. The first approach weights the distribution for word sampling based on the length of the target word. The second approach hardly restricts the vocabulary for word sampling to compositional subwords of the original word inspired by SR. These restrictions prevent the replacement of words with unrelated words and thus result in a stable improvement in NLP tasks even if the hyperparameter is varied. In addition, the sampling speeds of our methods are faster than those of SR because they do not require an alternative tokenization sequence. We empirically demonstrate the advantages of the proposed method for text classification and machine translation tasks.

2 Related Work

This work discusses the technique of word-level perturbation in NLP. One of the popular perturbation ways is word replacement (Bengio et al., 2015; Zhang and LeCun, 2015), which randomly choices input words and replaces them with other words in a vocabulary. Word dropout (Gal and Ghahramani, 2016) and unknown token replacement (Zhang et al., 2020) are variations of word replacement, which replace the selected words with zero embeddings and unknown tokens, respectively.

There are some techniques to prevent using unrelated words in word replacement. Zhang et al. (2015a) replaces randomly selected words with their synonyms. Kobayashi (2018) employs a language model to replace the chosen words. Our work focuses on the tokenization units to restrict vocabulary to prevent using unrelated words.

Subword regularization is another means of word-level perturbation. Kudo (2018) employs a unigram language model to sample tokenization for machine translation. Provilkov et al. (2020) modifies byte pair encoding to perturb the input tokenization. Hiraoka et al. (2019, 2020, 2021) introduces a technique to update the tokenizer during the training.

3 Proposed Method[1]

Before describing our method, we provide a brief overview of the base method: WR. Let $\boldsymbol{x} = x_1, ...x_i, ...x_I$ be a sequence of words whose length is I. The WR method randomly replaces x_i with $\tilde{x_i}$ with probability a using the following equations:

$$\tilde{x_i} \sim Q_V \tag{1}$$

$$x_i = \begin{cases} \tilde{x_i} & \text{with probability} \quad a \\ x_i & \text{with probability} \quad 1-a \end{cases}, \tag{2}$$

where Q_V is the uniform distribution on the entire vocabulary V, and a is the hyperparameter. We refer to x_i selected with a as the target word.

3.1 WR Considering Length (WR-L)

The conventional WR often samples words whose length is similar to the average length of words in the corpus regardless of the length of the target word[2] because we use a uniform distribution as Q_V. We address this problem with a distribution weighted by the Poisson distribution[3], whose mean is the target word length as follows:

$$p(\tilde{x}_i|x_i) = \frac{\text{Poisson}(L_{\tilde{x}_i}; \lambda = L_{x_i})}{Z}, \tag{3}$$

where L_{x_i} indicates the number of characters that comprise x_i, and Z is a normalization term that makes the sum of the probabilities 1.

3.2 Compositional Word Replacement (CWR)

WR often samples words unrelated to the target word owing to the uniform distribution Q_V. To address this problem, we propose CWR that restricts the source of sampling V to S_{x_i}, which consists of two subsets: Substrings and Overlapped Subwords. Substrings contain all the substrings of the target word, whereas Overlapped Subwords contain words that include the target word. Let us consider the target word "da" in "up/**da**/tion." Substrings are "d" and "a, " and Overlapped Subwords are "up**dat**," "**at**," and "**a**tion," as shown in Figure 1.

We pre-compute Overlapped Subwords for each target word by checking all tokenizations for each training sentence. During this extraction, we merge Overlapped Subwords for the same target word to save the memory footprint, even if the target word appears in different sentences. For example, when the target word "da" appears in "up/da/tion" and "pan/da," we merge "an**d**" in "pan/da" with the set containing "up**dat**," "**at**," and "**a**tion" as Overlapped Subwords of "da." Algorithm 1 in Appendix overviews the construction of S_{x_i}.

WR-L can be combined with CWR by weighting the uniform distribution over S_{x_i} with the Poisson distribution introduced in Section 3.1.

4 Experiment

We conducted experiments on text classification and machine translation. To confirm the effectiveness of our methods, we compared our method with regular training without word-level perturbation (**Vanilla**) and the following four word-level perturbation techniques in addition to **WR**:

Subword regularization (SR) samples the tokenization in each training epoch with the pretrained unigram language model. We employed SentencePiece (Kudo, 2018) for SR.

Word Dropout (WD) randomly replaces inputs with zero vectors (Gal and Ghahramani, 2016).

Unknown Token Replacement (UTR) randomly replaces words with unknown tokens (Zhang et al., 2020), i.e., we use an unknown token as $\tilde{x_i}$ in Eq.2.

Language Model (LM) randomly replaces words with words sampled depending on an LM[4].

In addition to the proposed methods, **WR-L** and **CWR**, we denote the combination of these methods as **CWR-L**. Table 1 presents the perturbed examples for each method. We controlled the above methods except SR with the hyperparameter a mentioned in Eq. 2. For SR, we controlled the diversity of the sampled tokenization with a hyperparameter, which we refer to as b[5]. For all datasets, we determined the hyperparameters for the perturbation using validation splits using a grid search ranging from 0.1 to 0.9 in increments of 0.1. Figures 2 and 3 indicate the effects of these variables.

4.1 Text Classification

Setup: We employed nine datasets in three languages for text classification. Twitter(En), Twitter(Ja), and Weibo(Zh) are sentiment analyses of short-text SNS in English, Japanese, and Chinese, respectively. Rating and Genre are datasets of rating prediction and genre prediction for e-commerce services: Amazon (He and McAuley, 2016) in English, Rakuten (Rakuten, Inc., 2014) in Japanese, and JD.com (Zhang et al., 2015b) in Chinese. Appendix A describes the preparation of the datasets in detail. We used SentencePiece (Kudo and Richardson, 2018) for tokenization with a vocabulary size of 16K for sentiment analysis and 32K for the others, after the pre-tokenization for the Japanese corpus with MeCab (Kudo, 2006) and the Chinese corpus with Jieba (Junyi, 2013). We employed a BiLSTM-based text classifier (Zhou et al., 2016) and trained it on the training split. For the English datasets, we also employed a BERT-base (Devlin et al., 2018) implemented by HuggingFace (Wolf et al., 2020), a well-known pretrained language model, as the classifier (+BERT) [6].

Results: Table 2 presents the performance of each word-level perturbation method. The results indicate that the proposed perturbation method with the Poisson distribution WR-L outperformed the original WR on nine out of 12 datasets. In addition, the combination of our methods, CWR-L, improved the performance on several datasets, including the setting where we employed BERT. The average scores of CWR-L over the entire dataset were higher than those of the other methods, and the scores of WR-L were comparable to those of CWR-L. By contrast, the method that only con-

Table 3: Experimental results for the machine translation task averaged over three runs (ScareBLEU (Post, 2018)). Bold and underline denote the highest scores and scores that significantly surpass WR ($p < 0.05$, bootstrap resampling (Koehn, 2004)), respectively.

siders tokenization, CWR, underperformed other methods on several datasets. These results demonstrate that WR-L contributes to the performance improvement of text classification, and considering tokenization, as is the case in CWR-L, it helps improve performance. Among the baseline methods, WR and LM ranked first in terms of the average score, whereas SR did not show any significant improvement on most datasets.

4.2 Machine Translation

Setup: For machine translation, we employed Transformer (Vaswani et al., 2017) implemented by Fairseq for the IWSLT setting (Ott et al., 2019). We conducted experiments on De-En, Vi-En, and Zh-En language pairs of the IWSLT corpora because previous studies reported that word-level perturbation is particularly effective in low-resource settings (Kudo, 2018). We tokenized each corpus using SentencePiece with a vocabulary size of 36K, and we pre-tokenized the Chinese corpus with Jieba. We trained the models with 50 epochs and chose the best model using the validation loss.

Results: Table 3 shows the results of each perturbation method for machine translation. The scores of SR were higher than those of the other baseline methods. CWR achieved competitive scores against SR, even though it does not strictly sample tokenization. Moreover, WR-L surpassed SR, and CWR-L achieved the highest performance in five out of six language pairs. These results indicate that the perturbation considering tokenization (SR, CWR) is effective for machine translation, and the methods considering the sampled length (WR-L, CWR-L) have a greater effect on the performance.

5 Discussion

5.1 Performance against Hyperparameters

In Section 4, we reported the performance with the hyperparameter that yielded the highest performance on the validation split for each method. To confirm the sensitivity of each method to the hyperparameters, we report the average performance over nine text classification datasets used in Section 4.1 against the hyperparameter scoped in the grid search. As shown in Figure 2, CWR-L outperformed the other perturbation methods in terms of most values. Although WR and LM achieved the higher performance among the baselines, the performance curve was much peaky. The peak performance of WR-L was higher than that of WR and competitive against LM, especially in lower hyperparameters that are often selected. These results indicate that LM, WR, and WR-L are sensitive to hyperparameters. Although CWR scores are almost the same as the vanilla performance, CWR-L is a tractable perturbation approach because its performance is not highly dependent on the hyperparameter. This demonstrates that using the Poisson distribution for sampling is effective for stable performance improvement.

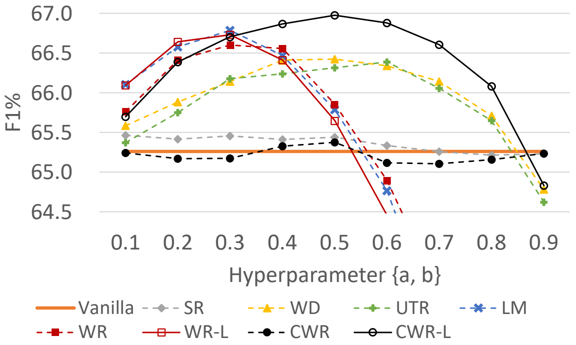

Figure 2: Average performances on test splits over the nine datasets excluding experiments with BERT.

5.2 Perturbation Speed

We aimed to develop a fast and effective perturbation method. In this subsection, we report the speed of the perturbation on the entire training dataset of the Amazon corpus used in Section 4.1, which con-

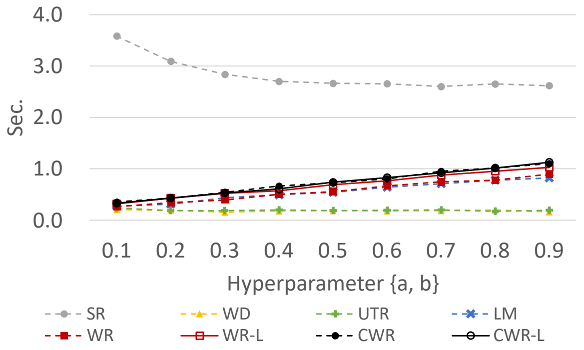

Figure 3: Average time to process 10K sentences in the training data of the Amazon corpus over 10 runs.

tains 96,000 sentences (84.91 words per sentence).

Figure 3 shows the averaged processing time over 10 runs for each perturbation method. Our methods were slightly slower than WR and LM because they have an additional step of restricting the sampled candidates to WR. By contrast, our methods were much faster than SR. This result indicates that the proposed methods, especially CWR-L, are better alternatives from the perspectives of both processing speed and performance.

6 Conclusion

We propose a fast and effective alternative for word-level perturbation. The experimental results showed that the proposed method, CWR-L, improved the performance of text classification and machine translation, particularly with the sampling strategy using Poisson distribution. We also empirically showed that CWR-L is more robust to hyperparameters than other perturbation methods and is faster than SR.

Ethical Considerations

Because word-level perturbation includes stochastic behaviour, the experimental results depend on random seeds. Ideally, tons of trials are required to compare the methods correctly. However, because of limitation of computational resources, we averaged the results of five trials for text classification and three trials for machine translation.

Word-level perturbation can be seen as a variation of data augmentation. Therefore, the effectiveness of word-level perturbation might be small when the training corpus is significantly large. However, this work does not discuss this point because preparing such a large training corpus is difficult.

Acknowledgments

This paper is based on results obtained from a project, JPNP18002, commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

A Dataset Preparation

In Section 4.1, we used nine datasets for text classification. We exploited the default settings for Twitter(En)[7] and Weibo(Zh)[8], but we preprocessed the other datasets. Twitter(En) contains 100,000 tweets and Weibo(Zh) contains 671,052 samples.

Twitter(Ja)[9]: We collected 352,554 tweets using Twitter API and used 162,184 tweets that had one sentiment label (positive: 10,319, negative: 16,035, or neutral: 135,830).

Rating&Genre(En): From the published Amazon dataset, we sampled 5,000 reviews for each of the 24 product genres that contained sufficient reviews. We counted the number of words using whitespaces, and we only extracted reviews whose length was less than 200 words. The total number of reviews was 120,000. We created datasets for Rating(En) and Genre(En) from the same reviews.

Rating&Genre(Ja): From the published Rakuten dataset, we sampled 5,000 reviews for each of the five rates and 21 genres that contained a sufficient number of reviews. We limited the maximum length of reviews to 100 characters, and the total number of reviews was 525,000. We created datasets for Rating(Ja) and Genre(Ja) from the same reviews.

Rating&Genre(Zh): From the published JD.com dataset, we sampled 6,000 reviews for each of the five rates and 13 genres that contained a sufficient number of reviews. We limited the maximum length of reviews to 100 characters, and the total number of reviews was 390,000. We created datasets for Rating(Zj) and Genre(Zh) from the same reviews.

We divided all the datasets in a ratio of 8:1:1 to obtain the training, validation, and test sets.

B Environment

In all the experiments, we implemented the proposed method with PyTorch. We ran all the experiments on a machine with an NVIDIA Tesla V100 (16 GiB) GPU and Intel Xeon E5-2680 V4 processor (Broadwell-EP, 14 cores, 2.4 GHz).

C Implementation

We employed the Poisson distribution to sample a replacement word by considering the word length, as expressed in Eq. 3. The sampling process using a non-uniform distribution takes a much longer time than sampling using a uniform distribution. Therefore, we avoided sampling using a nonuniform distribution via random sampling from a candidate list that reflects the Poisson distribution. We prepared a candidate list of a specified size K that contains replacement candidates with a Poisson distribution ratio for each target word. For example, when the replacement candidates of a word "A" are "B" and "C" with the probabilities of 0.4 and 0.6, respectively, the candidate list is "[B, B, C, C, C]" ($K = 5$). Sampling a word from this list can avoid the use of nonuniform distributions; thus, our method can be implemented as quickly as the proposed method without the Poisson distribution. In our implementation, the size of the list K was 1,000 for all the experiments.

Bridging Pre-trained Language Models and Hand-crafted Features for Unsupervised POS Tagging

Abstract

In recent years, large-scale pre-trained language models (PLMs) have made extraordinary progress in most NLP tasks. But, in the unsupervised POS tagging task, works utilizing PLMs are few and fail to achieve state-of-the-art (SOTA) performance. The recent SOTA performance is yielded by a Guassian HMM variant proposed by He et al. (2018). However, as a generative model, HMM makes very strong independence assumptions, making it very challenging to incorporate contexualized word representations from PLMs. In this work, we for the first time propose a neural conditional random field autoencoder (CRF-AE) model for unsupervised POS tagging. The discriminative encoder of CRF-AE can straightforwardly incorporate PLM word representations. Moreover, inspired by feature-rich HMM, we reintroduce hand-crafted features into the decoder of CRF-AE. Finally, experiments clearly show that our model outperforms previous state-of-the-art models by a large margin on Penn Treebank and multilingual Universal Dependencies treebank v2.0.

1 Introduction

Unsupervised learning has been an important yet challenging research direction in NLP (Klein and Manning, 2004; Liang et al., 2006; Seginer, 2007). Training models directly from unlabeled data can relieve painful data annotation and is thus especially attractive for low-resource languages (He et al., 2018). As three typical tasks related to syntactic analysis, unsupervised part-of-speech (POS) tagging (or induction), dependency parsing, and constituency parsing have attracted intensive interest during the past three decades (Pereira and Schabes, 1992; Christodoulopoulos et al., 2010, *inter alia*). Compared with tree-structure dependency and constituency parsing, POS tagging corresponds to simpler sequential structure, and aims to assign a POS tag to each word, as depicted in Figure 1. Besides the alleviation of labeled data, unsupervised POS tagging is particularly valuable for child language acquisition study because every child manages to induce syntactic categories without access to labeled data (Yuret et al., 2014).

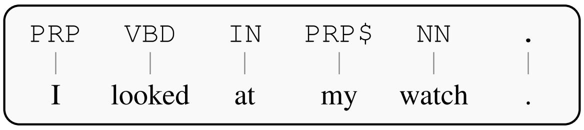

Figure 1: Example of POS tagging.

Nowadays, supervised POS tagging models trained on large-scale labeled data can already achieve extremely high accuracy, for example over 97.5% on English Penn Treebank (PTB) texts (Huang et al., 2015; Bohnet et al., 2018; Zhou et al., 2020). However, unsupervised POS tagging, though having attracted a lot of research interest (Lin et al., 2015; Tran et al., 2016; He et al., 2018; Stratos, 2019; Gupta et al., 2020), can only achieve at most 80.8% many-to-one (M-1) accuracy, where M-1 means multiple induced tags can be mapped to a single ground-truth tag when evaluating the model on the test data.

The generative Hidden Markov Models (HMMs) are the most representative and successful approach for unsupervised POS tagging (Merialdo, 1994; Graça et al., 2009). By treating POS tags as latent variables, a first-order HMM factorizes the joint probability of a sentence and a tag sequence $p(\mathbf{x}, \mathbf{y})$ into independent emission probabilities $p(x_i \mid y_i)$ and transition probabilities $p(y_{i-1} \mid y_i)$. The training objective is to maximize the marginal probability $p(\mathbf{x})$, which can be solved by the EM algorithm or direct gradient descent (Salakhutdinov et al., 2003). Berg-Kirkpatrick et al. (2010) propose a feature-rich HMM (FHMM), which further parameterizes $p(x_i \mid y_i)$ with many hand-crafted

Findings of the Association for Computational Linguistics: ACL 2022, pages 3276 - 3290
May 22-27, 2022

morphological features, greatly boosting M-1 accuracy to 75.5 from 63.1 of the basic HMM.

In the DL era, researchers have paid a lot of attention to HMMs for unsupervised POS tagging. Lin et al. (2015) propose a Gaussian HMM (GHMM), where $p(x_i \mid y_i)$ corresponds to the probability of the pre-trained word embedding (fixed during training) of x_i against the Gaussian distribution of y_i. Tran et al. (2016) propose a neural HMM model (NHMM), where $p(x_i \mid y_i)$ and $p(y_{i-1} \mid y_i)$ are all computed via neural networks with POS tag and word embeddings as inputs. He et al. (2018) extend the Gaussian HMM of Lin et al. (2015) by introducing an invertible neural projection (INP) component for the pre-trained word embeddings, which has a similar effect of tuning word embeddings during training. Their INP Gaussian HMM (INP-GHMM) approach achieves state-of-the-art (SOTA) M-1 accuracy (80.8) on PTB so far.

The major weakness of HMMs is the strong independence assumption in emission probabilities $p(x_i \mid y_i)$, which directly hinders the use of contextualized word representations from powerful pre-trained language models (PLMs) such as ELMo/BERT (Peters et al., 2018; Devlin et al., 2019). It is a pity since PLMs are able to greatly boost performance of many NLP tasks.

In this work, we for the first time propose a neural conditional random field autoencoder (CRF-AE) model for unsupervised POS tagging, inspired by Ammar et al. (2014) who propose a non-neural CRF-AE model. In the discriminative encoder of CRF-AE, we straightforwardly incorporate ELMo word representations. Moreover, inspired by feature-rich HMM (Berg-Kirkpatrick et al., 2010), we reintroduce hand-crafted features into the decoder of CRF-AE. In summary, this work makes the following contributions:

- We for the first time propose a neural CRF-AE model for unsupervised POS tagging.
- We successfully bridge PLMs and hand-crafted features in our CRF-AE model.
- Our model achieves new SOTA M-1 accuracy of 83.21 on the 45-tag English PTB data and outperforms the previous best result by 2.41.
- After a few straightforward adjustments, our model achieves new SOTA M-1 accuracy on the 12-tag multilingual Universal Dependencies treebank v2.0 (UD), surpassing the previous best results by 4.97 on average.

We release our code at `https://github.com/Jacob-Zhou/FeatureCRFAE`, including our re-implemented HMM and FHMM models.

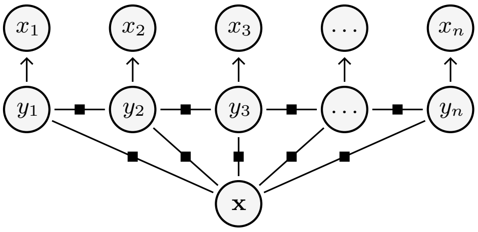

Figure 2: Illustration of CRF-AE.

2 Vanilla CRF-AE

In this work, we adopt the CRF-AE approach as our basic model for unsupervised POS tagging. The non-neural CRF-AE model is first proposed by Ammar et al. (2014) for unsupervised sequence labeling tasks, inspired by neural network autoencoders. Cai et al. (2017) also extend the idea to non-neural unsupervised dependency parsing. The basic idea is first producing latent structures, i.e., POS tag sequences, with a discriminative CRF over the observed sentence, and then reconstructing the original sentence given each latent structure. The two steps correspond to the encoder and the decoder respectively.

Training loss. We denote a sentence as $\mathbf{x} = x_1, x_2, \cdots, x_i, \cdots, x_n$, and a POS tag sequence as $\mathbf{y} = y_1, y_2, \cdots, y_i, \cdots, y_n$. Given an unlabeled dataset $\mathcal{D}$ which does not contain any POS tag sequences, the training loss is:

$$\begin{aligned}\mathcal{L}(\mathcal{D};\boldsymbol{\phi},\boldsymbol{\theta}) = -\sum_{\mathbf{x}\in\mathcal{D}} \log \mathbb{E}_{\mathbf{y}\sim p(\mathbf{y}\mid\mathbf{x};\boldsymbol{\phi})} p(\mathbf{x}\mid\mathbf{y};\boldsymbol{\theta}) \\ + \lambda\left(\|\boldsymbol{\phi}\|_2^2 + \|\boldsymbol{\theta}\|_2^2\right),\end{aligned} \tag{1}$$

where $p(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\phi})$ is the CRF encoder; $p(\mathbf{x} \mid \mathbf{y}; \boldsymbol{\theta})$ is the decoder; $\boldsymbol{\phi}$ and $\boldsymbol{\theta}$ are model parameters.

This training loss encourages the model to meet the intuition that a high-probability POS sequence should also permit reconstruction of the sentence with a high probability.

Ammar et al. (2014) adopt the *Expectation-Maximization* (EM) algorithm for training. In this work, we directly compute the training loss via the *Forward* algorithm. Then, we employ the powerful *AutoGrad* function of deep learning to compute the gradient of each parameter. Our preliminary experiments on HMM and feature-rich HMM show that this gradient-based approach is consistently superior to EM in both efficiency and performance.

Inference. During evaluation, we follow Ammar et al. (2014) and use both the CRF and the reconstruction probabilities to obtain the optimal tag sequence:

$$\mathbf{y}^* = \arg\max_{\mathbf{y}} p(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\phi}) p(\mathbf{x} \mid \mathbf{y}; \boldsymbol{\theta}), \quad (2)$$

which can be solved by the *Viterbi* algorithm.

CRF Encoder: $p(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\phi})$. As a discriminative log-linear model, the CRF encoder defines a conditional probability:

$$p(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\phi}) = \frac{\exp\left(S(\mathbf{x}, \mathbf{y}; \boldsymbol{\phi})\right)}{Z(\mathbf{x}; \boldsymbol{\phi}) \equiv \sum_{\mathbf{y}} \exp(S(\mathbf{x}, \mathbf{y}; \boldsymbol{\phi}))}, \quad (3)$$

where $Z(\mathbf{x})$ is the partition function, also known as the normalization term.

The score of $\mathbf{y}$ given $\mathbf{x}$ is decomposed into bigram scores:

$$S(\mathbf{x}, \mathbf{y}; \boldsymbol{\phi}) = \sum_{i=1}^{n} s\left(\mathbf{x}, y_{i-1}, y_i; \boldsymbol{\phi}\right). \quad (4)$$

Ammar et al. (2014) use hand-crafted discrete features to obtain bigram scores.

$$s\left(\mathbf{x}, y_{i-1}, y_i; \boldsymbol{\phi}\right) = \boldsymbol{\phi}^{\top} g(\mathbf{x}, y_{i-1}, y_i, i). \quad (5)$$

Decoder: $p(\mathbf{x} \mid \mathbf{y}; \boldsymbol{\theta})$. The decoder computes the reconstruction probability of $\mathbf{x}$ given a POS tag sequence $\mathbf{y}$, which is factorized into position-wise generation probabilities based on a strong independence assumption.

$$p(\mathbf{x} \mid \mathbf{y}; \boldsymbol{\theta}) = \prod_{i=1}^{n} p(x_i \mid y_i; \boldsymbol{\theta}). \quad (6)$$

Ammar et al. (2014) use a categorical distribution matrix $\boldsymbol{\theta}$, which is updated via EM training, to maintain all generation probabilities $p(x_i \mid y_i)$, i.e., a word x_i generated by a tag y_i.

3 Proposed Approach

In this work, we for the first time propose a neural CRF-AE and leverage **PLM representations** and **hand-crafted features** for unsupervised POS tagging.

3.1 CRF Encoder w/ PLM Representations

As discussed in §2, the CRF-AE framework consists of two major components, i.e., the CRF encoder and the decoder for sentence reconstruction. We first introduce how to enhance the CRF encoder.

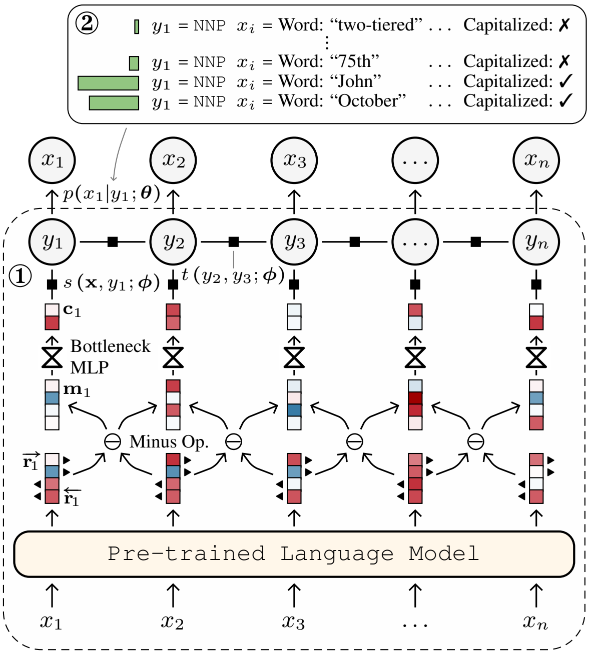

Figure 3: Model architecture of proposed model. ① is the "CRF encoder w/ ELMo representations" and ② is the "reconstruction w/ hand-crafted features".

The major challenge of the CRF encoder is how to induce latent sequences more accurately via effective contextual representations. Like most works before the DL era, Ammar et al. (2014) employ manually designed features to represent contexts.

One of the major advances brought by DL is the strong capability of contextual representation via neural networks like LSTM and Transformer. Furthermore, pre-trained language models, such as ELMo and BERT, greatly amplify this advantage and are shown to be able to substantially improve performance for almost all NLP tasks.

However, few works have tried to utilize such neural contextualized encoders for unsupervised POS tagging, except Tran et al. (2016) and Gupta et al. (2020). Most importantly, according to our knowledge, there is no work so far that successfully employ PLMs for unsupervised POS tagging.

In this work, we propose to employ the contextual representations from PLM to enhance the CRF encoder of the CRF-AE model. Here we use ELMo (Peters et al., 2018) to illustrate our method, which is the same for other PLMs like BERT.

ELMo outputs. The encoder of ELMo consists of three layers (Peters et al., 2018). The bottom layer computes context-free word representations via word-wise character-level convolutional neural networks. The top two layers, each with two unidirectional LSTMs (forward and backward), obtain context-aware word representations by concatenating the forward and backward representations.

After feeding an input sentence into ELMo, each word x_i has three representation vectors, i.e., $(\mathbf{h}_i^0, \mathbf{h}_i^1, \mathbf{h}_i^2)$, corresponding to three encoder layers respectively. Following the standard practice, we take the weighted arithmetic mean (`ScalarMix`) of output vectors as the final contextualized word representation $\mathbf{r}_i$ for $\mathbf{x}_i$:

$$\mathbf{r}_i = \gamma \sum_{k=0}^{K-1} \omega_k \mathbf{h}_i^k, \tag{7}$$

where $\omega_k \quad (0 \le k < K)$ are softmax-normalized weights[1] and K is the layer number; γ is the scale factor of the entire contextualized word representation. In our final model, we only use $\mathbf{h}_i^1$ and $\mathbf{h}_i^2$, since including $\mathbf{h}_i^0$ degrades performance (see Table 2).

Minus operation. Apart from specific information of the focused word x_i, the contextualized word representation $\mathbf{r}_i$ from ELMo also contains a lot of common contextual information shared by neighbour words (Ethayarajh, 2019). Therefore, inspired by previous works on constituent parsing (Wang and Chang, 2016; Cross and Huang, 2016), we adopt the minus operation for representations as follows:

$$\mathbf{m}_i = \begin{bmatrix} \overrightarrow{\mathbf{r}}_i \\ \overleftarrow{\mathbf{r}}_i \end{bmatrix} - \begin{bmatrix} \overrightarrow{\mathbf{r}}_{i-1} \\ \overleftarrow{\mathbf{r}}_{i+1} \end{bmatrix}, \tag{8}$$

where $\overrightarrow{\mathbf{r}}_i$ is the forward part of the final contextualized word representation $\mathbf{r}_i$ and $\overleftarrow{\mathbf{r}}_i$ is backward one. $\mathbf{m}_i$ is the word representation of x_i after the minus operation.

Bottleneck MLP. The ELMo adopts large dimensions d, i.e., 1024, to encode as much information as possible. Representations from ELMo contains syntax clues and even semantic ones besides the information about the POS. Inspired by supervised dependency parsing models (Dozat and Manning, 2017; Li and Eisner, 2019), we adopt a bottleneck MLP ($\texttt{MLP}^{\text{⧖}}$), whose output vector has a very low dimension. Because of the low dimension of the MLP output, redundant and irrelevant information will be stripped away:

Feature	John	75th	two-tiered
Word	John	0th†	`UNK`‡
Uni-gram Suffix	n	h	d
Bi-gram Suffix	hn	th	ed
Tri-gram Suffix	ohn	0th	red
Has Digit	✗	✓	✗
Has Hyphen	✗	✗	✓
Capitalized	✓	✗	✗

Table 1: Feature templates for feature-rich reconstruction. †: before extracting features, we replace continuous digits into a single "0" in each word. ‡: features appeared less then 50 times in the training data are replaced with a special `UNK` feature.

$$\begin{aligned} \mathbf{c}_i &= \texttt{MLP}^{\text{⧖}}(\mathbf{m}_i) \\ &= \texttt{LeakyReLU}\left(\mathbf{W}^{\text{⧖}} \cdot \texttt{LayerNorm}(\mathbf{m}_i) + \mathbf{b}^{\text{⧖}}\right), \end{aligned} \tag{9}$$

where the bottleneck size $d' \ll d$ is output dimensions of the bottleneck projection weight $\mathbf{W}^{\text{⧖}} \in \mathbb{R}^{d \times d'}$ and the bias $\mathbf{b}^{\text{⧖}} \in \mathbb{R}^{d'}$.

Scorer. The definition of a POS tagging sequence $\mathbf{y}$ given $\mathbf{x}$ is identical to equation 4. But the definition of bigram scores is different from the vanilla CRF-AE. Here, a bigram score consists of two parts: a unigram score $s(\mathbf{x}, y_i; \phi)$ estimated from ELMo representations and a matrix-maintained transition score $t(y_{i-1}, y_i; \phi)$.

$$s(\mathbf{x}, y_{i-1}, y_i; \phi) = s(\mathbf{x}, y_i; \phi) + t(y_{i-1}, y_i; \phi). \tag{10}$$

Specifically, $s(\mathbf{x}, y_i)$ is calculated as follows:

$$s(\mathbf{x}, y_i; \phi) = \texttt{LayerNorm}(\mathbf{W}^s \cdot \mathbf{c}_i + \mathbf{b}^s)[y_i], \tag{11}$$

where $\mathbf{W}^s \in \mathbb{R}^{d' \times |\mathcal{Y}|}$ is the projection weight of scoring, $\mathbf{b}^s \in \mathbb{R}^{|\mathcal{Y}|}$ is the scoring bias, and $\mathcal{Y}$ is the POS tag set. $[y_i]$ is the index selection operation.

3.2 Reconstruction w/ Hand-crafted Features

In Ammar et al. (2014), the reconstruction probabilities are stored and updated as a matrix. The conditional probability $p(x_i \mid y_i)$, i.e., generating x_i given y_i, is modeled at the whole-word level. This leads to the data sparseness problem. For rare words, the probabilities are usually unreliable.

Therefore, we borrow the idea of feature-rich HMM by Berg-Kirkpatrick et al. (2010). The idea

---

[1] The weights are trained only in the second stage of our training method.

is to utilize rich morphological information to learn more reliable generation probability. For example, suffixes usually provide strong clues to POS categories. In this work, we adopt the feature templates proposed by Berg-Kirkpatrick et al. (2010), as shown in Table 1.

With the hand-crafted features, we then parameterize tag-to-word emission probabilities as local multinomials:

$$p(x_i \mid y_i; \boldsymbol{\theta}) = \frac{\exp\left(\boldsymbol{\theta} \cdot f\left(x_i, y_i\right)\right)}{\sum_{x' \in \mathcal{V}} \exp\left(\boldsymbol{\theta} \cdot f\left(x', y_i\right)\right)} \qquad (12)$$

where $\boldsymbol{\theta}$ is the feature weight vector and $\mathcal{V}$ is the vocabulary set.

4 Experiments on English PTB

4.1 Settings

Data. Following previous works on unsupervised POS tagging, we conduct experiments on the Wall Street Journal (WSJ) data from PTB, yet with two distinct data settings.

(1) *WSJ-All*. Almost all previous works train and evaluate their models on the entire WSJ data. We report results on WSJ-All for comparison with previous works. However, this data setting is very unfriendly for selecting hyper-parameters, such as stopping and best epoch numbers, M-1 mappings, learning rates, network dimensions, etc. It is probable that some previous works make modeling choices by directly looking at the evaluation performance, since training loss (e.g., data likelihood) is quite loosely correlated with performance. Such details are usually omitted or only implicitly discussed in previous works.

(2) *WSJ-Split*. We follow the practice in unsupervised dependency parsing and divide the WSJ dataset into train (sections 02-21), dev (section 22) and test (section 23). We tune hyper-parameters and study the contributions of individual model components by referring to performance on WSJ-Dev. Moreover, we determine the best many-to-one mappings on WSJ-Dev, which are directly used to compute many-to-one accuracy (M-1) on both WSJ-Dev and WSJ-Test.

We strongly suggest that in future researchers can adopt the WSJ-Split setting. First, the WSJ-Split setting is more realistic because it is able to evaluate a model's generalization ability with out-of-vocabulary words. Second, it is more reasonable and fairer to use WSJ-dev to choose hyper-parameters and it is usually feasible to manually annotate a dev data, even if very small-scale.

Layer	M-1	1-1	VM	LL
0	79.98 ±0.3	59.13 ±3.4	73.06 ±0.9	-73.06 ±1.4
1	82.61 ±0.8	63.03 ±5.0	76.98 ±1.2	-79.52 ±0.8
2	82.45 ±1.0	60.29 ±3.2	76.27 ±1.0	-83.35 ±0.5
{0, 1, 2}	81.53 ±0.3	64.03 ±4.1	76.21 ±0.7	-76.89 ±0.4
$\{1, 2\}^{\oplus}$	82.28 ±1.3	63.54 ±4.5	76.91 ±1.3	-78.96 ±0.4
{1, 2}	**83.20** ±0.7	**65.17** ±2.3	**77.69** ±0.7	-80.49 ±0.5

Table 2: Results of utilizing different layers of the ELMo on WSJ-Dev. $\oplus$ means directly concatenating the representation vectors of different layers.

Evaluation metrics. Following previous works, we mainly adopt many-to-one accuracy, and also report one-to-one accuracy (1-1) and validity-measure (VM) values for better comparison. To reduce the effect of performance vibration, we follow previous works, run each model for five times with different seeds, and report the mean and standard deviation. Please see Appendix A for details.

Hyper-parameters. We set the number of predicted POS tags to 45 and the output dimensions of $\texttt{MLP}^{\texttt{x}}$ to 5. We train each model on the training data for at most 50 epochs, and select the best epoch based on data log-likelihood (LL). Please see Appendix B for full details of hyper-parameters.

Three-stage Training procedure. Unsupervised models are very sensitive to parameter initialization. Inspired by previous works (Han et al., 2017; He et al., 2018), we adopt a three-step progressive training procedure. 1) We train a feature-rich HMM model from random initialization, and produce the 1-best prediction from it for each training sentence. 2) The feature-rich HMM model is used as a teacher to pre-train the CRF-AE model. More concretely, we train the CRF encoder on the pseudo-labeled training data in a supervised fashion for 5 epochs; meanwhile we directly copy the feature weights from the feature-rich HMM model to the decoder of the CRF-AE model. 3) We train our full CRF-AE model on unlabeled training data with parameters obtained in the second step as initialization.

4.2 Model Development on WSJ-Split

Using which ELMo layers. As mentioned above, ELMo produces three representation vectors for each word x, corresponding to its three encoder layers. Since the usefulness of information contained in different ELMo layers is unknown for our task at hand, we conduct experiments to study which layers to use and how to use them. Table 2 shows the results. When using single-layer representations, it is obvious that using one of the top two layers (1/2) is superior to using the bottom 0-th layer[2]. This is in line with our expectation considering that the 0-th layer corresponds to context-independent word type embeddings. The first layer is superior to the second one, which is consistent with Peters et al. (2018), who also conclude that the information contained by the first layer are more suitable for POS tagging than the second layer.

Then we try to combine multiple layers by using aforementioned `ScalarMix` in Equation 7. It is clear that using the top two contextualized layers ($\{1, 2\}$) achieves best performance. We find that the weight contribution of layer 1 and 2 is about 92% vs. 8%, confirming again that the first contextualized layer provides the majority of syntactic information, while the second layer is more concerned with high-level semantics. We can also see that replacing `ScalarMix` with simple concatenation leads to large performance drop.

Comparing M-1, 1-1, VM, and LL, we can see that M-1, 1-1 and VM are highly correlated, whereas LL is quite loosely correlated with model performance, suggesting that training loss cannot be used for selecting models or tuning hyper-parameters.

In the following, we try to understand **the contribution of different components** by removing one from the full CRF-AE model at a time. Table 3 shows the results.

Model	M-1	1-1	VM
Full CRF-AE	**83.20** ±0.7	**65.17** ±2.3	**77.69** ±0.7
w/o Features	76.74 ±1.4	61.34 ±3.5	73.55 ±1.0
w/o PLM Repr.	78.40 ±0.9	61.31 ±4.9	72.55 ±1.6

ELMo → BERT	82.30 ±1.0	62.78 ±5.8	76.13 ±1.6

Table 3: The contribution of different components on WSJ-Dev by removing one component at a time.

Usefulness of hand-crafted features. In order to measure the effectiveness of hand-crafted features in the reconstruction part, we revert to the vanilla matrix-maintained version. We can see that rich hand-crafted features are critical and not using them leads to the largest performance drop.

Usefulness of PLMs. We first replace pre-trained ELMo with a conventional three-layer BiLSTM encoder that is trained from scratch. We use pre-trained word embeddings of He et al. (2018) as encoder inputs. As expected, performance also declines a lot. It shows that ELMo does provide very useful information. We have also tried to replace ELMo with BERT without much hyper-parameter tuning, as shown in the bottom row, but found that the performance decreases. The results are similar on the multilingual UD data in Table 6. We suspect the reasons are two-fold. First, we did not carefully tune the hyper-parameters for using BERT due to time and resource limitation. Second, we suspect the ELMo word representations suffice and are even more suitable for unsupervised POS tagging. The POS tag of a word usually heavily depends on neighboring words within a small window, which makes the BiLSTM encoder superior to Transformer. The latter is more powerful to capture long-distance dependencies.

Usefulness of minus operation. Besides the minus operation in Equation 8, the default choice is directly using the ELMo output, i.e., $\mathbf{r}_i$. As shown in the fourth row, models without the minus operation are inferior to the models with the minus operation. We believe it is because the original ELMo representations have a lot of common contextual information shared by neighbour words, and the minus operation can remove them.

Usefulness of the three-stage training procedure. To find out the effect of our three-step progressive training procedure, we randomly initialize model parameters. The result shows that the randomly initialization decreases model performances substantially. It proves that the three-stage training procedure helps models find relatively good initial parameters.

4.3 Results on WSJ-Test

We report results on WSJ-Test in Table 4 and hope future researchers adopt the WSJ-Split setting. Considering that INP-GHMM is the current SOTA

---

[2] Minus operations do not apply to vectors at the 0-th layer, i.e., context-independent word type embeddings, which are directly used as $\mathbf{m}_i$.

Model	M-1	1-1	VM
HMM (re-Impl.)	65.25 ±2.0	47.62 ±2.6	58.16 ±1.0
FHMM (re-Impl.)	73.91 ±1.0	59.13 ±6.4	68.69 ±2.5
INP-GHMM (re-Run)	76.10 ±1.5	53.83 ±3.2	72.19 ±0.8
Ours	**82.89** ±0.7	**65.32** ±2.5	**78.06** ±0.8

Table 4: Results on WSJ-Test. We re-implement HMM and Feature-rich HMM and re-run INP-GHMM.

model on English PTB, we re-run their open-source code[3] with default configuration on WSJ-Split. We re-implement vanilla HMM and feature-rich HMM of Berg-Kirkpatrick et al. (2010), and train them with Adam algorithm via direct gradient descent. Results show that our model is superior to the previous best one, and achieves current SOTA results.

4.4 Performance Comparison on WSJ-All

In order to compare with previous works, we report results on WSJ-All in Table 5. We directly use all hyper-parameters obtained from WSJ-Split.

We can see that our proposed model outperforms all previous works by large margin. The INP-GHMM model (He et al., 2018) achieves the previous best performance on WSJ-All. Our model outperforms theirs by 2.41 and 3.54 on M-1 and VM, respectively.

5 Experiments on Multilingual UD

5.1 Settings

Data. For more thorough comparison with previous works, we also report results[4] on the Multilingual Universal Dependencies treebank v2.0 (UD), consisting of 10 languages (McDonald et al., 2013). Similar to experiments on English PTB, we adopt two settings for the UD data, i.e., UD-Split and UD-All. For UD-Split, we adopt the default partition of the UD data.

Model	M-1	1-1	VM
HMM (B'10)	63.1 ±1.3	–	–
FHMM (B'10)	75.5 ±1.1	–	–
FHMM (re-Impl.)	74.70 ±2.2	60.88 ±4.3	68.53 ±2.1
Brown (C'10)	76.1	60.7	68.8
S-CODE (Y'12)	80.23 ±0.7	–	72.07 ±0.4
GHMM (L'15)	75.4 ±1.0	–	68.5 ±0.5
NHMM (T'16)	79.1	60.7	71.7
INP-GHMM (H'18)	80.8 ±1.3	–	74.1 ±0.7
MIM (S'19)	78.1 ±0.8	–	–
SyntDEC (G'20)	78.2 ±0.9	–	–
Ours	**83.21** ±1.2	**65.78** ±2.8	**77.64** ±0.5

Table 5: Results on WSJ-All. Here, B'10 is for Berg-Kirkpatrick et al. (2010), C'10 for Christodoulopoulos et al. (2010), Y'12 for Yatbaz et al. (2012), L'15 for Lin et al. (2015), T'16 for Tran et al. (2016), H'18 for He et al. (2018), S'19 for Stratos (2019), and, G'20 for Gupta et al. (2020).

Hyper-parameters. We directly adopt most hyper-parameters obtained for PTB with three important exceptions. First, The number of predicted POS tags is changed to 12. Second, since the scale of data for each language diverge a lot, we adjust the feature cutoff threshold to be proportional to the token number against English partition. For example, the “de” data contains about 293k tokens, which is about 28% of that of “en” (1M), and therefore we set the threshold to 14 (28% × 50). Third, we adjust the hand-crafted features to accommodate the 12-tag UD standard and characteristics of different languages, detailed in the following.

Modifications on hand-crafted features. The fine-grained 45-tag WSJ standard is greatly different from the coarse-grained 12-tag UD standard adopted by the multilingual UD datasets (Petrov et al., 2012). Therefore, we start from the features of Berg-Kirkpatrick et al. (2010) in Table 1 as the base, and make adjustments from two aspects.

(1) *Adjustments for UD*. We remove the “Capitalized” feature, which is originally purposed to distinguish proper and common nouns which correspond to a single UD tag. Moreover, we replace all punctuation marks with a special “`PUNCT`” word form, add a new feature template “is-Punctuation”, as UD uses a single tag for punctuation marks.

(2) *Adjustments for specific languages*[5]. The UD tag set doesn't distinguish inflections such as numbers, tenses, and genders. We find this can be accommodated by customizing suffix uni/bi/trigram features. We simply remove a certain number of ending characters (related to inflectional affixes)

---

[3] https://github.com/jxhe/struct-learning-with-flow

[4] We run each model for five times with different random seeds.

[5] We only adopt language-specific adjustments for “de”, “en”, “es”, “fr”, “it” and “pt-br”.

Table 6: M-1 accuracy on UD-Split. **Upper Part:** The contribution of different components on UD-Dev by removing one component at a time. ⋆ means adopting the language-specific suffix features for this language. "=" means the result is identical to that of Full CRF-AE. **Lower Part:** Performance comparison on UD-Test.

for a word form before extracting suffix features. We remove the last character for "it", and the last two characters for "de". For "fr", "es", and "pt-br", we remove last two characters if the word ends with "s", and the last one otherwise. For "en", we only remove the last "s" letter if applicable.

5.2 Results on UD-Split

Table 6 shows the M-1 results. For 1-1 and VM-results, please refer to Table 10 and Table 9 in the Appendix.

We perform ablation study on UD-Dev. Most of the results show the same trend as on WSJ-Dev. In particular, we find that our two adjustment strategies for the UD data are very helpful, and the UD adjustment is more helpful. After observation, we find that without UD-specific adjustments, punctuation marks are more likely to be divided into multiple tags. For example, models may assign three different tags to periods, commas, and quotation marks. Moreover, with the removal of the "Capitalized" feature, which is one of the UD adjustments, the models no longer distinguish common and proper nouns and assign one tag to them.[6]

Without language-specific adjustments, highly inflected languages, e.g., Italian (it) and Brazilian Portuguese (pt-br), are more likely to distinguish words by their number or gender rather than part-of-speech. For example, in English, models without making language-specific adjustments will tend to split nouns into two classes: single nouns and plural nouns ending with "s".

We report the M-1 results on UD-Test in Table 6. We run our implemented vanilla HMM and feature-rich HMM, and the latter adopt the same features after UD and linguage adjustments. Unfortunately, we are unable to re-run SyntDEC, the current SOTA on UD-All, since its authors (Gupta et al., 2020) have not yet released their code. We also re-run INP-GHMM (He et al., 2018) with their released code, which is the current SOTA on WSJ-All. We take context-free word representations (0-th layer) of ELMo as inputs of INP-GHMM, which should be better than Skip-Gram embeddings. Please see Appendix C for details of hyper-parameters.

Results show that our models achieve the highest M-1 accuracy on 9 out of 10 languages, except "de". After investigation on why our models fail to outperform INP-GHMM on "de", we find that the direct reason is that INP-GHMM is initialized

---

[6] However, we find that some models still divide nouns into multiple tags by some unknown criteria.

with GHMM, and the simple GHMM is already more superior to our model. Therefore, we replace FHMM with GHMM in the first stage of our training procedure. Results show that our models are substantially improved in "de". However, we still do not understand the reason behind these results, which we leave for future investigation due to time limitation.

5.3 Performance Comparison on UD-All

To compare with previous works, we report results on UD-All in Table 11 in the Appendix. For thorough comparison, we also re-run GHMM and INP-GHMM on UD-All. The results show identical trends as those on UD-Split.

6 Related Works

Unsupervised POS tagging. In addition to HMMs and the CRF-AE, other approaches for unsupervised POS tagging are as follows.

(1) *Clustering.* The clustering approach, as a mainstream unsupervised learning technique, is also investigated for unsupervised POS tagging Yatbaz et al. (2012); Yuret et al. (2014); Gupta et al. (2020). All these works adopt the k-means algorithm to divide word tokens into different groups. The main difference among them is how to represent words. Yatbaz et al. (2012) propose to learn context-free word embeddings by minimizing the distance between each word and its substituted words. Substituted words are selected according to a n-gram language model. Yuret et al. (2014) extend their previous work to produce context-sensitive word embeddings. Gupta et al. (2020) adopt a deep clustering approach that uses a feed-forward neural network to transform word representations from mBERT into a lower-dimension clustering-friendly space. Transformation with reconstruction loss and clustering are jointly trained. Unfortunately, all three works have not released their source code.

(2) *Mutual information maximization.* The mutual information maximization approach is proposed by Stratos (2019). The idea is that we can predict POS tags in two ways (using the words themselves or their context), and predictions from these two ways should agree as more as possible.

Utilizing PLMs for unsupervised tagging or parsing. As discussed earlier, SyntDEC (Gupta et al., 2020) is the only work that employs PLMs for unsupervised POS tagging based on deep clustering. As for unsupervised parsing, Wu et al. (2020) propose a perturbed masking technique to estimate inter-word correlations and then induce syntax trees from those correlations. Kim et al. (2020) extract constituency trees from the PLMs through capturing syntactical proximity between representations of two adjacent words (or subwords). If the proximity is loose, then it is likely that the middle position of the two words corresponds to some constituent boundary. Cao et al. (2020) successfully exploit PLMs for unsupervised constituency parsing based on constituency test, achieving SOTA performance.

Utilizing CRF-AE. Cai et al. (2017) apply CRF-AE to unsupervised dependency parsing. They use the encoder to generate a most likely dependency tree and then force the decoder to reconstruct the input sentence from the tree. Zhang et al. (2017) propose a neural CRF-AE for semi-supervised learning on sequence labeling problems (including POS tagging) and Jia et al. (2020) adopt a neural CRF-AE for semi-supervised semantic parsing.

7 Conclusions

This work bridges PLMs and hand-crafted features for unsupervised POS tagging. Based on the CRF-AE framework, we employ powerful contextualized representations from PLMs in the CRF encoder, and incorporate rich morphological features for better reconstruction. Our proposed approach achieves new SOTA on 45-tag English PTB and 12-tag multilingual UD datasets, outperforming previous results by large margin. Experiments and analysis show that rich features and PLM representations are critical for the superior performance of our model. Meanwhile, simple adjustments of hand-crafted features are key for the success of our model on languages other than English.

Acknowledgments

We thank the anonymous reviewers for the helpful comments. We are very grateful to Wei Jiang for his early-stage exploration on unsupervised POS tagging. We also thank Chen Gong, Yu Zhang, Ying Li, Qingrong Xia, Yahui Liu, and Tong Zhu for their help in paper writing and polishing. This work was supported by National Natural Science Foundation of China (Grant No. 62176173, 61876116) and a Project Funded by the Priority Academic Program Development (PAPD) of Jiangsu Higher Education Institutions.

A Details of Evaluation Metrics

The core issue of the unsupervised POS tagging evaluation is that we can not directly compute the tagging accuracy since the correspondence between ground truth tags and predicted tag indexes (index-to-tag mapping) is unknown and varies from model to model. The different evaluation metrics handle this issue in different way.

A.1 Many-to-One Accuracy (M-1)

M-1 is the most commonly used evaluation metric. It addresses the problem of correspondence by assigning each predicted tag index $j \in \mathcal{P}$ to its most frequent co-occurring ground truth tag $g_i \in \mathcal{G}$:

$$\text{M-1}(\mathbf{A}) = \sum_j \max_{g_i} \mathbf{A}_{g_i,j}, \qquad (13)$$

where $\mathbf{A} \in \mathbb{R}^{n \times n}$ is contingency matrix and the matrix item $\mathbf{A}_{g_i,j}$ is the number of words which are annotated as a g_i and predicted as a j by the model to be evaluated. This metric, obviously, allows different predicted indexes to map to the same ground truth tag[7].

A.2 One-to-One Accuracy (1-1)

Different from M-1 that we allows a ground truth tag g_i corresponding to multiple predicted indexes, 1-1 only allows one predicted index can be assigned to a ground truth tag, and vice versa. Calculating 1-1 is a typical assignment problem that finding a optimal bijection function $f : \mathcal{P} \rightarrow \mathcal{G}$ that maximums the correct matching count from all possible bijection functions $\mathcal{F}$:

$$\text{1-1}(\mathbf{A}) = \max_{f \in \mathcal{F}} \sum_j \mathbf{A}_{f(j),j}. \qquad (14)$$

In this paper we solve this assignment problem with the Hungarian algorithm[8].

A.3 Validity-Measure (VM)

VM (Rosenberg and Hirschberg, 2007) is an entropy-based measure, which do not require the index-to-tag mapping and considers two criteria: homogeneity h and completeness c. The homogeneity of a predicted index indicates the purity of its co-occurring ground truth tags. The predicted index j results the highest homogeneity when it

---

[7] In the WSJ-Split data setting, the index-to-tag mapping of metrics for WSJ-Dev and WSJ-Test are both observed from WSJ-Dev.

[8] `https://en.wikipedia.org/wiki/Hungarian_algorithm`

only co-occur with g_i, i.e., $\mathbf{A}_{g_i,j} = \sum_{g_{i'}} \mathbf{A}_{g_{i'},j}$, and has a low homogeneity it appears with different ground truth tags randomly. The homogeneity of a model is the simply the sum of the homogeneity of all index indicates. The completeness is symmetrical to homogeneity, merely exchanging the position of predicted indexes and ground truth tags. VM employs the conditional entropy to measure the value of homogeneity and completeness:

$$H(\mathcal{G} \mid \mathcal{P}, \mathbf{A}) = -\sum_j \sum_i \frac{\mathbf{A}_{g_i,j}}{N} \log \frac{\mathbf{A}_{g_i,j}}{\sum_{g_{i'}} \mathbf{A}_{g_{i'},j}}, \tag{15}$$

$$H(\mathcal{P} \mid \mathcal{G}, \mathbf{A}) = -\sum_i \sum_j \frac{\mathbf{A}_{g_i,j}}{N} \log \frac{\mathbf{A}_{g_i,j}}{\sum_{j'} \mathbf{A}_{g_i,j'}}, \tag{16}$$

where $\mathbf{A} \in \mathbb{R}^{n \times n}$ is contingency matrix and the matrix item $\mathbf{A}_{g_i,j}$ is the number of words which are annotated as a g_i and predicted as a j.

To alleviate the impact of the size of the dataset and the numbers of the POS class, the conditional entropy is normalized by the entropy of ground truth POS tag $H(\mathcal{G}, \mathbf{A})$ and $H(\mathcal{P}, \mathbf{A})$ for homogeneity and completeness, respectively:

$$h(\mathbf{A}) = 1 - \frac{H(\mathcal{G} \mid \mathcal{P}, \mathbf{A})}{H(\mathcal{G}, \mathbf{A})}, \tag{17}$$

$$c(\mathbf{A}) = 1 - \frac{H(\mathcal{P} \mid \mathcal{G}, \mathbf{A})}{H(\mathcal{P}, \mathbf{A})}, \tag{18}$$

where

$$H(\mathcal{G}, \mathbf{A}) = -\sum_i \frac{\sum_j \mathbf{A}_{g_i,j}}{N} \log \frac{\sum_j \mathbf{A}_{g_i,j}}{N}, \tag{19}$$

$$H(\mathcal{P}, \mathbf{A}) = -\sum_j \frac{\sum_{g_i} \mathbf{A}_{g_i,j}}{N} \log \frac{\sum_{g_i} \mathbf{A}_{g_i,j}}{N}. \tag{20}$$

Completeness is symmetrical to homogeneity, merely exchanging $\mathcal{G}$ and $\mathcal{P}$ in the formulas.

In order to balance the significance between homogeneity and completeness, VM is defined as the weighted harmonic mean of homogeneity and completeness:

$$\mathrm{VM}(\mathbf{A}) = \frac{(1+\beta) h(\mathbf{A}) c(\mathbf{A})}{\beta h(\mathbf{A}) + c(\mathbf{A})}, \tag{21}$$

where β are set to 1 in experiments.

B Details of Hyper-parameters

B.1 Model

The number of predicted POS tags is 45 for experiments on WSJ and 12 for Multilingual experiments. The ELMo parameters we use for experiments on WSJ are "`Original (5.5B)`"[9] from AllenNLP. The parameters for Multilingual are from "`ELMoForManyLangs`"[10] (Che et al., 2018). We use "`bert-base-cased`" (BERT) and "`bert-base-multilingual-cased`" (mBERT)[11] for the ablation study of PLMs on WSJ and UD respectively. We do not fine-tune ELMo parameters. The dropout value is uniformly set to 0.33, and the negative slope of the activation function Leaky-ReLU is set to 1×10^{-2}. The seeds we selected for experiments are $0, 1, 2, 3, 4$.

B.2 Feature

We set the feature cutoff threshold to 50, which means that all features that appear in the training data less than 50 times are replaced with a special "`UNK`" feature.

B.3 Training

We use a mini-batch update strategy with a batch size of 5000 words and optimize models with Adam. The learning rate used in the training of the FHMM in the first step is 0.5. The CRF encoder is then trained on pseudo-labeled data for 5 epochs with a learning rate of 2×10^{-3} in the subsequent pre-training step. In the final step, the CRF encoder has a learning rate of 1×10^{-2}, and we set the reconstruction learning rate to 2×10^{-1}. Other hyper-parameters are identical among all three steps in training procedure, The β_1 and β_2 are both 0.9. The learning rate decay is 0.75 per 45 epochs, the gradient clipping value is 5, and the weight decay value λ is 1×10^{-5}.

C Details of Re-run INP-GHMM Hyper-parameters

We use the word-wise character-level convolutional layer (0-th layer) of ELMo to extract word embeddings. We use 8 coupling layers. To accelerate the training of INP-GHMM, we increase the batch sizes from 32 to 512 sentences. We also decrease the learning rate from 1×10^{-3} to 5×10^{-4}, as we found that high learning rates lead to performance decreases as training progresses.

Table 8: Language-specific suffix features for the UD datasets. The underlined **characters** represent extracted suffix features.

D Explanation of adjustments for specific languages on UD

Most of European languages are inflected languages. Some words are inflected for number, gender, tense, aspect and so on. For example in English nouns are inflected for number (singular or plural); verbs for tense. A major way to inflect words is adding inflectional suffixes to the end of words, e.g., English nouns inflected for number with suffix "s" ("museum" → "museums"). Therefore, in some languages suffixes is more closely related to inflections than coarse-grained POS. For instance, as shown in Table 7, the last letter of Italian words is highly corresponding to gender and number, and haves little connection to coarse-grained POS. In this work, we simply remove a certain number of ending characters for a word form before extracting suffix features, as shown in Table 8.

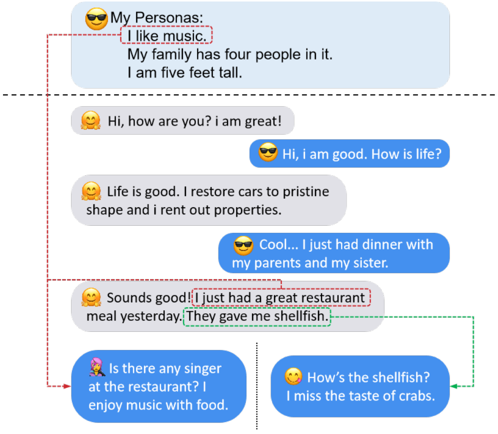
Abstract

The finetuning of pretrained transformer-based language generation models are typically conducted in an end-to-end manner, where the model learns to attend to relevant parts of the input by itself. However, there does not exist a mechanism to directly control the model's focus. This work aims to develop a control mechanism by which a user can select spans of context as "highlights" for the model to focus on, and generate relevant output. To achieve this goal, we augment a pretrained model with trainable "focus vectors" that are directly applied to the model's embeddings, while the model itself is kept fixed. These vectors, trained on automatic annotations derived from attribution methods, act as indicators for context importance. We test our approach on two core generation tasks: dialogue response generation and abstractive summarization. We also collect evaluation data where the highlight-generation pairs are annotated by humans. Our experiments show that the trained focus vectors are effective in steering the model to generate outputs that are relevant to user-selected highlights.

1 Introduction

Transformer-based models pretrained on large-scale text data have become the dominant paradigm for natural language generation (NLG) tasks (Roller et al., 2020; Lewis et al., 2019; Raffel et al., 2020). The attention module (Bahdanau et al., 2016; Vaswani et al., 2017), which aggregates information via a weighted average over word-level embeddings, plays a vital role in these models. The attention mechanism serves two major purposes: (1) It captures linguistic phenomena in the input (Clark et al., 2019; Kovaleva et al., 2019; Kobayashi et al., 2020); (2) It helps the model focus on relevant portions of the input (e.g., alignment in machine translation (Bahdanau et al., 2016) and abstractive summarization (Rush et al., 2015)).



My Personas:
I like music.
My family has four people in it.
I am five feet tall.

Hi, how are you? i am great!

Hi, i am good. How is life?

Life is good. I restore cars to pristine shape and i rent out properties.

Cool... I just had dinner with my parents and my sister.

Sounds good! I just had a great restaurant meal yesterday. They gave me shellfish.

Is there any singer at the restaurant? I enjoy music with food.

How's the shellfish? I miss the taste of crabs.

Figure 1: Illustration of our motivation: different highlights in the input (including persona) lead to different generations. This example is from our collected dialogue data for evaluation (Section 3).

The attention module is particularly useful as it does not require any explicit supervision: the model learns to attend to relevant parts of the input **by itself** through end-to-end training. However, this property makes it difficult to explicitly control the model's focus. **If the model happens to put focus on some span of context that the user thinks is not so important, we currently do not have a mechanism to correct it.** This is especially sub-optimal in some NLG applications involving a relatively long input such as dialogue or summarization: focusing on different spans of the input could result in completely different generations (illustrated in Figure 1). It would be attractive to give the user an option to control the model's focus.

In this work, we aim to develop a mechanism to steer the model to generate output relevant to some user-specified input spans (which we term as highlights).[1] This goal, however, brings about significant challenges. For one, many popular NLG datasets are collected in an end-to-end manner, i.e., without annotations of which spans of input are most relevant to the reference target. It would also be ideal for the proposed approach to be compatible

---

[1] To avoid confusion, our goal is *not* about controlling the attention modules inside the model, instead, we care about the actual generation.

Findings of the Association for Computational Linguistics: ACL 2022, pages 3291 - 3306
May 22-27, 2022

with existing pretrained transformer models, as retraining such models is often costly.

In this work, we propose an *focus vector* framework to address the challenges outlined above. Our contributions are as follows:

- To control the model's focus, we augment the pretrained model with trainable focus vectors which are directly applied to the encoder embeddings. The model itself is kept fixed, and no further changes to the model architecture is needed.
- The training of focus vectors does not require additional annotations. We utilize attribution methods to derive automatic highlight annotations from existing end-to-end training data.
- For principled evaluation and future work in this direction, we collect and release human evaluation data where the highlight-generation pairs are annotated by humans.
- We test our approach on two core NLG tasks: dialogue response generation and abstractive summarization. Experiments show that the trained focus vectors are effective in steering the model to generate a relevant output given the selected highlights.

2 Model Formulation

We assume the target model is a standard pretrained transformer encoder-decoder model (Vaswani et al., 2017) that has already been finetuned on end-to-end task-specific data (e.g., dialogue or summarization) with the standard negative log-likelihood (NLL) loss. Our goal is to establish a control mechanism whereby the user can highlight several spans of the input, and the model is supposed to generate outputs relevant to the highlighted text. Crucially, this mechanism should not change the base model, in order to allow the user to default back to the original model if desired.

We begin by establishing notation. We denote the end-to-end training data by $\{\mathbf{x}, \mathbf{y}\}$, where $\mathbf{x} = \{x_1, ..., x_n\}$ refers to the input token sequence, and $\mathbf{y}$ refers to the corresponding reference target token sequence. During evaluation, some spans of the input $\mathbf{x}$ will be highlighted, and we use a binary indicator c_i to indicate whether the i^{th} input token is to be highlighted during generation. In this work we only consider a set of complete sentences as a valid highlight span. This design choice is mainly for convenience during our human-annotated evaluation data collection, and our framework can readily be generalized to phrase-level highlights.

Suppose the encoder model is composed of L transformer layers. We denote the d-dimensional output embedding of the i^{th} position on the l^{th} encoder layer by $\mathbf{h}^l_i$. We use $\{\mathbf{h}^0_i\}$ to denote the input embeddings. Each decoder layer performs multi-head cross-attention on the outputs of the encoder, where the attention weight computation for the h^{th} head on the l^{th} decoder layer is formulated as below:

$$\alpha^{h,l}_{i,j} = \operatorname*{softmax}_{i \in \{1 \ldots n\}} \left(\frac{k(\mathbf{h}^L_i) \cdot \mathbf{q}^{h,l}_j}{\sqrt{d}} \right). \qquad (1)$$

Here $k(\cdot)$ is a linear transform, and $\alpha_{i,j}$ is the attention weight assigned to encoder output $\mathbf{h}^L_i$, for the j^{th} position decoder query vector $\mathbf{q}_j$. We use $P_{\mathrm{M}}(\mathbf{y}|\mathbf{x})$ to denote the probability assigned to $\mathbf{y}$ given input $\mathbf{x}$ by the original target model. For more details of the transformer encoder-decoder architecture, we refer readers to Vaswani et al. (2017).

Our proposed framework involves two stages. We first obtain automatic highlight annotations using attribution methods. Then, these annotations are used to train the focus vectors. In the next section, we review the attribution methods.

2.1 Attribution Methods

Many popular NLG datasets are collected end-to-end, i.e., without annotations of which spans of input are most relevant to the reference target. To obtain these annotations for focus vector training, we make use of existing attribution methods.

Attribution methods (Baehrens et al., 2010; Simonyan et al., 2014; Shrikumar et al., 2017; Adebayo et al., 2018; Sundararajan et al., 2017), also known as *saliency maps*, attribute the prediction of a (potentially black-box) model to its input features. It thus fits our need to extract relevant spans in the input given the reference target. Most saliency methods are originally designed for image classification, where an importance score is assigned for each dimension of the input feature. Therefore, slight modifications (e.g., dot-product with the word embeddings) are needed to apply them to language data (Ding and Koehn, 2021; Denil et al., 2014).

We implement and compare several popular attribution methods, which compute the attribution score for a given sentence S (denoting the set of token indexes in the sentence) in the input $\mathbf{x}$ for the target $\mathbf{y}$ and model P_{M}.

Leave-one-out (LOO) We replace the tokens in S by the `<pad>` token, and compute the difference in NLL:

$$A(S) = \log P_{\mathrm{M}}(\mathbf{y}|\mathbf{x}) - \log P_{\mathrm{M}}(\mathbf{y}|\mathbf{x}_{S\text{-padded}}). \quad (2)$$

LOO is also referred to as an *occlusion-based method* (Zeiler and Fergus, 2014; Li et al., 2016b) in the literature.

Attention-weight We sum up the attention weights assigned to tokens in S for all attention heads across all decoder layers:

$$A(S) = \sum_{i \in S} \sum_{j,h,l} \alpha_{i,j}^{h,l}. \quad (3)$$

Grad-norm We sum the norm of gradient for the input word embeddings in S:

$$A(S) = \sum_{i \in S} ||\nabla_{\mathbf{h}_i^0} \log P_{\mathrm{M}}(\mathbf{y}|\mathbf{x})||_2. \quad (4)$$

Grad-input-product Instead of taking vector norm, we compute the dot-product between the input embedding and its gradient:

$$A(S) = \sum_{i \in S} \left(\nabla_{\mathbf{h}_i^0} \log P_{\mathrm{M}}(\mathbf{y}|\mathbf{x}) \right) \cdot \mathbf{h}_i^0. \quad (5)$$

While more sophisticated attribution method have been proposed in the literature (Lei et al., 2016; Sundararajan et al., 2017; Bastings et al., 2019), we mainly experiment with the methods listed above due to their simplicity and popularity. Attribution methods have been used for interpreting black-box models—**applying them to derive labels that can further be used to control the focus of a model has to our knowledge not been explored before**.

Which attribution method best reflects the model's inner working is still an active research area (Ding and Koehn, 2021; Adebayo et al., 2018). The present work is primarily concerned with how well the attribution scores align with human-annotated highlights. In our experiments, we find that leave-one-out (LOO) has the best correlation on the human-annotated development set (Table 1, details given in Section 3). We therefore adopt LOO to derive the automatic highlight annotations.

More specifically, for the input-output pairs in the training set, we sort the LOO attribution scores of the sentences in the input from large to small, and mark the tokens in the first few sentences (the exact number varies by task) as highlights. We denote the highlight labels obtained from this automatic procedure by a binary indicator variables $\mathbf{c}^{\mathrm{attr}} = \{c_1^{\mathrm{attr}}, \ldots, c_n^{\mathrm{attr}}\}$, which will be used to train the focus vectors.

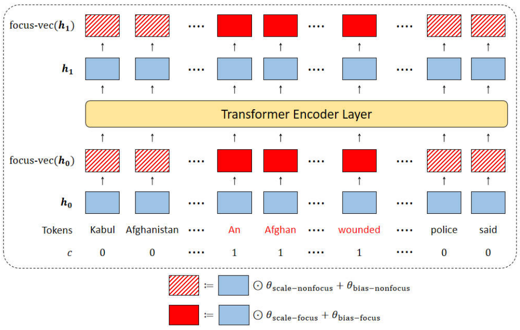


Figure 2: Illustration of our proposed focus vectors applied to a one-layer transformer encoder. The parameters of the transformer model are kept fixed. The highlighted spans are filled by red.

2.2 Focus Vectors

To control the model's focus, we introduce a set of d-dimensional vectors θ, named *focus vectors*. They are designed to act as *indicators* for the model, designating which parts of the input to focus on. We now assume the training set contains $\{\mathbf{x}, \mathbf{c}^{\mathrm{attr}}, \mathbf{y}\}$ triples, where $\mathbf{c}^{\mathrm{attr}}$ is obtained from the attribution method from the previous section. Focus vectors modify the forward pass of the encoder model by applying a simple transformation f on the output embeddings of each layer (including the input layer):

$$f(\mathbf{h}_i^l) = \begin{cases} \mathbf{h}_i^l \odot \theta_{\text{scale-focus}}^l + \theta_{\text{bias-focus}}^l, & \text{if } c_i^{\mathrm{attr}} = 1 \\ \mathbf{h}_i^l \odot \theta_{\text{scale-nonfocus}}^l + \theta_{\text{bias-nonfocus}}^l, & \text{if } c_i^{\mathrm{attr}} = 0 \end{cases}. \quad (6)$$

We provide an illustration in Figure 2. The total number of parameters introduced by the focus vectors is therefore $4 \times (L+1) \times d$, which is negligible in comparison to the large number of parameters of the fixed transformer model. We note that as the focus vectors operate directly on the encoder embeddings, it does not require an explicit attention module to exist in the model and is therefore applicable to non-attentional architectures such as LSTMs (Huang et al., 2015).

We train the focus vectors using the standard NLL loss with stochastic gradient descent (SGD):

$$\mathcal{L}(\mathbf{x}, \mathbf{y}, \mathbf{c}^{\mathrm{attr}}; \theta) = -\log P_{\mathrm{focus}}(\mathbf{y}|\mathbf{x}, \mathbf{c}^{\mathrm{attr}}), \quad (7)$$

where $P_{\mathrm{focus}}(\cdot|\mathbf{x}, \mathbf{c}^{\mathrm{attr}})$ denotes the distribution over the output after the focus vectors are applied. We

Attribution Method	PersonaChat P@1(%)	CNN/Dailymail P@1(%)
attention-weight	29.18	40.31
grad-norm	54.00	43.87
grad-input-product	44.05	32.60
leave-one-out	**62.31**	**64.43**

Table 1: Top-1 precision (%) of different attribution methods on the human-labeled development set.

re-iterate that during training of the focus vectors, the transformer model is kept fixed. This allows the user to default back to the pretrained model (i.e., without applying the focus vectors), if the user prefers not to specify any highlights.

Readers may wonder what is the difference between our approach and standard end-to-end training, as both cases use the same $\mathbf{x}, \mathbf{y}$ pairs. This is related to our key assumption that *different focus of the input lead to different generations*, and the fact that $\mathbf{c}^{\text{attr}}$ is the relevant span for $\mathbf{y}$ in the ideal case. Therefore, the focus vectors have the opportunity to give information about which span is more relevant to $\mathbf{y}$, before the model observes $\mathbf{y}$ on the decoder side. To reduce the loss $-\log P_{\text{focus}}(\mathbf{y}|\mathbf{x}, \mathbf{c}^{\text{attr}})$, the focus vectors need to steer the model's focus towards the spans marked by $\mathbf{c}^{\text{attr}}$.

At test time, the user will highlight several sentences in the input which we denote by $\mathbf{c}^{\text{user}}$. We apply the trained focus vector according to Equation 6, and decode the output from $P_{\text{focus}}(\cdot|\mathbf{x}, \mathbf{c}^{\text{user}})$.

3 Evaluation Data Collection

We test our method on two NLG tasks: dialogue response generation and abstractive summarization. For the dialogue task, we adopt the *PersonaChat* dataset (Zhang et al., 2018). It is an open domain multi-turn chit-chat dataset, where two participants are required to get to know each other by chatting naturally. Each of them is given a *persona*: several pieces of personal information such as *"I major in Computer Science"*, serving as background information. The participants are required to reflect their assigned persona in the conversation. For summarization, we adopt the *CNN/Dailymail* dataset (Hermann et al., 2015; Nallapati et al., 2016), which is a standard dataset for end-to-end abstractive summarization. To save space, we defer details and statistics of the datasets to Appendix A.

Both PersonaChat and CNN/Dailymail are created end-to-end and do not contain annotated highlight spans. **For principled evaluation, we utilize the Amazon Mechanical Turk (AMT) platform to collect evaluation sets where the highlight-generation pairs are annotated by humans.**

For PersonaChat, each turker[2] is shown a dialogue history and the corresponding persona of the speaker. The dialogue history is randomly selected from the original test set of PersonaChat. Then the turker is required to choose 1-3 sentences as highlights (for example, one sentence in persona, and one sentence in dialogue history), and write down a dialogue response that not only continues the current dialogue, but also is relevant to the chosen highlights. Finally, we ask the turker to repeat the above process, but select a different set of highlights and provide another response. After a few preliminary trials and modifications to our instructions / rewards, we find that turkers comply nicely with our instructions and provide high-quality highlight-response pairs.

For CNN/Dailymail however, we first found that turkers had difficulty writing a high-quality summary for a given news article, with many turkers giving random responses even after we increased the reward. This is perhaps unsurprising given that writing a good summary is challenging and the reference summaries are written by experts. After a few disappointing iterations, we turn to a compromise: we directly provide the turkers with the reference summary, and only ask them to select 2-5 relevant sentences in the article. This simplifies the task, and we are able to collect high-quality labels. This compromise is not ideal, as it reverses the order of highlighting and generation. However, we find that in most cases, the reference summaries in CNN/Dailymail are well covered by several "key" sentences in the article, which are highlighted by the turkers. Therefore, we believe this compromise does not hurt the soundness of our evaluation.

In order to ensure high data quality for both dialogue and summarization, we design a qualification test that turkers need to pass before conducting the actual tasks. Several automatic checks and a minimal time limit are added in the scripts to prevent trivial answers. We also manually monitor the incoming submissions, and ban misbehaving turkers and discard their submissions. More details about our AMT setup are provided in Appendix B.

Our final collected datasets include 3,902 highlight-generation pairs for PersonaChat, and 4,159 pairs for CNN/Dailymail. They are randomly split 50/50 into dev/test sets. **We in-**

clude a number of samples of our collected data in the supplementary materials. Our code and the collected dataset will be released in `https://github.com/Question406/LearningToFocus`. We hope that this evaluation data could facilitate future research in this direction.

Comparison of Attribution Methods We use the collected highlight-generation pairs in the dev set to compare which attribution method aligns best with human-annotated highlights. In particular, we compute the top-one precision of the sentence ranked highest by the attribution method. The result is shown in Table 1. We find that for both PersonaChat and CNN/Dailymail, LOO has the best alignment. We therefore use LOO to obtain automatic annotations for focus vector training. Interestingly, we observe low alignment between attention weight-derived attribution scores and human judgment, which indicates that controlling model generations via intervening on the attention distributions may not optimal. Finally, we note that this result does not mean LOO is the "best" attribution method, as attribution method is supposed to reflect the model's inner working, instead of a human's.

4 Experiments

4.1 Experiment Setting and Baselines

We use Blenderbot (Roller et al., 2020) as the base model for PersonaChat and BART (Lewis et al., 2019) for CNN/Dailymail, both of which are standard encoder-decoder transformer models. Our code is based on the *transformers* library (Wolf et al., 2020). We load the pretrained weights from `facebook/blenderbot-400M-distill` and `facebook/bart-base`. Blenderbot has 2 encoder layers and 12 decoder layers, while BART has 6 encoder layers and 6 decoder layers. To help Blenderbot cope with long dialogue context in PersonaChat, we extend its maximum position embedding index from 128 to 256. We use beam-search for decoding, where we follow the recommended configuration (Roller et al., 2020; Lewis et al., 2019) and use a beam size of 10 for Blenderbot and a beam size of 4 for BART.

For both tasks, we first finetune the base model on the original training set in the standard end-to-end manner. The model is then fixed and used to obtain automatic labels $\mathbf{c}^{\text{attr}}$ with the LOO attribution method on the same training set. For each training sample, we select the top-k sentences in the input ranked by LOO. Since we do not know the best value for k, we set it to be a random number from 1 to 3 for PersonaChat, and from 2 to 5 for CNN/Dailymail.

While the highlight labels in the training set used to train focus vectors are derived automatically, we use the human-labeled dev set for hyper-parameter tuning. This is to facilitate fair comparison with other baseline approaches which also utilize the human-labeled dev set. In our ablation study, we will show that this dependence on human-labeled dev set is not crucial for our approach to achieve strong performance. We perform a grid search over learning rate with $\{1,3,5\} \times \{1e^{-4}, 1e^{-3}, 1e^{-2}, 1e^{-1}\}$. The Adam optimizer (Kingma and Ba, 2014) is used with $\beta_1 = 0.9, \beta_2 = 0.999$, and a L2 decay weight of 0.01. For both tasks, we set the mini-batch size to be 16.

We compare the proposed focus-vector approach with several baselines:

Vanilla: The vanilla model, without any modification in both the model and the input.

Padding: One trivial way to control the model's focus is to replace all input by the `<pad>` token, except the spans highlighted by the user. However, we find that this direct padding during evaluation results in drastically worse perplexity. To alleviate this problem, we randomly pad a portion of sentences in the input during the standard end-to-end finetuning, to make the model aware that only partial input would be provided.

Keyword-control: Keyword-based prompts (Fan et al., 2017; He et al., 2020) has been a popular approach for controllable text generation. We adapt this idea to our focus-control setting. During model finetuning, we preprend key-phrases extracted from the reference target sequence to the original input. We utilize Yake (Campos et al., 2020), which is an unsupervised keyword extraction method. During evaluation, we extract and preprend key-phrases extracted from the highlighted sentences.

Attention-offset: As a direct way to control the model's attention, we add a positive scalar offset s^{offset} to the cross-attention heads before the softmax operation (Equation 1), for the highlighted spans. A similar technique has been used in Dong et al. (2021) to *modulate* the attention distribution to tackle neural text degeneration problems (Holtzman et al., 2019). This approach modifies the at-

Model	PersonaChat PPL	PersonaChat ROUGE-1/2/L	PersonaChat BERTScore	CNN/Dailymail PPL	CNN/Dailymail ROUGE-1/2/L	CNN/Dailymail BERTScore
vanilla (w.o. highlight)	28.73	17.02/2.73/14.52	85.41	4.51	43.48/21.01/30.98	89.23
padding	38.93	16.69/2.80/13.72	84.42	19.62	39.31/18.44/28.67	88.34
keyword-control	23.64	17.31/3.02/14.81	85.58	4.56	43.81/21.08/31.15	89.26
attention-offset	23.79	**21.10**/3.77/17.54	86.04	4.49	43.96/20.64/31.26	89.28
focus-vector	**22.51**	20.81/**3.98/17.58**	**86.13**	**4.48**	**45.92/23.03/32.98**	**89.78**

Table 2: Main evaluation results on the PersonaChat and CNN/Dailymail datasets with annotated highlights. The proposed focus vector approach shows strong performance across different metrics.

tention weights via:

$$\alpha'_{i,j} = \underset{i\in\{1\ldots n\}}{\text{softmax}}\left(\frac{k(\mathbf{h}_i^L)\cdot \mathbf{q}_j}{\sqrt{d}} + s^{\text{offset}}\cdot \mathbb{1}_{[c_i=1]}\right), \quad (8)$$

where s^{offset} is a hyper-parameter, and is applied to all cross-attention heads in the decoder. We tune s^{offset} on the human-annotated development set in a fine-grained manner. More details are given in Appendix C.

Whether the attention distribution faithfully explains a model's predictions is the subject of much debate (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Bastings and Filippova, 2020). Therefore this direct modification of the attention head may not be the optimal solution for focus control. Our proposed focus-vector framework, on the other hand, utilizes attribution methods, and directly operates on the encoder embeddings.

4.2 Results and Analysis

During evaluation, human-annotated highlights are fed to the model. In addition to perplexity, we evaluate the generations from different approaches using two popular NLG metrics: ROUGE (Lin, 2004), and BERTScore (Zhang et al., 2019).

We show the main results in Table 2. As expected, the padding baseline has poor performance, as a large portion of input is masked out. Comparing to various baselines, focus-vector obtains significantly improved ROUGE and BERTScore on both tasks. This validates the motivation of this work: focus-vec is effective in steering the model's focus, which leads towards the desired generation. For CNN/Dailymail, the perplexity of focus-vector is close to the vanilla model even though there is a large difference in ROUGE. We believe this is due to the constrained nature of the summarization task and how perplexity is computed: once the model observes the first few tokens, it is easy to figure out what the current highlight is. The other two metrics, on the other hand, are based on the actual generation, and therefore does not have this issue.

The performance of keyword-control, although better than the vanilla model, is inferior to attention-offset and focus-vector. We surmise this is due to the following two weakness: First, key-phrases can not fully represent the highlighted span. Second, there is a discrepancy of where the key-phrases are extracted between training and evaluation.

The performance gap (in ROUGE/BERTScore) between focus-vector and attention-offset is larger on the CNN/Dailymail dataset. We believe this is because the BART model has a deeper encoder than the Blenderbot model. As the encoder grows deeper, the embeddings become more "contextualized" and its *identifiability* (Brunner et al., 2020) degrades. And since the decoder attends to the last layer of the encoder, this direct manipulation of attention weights could be ineffective with deep encoders.

Table 3 shows generation samples from different focus-control approaches for PersonaChat. Spans of the generation that are relevant to the highlighted persona are marked in red. Comparing to the generation from the vanilla model, the generations from both attention-offset and focus-vector are highly relevant to the respective highlighted persona. One generation from att-offset is a little erratic (*"I am petro, my dog"*), which may be due to the inflexibility of att-offset.

We defer the generation examples for CNN/Dailymail to Table 6 and Table 7 (Appendix D) due to space constraints. We observe that the generation from focus-vector is more focused on the highlighted inputs. On the other hand, attention-offset's generation still remains similar to the vanilla model.

In Figure 3, we study how the outputs of attribution methods (attention-weight and grad-norm) change with different approaches (vanilla, focus-vector and attention-offset) for the CNN/Dailymail example (Table 6). Note that in this analysis, for the attribution methods we set the target $\mathbf{y}$ to be the decoded output from the respective modeling,

persona:	**I have a dog named pedro.** I like to eat muffins. I am five feet tall. I work in the healthcare industry.	I have a dog named pedro. I like to eat muffins. I am five feet tall. **I work in the healthcare industry.**
context:	[P-1]: Hello, how are you today? [P-2]: [TO ANSWER]	[P-1]: Hello, how are you today? [P-2]: [TO ANSWER]
reference:	Scared, i'm looking for my dog, his name is pedro. have you seen him?	Really tired, it's so busy in healthcare industry. I wish I can have a long vacation.
vanilla:	Hi! I am doing well, how about yourself? What do you do for a living?	Hi! I am doing well, how about yourself? What do you do for a living?
keyword:	I am doing well, how about yourself? What do you like to do for fun?	I am doing well. how about you? What do you do for a living? I am in healthcare.
att-offset:	I am doing well, and you? I am petro, my dog, and you?	I am doing well, and you? I am a healthcare worker in the health industry.
focus-vec:	I am good. Just got back from walking my dog. Do you have any pets?	I am doing well. How about you? What do you do for a living? I am in healthcare.

Table 3: Generation samples from different attention control approaches for PersonaChat. The inputs on both sides are identical, except a different piece of persona is highlighted (marked in bold), which leads to different generations for approaches with control. Another example is provided in Table 5 (Appendix D).

instead of the reference summary. The highlighted sentences are marked by the red rectangles.

We observe that for both attention-weight and grad-norm, the application of focus vector makes the highlighted sentences obtain the highest attribution scores, and the scores differ significantly from the vanilla model. In some of the non-highlighted sentences (marked by the blue rectangles), attention-offset is not strong enough to significantly reduce its attribution. We also tried larger values of s^{offset} for attention-offset but found it lead to performance degradation. This analysis shows that despite the small number of parameters associated with the focus vectors, they are able to effectively steer the model's focus. We provide a simple visualization of the trained focus-vector parameters in Figure 3 (Appendix D).

Ablation Studies Table 4 shows several variants of focus vector on CNN/Dailymail. We first tune the hyper-parameters of focus vector only with the original dev set with $\mathbf{c}^{\text{attr}}$, instead of human-annotated highlights. Despite this discrepancy, focus vector still achieves strong performance on the test set. This result shows that the use of human-annotated dev set is not crucial for our framework. We then conduct an ablation study where we only apply focus vector on the first or last layer of the encoder, which reduces the number of parameters. We find that this results in marginal performance degradation. Finally, we jointly finetune focus vector and the whole model with the same loss function (Equation 7), where a separate and smaller learning rate is used for the model. Interestingly, the gain from model finetuning is very limited, which demonstrates the effectiveness of focus vector.

Model	**CNN/Dailymail**		
	PPL	**ROUGE-1/2/L**	**BERTScore**
all-layer*	4.48	45.92/23.03/32.98	89.78

5 Related Work

Our proposed focus-vector framework is closely related to the research topics of controllable text generation, LM adaptation, and attention/attribution analysis, which we review below.

Controllable Text Generation Prior work on controllable summarization introduced various types of control mechanisms. Fan et al. (2017); Saito et al. (2020) extract entity, keyword or length, as additional supervision during training. Gehrmann et al. (2018) trains a token-level content selection module, where the supervision is by aligning the summaries to the documents. (Song et al., 2021) proposes a two-staged generation strategy and Goyal et al. (2021) incorporates multiple decoders into a transformer framework. Some recent work (He et al., 2020; Dou et al., 2020) uses prompts to control the generation. Lexically constrained decoding (Post and Vilar, 2018) has also been used to enforce certain key phrases to be included in the summary (Mao et al., 2020).

Existing work on controllable dialogue response generation include using conditional variational au-

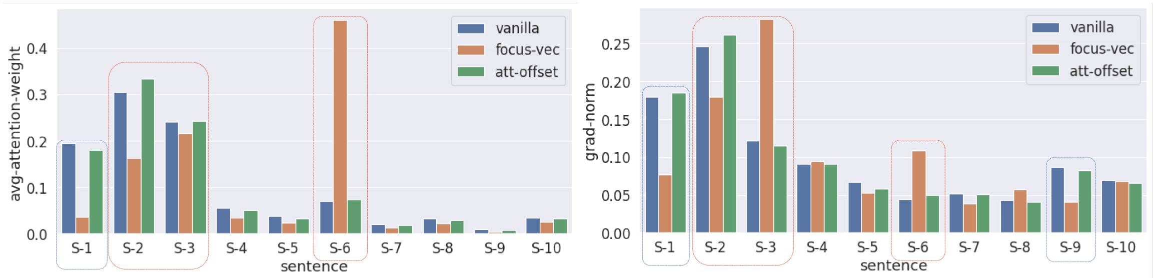

Figure 3: Attribution scores for each sentence in the input, with different focus-control approach applied to BART. The highlighted sentences are marked by red rectangles. The corresponding example is in Table 6 (Appendix D).

toencoders (Zhao et al., 2017; Li et al., 2020a), and incorporating external knowledge into the conversational agent using knowledge graphs (Cui et al., 2021; Moon et al., 2019), unstructured documents (Kim et al., 2020), or dialogue context (Zhao et al., 2020). There is also a line of work on promoting the diversity or consistency of the model (Li et al., 2016a; He and Glass, 2019; Li et al., 2020b).

In open-ended language generation, a series of approaches have been proposed to control for some attribute (e.g., topic) of the generation (Keskar et al., 2019; Dathathri et al., 2020; Krause et al., 2020; Yang and Klein, 2021). Some of these studies utilize a trained classifier to guide the generative model towards the desired attribute.

LM Adaptation Our proposed focus vector framework is also inspired by a series of recent works on prompting or light-weight LM adaptation. Li and Liang (2021), followed by Lester et al. (2021) and Zhong et al. (2021), propose *prefix tuning*, where continuous task-specific input vectors are tuned to adapt the pretrained LM to a downstream task with supervised data, and the model is kept fixed.

There is also a line of works on *adapter-tuning*, which insert and finetune task-specific layers (adapters) between each layer of the pretrained LM (Houlsby et al., 2019; Lin et al., 2020; Pfeiffer et al., 2021). More recently, Guo et al. (2021) and Ben-Zaken et al. (2020) propose to finetune only a small subset of a pretrained model's parameters, and achieves strong performance on GLUE or other tasks (Wang et al., 2018; He et al., 2021).

Attention Analysis and Attribution Methods Due to the ubiquity of the attention module in current NLP models, various work has studied how the module captures linguistic phenomena in the input (Clark et al., 2019; Kovaleva et al., 2019; Kobayashi et al., 2020). It has also been used as a tool to interpret the model's predictions (Wang et al., 2016; Lee et al., 2017; Ghaeini et al., 2018).

Recently, there have been a series of studies discussing the use of attention weights for interpretability (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Bastings and Filippova, 2020; Serrano and Smith, 2019), and it has been argued that attribution methods are a better choice to explain the model's predictions. The poor alignment performance of attention weights that we get in Table 1, on some level, are in agreement with that argument. Our work is also related to the line of work on interpreting black box models through *rationales* (Lei et al., 2016; Bastings et al., 2019), which are typically (discrete) subsets of the input that are used to predict the output. Finally, several recent works (Xu and Durrett, 2021; Ding and Koehn, 2021) have compared different attribution methods for interpreting NLP models.

In comparison to the aforementioned works, our major innovations are two fold: (1) Our goal is to control the *focus* of pretrained models, and thereby steer the model's generation, and our proposed focus vectors are compatible with the standard transformer architecture; (2) We utilize attribution methods to obtain automatic annotations for focus-vector training. Therefore, our framework can be applied to a wide range of NLG applications.

6 Conclusion

In this work we propose the focus vector framework as a light-weight solution to control the focus of pretrained transformer models. It has two major advantages: (1) Focus vectors act as simple transformations to the embeddings in the encoder, and the transformer model is kept fixed; (2) Attribution methods are utilized to get automatic highlight labels for training focus vectors.

We test our approach on two tasks: dialogue response generation, and abstractive summarization. For evaluation, we collect data where the highlight-generation pairs are annotated by humans. Experiments show that the trained focus vectors are effective in steering the model to generate output text that is relevant to the specified highlights.

Appendices

A End-to-end Datasets

The PersonaChat dataset contains 8,939 dialogues for training, 1,000 for validation, and 968 for test. For each turn in the dialogue, we concatenate the persona of the speaker and the dialogue history as input, and train the base model to generate the current utterance. In some cases, the dialogue history is long and exceeds the input limit of the model, in which case we truncate the dialogue at the sentence level. The average number of sentences is around 11 after truncation.

The CNN/Dailymail dataset contains 287,113 training examples, and 13,368 / 11,490 examples for validation / test. We apply the same truncation strategy as *PersonaChat* during preprocessing. The processed articles have an average length of 748 tokens, and the reference summaries have an average length of 67 tokens.

B Human-annotated Evaluation Data Collection

To improve the quality of collected dataset, we design a qualification test, which the turkers need to pass before they can work on real assignments. The test is designed to help turkers understand our task better. For PersonaChat, we give turkers two dialogue samples with pre-selected highlights, and ask them to choose the appropriate response that not only continues the dialogue, but also is relevant to the highlights. For CNN/Dailymail , the turkers are shown two example articles and the corresponding reference summaries. We have already picked some highlights in the article, but there is one highlight missing. And the turker is required to pick the missing highlight. The interface for the PersonaChat qualification test is shown in Figure 5.

We also add multiple checks in our script to prevent trivial answers. We ban trivial copy&paste from the given context. A time check is added that requires turker to spend at least 60 seconds on a single HIT. For the two assignments in PersonaChat, we add a content check that prevents duplicate highlights or response. We show our interface for PersonaChat in Figure 6. Despite these checks and the qualification tests, there still exist a small number of misbehaving turkers who attempt to cheat. Therefore we also manually monitor the incoming submissions, and ban misbehaving turkers and filter out their submissions.

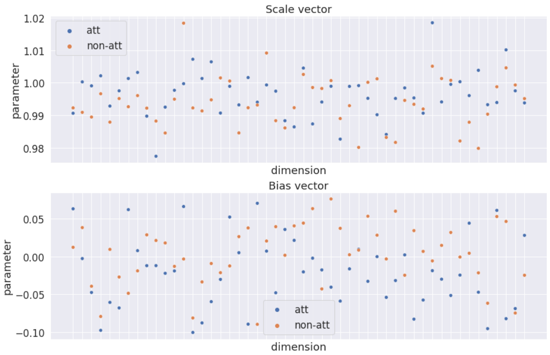

Figure 4: 50 random dimensions of the trained focus vector on first encoder layer of the BART model.

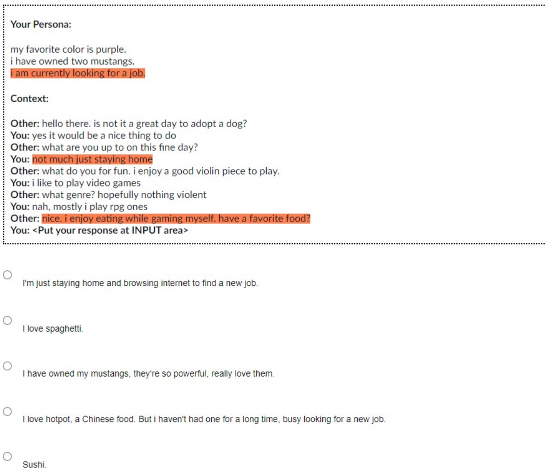


Your Persona:

my favorite color is purple.
i have owned two mustangs.
i am currently looking for a job.

Context:

Other: hello there. is not it a great day to adopt a dog?
You: yes it would be a nice thing to do
Other: what are you up to on this fine day?
You: not much just staying home
Other: what do you for fun. i enjoy a good violin piece to play.
You: i like to play video games
Other: what genre? hopefully nothing violent
You: nah, mostly i play rpg ones
Other: nice. i enjoy eating while gaming myself. have a favorite food?
You: <Put your response at INPUT area>

○ I'm just staying home and browsing internet to find a new job.

○ I love spaghetti.

○ I have owned my mustangs, they're so powerful, really love them.

○ I love hotpot, a Chinese food. But i haven't had one for a long time, busy looking for a new job.

○ Sushi.

Figure 5: An example of our AMT qualification test for PersonaChat. We have chosen the highlights in the context, and the turker is supposed to choose a response that not only continues the dialogue, but also is relevant to the highlights.

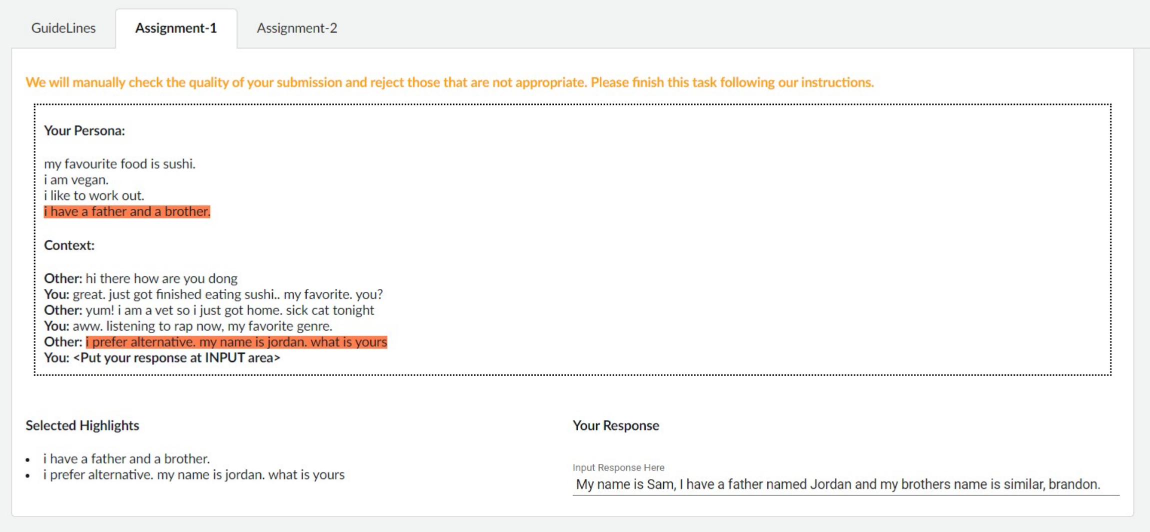
More examples of our interface and instructions can be found in our uploaded data samples.

C Implementation Details

For the attention-offset baseline, we tune the offset s^{offset} in a fine-grained manner, on the human-annotated dev set. We first set a relatively large max value (100) and get 20 evenly spaced numbers inside the interval $(0, 100)$. Then we calculate model PPL on the dev set with s^{offset} set to these different offsets. Then we do another search in the interval that has lowest PPL. We repeat this iteration multiple times, and stops when PPL change is smaller than $1e^{-3}$. The final tuned value for Blenderbot is around 3.02, and around 0.17 for BART.

D Auxiliary Results and Examples

In Figure 4, we provide a simple visualization of the trained focus vectors of BART. To make the



We will manually check the quality of your submission and reject those that are not appropriate. Please finish this task following our instructions.

Your Persona:

my favourite food is sushi.
i am vegan.
i like to work out.
i have a father and a brother.

Context:

Other: hi there how are you dong
You: great. just got finished eating sushi.. my favorite. you?
Other: yum! i am a vet so i just got home. sick cat tonight
You: aww. listening to rap now, my favorite genre.
Other: i prefer alternative. my name is jordan. what is yours
You: <Put your response at INPUT area>

Selected Highlights

- i have a father and a brother.
- i prefer alternative. my name is jordan. what is yours

Your Response

Input Response Here
My name is Sam, I have a father named Jordan and my brothers name is similar, brandon.

Figure 6: An example of our AMT interface on PersonaChat. The highlights and a response are labeled by a turker.

figure easy to grasp, we randomly sample 50 dimensions (out of 768) of trained focus-vector parameters. In the figure only the trained parameters for the first encoder layer is shown, and we find that the patterns for the other layers are similar.

We first find that the learned scaling parameters are close to 1 and the bias parameters are close to zero. This implies that the transformation defined by the focus-vec is not drastic, and a relatively small tweak could be enough to steer the model's focus.

An interesting pattern can be observed for the scaling vectors. $\theta_{\text{scale-nonfocus}}$ tends to down-scale the embedding, comparing to $\theta_{\text{scale-focus}}$. This matches our intuition that the embeddings on the non-highlighted positions should be down-played.

persona:	My parents did not want me. **It's a dead end job so i am looking for something different.** I was raised by my uncle and aunt.	My parents did not want me. It's a dead end job so i am looking for something different. **I was raised by my uncle and aunt.**

Comparative Opinion Summarization via Collaborative Decoding

Hayate Iso[♌] **Xiaolan Wang**[♌] **Stefanos Angelidis**[⅄] **Yoshihiko Suhara**[♌]
[♌]Megagon Labs [⅄]University of Edinburgh
`{hayate,xiaolan,yoshi}@megagon.ai` `s.angelidis@ed.ac.uk`

Abstract

Opinion summarization focuses on generating summaries that reflect popular subjective information expressed in multiple online reviews. While generated summaries offer general and concise information about a particular hotel or product, the information may be insufficient to help the user compare multiple different choices. Thus, the user may still struggle with the question "Which one should I pick?" In this paper, we propose the *comparative opinion summarization* task, which aims at generating two contrastive summaries and one common summary from two different candidate sets of reviews. We develop a comparative summarization framework CoCoSum, which consists of two base summarization models that jointly generate contrastive and common summaries. Experimental results on a newly created benchmark CoCoTrip show that CoCoSum can produce higher-quality contrastive and common summaries than state-of-the-art opinion summarization models. The dataset and code are available at `https://github.com/megagonlabs/cocosum`.

1 Introduction

Widely available online customer reviews help users with decision-making in a variety of domains (e.g., hotel, restaurant, or company). After creating a list of candidate choices based on initial conditions (e.g., area, price range, restaurant type), the user often has to compare a few choices in depth by carefully reading the reviews to make a final decision. However, it is time-consuming and difficult for the user to detect differences and similarities between the candidates, as those pieces of information are often scattered in different reviews.

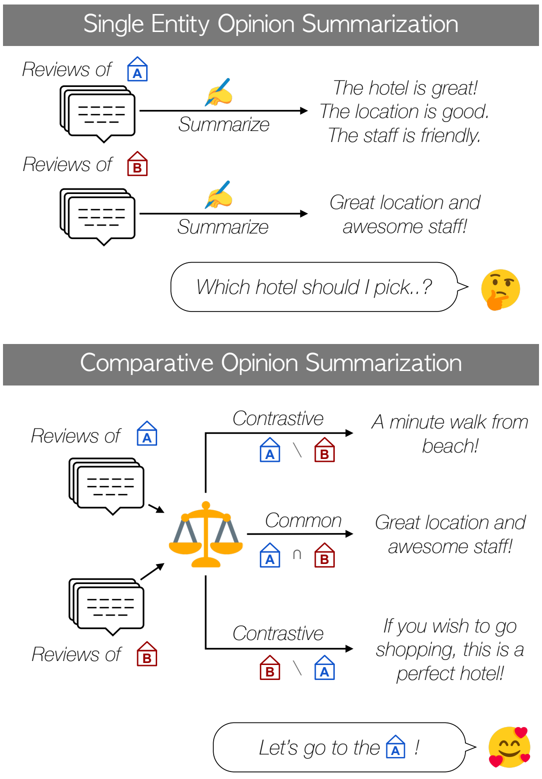

Figure 1: Overview of the comparative opinion summarization task. The model takes two set of reviews about different entities to generate two contrastive opinion summaries, which contain distinctive opinions, and one common opinion summary, which describes common opinions between the two entities.

The recent success of neural summarization techniques and the growth of online review platforms led to establishing the field of multi-document opinion summarization (Chu and Liu, 2019; Bražinskas et al., 2020b; Amplayo and Lapata, 2020; Suhara et al., 2020; Iso et al., 2021). The goal of multi-document opinion summarization is to generate a summary that represents salient opinions in input reviews of a particular hotel or product, which we refer to as an entity. However, existing opinion summarization techniques are designed to generate a *single-entity opinion* summary that reflects popular opinions for each entity, without taking into account *contrastive and common opinions* that are uniquely (commonly) mentioned in each entity (both entities) as depicted in Figure 1. Therefore, the user still needs to figure out which opinions are

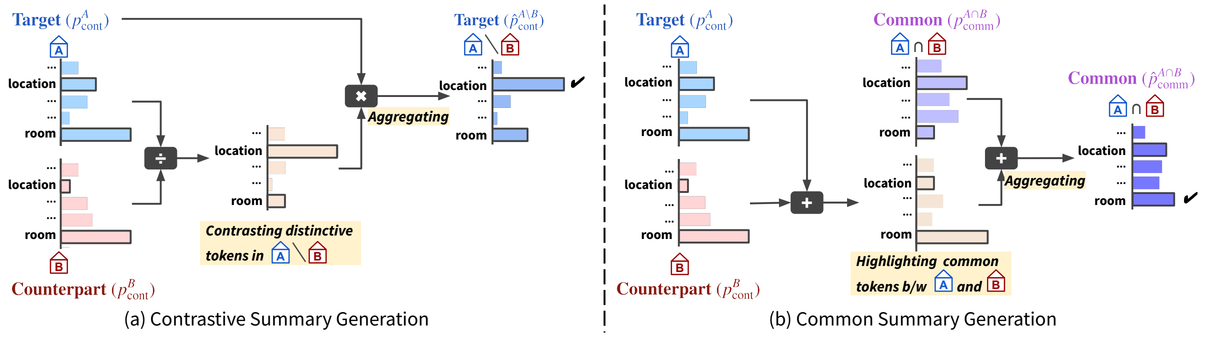

Figure 2: Illustration of Co-decoding: (a) For contrastive summary generation, distinctive words are emphasized by *contrasting* the token probability distribution of target entity against that of the counterpart entity. (b) For common summary generation, entity-pair-specific words are highlighted by *aggregating* token probability distributions of all base models to alleviate the overly generic summary generation issue.

contrastive or common between the entities by carefully reading and comparing summaries generated by existing opinion summarization solutions.

To this end, we take one step beyond the current scope of opinion summarization and propose a novel task of generating contrastive and common summaries by comparing multiple entities, which we refer to as *comparative opinion summarization*. In contrast to the conventional single-entity opinion summarization task that makes a general summary for each entity, the goal of comparative opinion summarization is to generate two contrastive summaries and one common summary from two sets of reviews about two entities. Thus, the user can easily understand distinctive and common opinions about multiple entities. In this paper, we consider pairwise comparison as it is the most common choice and the minimal unit for multiple comparisons.

A key challenge of building a summarizer for the task is that the model has to correctly distinguish what contrastive and common opinions from input reviews of two entities are. Existing opinion summarization models do not implement this functionality as they are designed to summarize popular opinions for a single entity.

To address this issue, we develop a comparative opinion summarization framework CoCoSum, which consists of two base summarization models for contrastive and common opinion summary generation. CoCoSum employs a novel Collaborative Decoding (Co-decoding) algorithm that takes two review sets as input to *compare and contrast* the token probability distributions of the models to generate more distinctive summaries as illustrated in Figure 2.

Experimental results on a newly created comparative opinion summarization benchmark CoCoTrip show that CoCoSum with Co-decoding generate substantially high-quality contrastive and common summaries compared to baseline models including state-of-the-art opinion summarization models.

Our contributions are as follows:

- We propose the novel task of comparative opinion summarization, which takes two review sets as input and outputs two contrastive summaries and one common summary.
- We develop CoCoSum, which consists of two base summarization models and implements a novel Co-decoding algorithm that facilitates generating distinctive and entity-pair-specific summaries by aggregating the token probability distributions of the models.
- We create and release a comparative opinion summarization benchmark CoCoTrip that contains manually written reference summaries for 48 entity pairs.

2 Comparative Opinion Summarization

2.1 Problem Formulation

Let $\mathcal{C}$ be a corpus of reviews on entities from a single domain (e.g., hotels). For each entity e, we define its review set $\mathcal{R}_e = \{r_{e,1}, r_{e,2}, \ldots, r_{e,|\mathcal{R}_e|}\}$.

We define *contrastive opinions* of a target entity A against a counterpart entity B as subjective information that is described only in $\mathcal{R}_A$ but not in $\mathcal{R}_B$ and refer to the summary that contains such contrastive opinions as a *contrastive summary* $y^{A\setminus B}_{\text{cont}}$. Similarly, we define *common opinions* of entities A and B as subjective information that is commonly described in $\mathcal{R}_A$ and $\mathcal{R}_B$ and refer to the summary that contains common opinions as a *common summary* $y^{A\cap B}_{\text{comm}}$. Note that $y^{A\cap B}_{\text{comm}}$ and $y^{B\cap A}_{\text{comm}}$

are identical, thus we consider a single common summary for an entity pair.

We formalize *comparative opinion summarization* as a task to generate two sets of contrastive summaries $y_{\text{cont}}^{A\setminus B}$, $y_{\text{cont}}^{B\setminus A}$, and one common summary $y_{\text{comm}}^{A\cap B}$ from two sets of reviews $\mathcal{R}_A$ and $\mathcal{R}_B$ for a pair of entities A and B. Compared to existing summarization tasks, comparative opinion summarization is the first work that aims to generate abstractive summaries for contrastive and common opinions.

2.2 The CoCoTrip Corpus

As the task requires three types of reference summaries for each *entity pair*, none of the existing benchmarks for single-entity opinion summarization can be used for evaluation. Therefore, we create a comparative opinion summarization corpus CoCoTrip that contains human-written contrastive and common summaries for 48 pairs of entities. We sampled the entity pairs and reviews from the TripAdvisor corpus (Wang et al., 2010).

We sampled 16 reviews for every pair (i.e., 8 reviews for each entity). For every entity pair, we collected 3 gold-standard summaries written by different annotators for two contrastive summaries and one common summary. Details of the corpus creation process are described in Appendix.

We summarize the CoCoTrip dataset and compare it with existing opinion summarization datasets in Table 1. We calculate novel n-grams in gold summaries to evaluate how abstractive/extractive CoCoTrip is. Considering the input and summary length, we confirm that CoCoTrip is sufficiently abstractive compared to the existing opinion summarization datasets.

3 CoCoSum

In order to summarize contrastive and common opinions from two sets of reviews, the comparative opinion summarization task requires the model to compare and contrast two sets of reviews; however, existing single-entity opinion summarization models do not have such functionality. Therefore, we design a "collaborative" decoding solution Co-decoding, which characterizes the target summary distribution by leveraging two base summarization models.

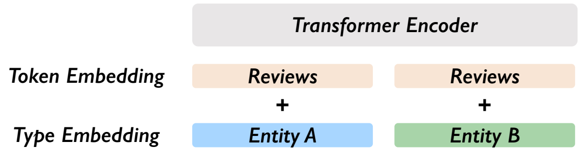

Figure 3: Encoder of the base common summarization model has *type embeddings* to distinguish the original entity.

3.1 Base Summarization Model

CoCoSum consists of two base summarization models. The base contrastive summarization model is a single-entity summarization model that takes only reviews of the target entity as input, while the base common summarization model takes reviews of two entities as input. In both cases, the input reviews are concatenated into a single sequence before encoding. To help the encoder distinguish the entity, we introduce additional *type embeddings* into the input layer of the encoder as shown in Figure 3.

For common summary generation (i.e., $y_{\text{comm}}^{A\cap B} = y_{\text{comm}}^{B\cap A}$), the model should generate the same common summary for the same entity pair regardless of the input order of review sets. Thus, we create two input sequences (i.e., $A \cap B$ and $B \cap A$) and merge the token probability distributions of the two sequences for a summary generation.

3.2 Collaborative Decoding

As illustrated in Figure 2, Co-decoding combines predictions of the target and the counterpart (and common, for common summary generation) opinion summarization models during the inference time. The key idea of Co-decoding is to aggregate token probability distributions of contrastive summarization model $p_{\text{cont}}(\cdot)$ and common summarization model $p_{\text{comm}}(\cdot)$ at each step, so the two models can collaboratively generate (1) contrastive summaries that contain distinctive opinions that do not appear in the counterpart review set and (2) common summaries that only contain common opinions that appear in both target and counterpart review sets.

Contrastive summary generation To improve the distinctiveness of generated contrastive summaries that only contains entity-specific opinions, we consider *penalizing* the tokens that are likely to appear in the counterpart entity. That is, we use two token probability distributions and highlight tokens that are distinctive compared to the coun-

	Task	Input length	Summary length	Domain	% of novel n-grams in gold summary			
					unigram	bigram	trigram	4-gram
CoCoTrip (Ours)	Contrastive	1529.4	132.9	Hotels	22.81	72.41	91.43	97.08
	Common		20.3		9.27	51.75	84.52	95.75
Chu and Liu (2019)	Single	581.1	70.4	Businesses	30.87	83.23	96.60	99.18
Bražinskas et al. (2020b)	Single	473.4	59.8	Products	26.23	77.52	93.24	97.43
Angelidis et al. (2021)	Single	16160.6	83.6	Hotels	1.98	21.13	47.14	63.86

Table 1: Statistics of CoCoTrip and other benchmarks. CoCoTrip has a comparable corpus size against the benchmarks while offering unique characteristics (i.e., three types of reference summaries for a pair of entities). The average input length in tokens is calculated using concatenated input reviews.

terpart entity by using the *token ratio distribution* between them. We also introduce a trade-off hyperparameter δ that controls the balance between the original token distribution and the token ratio distribution:

$$\hat{p}^{A\setminus B}_{\text{cont}}(y_t) \propto p^{A}_{\text{cont}}(y_t)\left(\frac{p^{A}_{\text{cont}}(y_t)}{p^{B}_{\text{cont}}(y_t)}\right)^{\delta}, \qquad (1)$$

where we denote the token probability distribution of the base contrastive summarization model given the previously generated tokens $y_{<t}$ and the set of input reviews $\mathcal{R}_e$ for entity $e \in \{A, B\}$ at t-th step by $p^{e}_{\text{cont}}(y_t) := p_{\text{cont}}(y_t \mid y_{<t}, \mathcal{R}_e)$. Note that for both $p^{A}_{\text{cont}}(y_t)$ and $p^{B}_{\text{cont}}(y_t)$, we use the same prefix $y_{<t}$. For the other contrastive summary $\hat{y}^{B\setminus A}_{\text{cont}}$, the token probability can be obtained by swapping A and B in Eq. (1).

Co-decoding for contrastive summary generation is illustrated in Figure 2 (a). The intuition behind this approach is that the token ratio distribution $\frac{p^{A}_{\text{cont}}(y_t)}{p^{B}_{\text{cont}}(y_t)}$ (i.e., $A \land \neg B$) highlights distinctive tokens that are relatively unique to the target entity, which are emphasized by combining with the original token distribution. This can be considered a variant of Product-of-Experts (PoE) (Hinton, 2002; Liu et al., 2021), which models Logical AND with multiple probabilistic distributions.

Common summary generation Common summaries should contain common opinions that are about a given pair of entities. However, we observe that simply fine-tuned summarization models tend to generate overly generic summaries that can be true for any entity pair.

To incorporate the entity-specific information into the common summary, we design Co-decoding to use the sum of the token probability distributions of the contrastive summarization model, which is then combined with the original token probability distribution using a trade-off hyperparameter γ:

$$\hat{p}^{A\cap B}_{\text{comm}}(y_t) \propto p^{A\cap B}_{\text{comm}}(y_t) + \gamma \sum_{E\in\{A,B\}} p^{E}_{\text{cont}}(y_t), \qquad (2)$$

where we denote the token probability distribution of the base common summarization model by $p^{A\cap B}_{\text{comm}}(y_t) := p_{\text{comm}}(y_t \mid y_{<t}, \mathcal{R}_A, \mathcal{R}_B)$.

Co-decoding for common summary generation is illustrated in Figure 2 (b). The intuition behind this approach is that we first identify salient tokens for the input entity pair by adding the token probability distributions of contrastive summaries: $p^{A}_{\text{cont}}(y_t) + p^{B}_{\text{cont}}(y_t)$ (i.e., $A \lor B$), which is then combined with the original distribution using the trade-off hyperparameter γ. This can be considered a variant of Mixture-of-Experts (MoE) (Jacobs et al., 1991), which models Logical OR with multiple probabilistic distributions and is suitable for *interpolating* the token probability distribution of models with different characteristics.

We would like to emphasize that Co-decoding is a token probability distribution calculation method for comparative opinion summarization based on two summarization models; thus, it is flexible of the choice of the base summarization model and the decoding algorithm.

4 Evaluation

4.1 Experimental Settings

We build two versions of CoCoSum using self-supervised training (Self-supervised) and few-shot learning (Few-shot). We evaluate the summarization performance of the two versions with and without Co-decoding. For all the base models, we use a pre-trained LED model (Beltagy et al., 2020), which uses sparse attention to handle long sequences and thus is suitable for the purpose.[1]

w/o Co-decoding ($\delta = \gamma = 0$.)	**43.65**	**12.83**	**24.93**	35.42	45.90	19.59	34.40	59.32	71.69
Human upper bound	47.37	13.00	26.03	37.69	52.26	19.16	39.89	61.10	71.79

Table 2: ROUGE and BERT scores (summarization quality) for contrastive and common summaries on CoCoTrip and the distinctiveness score (DS) of generated summaries. CoCoSum significantly improves the distinctiveness while keeping high summarization quality. Human upper bound is measured by calculating the corresponding score across multiple reference summaries.

For self-supervised training, we use the TripAdvisor review corpus (Wang et al., 2010) to construct pseudo review-summary pairs following Elsahar et al. (2021) with two modifications: 1) We filter reviews with different word length ranges for contrastive ($[100, 150]$) and common ($[15, 50]$) base models to accommodate the different average summary lengths. 2) For the self-supervised base common summarization model, as it takes two sets of reviews (i.e., $\mathcal{R}_A$, $\mathcal{R}_B$) as input, we retrieve and merge review-summary pairs, based on the summary similarity, to make a pseudo training dataset.

For few-shot learning, we use 20 instances of CoCoTrip for further fine-tuning self-supervised base summarization models. Detailed analysis of the few-shot learning strategies can be found in Appendix.

For evaluation, we used the remaining 10 instances of CoCoTrip for development and 18 instances for testing.

For Co-decoding, we used top-p vocabulary (Holtzman et al., 2020), which is the smallest token set whose cumulative probability exceeds p, with $p = 0.9$ for $p^{A}_{\text{cont}}(y_t)$, $p^{B}_{\text{cont}}(y_t)$, and $p^{A \cap B}_{\text{comm}}(y_t)$. We used Beam Search with a width of 4. We chose δ and γ using the dev set.

To access the quality of CoCoSum, we evaluated the performance of a variety of baseline approaches:

LexRank$_{\text{TFIDF}}$ (Erkan and Radev, 2004): The classic unsupervised opinion summarization solution;

LexRank$_{\text{BERT}}$ (Erkan and Radev, 2004; Reimers and Gurevych, 2019): LexRank approach with Sentence BERT (Reimers and Gurevych, 2019) embeddings[2];

MeanSum (Chu and Liu, 2019): the unsupervised single entity opinion summarization solution[3];

CopyCat (Bražinskas et al., 2020b): a single entity opinion summarization solution based on leave-one-out reconstruction[4];

BiMeanVAE (Iso et al., 2021): an optimized single entity opinion summarization solution[5] for MeanSum.

For those baseline models above, we use $\mathcal{R}_A$ (or $\mathcal{R}_B$) as input for the contrastive summary and both $\mathcal{R}_A$ and $\mathcal{R}_B$ as input for the common summary.

OpinionDigest (Suhara et al., 2020): a weakly supervised opinion summarization approach.[6] We customize OpinionDigest for comparative opinion summarization. Specifically, we categorize opinion clusters extracted from $\mathcal{R}_A$ and $\mathcal{R}_B$ as "contrastive" if the cluster only contains opinions from a single entity and "common" if the cluster contains opinions from both of the entities. In this way, OpinionDigest can leverage the extracted

opinion clusters to generate contrastive and common summaries.

4.2 Automatic Evaluation

Evaluation metrics For summarization quality, we use ROUGE 1/2/L F1 scores (Lin, 2004)[7] and BERTScore (Zhang et al., 2020)[8] as automatic evaluation based on reference summaries.

To evaluate the *distinctiveness* of generated summaries, we calculate the average distinctiveness score (DS) between generated contrastive summaries and common summaries for all entity pairs defined as follows:

$$\mathrm{DS} = 1 - \frac{\sum_{(y,z)\in\hat{\mathcal{Y}}^{(2)}} |\mathcal{W}_y \cap \mathcal{W}_z| - 2|\bigcap_{y\in\hat{\mathcal{Y}}} \mathcal{W}_y|}{|\bigcup_{y\in\hat{\mathcal{Y}}} \mathcal{W}_y|},$$

where $\hat{\mathcal{Y}} := \{\hat{y}^{A\setminus B}_{\text{cont}}, \hat{y}^{B\setminus A}_{\text{cont}}, \hat{y}^{A\cap B}_{\text{comm}}\}$, $\mathcal{W}_y$ is the token bag of generated summary $y \in \hat{\mathcal{Y}}$, and $\hat{\mathcal{Y}}^{(2)}$ is the 2-subsets of $\hat{\mathcal{Y}}$. The DS will be higher if the word overlaps between two generated contrastive summaries $\hat{y}^{A\setminus B}_{\text{cont}}$, $\hat{y}^{B\setminus A}_{\text{cont}}$, and a generated common summary $\hat{y}^{A\cap B}_{\text{comm}}$ are smaller.

Results As shown in Table 2, CoCoSum outperforms the baseline methods for the ROUGE and BERT scores (summarization quality) and the distinctiveness score (DS), showing the effectiveness of our self-supervised dataset and Co-decoding. Comparing the summarization quality by CoCoSum and CoCoSum w/o Co-decoding, we confirm that Co-decoding significantly improves the distinctiveness especially in self-supervised setting while maintaining the summarization performance.

Among the baseline methods, BiMeanVAE shows the highest ROUGE scores while performing poorly for the distinctiveness score. Although MeanSum and OpinionDigest show high distinctiveness scores, they show significantly worse performance on the common summary generation task. The results indicate it is challenging for existing opinion summarization models to improve the distinctiveness of generated summaries while keeping them high-quality for both of the tasks.

4.3 Human Evaluation

For human evaluation, we hired contractors from Upwork[9] platform and conducted three sets of human evaluation comparing CoCoSum with two representative baselines—BiMeanVAE and OpinionDigest.

First, we asked the human annotators to evaluate the overlapped content between the contrastive summaries and the common summary for a given entity pair. More specifically, for every sentence in the summary, we asked human annotators to judge if its content is *overlap*, *partially overlap*, or *not overlap* with the other two summaries. According to the problem formulation, less overlap, i.e., not or partially overlap, is preferred. As shown in Table 3, CoCoSum is significantly better than CoCoSum w/o Co-decoding, and is substantially better than BiMeanVAE and OpinionDigest. This result also aligns with our automatic evaluation on the distinctiveness (DS in Table 2), and it demonstrates that CoCoSum can produce more *distinctive* contrastive and common summaries.

Second, we conducted a summary content support study to evaluate how faithful the generated summaries are toward the input reviews. Similar to content overlap, for every sentence in the summary, we asked human annotators to judge if its content is *fully supported*, *partially supported*, or *not supported* by the corresponding input review sentences. Note that the input review sentences are selected based on sentence-level labels we acquired from CoCoTrip. The results show that CoCoSum is able to generate the most faithful

---

[8] DeBERTa NLI model (He et al., 2021) and baseline rescaling are used.

[9] `https://www.upwork.com`

summaries compared to all the other baselines.

Lastly, we asked the human annotators to give ratings (from 1 to 5) for the generated summaries with respect to three criteria, namely *coherence*, *informativeness*, and *non-redundancy*. We report the average ratings (Harpe, 2015) for the summaries generated from different methods in Table 3. As shown in the table, summaries generated by CoCoSum is slightly less coherent than CoCoSum w/o Co-decoding. This slight degradation is expected because Co-decodingadjusts the token probability to encourage contrastive/common content, thus it may also prioritize tokens that are less coherent. Other than coherence, CoCoSum shows slightly better informativeness and non-redundancy. Meanwhile, compared to BiMeanVAE and OpinionDigest, CoCoSum shows much better performance on all the three criteria.

5 Analysis

5.1 Distinctiveness in Generated Summaries

In addition to the summarization quality, distinctiveness is another important factor for comparative opinion summarization to help the user pick one against the other. Therefore, we conduct additional analysis to investigate the quality of distinctiveness in generated summaries.

How distinctive are generated contrastive summaries for each entity pair? To complement our experiments on the distinctiveness score (in Table 2), which considers both types of generated summaries, we further evaluate *intra-entity-pair BERTScore (Intra-BERTScore)* only between two contrastive summaries for each entity pair to measure the *intra-entity-pair distinctiveness* defined by the average of BERTScore($\hat{y}^{A\setminus B}_{\text{cont}}, \hat{y}^{B\setminus A}_{\text{cont}}$).

Figure 4 shows that in both self-supervised and few-shot settings, CoCoSum significantly outperforms the state-of-the-art opinion summarization model (BiMeanVAE). The results confirm that Co-decoding successfully generates more distinctive opinions of each other, and the hyperparameter δ controls the trade-off between the summarization quality (BERTScore) and the distinctiveness (Intra-BERTScore).

5.2 Analysis on Co-decoding Design

Our design of Co-decoding uses different types of distribution aggregation methods for contrastive (Eq. (1)) and common summary generation (Eq. (2)). To support those intuitive designs, we examine how the quality of generated summaries is affected when different configurations in Co-decoding are used for each task. The full table is presented in the Appendix.

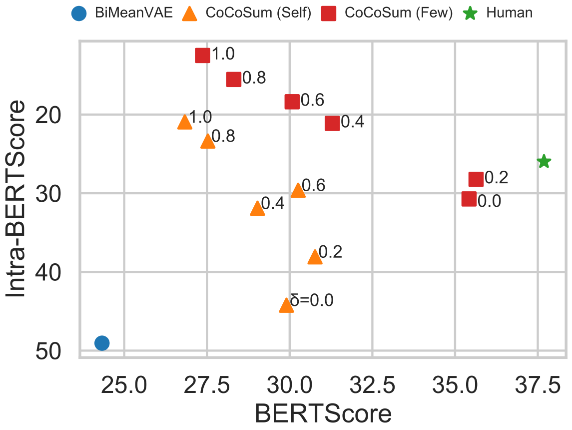

Figure 4: BERTScore and Intra-BERTScore for generated contrastive summaries with different hyperparameters δ. The goal is to generate high quality and distinctive summaries (upper right).

Contrastive summary generation First, we tested the MoE style aggregation that is used for contrastive summary generation. Specifically, we use addition to combine the original distribution and the ratio distribution instead of multiplication: $p^{A\setminus B}_{\text{cont}}(y_t) + \delta\left(p^{A\setminus B}_{\text{cont}}(y_t)/p^{B\setminus A}_{\text{cont}}(y_t)\right)$.

With this configuration, we observe significant degradation of summarization quality (e.g., 3.14 on R1) due to a serious distribution collapse issue in the aggregated token probability distribution. This is mainly caused by the lack of the *cancellation effect* obtained by the PoE style aggregation. That is, if the probability of a token were low in the ratio distribution, it would be canceled out via the *multiplication* operation.

We also tested another way to highlight contrastive opinions using the common summary generation model for the ratio distribution. That is, we replace the ratio distribution in Eq. (1) with $p^{A}_{\text{cont}}(y_t)/p^{A\cap B}_{\text{comm}}(y_t)$.

This configuration shows competitive performance as the original CoCoSum in both self-supervised and few-shot settings, supporting the effectiveness of Co-decoding regardless of the specific model choice. However, this configuration requires an additional base common opinion summarization model $p^{A\cap B}_{\text{comm}}$. Thus, we decided to use

CoCoSum	Intra-ROUGE1/2/L = (**36.84, 8.51, 23.16**)
Entity ID: 305813 **The Langham Place Hotel is a 4-star hotel.** It is centrally located **and has easy access to the mall and cinema next door. The room was lovely with a great view. The bed in the room was firm and not too comfy. The spa facilities here at the hotel are of a really high standard.** The staff at this hotel are generally excellent and very much co-operative. **The hotel had over priced buffet meals and snacks and drinks but the club floor facilities are of such a high standard that you know you are worth it.**	**Entity ID: 305947** **The Metropark Kowloon is a good hotel to stay at for a week or longer. It's ideally located for those who needs to shower and hit the bed after a full day of sightseeing/shopping.** The rooms in the hotel are clean, modern **and air-conditioning works well. The food served in the restaurant was varied and varied. The hotel provided a free shuttle service to Mongkok and the harbour area. The Ladies Market in Mong Kok is a pleasant walk away but the hotel bus route takes us close by.**
CoCoSum w/o Co-decoding	Intra-ROUGE1/2/L = (45.03, 11.64, 26.18)
Entity ID: 305813 **The hotel has a great spa and sauna facilities** and is centrally located to other attractions. **It is also worth booking into the club floor for the daily cocktail hour** and internet access. *The hotel could not do enough for you. The staff at the hotel were not very much co-operative and could not help enough.* **The spa facilities were of a very high standard** and the food was of a really good quality. *The taxi drivers take advantage of the hotel's direct access to the mall and cinema next door.*	**Entity ID: 305947** **The Metropark Kowloon is a good hotel to stay at for a week or longer.** The hotel is in a good location *and only a short walk away from the main shopping areas of Hong Kong.* The rooms in the hotel are clean **and with air conditioning but the rooms can be quite chilly compared to the humdity outside.** The staff at the hotel were very helpful and accommodating. **The buffet breakfast was really good and varied. The food served in the restaurant was really varied and tasty.** The Sip Sip bar offered a great variety of cocktails.

Table 4: Contrastive summaries generated by CoCoSum with and w/o Co-decoding for an example entity pair. Distinctive (common) opinions are highlighted in **blue** (magenta), and hallucinated content is in italics.

the simpler configuration Eq. (1) as the default setting.

Common summary generation Similarly, we verified the effectiveness of the PoE style configuration for common summary generation. That is, we use multiplication instead of addition: $p^{A\cap B}_{\text{comm}}(y_t)\prod_{E\in\{A,B\}} p^{E}_{\text{cont}}(y_t)^{\gamma}$.

This configuration consistently under-performs with the original Co-decoding for both summarization and inter-distinctiveness scores. This indicates that PoE focuses too much on the tokens that are likely to appear in both contrastive and common summaries, and thus it tends to generate overly generic summaries.

5.3 Qualitative Analysis

Does Co-decoding generate more distinctive opinions? Table 4 shows example generations by CoCoSum with and w/o Co-decoding for contrastive summary generation. While both models generate summaries that are consistent with the target entity reviews, the summaries generated by CoCoSum w/o Co-decoding tend to contain common opinions that are true for both of the entities and are against the purpose of comparative opinion summarization. On the contrary, CoCoSum actively generates opinions that can only be generated by the target entity's model p^{A}_{cont}, and thus the generated summary contains more **contrastive opinions** for users to compare the entities.

Do different pairs yield different summaries? Distinctive opinions can change when the entity to be compared changes. Table 5 shows the generated contrastive summaries using different entities as counterpart. As in the previous example, CoCoSum can generate generally consistent summaries with the target entity reviews in each setting, but also it uses **different opinions** to generate summaries. In other words, the model can highlight different opinions by comparing them with different entities, and thus generate summaries that include significantly different opinions for each.

6 Related Work

Abstractive opinion summarization aims to generate a fluent summary that reflects salient opinions in input reviews. Due to the lack of sufficient amount of reference summaries, the most common solution is the unsupervised approach (Chu and Liu, 2019; Bražinskas et al., 2020b; Amplayo and Lapata, 2020; Suhara et al., 2020; Amplayo et al., 2021; Iso et al., 2021; Elsahar et al., 2021; Im et al., 2021; Wang and Wan, 2021; Isonuma et al., 2021; Ke et al., 2022, *inter alia*).

Target Entity ID: 614392 vs Counterpart Entity ID: 1022738
The Pullman hotel is ideally situated for a city/beach vacation. **Port Olympic,** the Beach **and Barcelonetta** are all within walking distance. **The hotel has 2 great pools, one roof top pool with bar** and *one rooftop pool with a bar.* **It's not cheap though. The fitness centre in the hotel is tiny but there is a fitness park about 2 minutes walking distance for 16eur/day which provide a good facility.**
Target Entity ID: 614392 vs Counterpart Entity ID: 256595
The Pullman Hotel Barcelona is a stylish hotel next to the beach **with impeccable customer service.** The hotel is well situated in Barcelona, **not too far from the 5 star establishment, the Arts Hotel etc. The rooms in the hotel are of a good size and nicely decorated. The room has a great balcony and sea view and the bed is incredibly comfortable. The bathroom is also really luxurious. The staff at the hotel were really attentive and really go out of their way to treat all of their guests like they are royalty.The Mini bar was expensive so avoid at all costs FYI.**

Table 5: Contrastive summaries (Entity ID: 614392) generated by CoCoSum with Co-decoding using different entities as counterpart (Entity ID: 1022738 and 256595). The CoCoSum can generate completely different summaries by different conditioning. **Different opinions summarized** are color-coded and *hallucinated content* is in *italics*

Recent opinion summarization models use the few-shot learning approach that fine-tunes a pre-trained Transformer model with a limited amount of pairs of input reviews and reference summaries. Bražinskas et al. (2020a) and Oved and Levy (2021) show that the few-shot learning approach substantially outperforms unsupervised learning models.

All the existing methods listed above are designed for general opinion summarization and, thus, are not necessarily suitable for comparative opinion summarization, as shown in the experiments.

Comparative summarization There is a line of work on extracting comparative information from single/multiple documents. Lerman and McDonald (2009) defined the contrastive summarization problem and presented early work on the problem. Their method selects sentences so that two sets of summaries can highlight differences. Wang et al. (2013) developed an extractive summarization method for a problem of Comparative Document Summarization, which is to select the most discriminative sentences from a given set of documents. Bista et al. (2019) tackled a similar problem by selecting documents that represent in-cluster documents while they are useful to distinguish from other clusters.

Other studies (Kim and Zhai, 2009; Huang et al., 2011; Sipos and Joachims, 2013; Ren et al., 2017) tackled similar tasks by developing extracting sentences/phrases from given sets of documents for comparative document analysis. Topic models have also been used to capture comparative topics for better understanding text corpora, but they do not generate textual summaries (Ren and de Rijke, 2015; He et al., 2016; Ibeke et al., 2017).

Our work differs from the existing work in two points. First, none of them focuses on generating common summaries. Second, all of the previous studies for contrastive summary generation use the extractive approach. To the best of our knowledge, we are the first to develop an opinion summarization model and a benchmark for the abstractive contrastive and common summary generation tasks.

7 Conclusions

In this paper, we propose a new comparative opinion summarization task, which aims to generate contrastive and common summaries from reviews of a pair of entities, to help the user answer the question "Which one should I pick?" To this end, we develop a comparative summarization framework CoCoSum, which consists of two base summarization models; CoCoSum also implements Co-decoding, which jointly uses the token probability distribution of each model to generate more distinctive summaries in the decoding step.

For evaluation, we created a comparative opinion summarization benchmark CoCoTrip based on the TripAdvisor review corpus. Experimental results on CoCoTrip show that CoCoSum with Co-decoding significantly outperforms existing opinion summarization models with respect to both summarization quality and distinctiveness. We also confirm that Co-decoding successfully augments CoCoSum, so it can generate more distinctive contrastive and common summaries than other models through comprehensive analysis.

Table 6: Novelty of comparative opinion summarization against existing (opinion) summarization tasks. This work is the first task that targets to generate abstractive summaries (Abst.) for contrastive (Cont.) and common (Comm.) opinions. Note that Ren et al. (2017) extract keywords instead of creating textual summary.

A Comparative Opinion Summarization

Table 6 shows the task comparison against existing summarization tasks. Comparative opinion summarization is the first work that aims to generate abstractive summaries for contrastive and common opinions.

B The CoCoTrip Corpus

B.1 Entity-Pair Selection

For comparative opinion summarization, each of the selected entity pairs should always be comparable. To achieve this goal, we leverage the meta information of hotels in the TripAdvisor corpus to make sure that the selected entity pairs always locate in the same region (e.g., Key West of Florida).

B.2 Annotation

The input for each entity pair includes 16 reviews, which may be too difficult for human writers to write summaries from. Thus, we used a two-stage annotation method to ensure the quality of reference summaries.

Sentence Annotation Our first annotation task focuses on obtaining a set of sentences that contain contrastive and common opinions. Since the average number of sentences in each entity pair (90 in CoCoTrip) was too many to annotate at once, we grouped sentences based on their aspect category to further simplify the annotation task, In particular, we first split input reviews into sentences. Then, we grouped sentences into 6 aspect categories (i.e., general, staff, food, location, room, and others) using a BERT-based aspect category classifier trained with 3K labeled sentences. By doing so, we ensure that the number of sentences annotators need to review each time is no more than 20. For every sentence from entity e_A (e_B), we asked human annotators to compare it against a group of reference sentences of the same aspect category from entity e_B (e_A) and to distinguish whether it contains any common opinions that also appear in the reference sentences.

For the sentence annotation task, we hired 6 annotators from Appen's[10] expert worker pool with a cost of \$0.85 per annotation. We collected 3 annotations for each review and finalized the label through a majority vote. We obtained labels suggesting whether it contains contrastive or common opinions for every sentence in the entity pairs with the sentence annotation task. The inter annotator agreement (Fleiss' kappa) is 0.5048. The task interface is shown in Figure 5.

Summary Collection In the second annotation task, we first asked human writers to write aspect-based summaries. To exclude unreliable labels obtained in the previous step, we displayed two sets of sentences, one from each entity, to human writers for the summary collection task. This helps human writers ignore irrelevant or incorrectly labeled sentences. For example, to obtain the contrastive summary for aspect location, we first show two corresponding sets of contrastive sentences from both e_A and e_B based on the labels we collected in the previous annotation step. Then, we asked human writers to write two contrastive summaries for e_A and e_B, respectively. Similarly, we asked human writers to write a single common summary by showing two corresponding sets of common sentences. By doing so, we obtained aspect-based summaries for each entity pair, which are then concatenated into a reference summary.

Similar to the sentence annotation task, we also hired workers from Appen's expert worker pool. We hired 4 expert workers for the task with an hourly rate of \$18. For contrastive (common) summaries, annotators requires in average 208 (107) seconds to complete a summary. For every entity pair, we collected 3 reference summaries for each of *two* contrastive summary generation and *one* common summary generation tasks. The task interface is shown in Figure 6. Since it is a text summarization task, we report their agreement via ROUGE/BERTScore in Table 2 as *Human upper bound*. As shown, annotators acquires 47.37

---

Id:	Review sentences:	Reference sentences:
s1	the hotel is located well and the staff was also good .	Other than that , is close to everything .
s3	Hotel is located directly alongside major hwy and you hear the traffic all day and night long .	location .. close to agu conf centergood value for money if u do not stay much in the room but mostly outside .
s4	Clean , friendly , and good location for airport .	location not good for commuting at nightrooms quite conjested
s2	The hotel refunded $ 14 of my $ 21 cab fare ; vfor the return shuttle to the airport , the hotel clerk said it was pre - covered , and the cab driver expected ME to pay him .	The location is very good . Easy walk to Moscone if you take the right streets .
s5	Nothing is close by to see , and it seemed much farther away than less than 2 miles .	Corner by the hostel was n't the greatest area , but not anything you would n't expect for San Fran .

*Double click tokens to group sentences.

Please answer the following questions:

According to sentence s1, can you find similar description about *"Location"* from the reference sentences?

○ Yes
● No

Figure 5: Sentence Annotation Task. By showing sentences of the same aspect category, it is easier for annotators to compare two group of sentences (from two entities). To further facilitate the annotation process, we also provide several additional features, such as allowing workers to group sentences that contain the same token through double clicking, and to highlight sentences through hovering over the sentence label.

ROUGE-1 and 37.69 BERTScore, both are significantly higher than the baseline approaches.

C Additional Experimental Details

C.1 Training details

Major hyper-parameters for training models are reported in Table in 9 and 10 following the "Show-You-Work" style suggested by Dodge et al. (2019).

C.2 Training Dataset for Self-Supervision

We collected synthetic reviews-summary pairs from the TripAdvisor review corpus for self-supervised training. Algorithm 1 shows the review summary pair collection procedure, which is based on Elsahar et al. (2021) with a few modifications.

D Additional Evaluation Results

D.1 Analysis on Few-shot learning design

To explore the best few-shot learning design, we tested three different learning strategies, Self-then-Few, Multi-Tasking, and Only Few-Shot. The Self-then-Few strategy further fine-tunes the self-supervised summarization model by few-shot training examples. The Multi-Tasking strategy is to train the summarization model with self-supervised data and the few-shot data jointly. The Only Few-Shot only fine-times a transformer model initialized with a pre-trained checkpoint, which is the `led-base-16384` in our case.

The experimental results show in Table 8, and we found that while the Only-Few-Shot configuration shows surprisingly performs well compared to the Multi-Tasking, the Self-then-Few strategy performs generally well both on contrastive and common opinion summarizations. Thus, we adapt the Self-then-Few to build the base summarization models for our experiments.

Algorithm 1 The algorithm for building synthetic training dataset $\mathcal{C}_{\text{synthetic}}$

```
Input: Raw review sets $\mathcal{C}_{\text{raw}} = \{\mathcal{R}_e\}_{e \in \mathcal{E}}$, task $T \in \{\texttt{contrastive}, \texttt{common}\}$, number of input reviews $n$, number of synthetic data size $K$
Output: Synthetic reviews-summary pairs $\mathcal{C}_{\text{synthetic}}$ for task $T$
procedure BuildTrain($\mathcal{C}_{\text{raw}}$, $T$, $n$)

Find commonality between Hotel A and Hotel B

Highlights from Hotel A:
dirty unsafe thing redone lobby highly extra comfortable huge small

Highlights from Hotel B:
free coffee guests great location staff extremely helpful still highly

Hotel A	✔	✘
Dirty , unsafe , only thing really redone was the lobby ! !	☐	☐
I highly recommend to anyone needing some extra space and does nt care about being downtown !	☐	☐
The staff was very helpful and friendly .	☐	☐
The rooms were beautiful , and very clean , unless you looked directly behind the toilet , which could use a little extra scrubbing .	☐	☐
the room - comfortable , huge , it is literally the size of a small apartment , with a small kitchenette , a dining table a huge couch and and super comfortable bed ,	☐	☐
This is the place to stay in Key West .	☐	☐

Hotel B	✔	✘
/ free coffee for guests - great location -	☐	☐
right across from Gulf - Staff extremely helpful	☐	☐
The staff was extremely friendly and helpful .	☐	☐
Then today .. still good service from Angela the bartender	☐	☐
I would still highly recommend this Inn and its serene setting if some rules too the bartenders are made no drunken friends monopolizing the bar one incident does n't warrant a bad report .	☐	☐
Highly recommended .	☐	☐

*Double click tokens to group sentences.

Please summarize common opinions for Hotel A and Hotel B:

Abstract

The recent success of distributed word representations has led to an increased interest in analyzing the properties of their spatial distribution. Several studies have suggested that contextualized word embedding models do not isotropically project tokens into vector space. However, current methods designed to measure isotropy, such as average random cosine similarity and the partition score, have not been thoroughly analyzed and are not appropriate for measuring isotropy. We propose IsoScore: a novel tool that quantifies the degree to which a point cloud uniformly utilizes the ambient vector space. Using rigorously designed tests, we demonstrate that IsoScore is the only tool available in the literature that accurately measures how uniformly distributed variance is across dimensions in vector space. Additionally, we use IsoScore to challenge a number of recent conclusions in the NLP literature that have been derived using brittle metrics of isotropy. We caution future studies from using existing tools to measure isotropy in contextualized embedding space as resulting conclusions will be misleading or altogether inaccurate.

1 Introduction & Background

The first step in any natural language processing pipeline is to represent text in a vector space. Understanding how contextualized word embedding models project tokens into vector space is crucial for advancing the field of natural language processing. Several recent studies analyzing the spatial distribution of contextualized word embeddings claim that the point clouds induced by models such as BERT or GPT-2 do not uniformly utilize all dimensions of the vector space they occupy (Ethayarajh, 2019; Mickus et al., 2019; Cai et al., 2021; Coenen et al., 2019b; Gao et al., 2019).

Figure 1 illustrates a two-dimensional disk that uniformly utilizes the x and y axes in two-dimensional space, but does not uniformly utilize all dimensions when embedded into three dimensions.

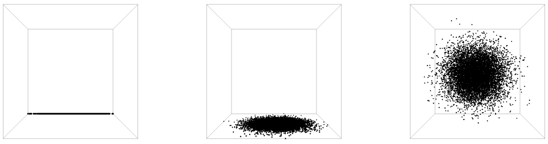

Figure 1: From left to right, a line, disk, and ball embedded in 3D space.

A distribution is *isotropic* when variance is uniformly distributed across all dimensions. Namely, a distribution is fully isotropic when the covariance matrix is proportional to the identity matrix. Several authors suggest that isotropy correlates with improved performance of embedding models (Biś et al., 2021; Wang et al., 2019; Coenen et al., 2019a; Gong et al., 2018; Hasan and Curry, 2017; Hewitt and Manning, 2019; Liang et al., 2021; Zhou et al., 2019, 2021). However, current methods of measuring the spatial utilization of contextualized embedding models do not truly measure isotropy. The most commonly used methods for measuring spatial distribution in embedding spaces include average random cosine similarity, the partition score, variance explained and intrinsic dimensionality estimation. In Section 5 we argue that all current methods of measuring isotropy have fundamental shortcomings that render them inadequate measures of spatial distribution.

To overcome these limitations, we introduce *IsoScore*: a novel tool for measuring the extent to which the variance of a point cloud is uniformly distributed across all dimensions in vector space. In contrast to previous attempts of measuring isotropy, IsoScore is the first score that incorporates the *mathematical definition* of isotropy into its formulation. As a result, IsoScore has the following desirable properties that surpass the capabilities of existing metrics: (i) It is a global measure of how

Findings of the Association for Computational Linguistics: ACL 2022, pages 3325 - 3339
May 22-27, 2022

uniformly distributed points are in vector space that is robust to changes in the distribution mean and scalar changes in covariance; (ii) It is rotation invariant; (iii) It increases linearly as more dimensions are utilized; and (iv) It is not skewed by highly isotropic subspaces within the data. This paper makes the following novel contributions.

1. This paper outlines essential conditions for measuring isotropy and uses a testing suite to empirically verify if a given method meets these conditions.
2. We highlight fundamental shortcomings of state-of-the-art tools and demonstrate that none of the existing methods accurately measure isotropy.
3. We present IsoScore, the first rigorously defined method for measuring isotropy in point clouds of data.
4. We share an efficient Python implementation of IsoScore with the community.[1]

The remainder of this paper is structured as follows: Section 2 reviews previous works attempting to study isotropy in contextualized word embeddings. Section 3 formally defines isotropy and describes existing tools in detail. The formal definition of IsoScore is presented in Section 4 and in Section 5, we report empirical results from experiments on contextualized word embeddings. Finally, Section 6 concludes with an outlook on future directions of work.

2 Related Work

2.1 Word Embeddings

In recent years, there has been an increased interest in analyzing the spatial organization of point clouds induced by word embeddings (Biś et al., 2021; Mickus et al., 2019; Ethayarajh, 2019; Coenen et al., 2019b; Cai et al., 2021; Mu et al., 2017; Liang et al., 2021). Several studies have concluded that contextualized embeddings form highly anisotropic, "narrow cones" in vector space (Ethayarajh, 2019; Cai et al., 2021; Gao et al., 2019; Gong et al., 2018). The most prevalent tools used to quantify the geometry of word embedding models calculate the average cosine similarity of a small number of randomly sampled pairs of points in embedding space. Ethayarajh (2019) claims that in some cases, contextualized embedding models have an average random cosine similarity that approaches 1.0, meaning all points are oriented in the same direction in space irrespective of their syntactic or semantic function.

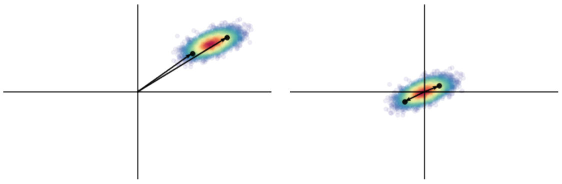

Figure 2: *Left:* Point cloud $X \subset \mathbb{R}^2$. *Right:* Result of applying a zero-mean transform to X.

In Section 5, we demonstrate that both average random cosine similarity and the partition score are significantly influenced by the mean of the data irrespective of how data points are distributed in vector space. Namely, if we normalize data to have zero-mean, average random cosine similarity and the partition score will artificially produce a score that reflects maximal isotropy. Figure 2 demonstrates that a applying a zero-mean transform to a point cloud increases the angle of randomly sampled points. Accordingly, the average random cosine of the left point cloud in Figure 2 approaches 1 while the average random cosine similarity of the right point cloud approaches 0. It is well known that word embedding models have non-zero mean vectors (Yonghe et al., 2019; Liang et al., 2021). In the case of GPT-2 embeddings obtained from the WikiText-2 corpus (Merity et al., 2016), we find values in the mean vector range from -32.36 to 198.19. Although cosine similarity has long been used to capture the "semantic" differences between words in static embeddings, adapting any cosine similarity-based methods to measure isotropy obscures the true distribution of contextualized word embeddings.

2.2 Existing Methods

We briefly review the most commonly used tools to measure the spatial distribution of point clouds $X \subseteq \mathbb{R}^n$. A mathematical exposition of these tools can be found in Appendix B.

Average Random Cosine Similarity: We define the *Average Random Cosine Similarity Score* as 1 minus the average cosine similarity of $N = 100,000$ randomly sampled pairs of points from X. **Note:** for ease of comparison to other methods, we

calculate 1 minus the absolute value of the average random cosine similarity so that 0 would indicate minimal isotropy and 1 would indicate maximal isotropy. We demonstrate in Section 5 that average random cosine similarity is not a measure of isotropy.

Partition Isotropy Score: Mu et al. (2017) define this score to be a particular quotient involving the partition function first proposed by Arora et al. (2015): $Z(c) := \sum_{x \in X} \exp(c^{\mathrm{T}} x)$, where c is carefully chosen from the eigenspectrum of XX^{T}. It is believed that a score closer to 0 indicates an anisotropic space, while a score near 1 indicates an isotropic space. We refer to this as the *Partition Score*.

Intrinsic Dimensionality: Algorithms for estimating intrinsic dimensionality aim to compute the true dimension of a given manifold from which we assume a point cloud has been sampled. Intrinsic dimensionality has been used to argue word embedding models are anisotropic (Cai et al., 2021). We use the MLE method to calculate intrinsic dimensionality (Levina and Bickel, 2004). Dividing the intrinsic dimensionality of $X \subseteq \mathbb{R}^n$ by n provides us with a normalized score of isotropy, which we refer to as the *ID Score*.

Variance Explained Ratio: The variance explained ratio, which we refer to as the *VarEx Score*, measures how much total variance is explained by the first k principal components of the data. We compute this by dividing the variance explained by the first k principal components by k/n. The VarEx Score requires us to specify *a priori* the number of principal components we wish to examine, which makes comparisons between vector spaces with different dimensions difficult and results in undesirable behavior, particularly when the dimension of the vector space is large.

Section 5 demonstrates that all existing methods have fundamental shortcomings that make them unreliable measures of spatial distribution. Using any of the above existing tools to make claims about isotropy will be misleading as none of the described methods truly measure isotropy.

3 Measuring Embedding Space Utilization

3.1 Definition of Isotropy

A distribution is *isotropic* if its variance is uniformly distributed across all dimensions. Namely, the covariance matrix of an isotropic distribution is proportional to the identity matrix. Conversely, an *anisotropic* distribution of data is one where the variance is dominated by a single dimension. For example, a line in n-dimensional vector space is maximally anisotropic. Robust isotropy metrics should return maximally isotropic scores for balls and minimally isotropic (i.e. anisotropic) scores for lines. Appendix D provides a geometric interpretation of "medium isotropy". We interpret a medium isotropic space in $\mathbb{R}^n$ to be one where the data uniformly utilizes approximately $n/2$ dimensions in space as defined below. Note that we exclude two edge cases for measuring isotropy. Firstly, since isotropy is a property of the covariance matrix of a distribution, the dimensionality of the space needs to be greater than 1. Secondly, we do not consider the extreme case where the data consists of a single point.

3.2 Dimensions utilized

Given a point cloud $X \subseteq \mathbb{R}^n$, we measure how many dimensions of $\mathbb{R}^n$ are truly utilized by X. For example, we denote by $I_n^{(k)}$ the $n \times n$ covariance matrix where $a_{i,i} = 1$ for $i \in \{1, 2, ..., k\}$ and all other elements are 0. Note that when $k = n$, we recover the identity matrix. Thus, $I_n^{(k)}$ represents a covariance matrix where the first k dimensions are being uniformly utilized. Figure 1 illustrates point clouds in $\mathbb{R}^3$ that have covariance matrix $I_3^{(1)}$, $I_3^{(2)}$, and $I_3^{(3)}$. These utilize 1, 2, and 3 dimensions in $\mathbb{R}^3$. To make this discussion rigorous and general, we make the following definition:

$\iota(I_9^{(1)})$	$\iota(I_9^{(2)})$	$\iota(I_9^{(3)})$	$\iota(I_9^{(4)})$	$\iota(I_9^{(5)})$	$\iota(I_9^{(6)})$	$\iota(I_9^{(7)})$	$\iota(I_9^{(8)})$	$\iota(I_9^{(9)})$
0.000	0.125	0.250	0.375	0.500	0.625	0.750	0.875	1.000

Table 2: Linearly increasing dimensions utilized in $\mathbb{R}^9$ linearly increases IsoScore. We prove in Appendix D that IsoScore satisfies the formula $\iota(I_n^{(k)}) = \frac{k-1}{n-1}$.

Definition 3.1. *Consider a point cloud $X \subseteq \mathbb{R}^n$. Let Σ be the covariance matrix of X and assume all the off-diagonal entries of Σ are zero. Let $\Sigma_D \in \mathbb{R}^n$ denote the diagonal of Σ.*

1. *We say X* utilizes k dimensions *in $\mathbb{R}^n$ if the first k entries of Σ_D are non-zero and the remaining $n-k$ entries are zero.*
2. *We say X* uniformly utilizes k dimensions *in $\mathbb{R}^n$ if X utilizes k dimensions in $\mathbb{R}^n$ and if all the non-zero entries in Σ_D are equal.*

Having a diagonal sample covariance matrix Σ implies there are no correlations between any coordinates of X. In Section 4, we reduce the general case of X to the case where the covariance matrix of X is diagonal. Figure 3 illustrates three point clouds in $\mathbb{R}^2$ that each utilize 2 dimensions. We argue that it is of practical importance to differentiate between the cases in Figure 3. The leftmost panel uniformly utilizes all dimensions of $\mathbb{R}^2$, while the rightmost panel does not uniformly utilize two dimensions of space. Note that average random cosine similarity returns maximal isotropy scores for each point cloud pictured in Figure 3.

Our proposed IsoScore reflects the dimensions utilized by a point cloud in a linear fashion. See Table 2 for a concrete example of how IsoScore reflects dimensions utilized in $\mathbb{R}^9$.

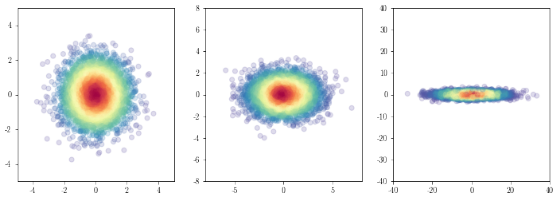

Figure 3: Points sampled from a 0 mean, 2D Gaussian with covariance $\left(\begin{smallmatrix} x & 0 \\ 0 & 1 \end{smallmatrix}\right)$ where $x = 1, 3, 75$.

3.3 Essential Properties of Isotropy

We now outline the essential properties that a measure of isotropy must possess.

1: Mean Agnostic. Recall that a distribution is isotropic if variance is uniform across all dimensions. It is essential to note that *isotropy is strictly a property of the covariance matrix* of a distribution. If changes to the mean of a distribution influence an isotropy score, then the given score does not measure isotropy.

2: Scalar Changes to the Covariance Matrix. Since isotropy is defined as the *uniformity* of variance across all dimensions, isotropy scores should not change when we multiply the covariance matrix of the underlying distribution of the data by a positive scalar value. If the covariance matrix of a distribution of data is equal to $\lambda \cdot I_n$ where $\lambda > 0$ is some scalar value and I_n is the $n \times n$ identity matrix, then a tool must return an isotropy score approaching 1.

3: Maximum Variance. As we increase the difference between the maximum variance value in our covariance matrix and the average variance value of the remaining dimensions, isotropy scores should monotonically decrease to zero. Figure 3 illustrates the effect of increasing the difference between the average variance value and the maximum value in the covariance matrix. Increasing the difference between the maximum variance value and the average variance value increases the amount of variance explained by the first principal component of the data. Namely, larger maximum variance values reduce the efficiency of spatial utilization.

4: Rotation Invariance. Given a point cloud $X \subset \mathbb{R}^n$, an ideal measure of spatial utilization should remain constant under rotations of X since the distribution of principal components remains constant under rotation. Accordingly, we consider the canonical distribution of the variance of X to be the variance after projecting X using principal component analysis. Figure 4 illustrates the process of PCA-reorientation.

5: Dimensions Used. As described in Subsection 3.2, there is a direct link between isotropy and the number of dimensions utilized by the data. Intuitively, increasing the number of dimensions uniformly utilized by the data expands the number of principal components it takes to explain all of the variance in the data. Accordingly, a good score of spatial utilization should increase linearly as we increase the number of dimensions uniformly utilized by the data. Figure 1 depicts data utilizing one, two, and three out of three ambient dimensions, respectively.

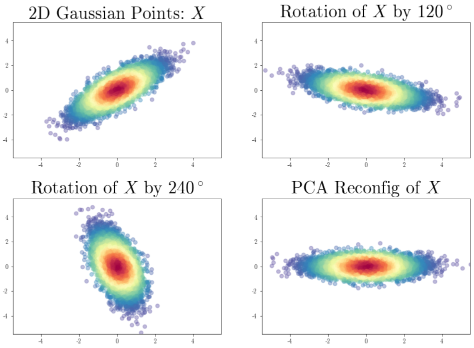

Figure 4: Left: 2D zero-mean Gaussian with covariance $\begin{pmatrix} 1 & 0.8 \\ 0.8 & 1 \end{pmatrix}$. We rotate X by 120° and 240°, respectively. Right: Points after applying PCA reorientation.

6: Global stability. A metric of efficient spatial utilization should be a *global* reflection of the distribution. A robust method should be stable even when the data exhibits small subpopulations where a score would return an extreme value.

We test this by computing IsoScore for the union of a noisy sphere and a line; we provide a geometric rendering of this in Figure 5 in Appendix E. We refer to this test as the "skewered meatball" test. A good score of spatial distribution for a "skewered meatball" should reflect the ratio of the number of points sampled from the line and the number of points sampled from the sphere.

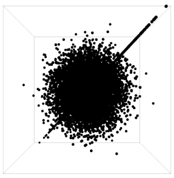

Figure 5: 2D rendering of a line in 3D space intersecting noisy sphere. AKA "skewered meatball."

In Table 1, we list which existing methods satisfy which essential conditions. Section 5 outlines the numerical experiments we execute to obtain this table. As each of the above properties have been derived from the mathematical definition of isotropy, an accurate tool for measuring isotropy needs to satisfy each essential condition.

4 IsoScore

This section introduces the proposed IsoScore metric of uniform spatial utilization.

4.1 Formal Definition of IsoScore

Algorithm 1 gives a high-level overview of the procedure. Afterwards, we discuss the individual steps in detail.

Step 1: Start with a point cloud $X \subseteq \mathbb{R}^n$. IsoScore takes as input a finite subset of $\mathbb{R}^n$ and outputs a number in the interval $[0, 1]$ that represents the extent to which X is isotropic.

Step 2: PCA-reorientation of data set. Execute PCA on X, where the target dimension remains the original n. Performing PCA reorients the axes of X so that the i'th coordinate accounts for the i'th greatest variance. Further, it eliminates all correlation between dimensions making the covariance matrix diagonal. We denote the transformed space as X^{PCA}.

Step 3: Compute variance vector of reoriented data. Compute the $n \times n$ covariance matrix of X^{PCA}; denote this matrix by Σ. Let Σ_D denote the diagonal of the covariance matrix. We refer to Σ_D as the *variance vector,* and we identify Σ_D as a vector in $\mathbb{R}^n$. Performing Step 2 causes all off-diagonal entries of the covariance matrix of X_T to vanish, which allows us to ignore off-diagonal elements for the rest of the computation.

Step 4: Length normalization of variance vector. We define the *normalized variance vector* to be

$$\hat{\Sigma}_D := \sqrt{n} \cdot \frac{\Sigma_D}{\|\Sigma_D\|},$$

where $\|(x_1, ..., x_n)\| := \sqrt{x_1^2 + \cdots + x_n^2}$ denotes the standard Euclidean norm on $\mathbb{R}^n$. Note that as a result of this normalization, we have $\|\hat{\Sigma}_D\| = \sqrt{n}$.

Step 5: Compute the distance between the covariance matrix and identity matrix. Denote the diagonal of the $n \times n$ identity matrix by $\mathbf{1} \in \mathbb{R}^n$. Then we define the *isotropy defect* of X to be

$$\delta(X) := \frac{\|\hat{\Sigma}_D - \mathbf{1}\|}{\sqrt{2(n - \sqrt{n})}}.$$

By definition of the Euclidean norm, we have $\|\hat{\Sigma}_D\| = \|\mathbf{1}\| = \sqrt{n}$. It follows from the triangle inequality that $\|\hat{\Sigma}_D - \mathbf{1}\| \in [0, 2\sqrt{n}]$. Crucially, we prove in Appendix C that achieving a value of $2\sqrt{n}$ using a valid covariance matrix is impossible. The largest value that can be attained is with the matrix $(a_{ij})_{i,j=1,...,n}$ defined by

Algorithm 1 IsoScore

```
begin Let $X \subset \mathbb{R}^n$ be a finite collection of points.
    Let $X^{\text{PCA}}$ denote the points in $X$ transformed by the first $n$ principal components.
    Define $\Sigma_D \in \mathbb{R}^n$ as the diagonal of the covariance matrix of $X^{\text{PCA}}$.
    Normalize diagonal to $\hat{\Sigma}_D := \sqrt{n} \cdot \Sigma_D / \|\Sigma_D\|$, where $\| \cdot \|$ is the standard Euclidean norm.
    The isotropy defect is $\delta(X) := \|\hat{\Sigma}_D - \mathbf{1}\| / \sqrt{2(n - \sqrt{n})}$, where $\mathbf{1} = (1, \ldots, 1)^\top \in \mathbb{R}^n$.
    $X$ uniformly occupies $\phi(X) := (n - \delta(X)^2(n - \sqrt{n}))^2 / n^2$ percent of ambient dimensions.
    Transform $\phi(X)$ so it can take values in $[0, 1]$, via $\iota(X) := (n \cdot \phi(X) - 1)/(n - 1)$.
    return: $\iota(X)$
end
```

$a_{11} = \sqrt{n}$ and $a_{ii} = 0$ whenever $i > 1$. One can compute that the Euclidean norm in this case is $\|\hat{\Sigma}_D - \mathbf{1}\| = \sqrt{2(n - \sqrt{n})}$. Choosing this normalization factor guarantees that $\delta(X) \in [0, 1]$, where 0 represents a perfectly isotropic space and 1 represents a perfectly anisotropic space.

Step 6: Use the isotropy defect to compute percentage of dimensions isotropically utilized. We argue in Heuristic D.1 that if X has isotropy defect $\delta(X)$, then X isotropically occupies approximately $k(X) = (n - \delta(X)^2(n - \sqrt{n}))^2 / n$ dimensions in $\mathbb{R}^n$. Because $\delta(X) \in [0, 1]$, one can estimate that $k(X) \in [1, n]$ so the fraction of dimensions utilized is $\phi(X) := k(X)/n \in [1/n, 1]$.

Step 7: Linearly scale percentage of dimensions utilized to obtain IsoScore. The fraction of dimensions utilized, $\phi(X)$, is close to the final IsoScore, but it falls within the interval $[1/n, 1]$. As we want the possible range of scores to fill the interval $[0, 1]$, we apply the affine function that maps $1/n \mapsto 0$ and $1 \mapsto 1$. Thus, $S : [1/n, 1] \to [0, 1] : x \mapsto (nx - 1)/(n - 1)$. Once we compose these transformations, we obtain IsoScore:

$$\iota(X) := \frac{(n - \delta(X)^2(n - \sqrt{n}))^2 - n}{n(n - 1)}. \tag{4.1}$$

4.2 Geometric Interpretation for IsoScore

In Subsection 4.1 we described how to compute an IsoScore $\iota(X)$ for any point cloud $X \subseteq \mathbb{R}^n$. We will now present a heuristic interpretation for a given IsoScore. Intuitively, our heuristic says that $\iota(X)$ is roughly the fraction of dimensions of $\mathbb{R}^n$ utilized by X. More precisely, the quantity of dimensions of $\mathbb{R}^n$ utilized by X is some number inside the interval $[\iota(X)n, \iota(X)n + 1] \cap [1, n]$. We formalize this below.

Heuristic 4.1. *When the ambient space $\mathbb{R}^n$ has large dimension, the IsoScore $\iota(X)$ is approximately the fraction of dimensions uniformly utilized by X.*

We prove this heuristic in Appendix D. Note in particular that $\iota(X) = 0$ implies that D.1 simplifies to a single dimension utilized and $\iota(X) = 1$ implies that D.1 simplifies to all n dimensions utilized.

Because IsoScore covers a continuous spectrum, one should carefully interpret what we mean when we say that X occupies approximately k dimensions of $\mathbb{R}^n$. For example, consider the 2D Gaussian distributions depicted in Figure 3. Heuristic D.1 predicts $k = 1.9996, 1.6105, 1.0281$ dimensions are used when $x = 1, 3, 75$, respectively. These should be interpreted as follows: "when $x = 75$, the points sampled are mostly using one direction of space" and "when $x = 3$, the points sampled are using somewhere between one and two dimensions of space."

5 Experiments

In Subsection 5.1, we present results from numerical experiments designed to test each of the isotropy scores presented in this paper against the six essential properties outlined in Section 3.3. Exact descriptions of the numerical experiments are provided in Appendix E. We reiterate that each of the essential conditions have been derived directly from the mathematical definition of isotropy and violating any of the essential properties disqualifies a method from being a correct measure of isotropy.

In Subsection 5.2, we demonstrate the merit of IsoScore by recreating the experimental setup presented in (Cai et al., 2021). We create word embeddings for tokens from the WikiText-2 corpus using GPT (Radford and Narasimhan, 2018), GPT-2 (Radford et al., 2019), BERT (Devlin et al., 2018) and DistilBERT (Sanh et al., 2019) and calculate isotropy scores for each layer of the model.

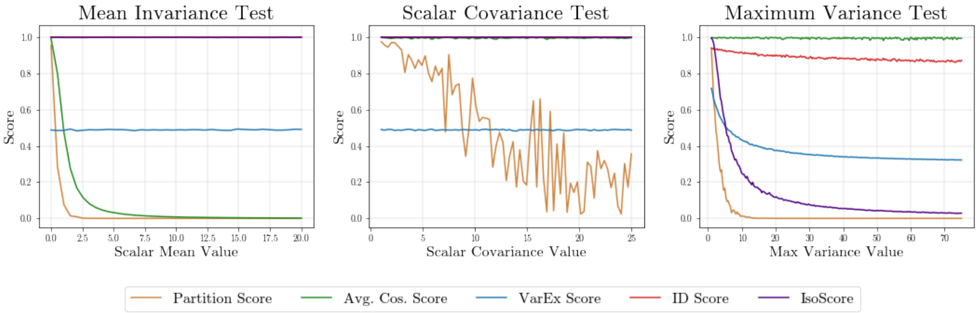

Figure 6: Left: Scores of points sampled from a 10-dimensional Gaussian with identity covariance and common mean vector ranging from 0 to 20. Center: Scores for the scalar covariance test for a 5-dimensional, zero-mean Gaussian. Right: Scores for the Maximum Variance test for 10-dimensional, zero-mean Gaussians.

5.1 Testing methods against the essential properties

Test 1: Mean Agnostic. When the covariance matrix of a distribution is proportional to the identity matrix, measures of isotropy should return a score of 1 regardless of the value of the mean. Figure 6 demonstrates that neither average random cosine similarity nor the partition score are mean-agnostic. IsoScore is mean-agnostic since it is a function of the covariance matrix. Importantly average random cosine similarity and the partition score are skewed by non-zero mean data. Our results show that, for an isotropic Gaussian with covariance matrix $\lambda \cdot I_n$ and mean vector $M = [\mu, \mu, ..., \mu]$, the average random cosine similarity of points sampled from this distribution will approach 0 as we increase the ratio between μ/λ. *Consequently, zero-centering data will cause average random cosine similarity to return maximally isotropic scores without impacting the distribution of the variance.*

Test 2: Scalar Changes to the Covariance Matrix. For a 5-dimensional Gaussian distribution with a zero mean vector and covariance matrix $\lambda \cdot I_n$, scores should reflect uniform utilization of space for any $\lambda > 0$. Figure 6 shows that IsoScore and the intrinsic dimensionality score are the only metrics that are agnostic to scalar multiplication to the covariance matrix and return a score 1 for each value of λ. In Step 4 of IsoScore, we normalize the diagonal of the covariance matrix to have the same norm as the diagonal of the identity matrix, which ensures IsoScore is invariant to scalar changes in covariance.

Test 3: Maximum Variance. An effective score should monotonically decrease to 0 as we increase the difference between the maximum variance value and average variance. Steps 4 and 5 of IsoScore ensure that the less equitably the mass in the covariance vector is distributed, the greater the isotropy defect will be. Figure 3 visualizes this phenomenon for a 2 Dimensional Gaussian. The ID Score fails this test since the intrinsic dimensionality estimate is 2.0 for all point clouds depicted in Figure 3.

Table 3: Performance of current methods on Test 4: Rotation Invariance

	IsoScore	AvgCosSim	Partition	ID Score	VarEx
X	0.216	0.990	0.445	1.000	0.500
X^{120°	0.216	0.968	0.673	1.000	0.500
X^{240°	0.216	0.981	0.669	1.000	0.500
X^{PCA}	0.216	0.993	0.446	1.000	0.500

Test 4: Rotation Invariance. We rotate our baseline point cloud X by 120° and 240°. Lastly, we project X using PCA reorientation while retaining dimensionality to obtain a point cloud X^{PCA}. We record results in Table ??. Only IsoScore, ID Score, and VarEx Score return constant values. The partition score would return a constant value if it were feasible to compute the true optimization problem. The approximate version of the partition score, however, depends too strongly on the basis. IsoScore is rotation invariant by design. In Step 2, IsoScore projects the point cloud of data in the directions of maximum variance before computing the covariance matrix of the data.

Test 5: Dimensions Used (Fraction of Dimensions Used Test). The number of dimensions used in a point cloud $X \subset \mathbb{R}^n$ provides a sense of how uniformly X utilizes the ambient space. A reliable metric should return scores near $0.0, 0.5$, and 1.0 when number of dimensions used is 1, $\lfloor n/2 \rfloor$, and n, respectively. Figure 7 shows that only IsoScore models ideal behavior for the dimensions used test.

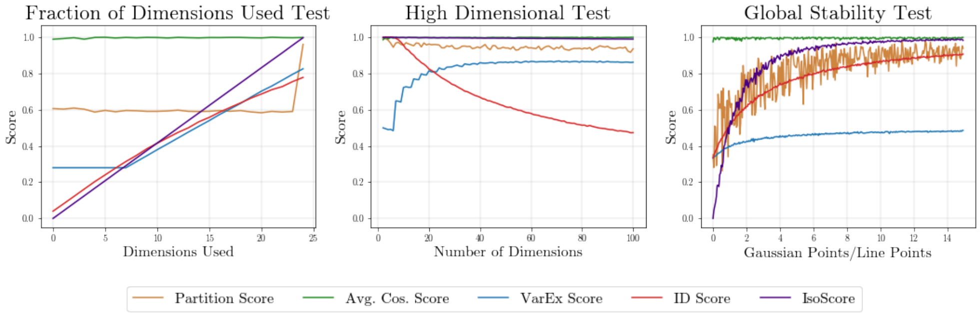

Figure 7: Left and center: Scores for the two Dimensions Used tests. Right: Scores for the "skewered meatball" test in 3 dimensions.

A rigorous explanation of why IsoScore reflects the percentage of 1s present in the diagonal of the covariance matrix is provided in Heuristic 4.1. Although the intrinsic dimensionality score monotonically increases as we increase k, it fails to reach 1 when all dimensions are uniformly utilized. Average cosine similarity fails this test, as it stays constant near 1 regardless of the fraction of dimensions uniformly utilized.

Test 5: Dimensions Used (High Dimensional Test). Metrics of spatial utilization should allow for easy comparison between different vector spaces even when the dimensionality of the two spaces is different. Figure 7 illustrates that IsoScore, the average cosine similarity score, and the partition score pass this test, as they stay constant near 1. Note that the line for IsoScore decreases slightly. By the law of large numbers, the more data points we sample from the Gaussian distribution, the closer the covariance matrix will be to the covariance matrix from which it was sampled. The VarEx Score is not stable under an increase in dimension primarily because it requires the user to specify the percentage of principal components used in calculating the score. Note that the ID Score begins to decrease simply by increasing the dimensionality of the space since the MLE method is not very well suited for estimating the intrinsic dimension of isotropic Gaussian balls.

Test 6: Global Stability. To evaluate which scores are not skewed by highly concentrated subspaces, we design the "skewered meatball test" (see Figure 5 for a geometric rendering). As we increase the ratio between the number of points sampled from a 3D isotropic Gaussian and a 1D anisotropic line, we should see isotropy scores increase from 0 to 1, and hit 0.5 precisely when the number of points sampled from the Gaussian distribution and the line are equal. Results from the skewered meatball test in Figure 7 indicate that the partition score, IsoScore and intrinsic dimensionality estimation are the only metrics that are global estimators of the data.

5.2 Isotropy in Contextualized Embeddings

Recent literature suggests that contextualized word embeddings are anisotropic. However, as demonstrated in Subsection 5.1, no existing methods truly measure isotropy. We replicate experiments by (Cai et al., 2021), and present isotropy scores for the vector space of token embeddings generated from the WikiText-2 corpus for GPT (110M parameters) and GPT2 (117M parameters) in Figure 8, as well as the scores for BERT (base, uncased) and DistilBERT (base, uncased) in Figure 9.

Figure 8: The 5 scores for each of the 12 layers of GPT-2 and GPT

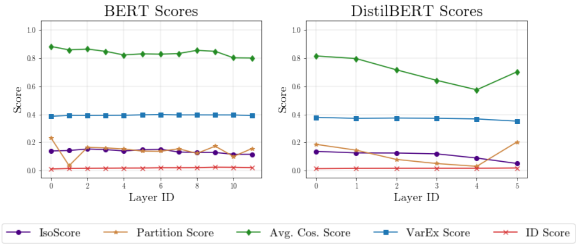

Figure 9: The 5 scores for the 12 layers of BERT, and the 6 layers of DistilBERT

Our findings using IsoScore challenge and extend upon the literature in the following ways. Contextualized embedding models (i) utilize even fewer dimensions than previously thought; (ii) do not utilize fewer dimensions in deeper layers; and (iii) in agreement with Biś et al. (2021), contextualized embedding models do not necessarily occupy a "narrow cone" in space.

IsoScore returns values of less than 0.18 for every considered contextualized embedding model. GPT and GPT-2 embeddings do not even isotropically utilize a single dimension in space, in the sense of Heuristic D.1. Using average random cosine similarity, Cai et al. concluded that earlier layers in contextualized embedding models are more isotropic than layers deeper in the network. While this may appear to be true using inaccurate measures of isotropy, there is no significant decrease in IsoScore between the earlier and later layers of contextualized embedding models. Biś et al. (2021) argue that isotropy improves performance for contextualized embedding models and that enforcing zero mean embeddings recovers "isotropy". The author's claim to improve isotropy by subtracting the mean vector from the point clouds of embeddings produced from BERT, GPT-2 and RoBERTa, however, the authors use the partition score in attempts to measure isotropy which will return values close to 1 when the data is zero-mean. As demonstrated throughout the paper, isotropy is strictly a property of the covariance matrix of a distribution and is by definition mean-agnostic.

Note that our average random cosine similarity score finds contextualized embedding models to be much more isotropic then previously reported. When computing the average random cosine similarity score for contextualized word embeddings we sample 250,000 pairs of points. Prior studies such as Ethayarajh (2019) and Cai et al. (2021) sample as few as 1000 pairs of points when calculating average random cosine similarity. In both cases, the point clouds contain millions of tokens embedded into 768 dimensional vector space and differences in reported scores are likely due to sampling noise. We found empirically that the quantity of points sampled should be orders of magnitude larger than the dimension.

The notion of isotropy is often conflated with geometry. The geometry of isotropic vector spaces, however, will differ depending on the distribution that generates the points in space. For example, multivariate isotropic Gaussians form n-dimensional balls and uniform distributions form n-dimensional cubes, yet both distributions receive an IsoScore of 1. For an illustrated example of points generated from different isotropic distributions, consult Appendix F. It is therefore not necessarily the case that even highly anisotropic embedding spaces form narrow, anisotropic cones.

6 Conclusion & Future Works

Several studies have attempted to study isotropy in contextualized embedding models. Using mathematically rigorous tests, we demonstrate that current methods do not accurately measure isotropy. This paper presents IsoScore: a novel method for measuring isotropy that corrects the current misunderstandings in the literature. IsoScore is the only tool that is mean agnostic, robust to scalar changes to the covariance matrix and rotation invariant. Furthermore, IsoScore scales linearly with the number dimensions used and is stable when distributions contain highly isotropic subspaces. Future studies should avoid using existing methods to measure isotropy as resulting conclusions will be misleading or altogether inaccurate.

There are several promising directions for future work. Current studies have used inaccurate methods to claim that increasing isotropy improves the performance of contextualized embedding models. However, we believe that further decreasing isotropy could improve performance, especially in language modeling applications. IsoScore could be used as a regularizer when fine tuning word embeddings to penalize distributions that exhibit isotropy.

As point clouds of data arise in nearly all deep learning applications, IsoScore presents itself as a useful tool to study and refine a variety of models beyond the domain of NLP.

A Interpretation: IsoScore as a Summary Statistic

We will now provide an intuitive interpretation for the IsoScore of a point cloud $X \subseteq \mathbb{R}^n$. The interested reader should consult Appendix D for an in-depth explanation of this heuristic.

Heuristic A.1. *The IsoScore of X is roughly the fraction of dimensions uniformly utilized by X.*

For example, an IsoScore near 0.5 indicates that around half of the dimensions are utilized; and more generally, an IsoScore near $\alpha \in [0, 1]$ indicates that approximately $n \cdot \alpha$ of the dimensions of $\mathbb{R}^n$ are uniformly utilized by X. Table 2 illustrates this trend where IsoScore increases linearly as more dimensions are uniformly utilized in $\mathbb{R}^9$.

B Pre-existing metrics, in detail

Average Cosine Similarity: We define the *Average Cosine Similarity Score* as 1 minus the average cosine similarity of N randomly sampled pairs of points from X. That is,

$$\text{AvgCosSim}(X) := 1 - \left| \sum_{i=1}^{N} \frac{\cos(x_i, y_i)}{N} \right|, \quad \text{(B.1)}$$

where $\{(x_1, y_1), \ldots, (x_N, y_N)\} \subseteq X \times X$ are randomly chosen with $x_i \neq y_i$ for all i, and $\cos(x_i, y_i)$ denotes the cosine similarity of x_i and y_i. Some authors define the average cosine similarity score to be exactly the average, rather than one minus the average. However, for ease of comparison to other metrics, our score ensures that $\text{AvgCosSim}(X)$ is between 0 and 1. Under our convention, it is commonly believed that a score of 0 indicates that the point cloud X is anisotropic and a score of 1 indicates that X is isotropic. In Section 5, we demonstrate that this is not the case.

Partition Isotropy Score: For any unit vector $c \in \mathbb{R}^n$, let the partition function be denoted as $Z(c) := \sum_{x \in X} \exp(c^{\mathrm{T}} x)$. Mu et al. (2017) measure isotropy as $I(X) := (\min_{||c||=1} Z(c))/(\max_{||c||=1} Z(c))$. It is believed that a score closer to zero indicates an anisotropic space while a score closer to one indicates an isotropic space. Mu et al. (2017) demonstrate that a score of 1 implies that the eigenspectrum of X is flat. Computing $I(X)$ explicitly is intractable since the set of unit vectors is infinite. Accordingly, Mu et al. (2017) approximate $I(X)$ by

$$I(X) \approx \frac{\min_{c \in C} Z(c)}{\max_{c \in C} Z(c)} \quad \text{(B.2)}$$

where C is the set of eigenvectors of $X^{\mathrm{T}} X$. For the remainder of the paper we refer to (B.2) as the *Partition Score.*

Intrinsic Dimensionality: Given a point cloud $X \subseteq \mathbb{R}^n$, it is sometimes useful to assume that X is sampled from a manifold of dimension less than n. For example, points in the left panel in Figure 1 are sampled from a 1-dimensional space and points in the middle panel are sampled from a 2-dimensional space. Algorithms for intrinsic dimensionality aim to estimate the true dimension of a given manifold from which we assume a point cloud has been sampled. Intrinsic dimensionality has been used to argue that word embedding models are anisotropic (Cai et al., 2021). For a point cloud $X \subset \mathbb{R}^n$, it is commonly thought that the more isotropic X is, the closer the intrinsic dimensionality of X is to n. Dividing the intrinsic dimensionality of X by n provides us with a normalized score of isotropy, which we refer to as the *ID Score*. We use the maximum likelihood estimation (MLE) method to calculate intrinsic dimensionality. For a detailed description of the MLE method for intrinsic dimensionality estimation please consult (Levina and Bickel, 2004; Campadelli et al., 2015).

Variance Explained Ratio: The variance explained ratio measures how much total variance is explained by the first k principal components of the data. Note that when all principal components are considered, the variance explained ratio is equal to 1. Examining the eigenspectrum of principal components is undoubtedly a useful tool in quantifying the spatial distribution of high dimensional data. However, the variance explained ratio requires us to specify *a priori* the number of principal components we wish to examine. We divide the variance explained by the first k principal components by k/n to convert the variance explained ratio into a normalized score.

C Bounds on IsoScore

Proposition C.1. *Let $X \subseteq \mathbb{R}^n$ be a finite set. Then $\iota(X) \in [0, 1]$.*

Proof. Define Σ to be the $n \times n$ sample covariance matrix of X^{PCA}. Let $c > 0$ be so that if we define $\hat{\Sigma} := c \cdot \Sigma$, then $\|\hat{\Sigma}_D\| = \sqrt{n}$. Let us enumerate the entries of this vector as $\hat{\Sigma}_D = (\text{Var}(x_1), \ldots, \text{Var}(x_n))$. In order to show that $\iota(X) \in [0, 1]$, it is equivalent to show that $\|\hat{\Sigma}_D - \mathbf{1}\| \in [0, \sqrt{2(n - \sqrt{n})}]$, and by definition of the Euclidian norm, the latter estimate is equivalent to

$$2(n - \sqrt{n}) \;\geq\; \sum_{i=1}^{n} (\text{Var}(x_i) - 1)^2. \quad \text{(C.1)}$$

But the identity $\|\hat{\Sigma}_D\| = \sqrt{n}$ implies that $\sum_{i=1}^{n} \text{Var}(x_i)^2 = n$, so in fact (C.1) is equivalent to

$$\sum_{i=1}^{n} \text{Var}(x_i) \geq \sqrt{n}.$$

If this inequality were flipped, then we could estimate that

$$\begin{aligned} n &= \mathrm{Var}(x_1)^2 + \cdots + \mathrm{Var}(x_n)^2 \\ &\le (\mathrm{Var}(x_1) + \cdots + \mathrm{Var}(x_n))^2 \\ &< n, \end{aligned}$$

which is a contradiction. $\square$

D Interpretation of IsoScore, in Detail

This appendix provides rigorous mathematical justification for the claims that we made in Appendix A about the interpretation of IsoScore. It is split into two parts. In Appendix D.1 we formalize, and prove, the claim that the IsoScore for a point cloud X is approximately the fraction of dimensions uniformly utilized by X. And in Appendix D.2 we argue that IsoScore is an honest indicator of uniform spatial utilization.

D.1 IsoScore Reflects the Fraction of Dimensions Uniformly Utilized

In Section A we provided an interpretation for the value of the IsoScore $\iota(X)$ in Heuristic A.1. Intuitively, our heuristic says that $\iota(X)$ is roughly the fraction of dimensions of $\mathbb{R}^n$ utilized by X. We will now explain and justify this heuristic in detail. We formalize our heuristic below.

Heuristic D.1. *Suppose that a point cloud $X \subseteq \mathbb{R}^n$ gives an IsoScore $\iota(X)$. Then X occupies approximately*

$$k(X) := \iota(X) \cdot n + 1 - \iota(X) \tag{D.1}$$

dimensions of $\mathbb{R}^n$.

Note in particular that $\iota(X) = 0$ implies that (D.1) simplifies to a single dimension utilized and $\iota(X) = 1$ implies that (D.1) simplifies to all n dimensions utilized.

In the remainder of this subsection, we will justify the above heuristic. We will make reference to the notations and equations in Section 4. Fix $n \geq 1$ and $k \in \{1, \dots, n\}$, and consider the matrix $I_n^{(k)}$. Recall that $I_n^{(k)}$ is the covariance matrix for a k-dimensional uncorrelated Gaussian distribution in $\mathbb{R}^n$. For example, spaces sampled using the matrices $I_3^{(k)}$, for $k = 1, 2, 3$ are rendered in Figure 1 as a line, a circle, and a ball, respectively. One can compute directly that the IsoScores for these three spaces are

$$\iota(I_3^{(1)}) \approx 0.0, \qquad \iota(I_3^{(2)}) \approx 0.5, \qquad \iota(I_3^{(3)}) \approx 1.0.$$

Our main insight in this section is that it is worthwhile to apply these statistics for reverse reasoning in the following sense: suppose you have some point cloud $X \subseteq \mathbb{R}^3$ which satisfies $\iota(X) \approx 1/2$. Then this IsoScore should allow you to infer that X uniformly occupies approximately 2 dimensions of $\mathbb{R}^3$.

In Heuristic D.1, we provide the closed formula (D.1) for generalizing the above reasoning to all dimensions n. We will now prove this formula.

Proof of Heuristic D.1. Once we normalize $I_n^{(k)}$ so that its Euclidean norm is $\sqrt{n}$, we get that the first k diagonal entries are $\sqrt{n/k}$. Therefore, the isotropy defect is

$$\begin{aligned} \delta(I_n^{(k)}) &= \frac{\|\hat{I}_n^{(k)} - \mathbf{1}\|}{\sqrt{2(n - \sqrt{n})}} && \text{(D.2)} \\ &= \frac{\sqrt{k(1 - \sqrt{n/k})^2 + n - k}}{\sqrt{2(n - \sqrt{n})}} && \text{(D.3)} \\ &= \frac{\sqrt{n - \sqrt{nk}}}{\sqrt{n - \sqrt{n}}}. \end{aligned}$$

It is natural to consider the map $k \mapsto \delta(I_n^{(k)})$. A priori, this is a discrete function defined on $\{1, \dots, n\}$; a fortiori, this is in fact a continuous, monotonically decreasing bijection on the connected interval $[1, n]$. Therefore, the function defined by

$$\tilde{\delta}_n : [1, n] \to [0, 1] : k \mapsto \delta(I_n^{(k)})$$

is invertible, and one can compute that its inverse is

$$\tilde{\delta}_n^{-1} : [0, 1] \to [1, n] : d \mapsto \frac{(n - d^2(n - \sqrt{n}))^2}{n}.$$

The truth of this heuristic rests upon the validity of the following assumption, which is reasonable to use in many contexts.

Assumption Underpinning The Heuristic. *The isotropy defect corresponding to a point cloud sampled using the covariance matrix $I_n^{(k)}$ is the prototypical isotropy defect for any point cloud in $\mathbb{R}^n$ which uniformly utilizes k dimensions.*

We will now invoke this assumption. Let $\delta(X)$ be the isotropy defect for an arbitrary point cloud X. If we assume that we are in the nontrivial case where $\delta(X) > 0$, then $\tilde{\delta}_n^{-1}(\delta(X))$ is in the interval $[1, n)$. Because $\tilde{\delta}_n^{-1}$ is bijective, there exists a unique $k \in \{1, \dots, n-1\}$ with the property that $\tilde{\delta}_n^{-1}(\delta(X)) \in [k, k+1)$. But by construction, $[k, k+1) = [\tilde{\delta}_n^{-1}(\delta(I_n^{(k)})), \tilde{\delta}_n^{-1}(\delta(I_n^{(k+1)})))$. By monotonicity of $\tilde{\delta}_n^{-1}$, this implies that

$$\delta(X) \in [\delta(I_n^{(k)}), \delta(I_n^{(k+1)})).$$

Therefore, by the assumption underpinning the heuristic, we can deduce that X is uniformly utilizing between k and $k+1$ dimensions of $\mathbb{R}^n$. To be specific, we say that X is uniformly utilizing $\tilde{\delta}_n^{-1}(\delta(X)) \in [k, k+1)$ dimensions. Recalling Section 4, we can recognize that in Step 6, the formula for $k(X)$, the quantity of dimensions uniformly utilized by X, is precisely $k(X) := \tilde{\delta}_n^{-1}(\delta(X))$; likewise, the formula for $\phi(X)$, the fraction of dimensions uniformly utilized by X, is $\phi(X) := \tilde{\delta}_n^{-1}(\delta(X))/n$.

Now we are in a position to verify Equation D.1, the main claim of Heuristic D.1. By the assumption underpinning the heuristic, it is sufficient to verify Equation D.1 in the case of $I_n^{(k)}$, for $k = 1, \dots, n$. This is because all functions that we will utilize are monotonic bijections. Using the notation in Steps 6 and 7 in Section 4, we can compute that

$$\begin{aligned} \iota(I_n^{(k)})(n-1) + 1 &= S(\phi_n(I_n^{(k)}))(n-1) + 1 \\ &= n \cdot \phi_n(I_n^{(k)}) \\ &= k(I_n^{(k)}). \end{aligned}$$

Using the formula $k(X) = (n - \delta(X)^2(n - \sqrt{n}))^2/n$, we can continue:

$$\begin{aligned} k(I_n^{(k)}) &= \frac{(n - \delta(I_n^{(k)})^2(n-\sqrt{n}))^2}{n} \\ &= \frac{(n - \frac{n-\sqrt{nk}}{n-\sqrt{n}}(n-\sqrt{n}))^2}{n} \\ &= k, \end{aligned}$$

where in the penultimate equality we used Equation D.2. This completes the proof. ☐

Because IsoScore covers a continuous spectrum, one should carefully interpret what we mean when we say that X occupies approximately k dimensions of $\mathbb{R}^n$. For example, consider the 2D Gaussian distributions depicted in Figure 3. Heuristic D.1 predicts $k = 1.9996, 1.6105, 1.0281$ dimensions are used when $x = 1, 3, 75$, respectively. These should be interpreted as follows: "when $x = 75$, the points sampled are mostly using one direction of space" and "when $x = 3$, the points sampled are using somewhere between one and two dimensions of space."

Heuristic D.1 suggests that an IsoScore near $1/2$ means that the corresponding point cloud X occupies approximately half of the dimensions of its ambient space. We can make this reasoning rigorous as follows: for any $n \geq 2$, one can compute that

$$\iota(I_n^{(k)}) = \frac{k-1}{n-1} \approx \frac{k}{n}, \qquad \text{for any } k = 1, \dots, n. \tag{D.4}$$

Proof of (D.4). In Equation D.2 computed that the isotropy defect is $\delta(I_n^{(k)}) = \sqrt{n - \sqrt{nk}}/\sqrt{n - \sqrt{n}}$. If we substitute this expression into (4.1), then we obtain the formula $\iota(I_n^{(k)}) = \frac{k-1}{n-1}$. Furthermore, one can easily estimate that $|\frac{k-1}{n-1} - \frac{k}{n}| \leq \frac{1}{n}$. ☐

Table 2 illustrates this formula in the concrete case of $\mathbb{R}^9$. This formula implies the following key relationship:

$$\lim_{n \to \infty} \iota(I_n^{(\lfloor n/2 \rfloor)}) = 1/2.$$

Generalizing this line of reasoning yields our second heuristic explanation for the meaning of IsoScore, Heuristic 4.1. We copy it here:

Heuristic D.2. *When the ambient space $\mathbb{R}^n$ has large dimension, the IsoScore $\iota(X)$ is approximately the fraction of dimensions uniformly utilized by X.*

Proof of Heuristic 4.1. By the assumption underpinning Heuristic D.1, it suffices to show this in the case of matrices of the form $I_n^{(k)}$. Fix $\alpha \in [0, 1]$, and consider the covariance matrix $I_n^{(\lfloor \alpha n \rfloor)}$. For large n, the fraction of dimensions uniformly utilized by $I_n^{(\lfloor \alpha n \rfloor)}$ is approximately α, according to Definition 3.1. But by (D.4), we can compute that

$$\lim_{n \to \infty} \iota(I_n^{(\lfloor \alpha n \rfloor)}) = \lim_{n \to \infty} \frac{\lfloor \alpha n \rfloor - 1}{n-1} = \alpha.$$

This completes the proof. ☐

D.2 The IsoScore for $I_n^{(k)}$ Reflects Uniform Utilization of k Dimensions

We will now investigate what range of IsoScores are obtained by sample covariance matrices that utilize k out of n dimensions. It is easy to see that these scores at least fill the interval $(0, \iota(I_n^{(k)})]$, since the map

$$\begin{aligned} [1,\infty) &\to (0, \iota(I_n^{(k)})] \\ x &\mapsto \iota(\operatorname{diag}(x, 1, \ldots, 1, 0, \ldots, 0)) \end{aligned}$$

is surjective. Conversely, we can show that this interval is the only possible range of IsoScores corresponing to such covariance matrices. We make this claim rigorous in the following proposition.

Proposition D.3. *Fix* $n \geq 2$. *For any* $k = 1, \ldots, n$, *we have that*

$$I_n^{(k)} = \operatorname{argmax}\big\{\iota(J) : J \text{ utilizes } k \text{ out of } n \text{ dimensions}\big\}. \tag{D.5}$$

This result justifies the use of IsoScore for measuring the extent to which a point cloud optimally utilizes all dimensions of the ambient space because it demonstrates that $\iota(I_n^{(k)})$ is the maximal IsoScore for any covariance matrix with k non-zero entries and $n - k$ zero entries.

Proof of Proposition D.3. In this section we let $\operatorname{Diag}^+(n)$ denote the set of $n \times n$ real matrices which vanish away from the diagonal and whose diagonal entries are all non-negative. The set $\operatorname{Diag}^+(n)$ parameterizes the set of all $n \times n$ sample covariance matrices after performing PCA-reorientation. We also let $\operatorname{Diag}^+(n, k) \subseteq \operatorname{Diag}^+(n)$ denote that subset whose first k diagonal entries are non zero and whose last $n - k$ diagonal entries are zero. The set $\operatorname{Diag}^+(n, k)$ parameterizes the set of sample covariance matrices post-PCA reorientation which utilize k out of n dimensions of space. Covariance matrices in $\operatorname{Diag}^+(n, k)$ represent point clouds with the property that $\operatorname{Var}(x_i) > 0$ for $i = 1, \ldots, k$, and $\operatorname{Var}(x_i) = 0$ for $i = k + 1, \ldots, n$.

It suffices to show that, for every $J \in \operatorname{Diag}^+(n, k)$, we have that $\iota(J) \leq \iota(I_n^{(k)})$, or equivalently, $\delta(J) \geq \delta(I_n^{(k)})$. Write $\hat{I}_{n,D}^{(k)} = (\sqrt{n/k}, \ldots, \sqrt{n/k}, 0, \ldots, 0)$ and $J_D = (a_1, \ldots, a_k, 0, \ldots, 0)$, where $a_1^2 + \cdots a_k^2 = n$. Then we must show that $\|J_D - \mathbf{1}\| \geq \|\hat{I}_{n,D}^{(k)} - \mathbf{1}\|$, or equivalently,

$$\sum_{i=1}^{k} (a_i - 1)^2 + n - k \geq \sum_{i=1}^{k} (\sqrt{n/k} - 1)^2 + n - k.$$

This latter estimate is equivalent to

$$\sum_{i=1}^{k} a_i \leq \sqrt{nk}.$$

By Jensen's inequality, applied with the convex function $f(x) = x^2$, we have that

$$f\left(\sum_{i=1}^{k} \frac{a_i}{k}\right) \leq \sum_{i=1}^{k} \frac{f(a_i)}{k}.$$

Simplifying, this implies that $(a_1 + \cdots + a_k)^2 \leq kn$. This completes the proof. □

E Numerical Experiments

In this section, we provide explicit details of how each test is designed. We provide code for all experiments at: *https://github.com/bcbi-edu/p_eickhoff_isoscore*.

1. **Test 1: Mean Invariance.** To assess whether the five scores are mean invariant, we start with $100,000$ points sampled from a 10-dimensional multivariate Gaussian distribution with covariance matrix equal to the identity and a common mean vector $M = [\mu, \mu, ..., \mu]$. We compute scores for $\mu = 0, 1, 2, ..., 20$.

2. **Test 2: Scalar Invariance.** We test for the property of scalar invariance by sampling $100,000$ points from a 5D Gaussian distribution with common mean vector $M = [3, 3, 3, 3, 3]$ and covariance matrix equal to $\lambda \cdot I_5$. We then compute scores for each point cloud as we increase λ from 1 to 25.

3. **Test 3: Maximum Variance.** We start by sampling $100,000$ points from a 10D multivariate Gaussian distribution with zero common mean vector and a diagonal covariance matrix with nine entries equal to 1 and one diagonal entry equal to x. In our experimental setup, we compute all five scores as we increase x from 1 to 75.

4. **Test 4: Rotation Invariance.** Our baseline point cloud $X \subset \mathbb{R}^n$ consists of $100,000$ points sampled from a 2D zero-mean Gaussian distribution with a covariance matrix equal to $\left(\begin{smallmatrix} 1 & 0.8 \\ 0.8 & 1 \end{smallmatrix}\right)$. We rotate X by $120°$ and $240°$. Lastly, we project X using PCA reorientation while retaining dimensionality to obtain a point cloud X^{PCA}.

5. **Test 5: Dimensions Used (Fraction of Dimensions Used Test).** For our first experiment, which we term the "fraction of dimensions used test," we sample $100,000$ points

from a 25D multivariate Gaussian distribution with a zero common mean vector and a diagonal covariance matrix where the first k entries are 1 and the remaining $n - k$ diagonal elements are 0. We refer to k as the number of dimensions uniformly used by our data (see Definition 3.1). For our experiment we let $k = 1, 2, 3, ..., 25$, and compute the corresponding scores.

6. **Test 5: Dimensions Used (High Dimensional Test).** A good score of spatial utilization should allow for easy comparison between different vector spaces even when the dimensionality of the two spaces is different. We sample $100,000$ points from a zero-mean Gaussian distribution with identity covariance matrix I_n and increase the dimension of the distribution from $n = 2, \dots, 100$.
7. **Test 6: Global Stability.** We generate a "skewered meatball" by sampling $1,000$ points from a line in 3D space and increase the number of points sampled from a 3-Dimensional, zero-mean, isotropic Gaussian from 0 to $150,000$.

F Geometry of Isotropy

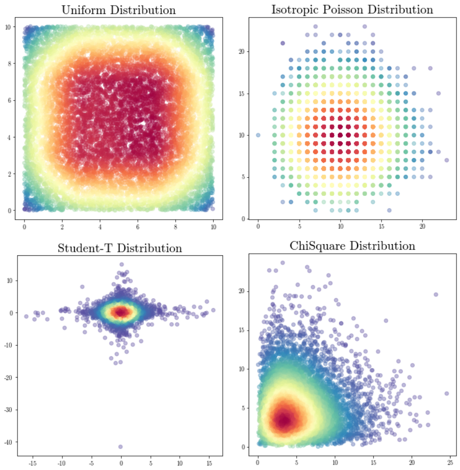

Figure 10: Points sampled from a Uniform distribution, Poisson distribution, Student-T distribution and ChiSquare distribution respectively

Each of the distributions illustrated in Figure 10 has a covariance matrix proportional to the identity and is therefore maximally isotropic. Namely, the variance is distributed equally in all directions. Despite receiving an IsoScore of 1, the geometry of the point clouds are vastly different. We can only comment on the geometry of the point cloud if the underlying distribution of the space is known.

A Natural Diet: Towards Improving Naturalness of Machine Translation Output

Markus Freitag, David Vilar, David Grangier, Colin Cherry, George Foster
Google Research
{freitag, vilar, grangier, colincherry, fosterg}@google.com

Abstract

Machine translation (MT) evaluation often focuses on accuracy and fluency, without paying much attention to translation style. This means that, even when considered accurate and fluent, MT output can still sound less *natural* than high quality human translations or text originally written in the target language. Machine translation output notably exhibits lower lexical diversity, and employs constructs that mirror those in the source sentence. In this work we propose a method for training MT systems to achieve a more natural style, i.e. mirroring the style of text originally written in the target language. Our method tags parallel training data according to the naturalness of the target side by contrasting language models trained on natural and translated data. Tagging data allows us to put greater emphasis on target sentences originally written in the target language. Automatic metrics show that the resulting models achieve lexical richness on par with human translations, mimicking a style much closer to sentences originally written in the target language. Furthermore, we find that their output is preferred by human experts when compared to the baseline translations.

1 Introduction

Machine translation has made tremendous progress in recent years with the advent of neural methods (Bahdanau et al., 2015; Vaswani et al., 2017). This is especially true for language pairs with a large amount of available bilingual text for training (Barrault et al., 2020a). However MT output still can be improved: it currently trails human translators in expert evaluation (Toral et al., 2018; Freitag et al., 2021) and its language is perceived as poorer and more synthetic (Vanmassenhove et al., 2021). In this work, we aim to produce machine translation output that has a more *natural* style.

Source Es wird befürchtet, dass die Opferzahlen noch deutlich in die Höhe gehen.

Translationese It is feared that the number of victims will increase significantly.

Natural It is feared that the death toll will rise significantly.

Figure 1: Example De→En translations: This work sets the goal to generate more natural translations like *death toll/rise* in comparison to literal translations like *number of victims/increase*.

Although difficult to define precisely, we consider a translation to be natural if it is an adequate and fluent translation, whose style matches that of high quality monolingual text. Such a translation should contain few translationese constructs and use a rich vocabulary. This is exemplified in Figure 1. The translationese sentence uses the construct "number of victims", which is a literal translation for the German "Opferzahlen". Although correct (i.e. adequate and fluent), "death toll" shows a much more natural word choice for this translation.

Our objective in this paper is to study how the naturalness of machine translation output can be improved. In particular, we focus on how available measures can guide the translation process towards this goal. There have been several studies analyzing the naturalness of generated texts (see Section 2), but in contrast we concentrate on actively improving this aspect by modifying how NMT output is produced.

Our methodology follows a simple intuition: training data whose target side resembles high-quality text naturally written in the target language can bring model outputs closer to this style of text. We exploit the fact that bilingual training sets typically mix examples originating from both translation directions: source-to-target and target-to-source. We rely on contrasting language models (LMs) (Manning and Schütze, 1999; Moore and Lewis, 2010) to identify natural data: we train sep-

Findings of the Association for Computational Linguistics: ACL 2022, pages 3340 - 3353
May 22-27, 2022

arate models on target-language data known to be translations, and on data known to be mostly originally written in the target language. We then use these LMs to tag parallel training data as having a natural or translated target side. Comparing to hard filtering of the data, tagging offers more flexibility without sacrificing coverage (Caswell et al., 2019).

Our contributions are as follows: (1) We use contrastive language model scoring to separate natural from translated text. (2) We demonstrate that optimizing BLEU scores on tgt-original test sets while avoiding high BLEU scores on src-original test set is a valid strategy to improve the naturalness of MT output. (3) We show that our more natural MT output is more similar to natural sentences based on lexical diversity. (4) Human evaluations show that the style of our more natural translations are preferred by humans, albeit with a minimal loss in translation accuracy.

2 Related Work

2.1 Translationese

Translations differ from text originally written in the target language due to a combination of factors that may include the intentional use of explicitation and normalization, or unintentional lexical or structural artifacts. The style resulting from the combination of these factors is often referred to as *translationese*. The effects of translationese in training data on MT quality and evaluation have been investigated by many authors (Kurokawa et al., 2009; Lembersky et al., 2012; Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2020; Freitag et al., 2019; Edunov et al., 2020; Freitag et al., 2020b). Several papers (Kurokawa et al., 2009; Koppel and Ordan, 2011; Shen et al., 2019; Riley et al., 2020) proposed to train classifiers to detect translationese sentences in monolingual corpora. Similar to our work, Kurokawa et al. (2009) used their classifier to preprocess MT training data, but they removed target-original pairs while we emphasize them. Lembersky et al. (2012) kept both types of data but introduced entropy-based measures that allowed their phrase-based decoder to favor lower entropy translationese entries. Riley et al. (2020) used a convolutional classifier to distinguish natural from translationese text. We train contrastive language models to partition the training data into original and translated sentences to bias the model to generate more natural translations.

2.2 Training Data Tagging for NMT

We use tags to differentiate subsets of the training data, with the objective of training a model that will decode differently depending on the tag provided at inference. This strategy has been explored with various objectives in prior work. Tagging to control inference has notably been used to indicate target language in multilingual models (Johnson et al., 2016), formality level (Yamagishi et al., 2016), politeness (Sennrich et al., 2016a), gender from a gender-neutral language (Kuczmarski and Johnson, 2018), backtranslation (Caswell et al., 2019), as well as to produce domain-targeted translation (Kobus et al., 2017). Shu et al. (2019) use tags at training and inference time to increase the syntactic diversity of their output while maintaining translation quality; similarly, Agrawal and Carpuat (2019) and Marchisio et al. (2019) use tags to control the reading level (simplicity/complexity) of the output.

2.3 Evaluation of Naturalness

Evaluation of MT usually focuses on accuracy and/or fluency (Barrault et al., 2020a; Läubli et al., 2020). Recent work has started to look at the richness and complexity of MT output. Vanmassenhove et al. (2019, 2021) address the effects of statistical bias on language generation. They assess lexical diversity and sophistication, and conclude that the translations produced by MT systems are consistently less diverse than the original training data, containing a higher number of frequent patterns while reducing the infrequent ones when compared to original texts. Toral (2019) compared MT output with human generated translations and found that there is a measurable difference between the two. In this work we use the diversity metrics introduced by Vanmassenhove et al. (2021) to demonstrate that we can build an MT system with lexical diversity similar to human translations (HT). We also incorporate the findings of Freitag et al. (2019), and show how to reliably evaluate more natural translations on target-original test sets while allowing the model to decrease BLEU scores on source-original test sets.

3 Approach

Our first objective is to distinguish text originally written in the target language (natural text) from translations. For that purpose, we train a pair of sentence-level language models to contrast their likelihood, a proven method for domain adaptation (Moore and Lewis, 2010; Axelrod et al., 2011). These language models are then used to tag MT training data as natural target (`<nat>`) or translationese target (`<trans>`), in order to train an MT system which can favor natural hypotheses.

3.1 Inferring Naturalness Tags

Our natural language model is trained on the monolingual newscrawl dataset from WMT (Barrault et al., 2020a). This data consists of web-crawled sentences from newspapers and other news sites from the countries speaking the corresponding language (e.g. Germany, Austria and Switzerland for German). Although it is not unusual to have contributions from foreign reporters or even translations of articles from foreign newspapers, we expect that the majority of the data collected this way will be natural text.

Our translationese LM is trained on machine-translated newscrawl data, as a proxy for human translated data. This approach does not require finding large amounts of existing text in the target language known to be translations, which is a challenging problem as the necessary metadata is not available for most corpora.

For our language models, we use a decoder-only transformer architecture comparable to *transformer-big* (Vaswani et al., 2017). We classify new sentences by thresholding the difference in average log probability under the two models.

For training our MT system we label each bilingual training example by prepending a special token in the source sentence denoting the class of the target sentence (`<nat>` or `<trans>`). At inference, we favor natural generation by prepending the natural token (`<nat>`) to the input. We call these models *natural-to-natural* (N2N) as their ultimate purpose is to translate natural source sentences into natural target sentences.

3.2 Potential Domain Biases

Domain bias might arise with our strategy. Our translated data originates from source language news and focuses on topics/domains of interest to a source-language speaker, while our natural data originates from target language news and therefore focuses on topics/domains of interest to a target-language speaker. When training a system that mainly concentrates on training data that originates from the target language, we might run into the problem that the model does extremely well on domains important in the target language while being poor on domains that are only important in the source language.

To counteract this problem, instead of relying on sentences originated in the target language only, we train on all the training data, but use tags to help the model learn the differences between the two training corpora. We then guide the inference algorithm (by using one of the two tags) to emphasize the characteristics important for one of the two training corpora only. The tagging approach helps the model to be familiar with the domains only important in the source language even when using a tag that emphasizes the characteristics of the target-original training data.

Finally, all human evaluations in this work are conducted with test sentences originating in the source language only, even when using the target-original tag. We will later show that humans prefer translations of sentences originated in the source language when using the target-original tag which demonstrates that by putting emphasis on the target-original training data, the model learns to translate better even though there is a mismatch between the domains of the training data and the test sentences.

4 Experimental Setup

We experiment on the WMT news translation tasks for evaluation (Bojar et al., 2016; Barrault et al., 2020b), focusing on the German↔English language pair. For this language pair there is abundant training data available, and MT systems achieve high quality translations. This is a good setting for our work since improving naturalness becomes a worthwhile endeavor only if high accuracy and fluency levels are reached.

4.1 Training Data

We use news-commentary-v15, paracrawl-v5.1, europarl-v10 and commoncrawl as training corpora (see Table 2). Noisy data is filtered out with contrastive data selection as proposed by Wang et al. (2018). Finally, we add back-translated data (Sennrich et al., 2016b) from the monolingual newscrawl (2007-2018) dataset for each target language, and mark synthetic source sentences with an additional special tag on the source side (`<bt>`) (Caswell et al., 2019). The BT data has been generated with a bitext only model from the reverse translation direction.

	Diversity Metrics											
model	B1↓	B2	B3↑	TTR↑	Yule's I↑	MTLD↑	H↑	D↓	PTF↓	CDU↓	SynTTR↑	cLM ↓
MT	68.55	6.31	25.13	0.1028	0.9375	144.07	12.64	92.22	0.7637	0.3938	0.1587	1.21
HT	68.25	6.30	25.44	0.1184	1.3980	148.08	12.93	92.00	0.7450	0.3781	0.1621	1.16
NAT	65.98	6.12	27.90	0.1553	2.9612	169.93	11.13	93.04	0.7133	0.3861	0.2108	0.77

Table 1: En→De: Diversity metrics calculated on the concatenation of newstest2011-2020 (∼25k sentences). HT scores are calculated on the src-orig half while NAT is calculated on the tgt-orig half. The cLM shows the ratio between the contrastive translationese and natural LMs. The arrows by the metric names indicate the desired behaviour towards more natural style. B2 does not have a clear desired behaviour.

4.2 Automatic Evaluation

4.2.1 Translation Quality

We use sacreBLEU (Post, 2018)[1] to automatically evaluate translation quality with BLEU, with the primary goal of improving scores on the *target-original* test sets. Since 2019, all WMT test sets have been composed only of source original (src-orig) sentence pairs. To create target original (tgt-orig) sets, we just flip the source and target of the test sets for the reverse direction. In previous years, the WMT test sets were a mixture of source- and target-original texts, each human-translated into the other language. For these years we split the test sets based on their original language and report results on the two subsets. Optimizing MT systems on these two settings can yield very different conclusions.

src-orig Beyond a certain level, BLEU scores on src-orig test sets are biased in favor of simpler and more literal translations (Freitag et al., 2020b); increasing scores above this threshold can have a negative impact on translation quality. Consequently, our goal is to avoid very high src-orig BLEU scores while increasing tgt-orig scores, a strategy that Freitag et al. (2020a) have demonstrated to be effective for improving translation quality.

tgt-orig Freitag et al. (2019); Edunov et al. (2020) found that MT systems trained with BT training data mostly improve on tgt-orig test sets. One explanation is that BT increases the fluency and naturalness of MT output, a property that can more easily be measured by comparing to natural target-language text than typical human translations, which have lower lexical diversity. Contrary to src-original test sets, generating literal, simple translation output decreases BLEU scores on tgt-orig test sets and cannot be used as a strategy to inflate BLEU scores. To further our main goal of generating more natural translations, we focus on improving BLEU scores on tgt-orig test sets.

4.2.2 Diversity Scores

Vanmassenhove et al. (2021) proposed a series of metrics to measure the lexical diversity of a text. They range from measures like type-to-token ratio (TTR) or the entropy of word forms given a lemma, to novel metrics that analyse synonym frequencies. They show that MT text has a lower degree of diversity than human-generated text but do not distinguish between original text and HT.

We refer the reader to the original paper for the metric definitions, although we also provide a short overview in the appendix. For better interpretability, in the results table we provide an indication of the desired direction for each metric. Note however that our goal is *not* to optimize these metrics, rather we want to build an MT system whose output is most similar to natural sentences. To illustrate this, assume we have a "translation model" that just generates random words. Such a system will certainly score high in diversity metrics (e.g. it will have a high entropy), but the resulting text will certainly not be natural. In fact, for a few metrics, our baseline system already gets a "better" score than natural sentences. Thus, for those metrics we should steer them in the "wrong" direction to achieve a style closer to natural sentences.

We used the implementation provided by the authors except for the "Synonym Frequency Analysis" metrics, which we reimplemented using an in-house synonym dictionary. Note also that some of these metrics are sensitive to the corpus size they are applied on (e.g. TTR, the type-to-token ratio, decreases as the corpus size increases). Thus not all numbers are in the same range as the results reported by Vanmassenhove et al. (2021).

---

[1] sacreBLEU signatures: BLEU+case.mixed+lang.LP +numrefs.1+smooth.exp+SET+tok.13a+version.1.5.1

4.3 Human Evaluation

We hired 4 professional translators (native in the target language) and conducted 2 types of human evaluations to evaluate (a) the overall translation quality, and (b) the naturalness of our MT output. We randomly chose 62 documents (roughly 1,000 sentences) from the src-original halves of newstest2019 for human evaluation to avoid human translated source sentences (Läubli et al., 2020).

Quality We measure quality with an in-context version of MQM (Lommel et al., 2014) which mimics the setup proposed by Freitag et al. (2021). This includes using the same error categories, severity levels and error weighting schema, which were adapted for the MT use case. As suggested in the study, we weight each major error with 5 and each minor error with 1, except for minor punctuation errors which get a score of 0.1.

Naturalness The preferred setup to evaluate naturalness is to present two translations of the same source sentence to native speakers without showing the source sentence. We ask the raters whether they prefer one of the outputs or rate them equally based on naturalness and natural phrasing. We emphasize that this evaluation is carried out in a monolingual manner, as showing the source can bias the human judges towards the translation that mimics the original sentence, as it is easier to evaluate.

4.4 Training Details

We train NMT models similar to the transformer-big (Vaswani et al., 2017) architecture (6 encoder and 6 decoder layers, model dimension size of 1,024, hidden dimension size of 8,192, 16 multi-attention heads). Our models use a vocabulary of 32k subword units (Kudo and Richardson, 2018) ands are trained for 250k updates with a batch size of 32k sentences. The baseline system uses only `<bt>` tags to tag all BT training examples while keeping the bitext data untagged. Our proposed system (denoted as N2N) is enhanced with the `<nat>` and `<trans>` tags to also tag the bitext data. During inference, in order to produce more natural output we tag the input sentence with the `<nat>` tag. For comparison purposes, we also analyze the output when using the `<trans>` tag.

5 Experimental Results

Due to space constraints and German being the more morphologically rich language, we focus our analysis mainly on the English→German (En→De) translation direction, but we provide translation results for the reverse direction (De→En) as well.

	size	NAT
news-commentary	251k	15.3%
commoncrawl	1.5M	39.6%
europarl	452k	44.1%
paracrawl	54.7M	30.4%
newscrawl-de	271M	92.0%*

Table 2: En→De: Training data statistics and fraction of natural target sentences. *This fraction is overestimated since this set is used for LM training.

5.1 Naturalness Classification

Our naturalness classifier contrasts the natural and translation LMs introduced in Section 3. We need to find a threshold to be able to classify the training data based on their target side as natural or translation. We chose 0.95 for both directions, resulting in $\sim 90\%$ sentence-level classification accuracy on newstest2018. Table 1 (last column) shows the contrastive language model (cLM) scores for the concatenation of newstest 2011-20 for En→De for natural, (human) translated (HT) and machine translated (MT) sentences and shows that 0.95 seems a reasonable decision.

Table 2 reports the fraction of data classified as natural for each subset of the German side of our training corpus along with subset sizes. The fraction of natural target sentences per dataset varies between 30.4% and 44.1%, except for newscrawl-de (92.3%) which is our training set to define natural language and news commentary (15.3%) which mostly seems to have translations on the target side. The 44.1% of natural German sentences for Europarl is probably an overestimate and reflects the high quality of the translations in this particular corpus. Overall, the parallel corpora have less than 50% natural target sentences which means that the training data in this translation direction is dominated by translated text on the target side.

Table 3 shows the diversity metrics on a 15k sample of the training data. We can clearly see that the sentences considered natural are more lexically diverse than the sentences marked as translations, suggesting a valid classification by our model. Note that, as pointed out above, the lack of labelled data hinders reporting classification accuracy measures for the training data.

classified	B1↓	B2	B3↑	TTR↑	Yule's I↑	MTLD↑	H↑	D↓	PTF↓	CDU↓	SynTTR↑
TRANS	70.74	6.98	22.28	0.0918	0.9484	211.73	15.13	90.75	0.7296	0.3528	0.1328
NAT	68.91	7.16	23.93	0.1103	1.3501	303.05	14.94	90.69	0.7140	0.3726	0.1636

Table 3: En→De: Diversity metrics calculated on a 15k sample of the classified training data.

5.2 Translation Results

We evaluate three types of translations: the output of a regular baseline MT system and the outputs of our natural-to-natural (N2N) system trained with tags, decoding with either the `<nat>` or the `<trans>` tag. BLEU scores are reported in Table 4. We report average scores over all test sets (newstest 2011 through 2020), separate results for each set can be found in the appendix.

Focusing on En→De, for the src-orig half of the test sets, we obtain an average drop of 4.6 BLEU points when using the `<nat>` tag. For src-orig data, the references are translated text and the BLEU evaluation does not strongly reward text which does not adopt a translation style. When we instruct the system to produce translationese text using the `<trans>` tag, we recover the BLEU score of the baseline system. We thus have a clear indication that the system is learning to produce different texts depending on the given tag. This behaviour is consistent across all test sets, it is not just an effect due to averaging (see the Appendix for the detailed numbers).

We now turn our attention to the results on target-original data. In this situation the BLEU scores show a behaviour opposite to the previous case. Using the `<nat>` tag for translation, we get an improvement of 1.0 BLEU on average compared to the baseline. Remember that for this condition, the original text is on the target side, i.e. on the references we are evaluating against. This is thus an indication that we are indeed generating text that is closer to human natural text. When switching to `<trans>` translation, we see a drop of 2.4 points.

For the opposite direction we see a similar trend for both conditions (right part of Table 4).

5.3 Lexical Diversity Scores

In Section 5.2 we showed how BLEU scores change when applying our proposed method, and we observed an improvement on the target-original test sets, which may indicate improved naturalness in the output text. This evaluation setting is however artificial since it relies on translated source text while MT systems generally need to translate text originally written in the source language. We thus turn to a more detailed analysis of the produced translations, focusing on the src-original test sets.

Table 5 shows the diversity metrics computed on the concatenation of all the source-original test sets. It can be seen that the N2N system gets diversity scores much closer to ones calculated on natural sentences (NAT) when compared to the baseline system in all categories. In fact, it even obtains better scores than the human translations for some of them. We do not claim to outperform humans on translation quality: natural text shows certain characteristics that can be measured by these metrics, but improving on these metrics alone does not necessarily imply better translations. However, these results combined with the metrics from the previous section are positive indicators which motivate a human evaluation.

6 Human Evaluation

6.1 MQM

We carry out a human evaluation using the MQM framework (Lommel et al., 2014), which provides a detailed categorization of errors found in the text. The evaluation was carried out by professional translators. The results comparing the baseline output with the output of our N2N models with `<nat>` tag can be found in Tables 6 and 7.

Looking into the error categorization for En→De, we see a clear advantage of the N2N system for the style metrics, halving the number of major errors and reducing the number of minor errors by one third. The number of grammar errors has also been significantly reduced, from 56 minor errors in the baseline system to 29 in the N2N system, although with an increase of 6 major errors. For N2N we observe an increase in minor punctuation errors (mainly repetition of punctuation signs) and spelling errors, which can be traced back to the German orthography reform: the N2N seems to prefer the old writing form[2] which is now officially considered incorrect.[3]

---

[2] E.g. the N2N seems to generate more occurrences of "daß" instead of "dass".

[3] These errors could easily be corrected in a rule-based

Table 5: En→De: Diversity metrics computed on the concatenation of newstest2011 to newstest2020, source-original test sets. Both the base and the N2N include backtranslated data. The arrows by the metric names indicate the desired behaviour towards more natural style. B2 does not have a clear desired behaviour.

For the accuracy errors, we also see an important reduction of mistranslation errors, from 79 to 26, but at the cost of increasing the number of major errors from 44 to 51. The other categories show comparable results between the two systems. Looking at the total number of errors, we see that the total number of errors decreases for the N2N system, from 508 for the baseline to 407 for the N2N system. The shift in errors is however not uniform across major and minor errors: while we achieve a drop of 30% in the number of minor errors (from 395 to 275), we increase the number of major errors by 16% (from 113 to 132). Overall, using the weighting approach proposed by (Freitag et al., 2021),[4] N2N achieves a better global score of 0.88, compared to 0.91 for the baseline system.

For the De→En translation direction, the results are mixed: we again obtain an important reduction in the number of minor style and grammar errors, but with with a slight increase of major errors. However the number of accuracy errors is also increased, which leads to a worse global score for the N2N system (0.49 vs. 0.55).

6.2 Side-by-side

The MQM analysis shows that the N2N system is able to produce grammatically better sentences, with some slight degradation in accuracy when compared with the baseline system. But, as pointed out before, a *natural* text might require more than grammatical and fluent text. In order to judge the naturalness, we carry out an additional evaluation where we present the translations produced by the baseline system and the N2N system to native speaker crowdworkers, and ask them to choose the better sounding one. Since MQM already judges the accuracy of the translations, this evaluation is *monolingual* and focuses solely on the naturalness of the sentences. Showing the source sentence may steer the human judges to choose the translation that is closer to it, as it is easier to judge, and we wanted to avoid this bias. The results can be found in Table 8. It can be seen that the human evaluators do have a preference for sentences generated by our N2N system. The difference is particularly important for the De→En translation direction. Some example translations are given in Table 9.

---

post-processing step.

[4] This weighting approach has been adapted for the machine translation use case, and differs from the standard weighting scheme used for human-produced translations.

7 Conclusion

We propose a method for achieving more natural translations, i.e. translations which adopt a style closer to text originally written in the target language. Using contrastive language model scoring we classify our training data depending on whether the target side was originally written in the target language or whether it is a translation. This information is given to the translation system via an input tag, so that we can bias the generation process towards producing output closer to natural text. We demonstrate that building an MT system focusing on natural translations can be evaluated by optimizing BLEU on target-original test sets while avoiding high BLEU scores on src-original test sets. Through automatic metrics we show that the N2N method achieves lexical diversity closer to that of natural sentences indicative of more natural text. Indeed, human evaluations show that the produced translations are preferred by human judges when asked to choose the more natural translation. There is some drop in translation accuracy, as shown by the MQM analysis, however this can be an acceptable trade-off for some applications. For example, when considering post-editing, a more natural initial proposal will most certainly result in a more natural final output, while accuracy errors are usually easier to detect and fix for human post-editors.

The main contribution of this work lies in highlighting the potential for more natural translations by appropriate manipulation of the training data and evaluation measures. Our approach for using this information through tagging is a good first step, but it is a straightforward data manipulation. Other techniques that modify the model architecture or training objective may allow us to achieve the same improvements in naturalness without loss in translation accuracy.

Source	Es wird befürchtet, dass die Opferzahlen noch deutlich in die Höhe gehen.
Baseline	It is feared that the **number of victims** will **increase** significantly.
N2N	It is feared that the **death toll** will **rise** significantly.
Source	Der Neubau sollte möglichst freundlich und hell gestaltet werden, damit sich die Bewohner darin wohlfühlen können, so der Architekt.
Baseline	The new building should be designed as friendly and bright as possible so that the residents can feel comfortable in it, according to the architect.
N2N	According to the architect, the new building should be made as friendly and bright as possible so that the residents can feel at ease in it.

N2N	Jens Spahn, Germany's Minister of Health, has called for a new regulation of organ donation.
Source	Grüß war schon vor zwei Jahren als damals 14-Jähriger in Bielefeld dabei.
Baseline	Grüß was already there two years ago as a 14-year-old in Bielefeld.
N2N	Grüß was in Bielefeld, Germany two years ago when he was 14 years old.

Table 9: Example translations for the German→English direction. The N2N translations have a more natural sentence structure when compared to the baseline translations. Further, N2N uses wordings that are more typically in natural written English text. For instance, when looking at the first examples: *number of victims* and *increase* are more literal translation than *death toll* and *rise* which are the more natural word choices in this context.

A Additional Results

A.1 Accuracy of Contrastive LM

The accuracy of the contrastive language model for all test sets for English→German are shown in Table 10. The accuracy is mostly around 90% for all test sets. In 2020, the test sets have been generated on the paragraph-level which could be the reason for the lower precision on the natural half. Some of the reference translations in earlier years have been post-edited from MT output which could be the reason why newstest2011 and newstest2013 have lower accuracy numbers for the natural sentences.

A.2 Per Test-set Results

Table 11 shows BLEU results for each separate test. It can be seen that all test set exhibit the same behaviour: increase tgt-orig and decrease in src-orig when using `<nat>`, the opposite for `<trans>`.

A.3 Results Without Backtranslation

Table 12 shows BLEU scores for the English→German translation direction, without using backtranslated data. We confirm that the N2N system using the `<nat>` also outperforms the baseline system on the tgt-original condition, while obtaining worse BLEU scores on the src-original evaluation. Using the `<trans>` tag, the score of the baseline system on the src-orig conditional is recovered.

Comparing the base system from Table 12 with the base system in the original paper, we see that the addition of backtranslated data, which is by construction natural on the target side, also behaves differently for the two evaluation conditions. Although it achieves improvements for both source and target original data, for the source-original condition it is only a minor improvement of 0.5 BLEU. On the other hand, for the target-original data we see a big gain of 3.1 points, further pointing towards the fact that the system generates more natural text.

B Short Overview of Diversity Metrics

In this section we provide a short overview of the diversity metrics used in this paper. For a full description, the reader is referred to (Vanmassenhove et al., 2021).

Lexical Frequency Profile (B1, B2, B3) The vocabulary is divided into three subsets: the 1000 most frequent words (B1), the next 1000 words (B2) and the rest (B3). The metric gives the percentage of running words in a text in each category.

TTR Type-to-token ratio, defined as the size of the vocabulary divided by the number of running words.

Yule's I Extension of TTR that is more robust to fluctuations due to text length.

MTLD Mean length of sequential words strings in the text that maintains a given TTR value.

H Shannon's entropy of word forms given a lemma.

D Simpson's diversity index of word forms given a lemma.

PTF Percentage of times the "primary" translation was chosen for source words with multiple translations.

CDU Cosine distance between the distribution of translation alternatives for a source word and a uniform distribution.

SynTTR Modified TTR limited to words with different translation alternatives.

From Stance to Concern:
Adaptation of Propositional Analysis to New Tasks and Domains

Abstract

We present a generalized paradigm for adaptation of propositional analysis (predicate-argument pairs) to new tasks and domains. We leverage an analogy between *stances* (belief-driven sentiment) and *concerns* (topical issues with moral dimensions/endorsements) to produce an *explanatory* representation. A key contribution is the combination of semi-automatic resource building for extraction of domain-dependent concern types (with 2-4 hours of human labor per domain) and an entirely automatic procedure for extraction of domain-independent moral dimensions and endorsement values. Prudent (automatic) selection of terms from propositional structures for lexical expansion (via semantic similarity) produces new moral dimension lexicons at three levels of granularity beyond a strong baseline lexicon. We develop a ground truth (GT) based on expert annotators and compare our concern detection output to GT, to yield 231% improvement in recall over baseline, with only a 10% loss in precision. F1 yields 66% improvement over baseline and 97.8% of human performance. Our lexically based approach yields large savings over approaches that employ costly human labor and model building. We provide to the community a newly expanded moral dimension/value lexicon, annotation guidelines, and GT.

1 Introduction

This paper presents a generalized paradigm for adaptation of tasks involving predicate-argument pairs, i.e., combinations of actions and their participants, to new tasks and domains. Predicate-argument analysis has been a longstanding area of research for many tasks: event detection (Du and Cardie, 2020; Zhang et al., 2020), opinion extraction (Yang and Cardie, 2013), textual entailment (Stern and Dagan, 2014), and coreference (Shibata and Kurohashi, 2018). We refer to the induction of such representations as *propositional analysis*. We induce a proposition PREDICATE(x_1,x_2,...) to represent sentences such as *John wears a mask*: wear(John,mask). We pivot off this **explanatory** representation to answer questions such as *What is John's stance towards mask wearing?* or *What concerns does John have about mask wearing?*

Stance detection has recently (re-)emerged as a very active research area, yet many approaches generally equate stance to raw (bag-of-word) sentiment and often employ machine-learning based models requiring large amounts of (labeled or unlabeled) training data. Within such approaches, the notion of *stance* varies, but generally falls into one of a handful of "sentiment-like" categories for *stance holder* X regarding topic Y, i.e., X agrees/disagrees with Y (Umer et al., 2020), X favors/disfavors Y (Krejzl et al., 2017), X is pro/anti Y (Samih and Darwish, 2021), X has a positive/negative opinion about Y (AlDayel and Magdy, 2021), or X is in favor/against/neither Y (Küçük and Can, 2020).

We adopt the stance definition of Mather et al. (2021), originally formulated for Covid-19. There, a stance is a **belief-driven sentiment**, derived via propositional analysis (i.e., *I believe masks do not help [and if that belief were true, I would be anti-mask]*), instead of a bag-of-words lexical matching or embedding approach that produces a basic pro/anti label. This variant of stance detection uses a proposition to identify a domain-relevant belief in the Covid-19 domain; the belief is leveraged to compute a belief-driven sentiment and attitude toward a topic in that domain (e.g., *masks*). For example, *I believe masks do not protect me* is rendered as a belief type PROTECT with an underlying proposition protect(masks) and a negative overall stance toward the propositional content: *masks*.

We implement and evaluate an analogous propositional framework for a new task, *concern detection*. Table 1 shows stance and concern detection output on a tweet from an English subset of a Kaggle Twitter dataset (1.9M tweets) for a new domain, the 2017 French Elections (Daignan, 2017). The

Findings of the Association for Computational Linguistics: ACL 2022, pages 3354 - 3367
May 22-27, 2022 ©2022 Association for Computational Linguistics

proposition common to both is ruin(jean-luc melenchon, economy). For stance, a belief *type*, DESTROY, is coupled with *values*: (1) Belief strength ranges from certainty that the belief is not true (-3) to certainty that the belief is true (+3), with 0 as "uncommitted"; and (2) Belief-driven sentiment strength ranges from extremely negative (-1) to extremely positive (+1), with 0 as "neutral".

We define a *concern* to be a topical *type* (e.g., ECONOMIC) coupled with a set of *values*: (1) moral dimensions from Moral Foundations Theory (MFT) (Haidt and Joseph, 2004; Graham et al., 2009, 2011, 2012), represented as vice/virtue pairings (authority/subversion, care/harm, fairness/cheating, loyalty/betrayal, and purity/degradation); and (2) corresponding endorsement values, where "vice" is between 1 to 5 and "virtue" is >5 to 9 (1 is strong vice and 9 is strong virtue). Dimensions and endorsements shown in Table 1 are derived from a state-of-the-art baseline (Moral 1), see §3.

Propositional representation is the centerpiece of both stance detection and concern detection, distinguishing our lexical-based approach from model-based approaches trained on word-level annotations. Predicate-argument structure captures relationships between multi-word constituents that need not be contiguous, thus inducing **explainability**. That is, *Jean-Luc Melenchon* is not adjacent to *economy*, yet these terms are crucially related via the intermediate term *ruin*. This enables answers to questions such as *What does the author believe Jean-Luc Melenchon did to the economy?*

Moreover, domain adaptation is streamlined through predicate-argument annotation, reducing effort needed for human annotation. Annotation at the level of predicate-argument pairs factors out commonalities, reducing redundancy in the resource building process. During resource building each verb is visited only once rather than the multiple times required for word-level corpora annotation (see §3). For example, annotation of the word *lead* is done all in one shot with a handful of automatically presented de-duplicated cases, whereas corpus-based annotation requires repeated annotations of *lead*, substantially increasing human labor.

We demonstrate that the key to reduced adaptation time is the coupling of semi-automatic resource building for concern types with automated expansion of domain-independent concern values using semantic similarity. We develop a ground truth (GT) based on expert annotators and compare concern detection output to GT. We also demonstrate that, with each lexicon expansion, the performance of concern detection improves significantly over a state-of-the-art baseline moral dimension lexicon. We obtain a 231% improvement in recall over a strong baseline for our best performing system, with only a 10% loss in precision.

Stance Proposition: *ruin(jean-luc melenchon, economy)*	
Belief Type	**Belief/Sent Values**
DESTROY	belief strength: 2.5, sentiment strength: -1

Concern Proposition: *ruin(jean-luc melenchon, economy)*	
Concern Type	**Moral Dims/Values**
ECONOMIC	care: 1.4, purity: 2.75

Table 1: Representative Stance and Concern system output for a given tweet in the 2017 French Election Domain: *Marine Le Pen LEADS in French poll as far left Jean-Luc Melenchon 'could ruin economy'*. Belief ranges from -3 to 3, sentiment from -1 to 1, and the moral dimensions from 1 to 9.

2 Background and Motivation

This section provides background and motivation for task and domain adaptability applied to concern detection in the 2017 French Election domain (§2.1, §2.2), including concern values induced from Moral Foundations Theory (MFT) (§2.3).

2.1 Task and Domain Adaptability

Task adaptability and domain adaptability are two supporting areas of research for this work. Prior domain adaptation approaches, surveyed by Ramponi and Plank (2020), have been applied to tasks such as sentiment analysis (Ben-David et al., 2020; Ghosal et al., 2020), stance detection (Xu et al., 2019), and event trigger identification (Naik and Rose, 2020). Task adaptation approaches (Gururangan et al., 2020; Garg et al., 2020; Ziser and Reichart, 2019) have been applied to tasks such as answer selection for question answering.

To date, both types of adaptation rely heavily on machine learning (ML) techniques, many of which require a large amount (e.g., 1M+, Gururangan et al. (2020)) of training data (whether labelled or not). Some approaches employ smaller datasets, e.g., 10K+ Amazon reviews, fake news articles (Ben-David et al., 2020; Xu et al., 2019). Additionally, while explainability has recently been brought to the fore in deep learning approaches, as surveyed by Xie et al. (2020), such systems have not focused on task and domain adaptability.

We develop a general framework for resource building techniques that features task adaptability and retains the ability to adapt quickly to new domains. Our dataset requirements are much more minimal than prior approaches (2500 tweets per domain), there is no human labeling of corpora, and no model training is required. Moreover, explainability is achieved by virtue of inclusion of propositional information (who did what to whom) that serves as a window into the process of detecting concern types and moral dimensions.

2.2 Stance and Concerns

Pirolli et al. (2021) apply a belief-based formulation of stance in the Covid-19 domain, with topics such as *mask wearing* and *social distancing*. For example, a *stance* assigned to *Wear a mask!* includes a PROTECT belief *type*, where the predicate *wear* is considered a "trigger" and *a mask* is considered the "content" of the belief. The *values* associated with this stance include a belief strength of +3 and a sentiment strength of +1. The final *stance* is thus a belief-oriented sentiment with this interpretation: the person posting the tweet is positive toward "masks," assuming the belief that masks are protective is true. In the 2017 French Election domain, a stance representation (e.g., for the example in Table 1) would be: <DESTROY(*ruin(jean-luc melenchon, economy)*), Bel:+2.5, Sent:-1>.

While this prior framework lays the groundwork for domain adaptability, it has not been shown to be generalizable to new tasks (within or across domains), which is the focus of this paper. We leverage the propositional underpinnings of the framework of Mather et al. (2021) to enable a straightforward adaptation from stance detection to a new task, *concern detection*, while also retaining domain adaptability. This task involves extraction of a *concern type* (e.g., *immigration, taxation*) associated with a given domain (e.g., *2017 French Elections*), analogous to the extraction of a *belief type* for a given stance detection domain.

In this paper, we demonstrate that it is straightforward to port belief-targeted stance both to a new domain (French elections) and, through an analogous proposition-based extraction, to a new task: Concern detection. An example of a formal Concern representation in the 2017 French Election domain for the example in Table 1 would be: <ECONOMIC(*ruin(jean-luc melenchon, economy)*), Care: 1.4, Purity: 2.75>.

The approach described herein focuses on lexicon expansion obtained automatically through semantic similarity to map key terms in propositional statements to moral foundation lexicon words, using WordNet (Fellbaum, 1998).[1] Three different variants of lexicon expansion (described in §3.3) improve on results obtained using the current state-of-the-art moral lexicon of Araque et al. (2020), which we take to be a strong baseline (henceforth referred to as 'Moral 1'). The advance beyond this prior work lies in the prudent (automatic) selection of terms designated for expansion, based on propositional structure, and the combination of moral dimensions with concern types.

2.3 The MFT Framework and Influence

We focus on concern detection because identifying critical issues discussed online within a particular domain is important and useful, as is identifying the moral justifications or deliberate appeals to moral identity in these discussions. We use the Moral Foundations Theory (MFT) framework (Haidt and Joseph, 2004; Graham et al., 2009, 2011, 2012) to encode the moral dimensions of social media contributions. These moral dimensions may serve as potential indicators of influence attempts, as in *When it comes to immigration it's not about children, it's about damaging our country!*, where the Concern type is IMMIGRATION_REFUGEE and there is an appeal to the vice side (*harm*) of the *care/harm* moral dimension.

An emphasis on highly controversial and/or polarizing topics in online posts/messages may be indicative of an attempt to sway others. More importantly, if these posts/messages are interwoven with language that reflects (and speaks to) the moral values of the target audience it can increase in-group cohesion, and that may further contribute to polarization. Additionally, deliberate use of morality to justify harmful intentions towards others may foster online outrage disguised as ethical conduct (Bandura et al., 1996; Friedman et al., 2021).

Several studies show that social groups provide a framework in which moral values are endorsed, and when these values are threatened by e.g., opposing political ideology, existing beliefs of the group are

---

[1] Wordnet is released under a BSD style license and is freely available for research and commercial use.

strengthened (Van Bavel and Pereira, 2018). Thus, when presented with information that is incongruent with our identity and in-group, we tend to override accuracy motives in favor of social identity goals (partisan bias). When accuracy and identity goals are in conflict, moral values determine which belief to endorse and thus how to engage with information. This makes moral values an ideal breeding ground for influence campaigns, but also very useful for our stance and concern detection tasks.

We note that most studies of cross-cultural values, beliefs, and morality have been conducted by WEIRD (western, educated, industrialized, rich, and democratic) countries (Goodwin et al., 2020; Henrich et al., 2010). Inglehart's model of World Values (Inglehart and Welzel, 2010) has surveyed 60 countries over the last 40 years, taking into account that many nations are more concerned with economic and physical security (e.g. survival), while self-expression values are more reflective of Western countries. For example, in Pakistan or Nigeria 90% of the population say that God is extremely important in their lives, while in Japan only 6% take this position. Similarly, Schwartz' Theory of Basic Values (Schwartz, 2012) uses a different set of organizing principles, e.g., values that relate to anxiety (e.g., tradition, security, control of threat) which may lead to an increased belief in misinformation (Jost et al., 2003). Thus, moral dimensions combined with concern types are a potential indicator of a common actor (possibly an outside influencer) if several individuals or accounts (potentially purporting to be individuals) invoke the same moral dimensions across their messages.

3 Task and Domain Adaptation

Adaptation of stance detection to concern detection gives rise to a new framework for rapid development of a task-adapted system that retains domain adaptability and uses relatively low amounts of data, with only 2-4 hours of human categorization.

3.1 Resource Building Generalizations

We generalize to a new task while retaining domain adaptability by leveraging the stance-concern analogy, through: (a) semi-automatic domain-dependent extraction of *types* from propositional analysis, i.e., moving from *belief types* for stances to *concern types* for concerns; and (b) fully automatic domain-independent induction of associated *values* from a combination of propositional arguments and lexical and semantic resources, i.e., belief/sentiment *strengths* (cf. (Baker et al., 2012)) for stances and moral dimensions and endorsements (cf. (Graham et al., 2012)) for concerns.

Resource building for domain-dependent stance *types* involves propositional analysis using semantic role labeling (SRL) (Gardner et al., 2018)[2] to detect positions with the most highly relevant content terms, e.g., *masks*. The work of Mather et al. (2021) indicates that these positions are ARG0 and ARG1. To port this approach over to the induction of domain-specific concern *types*, we conducted a similar analysis and found that the same positions (ARG0 and ARG1) contain the most highly relevant terms for concerns, e.g., *economy*. Semi-automatic induction of concern types thus leverages these positions, as described in §3.2.

Just as stance resource building induces domain-independent stance *values* (belief / sentiment strengths), concern resource building induces domain-independent concern *values* (moral dimensions / endorsements). A deeper propositional analysis reveals that additional SRL positions have a high likelihood of association with moral dimension terms, e.g., *ruin*: V, ARG2, ARGM-ADV, ARGM-MNR, ARGM-PRD. This discovery further generalizes the original stance resource-building approach and enables rapid task adaptation to concerns through entirely automatic means. We leverage these additional SRL positions to extract candidate terms for expansion of moral dimensions. Associated endorsements are then inherited from semantically similar terms from baseline Moral 1. Further details about the expansion of moral dimensions are provided in §3.3.

Domain adaptability is retained—on analogy with stance detection—by separating and independently addressing two aspects of concern detection: (a) induction of domain-specific concern types; (b) induction of domain-independent moral dimensions. Lexicon expansion using this approach can thus be applied to domains beyond the French Elections presented herein.

3.2 Concern Type Induction

We adopt a generalized semi-automatic process for **lexically based** concern type induction that retains domain adaptability (later referred to as 'Concern 1'). A small set (approximately 15) of domain-

---

[2] We use AllenNLP 2.7.0 2020 structured-prediction-srl-bert model for SRL.

relevant key terms (e.g., health, taxation, immigration), is provided by a domain expert as input to a semi-automatic resource building tool. These terms are used to filter the domain-relevant dataset. The filtered tweet subset (214k) is then divided into training (2500),[3] and development (211,500) subsets, and propositional analysis is applied to the training set in a 3-step process.

First, the top 25 most frequent terms are extracted (e.g., *economy)*,[4] ignoring functional elements such as stop words. Second, the verbs whose relevant SRL positions (defined in §3.1) contain any of these top 25 terms are extracted, and the top 40 most frequent verbs e.g., *ruin, restrict* are selected for further processing. Lastly, the top 10 most frequent terms associated with relevant SRL positions (for each of the 40 verbs) are extracted automatically from domain-relevant data, e.g., *economy and business*, yielding 400 propositions, e.g., *ruin(economy), restrict(business)*.[5]

These, coupled with terms from the original domain-relevant key terms, are presented to the domain expert who constructs a small set of concern types—10 in the case of French Election: textscimmigration_refugee, ELECTORAL_PROCESS_VOTING_LAWS, ENVIRONMENT_CLIMATE_CHANGE, HEALTH_CARE, TAXATION, ECONOMIC, SOCIAL_SERVICES, INTERNATIONAL_TRADE, MILITARY_ENGAGEMENT, CRIMINAL_JUSTICE. Terms left uncategorized by the expert are dropped. This semi-automated concern-type induction takes 2–4 hours owing to the automatic extraction of high frequency domain relevant propositions.

3.3 Concern Value Induction

Concern *values* leverage MFT (Haidt and Joseph, 2004; Graham et al., 2009, 2011, 2012) and particularly the moralstrength library (Araque et al., 2020), which serves as a strong baseline (referred to as 'Moral 1').[6] This baseline lexicon includes manually developed moral dimensions (e.g. care/harm, loyalty/betrayal) and endorsement values (1–9). Our approach transcends this earlier paradigm in its application of propositional analysis with semantic-role labeling (SRL Gardner et al. (2018)), coupled with a more in-depth WordNet (WN Fellbaum (1998)) expansion to enrich the lexicon. This results in higher recall while retaining linguistically relevant constraints to achieve acceptable precision.

Expansion of moral dimensions relies on propositional analysis, SRL, and WordNet expansion. We select candidates for moral dimension expansion through extraction from propositional statements, and then induce three lexicon variants (in addition to the Moral 1 baseline, and a Moral 0 random chooser described in §6) using a progression of finer-grained WordNet-based semantic-similarity functions. This expansion supports the goal of task adaptability, as required in the transition from stance detection to concern detection.

The end result is a general approach to induction of *values* for specific tasks, rendered in the form of domain-independent lexicons. That is, analogous to belief/sentiment terms of stance detection (*might*, *probably*, *hate*, *love*), we induce vice/virtue moral dimensions and their corresponding endorsement values for concern detection.

This expansion results in three different system variations for moral dimension/values (referred to as Moral 2, Moral 3, Moral 4) beyond the Moral 1 baseline. We note that moral dimensions are assigned automatically to each lexical entry via semantic similarity to Moral 1 terms; the endorsement values are then *inherited* from the most semantically similar term from the Moral 1 lexicon. An excerpt of lexicon output is shown below, from the best performing lexicon (Moral 4):

hypocrite - dim: betrayal; endorse: 1.0 (strong)
appreciation - dim: care; endorse: 8.57 (strong)

Lexicon Expansion Details: Moral 2-4 rely on automatic propositional analysis for prudent selection of words from the training data (via SRL, see §3.1) to be considered candidates for lexicon expansion. The highest similarity match is recorded to inherit the corresponding moral endorsement value from Moral 1. A brief description of all lexicon expansions used for induction of moral dimensions and values for concern detection is provided below. (See detailed description in Appendix A and links to Moral 2-4 lexicons in Appendix B.)

***Note:** The term "lemma-matched" below refers to a match between a word in a training tweet and a synset's first lemma.*

---

[3] Training data are strictly for one-time semi-automatic resource building, not for model training.

[4] spaCy 3.1.0 with model en_core_web_sm (Honnibal et al., 2020) is used for sentence splitting and POS tagging.

[5] The thresholds of 25, 40, and 10 are selected empirically in preliminary experiments (not reported here) ascertaining a balance between adequate coverage of the data and time spent manual categorization by the expert.

[6] https://github.com/oaraque/moral-foundations.

Moral 1: This initial moral dimension lexicon developed by Araque et al. (2020) serves as a strong baseline, with 2800+ terms across five moral dimensions. This was derived by expanding an initial crowd sourced lexicon of about 480+ terms, annotated for moral dimensions and endorsements. Expansion to 2800+ terms was via WordNet synset matching, without regard to propositional analysis.

Moral 2: (Added 214 terms, for total of 3064) This lexicon expansion yields a set of terms whose lemma-matched synsets are semantically similar (above a threshold) to lemma-matched synsets of the words in the strong baseline (Moral 1) lexicon.

Moral 3: (Added 995 terms, for total of 3845) This lexicon expansion yields a set of terms whose lemma-matched synsets and their descendents are semantically similar (above a threshold) to lemma-matched synsets and their descendents of the words in the strong baseline (Moral 1) lexicon.

Moral 4: (Added 5623 terms, for total of 8473) This lexicon expansion yields a set of terms drawn from **all** synsets and their descendents that are semantically similar (above a threshold) to **all** synsets and their descendents of words in the strong baseline (Moral 1) lexicon, without lemma matching.

Example 1: *Vatican's completely surrounded by a wall w/an entrance that's guarded 24/7 & refugees r not allowed* **Concern type**: IMMIGRATION_REFUGEE **Proposition**: *surrounded(vatican, by a wall ...guarded 24/7 & refugees r not allowed))* **Dimensions & Endorsements**: Harm: 3.46, Authority: 6.02, Degradation: 2.71
Example 2: *Where is the justice?* **Concern type**: CRIMINAL_JUSTICE **Proposition**: *is(where, the justice)* **Dimensions & Endorsements**: Fairness: 7.6
Example 3: *Most Melanchon voters care more about their country than their ideological purity.* **Concern type**: ELECTORAL_PROCESS_VOTING_LAWS **Proposition**: *care(most melanchon voters, more about their country)* **Dimensions & Endorsements**: Care: 8.80, Loyalty: 7.14, Authority: 5.57, Degradation: 3.69

Table 2: Sample Output from Concern Detection on Kaggle 2017 French Elections; SRL output is reproduced including any errors

4 Annotation for Ground Truth

We conduct an annotation task to develop Ground Truth (GT), against which to compare our concern detection system variants, based on 50 held-out tweets from the held-out development portion of the English subset of the Kaggle Twitter dataset on 2017 French elections (Daignan, 2017). Ground truth was produced for concern types and vice/virtue pairs for any of five moral dimensions, in accordance with guidelines in Appendix C. Annotation was completed by two non-algorithm developers (one with expertise in linguistics, the other with expertise in psychosocial moral indicators). For concern types the inter-rater reliability (IRR) is calculated through macroaveraging of kappa scores (Carletta, 1996) which produces a 66% agreement, considered **Strong** according to (McHugh, 2012). By contrast, the macroaveraged IRR for moral dimensions is low (16%), which is considered **Weak**.

Given the high annotator reliability for concern types, system output is compared against the union of both annotators, yielding the concern type scores in Table 3. However, the lower IRR for moral dimensions is an indication that research in this realm is still in nascent stages and significant training for the task is required to achieve a reliable GT. We note that "ground truth" is inherently problematic with moral indicators given the complex way in which dimensions vary with socio-cultural factors. Thus, for moral dimensions, system output is compared only against the single annotator with expertise in psychosocial moral indicators.

Appendix D presents the Ground Truth resulting from these annotations. Kaggle data (Daignan, 2017) are open and publicly available, intended for research on text analytics. The data carry no privacy or copyright restrictions. Furthermore, IRB designates our work as non human subject research. Annotators spent two hours apiece on the task.

5 Sample Runs

We have implemented/validated a system to detect concerns based on induced lexical resources, using spaCy and SRL. We derive a proposition coupled with a concern *type* and *values* (moral dimensions/endorsements). Systems produce <concern,vice/virtue> pairs, with an average runtime of 0.6s per tweet on Mac, with no GPUs required.

Representative outputs on a 1K-tweet held-out portion of the development dataset from Kaggle 2017 French Elections are shown in Table 2. These are taken from our best performing variant described in §6. In Example 1, IMMIGRATION_REFUGEE (triggered by *refugees*) is coupled with moral dimension/endorsement *values*, Harm (*wall, entrance, guard*), Authority (*wall, guard*), and Degradation (*entrance*). In Example 2, CRIMINAL_JUSTICE (triggered by *justice*) is coupled with moral dimension/endorsement *values*: Fairness (*justice*). Both are reasonable outputs.

In example 3, ELECTORAL_PROCESS_VOTING_LAWS (triggered by *voters*) is coupled with moral dimension/endorsement *values*, Care (*care*), Loyalty (*country*), Authority (*care, country*), and Degradation (*care, voters*). This example overgenerates, assigning Degradation based on the terms *care and voters*. A further lexicon enhancement is needed (as alluded to in §7) for elimination of spurious lexical entries that lead to false positives (i.e., a reduction in Precision).

6 Results and Analysis

We explore the performance of each of our four moral dimension lexicons by comparing <concern,vice/virtue> outputs against GT for each lexicon. Concerns types are evaluated for an exact match against the GT concern (e.g., CRIMINAL_JUSTICE) and moral values are evaluated for an exact match against the binary choice in the GT (vice or virtue). Concern 1 represents the lexicon-based chooser described in §3.2. Our (strong) baseline for moral values is "Moral 1" (Araque et al., 2020). Subsequent variants (Moral 2-4) are the expanded moral dimension lexicons using the techniques described in §3.3. We also compare against random choosers for Concern *Types* (Concern 0) and *Values* (Moral 0). Table 3 shows the results of each system output compared to GT.

System performance is measured by weighted macro-averaged precision (P), recall (R), and F1 scores. Domain-dependent Concern *Type* is not affected by moral lexicon variants and independently has its own P/R/F1 scores. Concern *Values* (i.e., moral Dimensions) are impacted by lexicon variants and therefore have a row corresponding to each variant. We note the importance of applying a **weighted** macro average to these scores due an imbalance in the distribution of classes (Delgado and Tibau, 2019), where the probability of one class can be substantially higher or lower from others. For example, we observed that the number of ELECTORAL_PROCESS_VOTING_LAWS annotations is 2.3 times higher than the number of INTERNATIONAL_TRADE annotations.

System	TP	FP	FN	P	R	F1
Concern 0	35	233	25	12.69	53.88	20.54
Concern 1	**40**	**1**	**20**	**91.60**	**66.67**	**77.17**
Moral 0	33	225	33	12.74	43.01	19.65
Moral 1	13	**28**	53	**32.99**	19.69	24.67
Moral 2	17	58	49	31.20	25.76	28.22
Moral 3	24	122	42	31.38	36.36	33.69
Moral 4	**43**	181	**23**	29.75	**65.15**	**40.85**

Table 3: Evaluation of (Domain-Dependent) Concern Types and (Domain-Indepenent) Moral Dimensions: Unweighted sum of true positives (TP), false positives (FP), and false negatives (FN) across all labels. Precision (P), recall (R), and F1 numbers for all systems are weighted macro-averages except for the random choosers (Concern 0 and Moral 0). Lexicon variants affect only the moral dimensions.

One might expect random choosers (Concern 0 and Moral 0) to have a decent likelihood of getting many hits, with an expected rate of about 50% that each Concern type and Moral value will be selected. If so, this would result in an expected 250 positive selections for concern types (whereas the two annotators together only made 60 positive selections) and an expected 250 positive selections for moral values (whereas the expert annotator only made 66 positive selections). However, the results in Table 3 indicate that, while the increased number of hits leads to a reasonably high recall, the number of false positives (233) swamps out the hit rate, leading to a low F1 score (20.54). Accordingly, Concern 1 easily beats the random choice baseline by a healthy margin, with an F1 score of 77.17.

In contrast, Moral 0 achieves 79.65% of the performance of the Moral 1 baseline, with an F1 score of 19.65—not too far off from the 24.67 baseline F1 score. Moreover, the F1 scores for Moral 2-4 surpass this baseline, with statistically significant improvements indicated between all system pairs at the 3.5% level or better, according to the McNemar statistical test (McNemar, 1947).[7] That is, all lexicon expansion improvements are statistically significant. Notably, a 231% improvement in Recall is achieved for Moral 4 over the strong baseline (Moral 1): 65.15 vs. 19.69. This is achieved with only a 10% loss of precision, ultimately yielding an F1 score of 40.85 which is a 66% improvement.

---

[7] Tested values are correct responses (TP or TN) vs. incorrect responses (FP or FN), for determining significance of change in total error rate.

We observe that the precision-recall gap increases as the notion of similarity is loosened: (1) *lead* is similar to *strip* in Moral 4, but not in Moral 3 (reducing Moral 4 precision); (2) *price* is similar to *value* in Moral 4 but not in Moral 3 (increasing Moral 4 recall). We further assess system performance by comparing Concern 1 performance to human performance. Average F1 score for the two annotators is 78.88, and Concern 1 performance is 77.17 F1. Concern detection thus yields 97.8% of human performance on concern type detection.

Error analysis of FP/FN's for concern *types* reveals that concern detection fails to assign any concern type (FN) to *Infighting among left-wing could hand Front National VICTORY*, which is annotated as ELECTORAL_PROCESS_VOTING_LAWS, because terms like *Front* and *left-wing* are not present in the concern type lexicon.

For concern *values*, the annotator does not assign a moral dimension to *Macron is center right*, yet Moral 4 inaccurately detects (FP) Care, Authority, and Betrayal due to the existence of the word *center* and also detects Purity from the word *right*. For this same sentence Moral 1 also inaccurately detects Fairness from the word *right*. Many cases similar to these impact precision values for each Moral 1-4, potentially requiring lexicon tuning (see §7).

We conduct further analysis to determine whether performance is impacted by potential overfitting of concern value detection to the domain of interest during development. We compare Araque's original concern value detection tools (Araque, 2021), a unigram model trained on Hurricane Sandy data from the Moral Foundations Twitter Corpus (MFTC) (Hoover et al., 2020), to our proposition-based concern value detection that uses semantically expanded lexicons based on the Kaggle French elections data. We level the playing field by applying both approaches to both datasets, measuring each against their respective GTs.

Araque (2021)'s Unigram Model performs best on Hurricane Sandy test data (Table 4), with weighted macroaverage F1, using both Moral 1 and Moral 4 lexicons (60.55), but does not perform as well on Kaggle test data (30.38 and 22.43). This is a potential indicator of overfitting to the Hurricane Sandy data during training. Similarly, proposition-based concern value detection (§3.3) performs better on Kaggle test data (40.85) than on Hurricane Sandy Data (29.99)—a sign of overfitting in the opposite direction during lexicon expansion.

Kaggle 2017 French Elections		**P**	**R**	**F1**
Moral 1	Proposition (§3.3)	32.99	19.69	24.67
	Unigram Model (Araque, 2021)	29.07	31.82	30.38
Moral 4	Proposition (§3.3)	29.75	65.15	40.85
	Unigram Model (Araque, 2021)	20.88	24.24	22.43

MFTC Hurricane Sandy		**P**	**R**	**F1**
Moral 1	Proposition (§3.2)	65.58	17.56	27.68
	Unigram Model (Araque, 2021)	56.02	65.89	60.55
Moral 4	Proposition (§3.3)	26.10	35.29	29.99
	Unigram Model (Araque, 2021)	56.02	65.89	60.55

Table 4: Comparison of two Concern Value (Moral Dimensions) detection algorithms across two domains (Kaggle 2017 French Elections and MFTC Hurricane Sandy) using Moral 1 and Moral 4 lexicons.

Kaggle 2017 French Elections		**P**	**R**	**F1**
Moral 1	Full Input Text	**34.05**	21.21	26.14
Moral 4	Full Input Text	32.42	**62.12**	**42.61**

MFTC Hurricane Sandy		**P**	**R**	**F1**
Moral 1	Full Input Text	**67.23**	22.91	34.13
Moral 4	Full Input Text	36.79	**49.08**	**42.03**

Table 5: Test for Domain Stability of Concern Value (Moral Dimensions) detection across two domains (Kaggle 2017 French Elections and MFTC Hurricane Sandy), using Moral 1 and Moral 4 lexicons on full text input.

Testing our moral lexicon expansion for stability retention across domains, we level the playing field by relaxing the constraint that only a propositional sub-portion of the text is considered as input. We apply our algorithm to the entire text (full tweet) to induce a fairer comparison with Araque et al's Unigram model. Table 5 shows comparable or better macroaveraged F1 scores than those shown for "Proposition" in Table 4.

More importantly, our expanded Moral 4 lexicon demonstrates stability across domains: 42.61 for 2017 French Elections and 42.03 for Hurricane Sandy (vs. 26.14 and 34.13, respectively, for Araque et al's Moral 1 lexicon). This illustrates the potential for proposition-based **domain adaptability** but highlights the need for hybridized detection to ensure both **task adaptability** and **explainability** (discussed further below).

7 Conclusions, Limitations, Future Work

We implement and validate a generalized paradigm for adaptation of tasks involving propositions to a new task (concern detection) and domain (French elections). Our primary contribution is the provision of a framework for rapid adaptability, based on: (a) semi-automatic domain-dependent extraction of *types* from propositional analysis; and (b) fully automatic domain-independent induction of *values* from propositional arguments and semantic resources. We demonstrate that the coupling of (a) and (b) leads to rapid ramp-up resource construction for a new task and domain (2-4 hours).

We demonstrate that a deeper propositional analysis is key to generalizing domain-adaptable resource-building for new tasks. We develop an automatic procedure for expanding moral dimensions that incorporates propositional analysis, semantic-role labeling, and in-depth WordNet (WN) expansion, to produce three increasingly expanded moral dimension/endorsement lexicons. We develop a ground truth (GT) based on expert annotators and compare our concern detection output to GT, to yield 231% improvement in recall over baseline, with only a 10% loss in precision. F1 yields 66% improvement over baseline and 97.8% of human performance. Our approach yields large savings over those that employ costly human labor and model building. Work produced herein provides the community with a newly expanded moral dimension/value lexicon, annotation guidelines, and GT for 50 tweets, intended for research purposes.

We show that our proposition-based moral lexicon expansion provides stability across domains. However, the results of concern value detection using the full text of an input (a tweet) highlight the importance of adopting a hybrid approach that captures fine-grained distinctions and produces an explainable representation that is not otherwise available (e.g., in the unigram language model of Araque (2021)). An avenue of future research is to explore a hybridized approach that makes fine-grained concern value distinctions for *domain adaptability*, while leveraging an explainable propositional representation for *task adaptability*. As a first step, we will apply our propositional analysis iteratively on full-text inputs to detect answers to questions not otherwise extractable from raw textual strings (see related discussion in §1).

Our results do not require any tuning of the lexicons to remove terms that result in a high number of false positives (FP) and false negatives (FN). Future work will explore fine tuning of the lexicons to address cases seen in §6 with an eye toward improving the precision without a large drop in recall, to yield an even higher F1-score.

A current limitation (for future study) is the omission of additional moral dimensions, e.g., liberty/oppression (Haidt, 2012). This reflects political equality related to dislike of oppression and concern for victims, not a desire for reciprocity. In political discourse, this is apparent in anti-authoritarianism and anti-government anger, which makes it an important dimension for the topic of the French election (Iyer et al., 2012) and widens the range of potentially relevant information that could indicate influence attempts.

Future work also includes exploration of other cultural frameworks, in addition to or in place of Moral Foundations Theory, e.g., Inglehart's Cultural Map model (Inglehart and Welzel, 2010) and Schwartz Value Theory (Schwartz, 2012). Cultural models that allow more room for non-Western values (e.g. survival needs) are important for reducing bias, and a feasible avenue for improving the performance and applicability of concern detection.

Another limitation is that GT development for a given cultural context is difficult, especially with diverse annotators. Prabhakaran et al. (2021) show that systematic disagreements between annotators with differing socio-cultural backgrounds are obfuscated through aggregating crowd-sourced annotations. Future work will explore vector-based approaches to assign weights based on their representativeness in a given culture.

Cultural values are also reflected in language (e.g., gendered vs. non-gendered languages, culturally intrinsic concepts). Accordingly, our future work involves processing concerns for other languages through adaption of SRL (Gardner et al., 2018) to multilingual input, starting with French, employing multilingual preprocessing via spaCy (Honnibal et al., 2020) and EuroWordNet and related multilingual WordNets (Bond and Paik, 2012; Bond and Foster, 2013), to expand moral dimensions to other languages.

Ethical Considerations

Annotation was completed by two non-algorithm developers (one with expertise in linguistics, the other with expertise in psychosocial moral indicators), compensated appropriately for their work. A two-level institutional review board (at both the sponsored site and at the sponsoring site) deemed this work as "research not involving human subjects," as it does not involve a living individual about whom an investigator conducting research obtains information through intervention or interaction with the individual, or obtains, uses, studies, analyzes, or generates identifiable private information.

The data used for the software development is provided from Kaggle's existing public research Twitter dataset, focusing on an English subset for the 2017 French Elections of 1.9 million tweets (Daignan, 2017) at `https://www.kaggle.com/jeanmidef/french-presidential-election`. Kaggle data contain user names, but the dataset is open and publicly available.

Potential risks may emerge from language biases in standard resources on which some of our work is built. For example, cultural idioms like *fluctuat nec mergitur* may be translated from Latin into the correct literal meaning of *tossed [by the waves], but not sunk*, but the culturally distinct values (Paris' coat of arms and motto with a deep affective history) will get lost in translations into English, and with it, its cultural meaning. Similarly, while English WordNet provides one of the most comprehensive semantic ontology of words in English, embedded biases are still present today, e.g., offensive, racist, and misogynistic slurs (Crawford and Paglen, 2021). These issues need to be addressed within the language resource community.

Risk of misuse of this technology is mitigated by the transparent nature of concern detection, owing to the propositional representations that underlie and inform algorithmic decisions. In contrast to ML approaches, misuse within the technology would be easily discoverable. The technology further serves as a framework within which cultural distinctions may be studied and better understood, thus mitigating the potential for cross-culturally undetected misuse.

A Lexicon Expansion Detailed Descriptions

Below is the detailed description of each expansion algorithm. **Basic definitions:**
$w =$ word in training tweet (e.g., ‘concerned’)
$m =$ moral foundations word (e.g., ‘concern’)
$wn =$ wordnet package
$S_w =$ wn.synsets(w) (set of synsets for word w)
$s_{w,1} =$ wn.synsets(w)[0] (1st synset for word w)
$L_i =$ lemmas associated with S_i
$l_{i,k} =$ s.lemmas() (lemmas for synset s_i)
$l_{i,1} =$ s.lemmas()[0].name() (1st lemma synset s_i)
Note: Use of the term “lemma-matched” below refers to a match between a word in a training tweet and a synset’s first lemma.

Lexicon Expansion: All lexicon expansions (Moral 2-4 below) beyond a strong baseline (Moral 1) rely on propositional guidance to select words from the training data to be considered candidates for lexicon expansion. The highest similarity match is recorded for future selection of the moral endorsement value. All moral lexicon expansions (Moral 2-4 below) beyond a strong baseline (Moral 1) apply to each pair (w, m) for each word of interest w and each moral foundations word m ($w \times m$ iterations):

Moral 1: This initial moral dimension lexicon developed by Araque et al. (2020)[8] serves as a strong baseline, with 2800+ terms across five moral dimensions. This was derived by expanding an initial

---

[8] https://github.com/oaraque/moral-foundations.

crowd sourced lexicon of about 480+ terms, annotated for moral dimensions and endorsements. Expansion to 2800+ terms was via WordNet synset matching, without regard to propositional analysis.

Moral 2: (Added 214 terms) This lexicon expansion yields a set of terms whose lemma-matched synsets are semantically similar (above a threshold) to lemma-matched synsets of the words in the strong baseline (Moral 1) lexicon, using the following steps: (a) Extract all synsets $s_{w,i}$ in S_w (for word w) whose first lemma $l_{i,1}$ exactly matches w, producing S_x.(b) Extract all $s_{m,j}$ in S_m (for word m) whose first lemma $l_{j,1}$ exactly matches m, producing S_y. (c) Return all lemmas $l_{k,1}$ of any $s_{x,k}$ in S_x that matches any $s_{y,h}$ in S_y using wordnet wup_similarity w/ threshold 0.9 (if any). Example: concerned → concerned.a.01.

Moral 3: (Added 995 terms) This lexicon expansion yields a set of terms whose lemma-matched synsets and their descendents are semantically similar (above a threshold) to lemma-matched synsets and their descendents of the words in the strong baseline (Moral 1) lexicon, using the following steps: (a) Extract all synsets $s_{w,i}$, in S_w (for word w) whose first lemma $l_{i,1}$ matches exactly w, producing S_x. Extract all synsets $s_{m,j}$ in S_m (for word m) whose first lemma $l_{j,1}$ matches exactly m, producing S_y. (First part of 2 up to this point.) (b) Expand lemmas from both sets: (i) collect all lemmas for all synsets in S_x, producing L_x; (ii) collect all lemmas for all synsets in S_y, producing L_y. (c) Extract synsets for these lemma expansions: (i) collect all synsets for all lemmas in L_x, producing S_a; (ii) collect all synsets for all lemmas in L_y, producing S_b. (d) Return all unique lemmas $l_{c,1}$ of any synset $s_{a,c}$ in S_a that matches a synset $s_{b,d}$ in S_b using wup_similarity w/ threshold 0.9 (if any). Example: concerned → concerned.a.01 → implicated → implicated.s.01

Moral 4: (Added 5623 terms) This lexicon expansion yields a set of terms drawn from **all** synsets and their descendents that are semantically similar (above a threshold) to synsets and their descendents of words in the strong baseline (Moral 1) lexicon—without lemma matching—using the following steps: (a) Extract all synsets $s_{w,i}$ in S_w (for word w), producing S_x. Extract all $s_{m,j}$ in S_m (for word m), producing S_y. (b) Expand lemmas from both sets: (i) collect all lemmas for all synsets in S_x, producing L_x; (ii) collect all lemmas for all synsets in S_y, producing L_y. (c) Extract synsets for these lemma expansions: (i) collect all synsets for all lemmas in L_x, producing S_a; (ii) collect all synsets for all lemmas in L_y, producing S_b. (d) Return all unique lemmas $l_{c,1}$ of any synset $s_{a,c}$ in S_a that matches a synset $s_{b,d}$ in S_b using wup_similarity w/ threshold 0.9 (if any) Example: concerned → refer.v.02 → refer → pertain.v.02

B Moral Dimension/Value Lexicons: Moral 2-4

Three moral lexicons are induced automatically via propositional analysis, SRL, and semantic lexicon expansion:

- Moral 2: Moral 2 Lexicon
- Moral 3: Moral 3 Lexicon
- Moral 4: Moral 4 Lexicon

C Annotation Guidelines

Steps below refer to column labels in the Blank Annotation Sheet found **here**.

1. For each tweet excerpt in the "Text" column A, apply steps 2–8 below.

2. Columns B through K are the potential Concern types. Put a "1" in a single column corresponding to the applicable Concern type. Leave empty if none appears to apply.

3. Columns L through W are moral dimensions. Put a "1" in any column that has an applicable moral dimension, in either the vice subcolumn or the virtue subcolumn. Leave the vice/virtue cells empty for any moral dimension that is not applicable. Refer to the moral dimensions described in the Graham and Haidt tables for this task (see links in 4a and 4b below).

4. Provide annotations only for explicitly represented material. Do not infer context that is not stated and do not apply any subject-matter background knowledge. The only background knowledge to be used for this task is the moral dimensions description in tables below from:
    (a) [Graham and Haidt, 2012] (see page 16)
    (b) [Graham et al., 2013] (see page 68)

5. Do not try to force the Text into a particular moral dimension. If a moral dimension appears to be applicable, but it is unclear

whether the vice or virtue is active, put “DK” in either the vice cell or virtue cell, instead of leaving it blank.

6. Consider only the content of the Text without regard to grammaticality or punctuation.
7. Assume no sarcasm is present. Annotate the literal sense.
8. Use the last column (optionally) for any annotation notes, eg, the reasoning behind the chosen annotations.

D Ground Truth

We conduct an annotation task to develop Ground Truth (GT), against which to compare our concern detection system variants, based on 50 held-out tweets from the held-out development portion of the Kaggle English Twitter dataset on 2017 French elections (Daignan, 2017). Annotation was completed by two non-algorithm developers (one with expertise in linguistics, the other with expertise in psychosocial moral indicators). Annotators were provided guidelines (Appendix C) for both concern types and moral dimensions. For concern types the interrater reliability (IRR) is calculated through macroaveraging of kappa scores (Carletta, 1996) which produced a 66% agreement, considered **Strong** according to (McHugh, 2012). By contrast, the macroaveraged IRR for moral dimensions is considered none to slight (16%), which is deemed **Weak**. [Link to GT]

CUE Vectors: Modular Training of Language Models Conditioned on Diverse Contextual Signals

Abstract

We propose a framework to modularize the training of neural language models that use diverse forms of sentence-external context (including metadata) by eliminating the need to jointly train sentence-external and within-sentence encoders. Our approach, contextual universal embeddings (CUE), trains LMs on one set of context, such as date and author, and adapts to novel metadata types, such as article title, or previous sentence. The model consists of a pretrained neural sentence LM, a BERT-based context encoder, and a masked transformer decoder that estimates LM probabilities using sentence-internal and sentence-external information. When context or metadata are unavailable, our model learns to combine contextual and sentence-internal information using noisy oracle unigram embeddings as a proxy. Real contextual information can be introduced later and used to adapt a small number of parameters that map contextual data into the decoder's embedding space. We validate the CUE framework on a NYTimes text corpus with multiple metadata types, for which the LM perplexity can be lowered from 36.6 to 27.4 by conditioning on context. Bootstrapping a contextual LM with only a subset of the context/metadata during training retains 85% of the achievable gain. Training the model initially with proxy context retains 67% of the perplexity gain after adapting to real context. Furthermore, we can swap one type of pretrained sentence LM for another without retraining the context encoders, by only adapting the decoder model. Overall, we obtain a modular framework that allows incremental, scalable training of context-enhanced LMs.

1 Introduction

Language models (LMs) estimate the prior probabilities of token sequences and are key probabilistic modeling components in a variety of applications, such as speech recognition, machine translation, or software keyboards. When modeling linguistic token sequences, typical LMs model one sentence or utterance at a time, reflecting the fact that the strongest predictors of words are syntactic constraints and semantic associations within the sentence. However, it has long been recognized that *context* beyond the sentence has substantial influence on the word probabilities within a sentence. Context literally means the surrounding text (or preceding text, when predicting words in temporal order), but can also refer to any extra-linguistic information, such as metadata (e.g., authorship, time, location) or associated other modalities (e.g., visual cues associated with a spoken utterance).

There is a large literature on leveraging such contextual information for language modeling, some of which we review below (Section 2). However, including context in language modeling presents major challenges for operational settings, especially when LMs need to be trained and deployed at scale:

- Context data is hard to come by. Many language corpora have no or very limited metadata, or contain unordered sentences that do not provide sequential context.
- Context types are specific to a given source. A newspaper corpus has metadata that is very different from spoken language data.
- Use of context renders models context-specific, and therefore, less universally applicable. With each type of context, a new model, or even model architecture, is required.
- Context modeling requires more parameters, compute complexity and more training data.

All these difficulties lead to context being used sparingly in most practical settings, and only when it yields substantial benefits (such as in using a user's personal contact list in voice dialing).

In this paper, we propose a modular modeling framework for contextual language models, called

Findings of the Association for Computational Linguistics: ACL 2022, pages 3368 - 3379
May 22-27, 2022

contextual universal embeddings (CUE). The fundamental idea is to separate the modeling of (1) sentence-internal LM, (2) context embedding and (3) combination of sentence-internal and contextual information each into their own modules. First of all, we show that this architecture is an effective way to bring context to bear on the LM task, achieving 25% relative perplexity reduction over a sentence-internal model, on a corpus of newspaper articles with rich metadata. More importantly, each module can be trained separately, as opposed to jointly with the other modules. Through experimentation we show that, for the practically important use-cases, training modules separately or incrementally preserves most of the achievable gain from contextual information.

Specifically, we can replace one type of context with another, while only adapting the context encoders to the new context, and retain 85% of the best-case perplexity gain. Maybe more surprisingly, we can train the decoder that combines context and sentence-internal information *without any actual context*, instead using noisy oracle unigram embeddings as a proxy. This recovers 67% of the best-case gain after adapting to real context. (Adapting the context encoders affects much fewer parameters, and takes much less data, than the model overall.)

Finally, we show that context encoders can be frozen and a whole different sentence-LM architecture swapped into the model ensemble. After adapting only the combiner-decoder we obtain perplexity gains close to the optimum that would have been achieved by joint training of combiner and context embedding.

2 Prior Work

Longer text history is the most commonly used context in language models (LMs) (Mikolov and Zweig, 2012; Jaech and Ostendorf, 2018a; Ji et al., 2015; Lin et al., 2015). A naive way to bias a LM over text history is to ignore the sentence boundaries and train the contextual LM as the standard neural LM (Ji et al., 2015). However, recurrent neural networks suffer training difficulties on longer sequences (Bengio et al., 1994) while transformer-style models are effective at incorporating this extra information (Dai et al., 2019; Brown et al., 2020).

Another approach is to summarize context into a single context embedding using a separate model. For example, Mikolov and Zweig (2012) and Le and Mikolov (2014) use topic information extracted from the context. Mikolov and Zweig (2012) use a pretrained Latent Dirichlet Allocation (LDA) model while Le and Mikolov (2014) use paragraph embeddings learned during LM training. Wang and Cho (2016) on the other hand, use a bag-of-words of whole text or individual sentences in the context to build the context vector. Roh et al. (2020) and Lin et al. (2015) further extend sentence-based contextual models by using hierarchical embedding techniques. This approach learns a representation of the context that is directly used as input to a neural LM.

Other sequence tasks in natural language processing (NLP) also leverage contextual information. Neural machine translation (NMT) capitalizes on the availability of previous sentences on the source and target sides when translating documents (Yun et al., 2020; Sugiyama and Yoshinaga, 2021; Zhang et al., 2018). The only difference in the approaches is how the context is encoded into a representation optimized for NMT.

Automatic speech recognition (ASR) and conversational dialog systems also use contextual information, such as recent advances in shallow or deep fusion of end-to-end neural architectures (Zhao et al., 2019; Williams et al., 2018; Kim and Metze, 2018; Munkhdalai et al., 2021; Jain et al., 2020). Recent papers have also considered biasing LMs with context beyond the previous sentence and incorporate additional signals such as date-time, geolocation or gender (Ma et al., 2018; Diehl Martinez et al., 2021) or application metadata like dialog act or intent (Masumura et al., 2019; Shenoy et al., 2021; Liu and Lane, 2017). Other sources of context used to bias LMs are personalized content (Jaech and Ostendorf, 2018b; Fiorini and Lu, 2018); conversational turn-taking (Xiong et al., 2018); multi-modal sources (Moriya and Jones, 2018); or even user demographics to suggest fashion suggestions (Denk and Peleteiro Ramallo, 2020).

3 Architecture

Our task is to estimate an auto-regressive language model conditioned not only on the previous words in the sentence, $W = w_1, w_2, \ldots, w_n$, but also on several contextual signals,

$$P(W|C) = \prod_{i=1}^{n} P(w_i|w_{i-1}, w_{i-2}, \ldots, C) \quad (1)$$

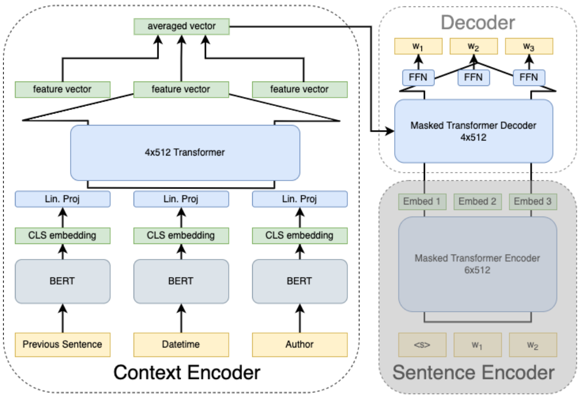

Figure 1: *Overview of CUE architecture.* Pretrained sentence encoder and DistilBERT modules are frozen.

where $C = [c_1, ..., c_K]$ represents a set of K contextual inputs that may vary with each sentence, and where each c_k is a sequence of tokens from the same vocabulary as the target sentence.

Adapting recent work in hierarchical contextual embeddings (Yun et al., 2020), our CUE architecture has three components (see Figure 1):

- An auto-regressive transformer **sentence encoder** conditioned on within-sentence history.
- A transformer **context encoder** with a BERT-based embedding combines multiple context signals into one CUE vector.
- An auto-regressive transformer **decoder** to predict the current word based on the context and within-sentence embeddings.

Our goal is to train a separate context encoder that can be updated without modifying the sentence encoder or decoder and run inference independently of the other modules. This is important for operational practicalities, to precompute context embeddings and update them incrementally without requiring downstream components to change.

3.1 Context Encoder

We present all the contextual signals to the context encoder as strings. Non-textual signals, like datetime, are converted into English, such as "Wednesday 29 May 1985". Similarly, we represent any categorical or symbolic context by its English text string.

The encoder projects the set C of K context types into one compact embedding. These may consist of the previous K sentences, K different metadata types such as datetime, or a mix of both. We then encode each context string c_k with DistilBERT (Sanh et al., 2019) and represent each context by its `CLS` embedding to generate the intermediate representation

$$g_k = FFN(BERTEncoder(c_k)). \quad (2)$$

We do not fine-tune DistilBERT since empirically it gave negligible gains on our experimental corpora.

The set of intermediate representations $G = [g_1; \ldots; g_K]$ is then passed through transformer blocks to learn dependencies between the context types and to generate the self-attended embeddings $E = [e_1; \ldots; e_K]$, where

$$E = TransformerEncoder(G). \quad (3)$$

The contextual encoder is invariant to the ordering of context types since we treat context as a "bag of sequences" and do not add positional embedding to the `CLS` embeddings. Additionally, we do not use query values from the within-sentence encoder, so as to preserve the modularity of our architecture; our goal is to use one context encoder with multiple sentence encoders or modeling tasks. The empirical gain was small for conditioning the context attention on the history at each word position (thus giving a different context vector for each token).

Finally, the per-context embeddings e_k are averaged to produce our compact representation,

$$e_{\text{cue}} = \frac{1}{K} \sum_k e_k. \quad (4)$$

3.2 Sentence Encoder

The sentence encoder is a familiar auto-regressive masked language model with a transformer encoder and a final softmax layer to generate a distribution over the vocabulary (Vaswani et al., 2017). We used six layers of 512 dimensions each with 4 attention heads and used a standard language modeling task to fit the parameters; no context was used to train this module. In our experiments, the sentence-encoder parameters are frozen and never fine-tuned when biasing the decoder with context. We assume that the sentence encoder was trained on a very large general text corpus. It uses the same DistilBERT tokenizer as the context encoder, but do not use DistilBERT for word embeddings since our model is causally auto-regressive.

3.3 Decoder

The decoder is a masked transformer decoder as described in Vaswani et al. (2017) with six layers of

Module	# Params	Train	Adapt.
Sentence encoder	24.5M	N	N
DistilBERT	65M	N	N
Decoder	40M	Y	N
Context encoder	6.6M	Y	Y
Total	136M	-	-

Table 1: *CUE components.* Some modules are updated or frozen depending on context training or adaptation.

512 dimensions and 4 heads for multi-headed attention. The sentence-internal embeddings (before the softmax layer) are passed as the shifted outputs to the decoder; along with the contextual CUE vector e_{cue} as input to the multi-headed attention module in the decoder.

4 Adapting to Evolving Context

We now no longer assume that the set of context types is static between training and test. For example, an API providing context may be retired; or business rules improving customer privacy may remove geographic information. The set of contexts may evolve over the life-cycle of our CUE encoder and we now introduce an adaptation step.[1]

Ideally, we would jointly fine-tune the entire model architecture (context encoder, sentence encoder and decoder) on annotated data that contains the new context types. However, this creates an operational burden since different downstream decoders that use context embeddings would each need retraining. Our goal is to adapt the CUE context encoder while leaving the decoder parameters frozen. This will minimize the number of parameters to be retrained and simplify model deployment by factoring the context encoder from the decoder.

We break the training process into two phases: *Training* constructs the initial set of model parameters and is not constrained by operational needs. *Adaptation* happens at some later point in time after the set of context types changes. Section 4.1 considers the scenario where new context types are added to or replace the initial training types. Section 4.2 assumes *no* context is available during model training, only at adaptation time.

4.1 Adapting with annotated data

Our adaptation strategy is to fine-tune only the context encoder, leaving the other parameters unchanged. Since the context encoder consumes sequences of text, our approach benefits from DistilBERT projecting sentences into a shared embedding space through the `CLS` token prepended to the beginning of the sentence. We fine-tune the context transformer that operates on the per-context DistilBERT embeddings before averaging (see Figure 1). This component has 6.6M parameters, roughly 5% of the total number of parameters (see Table 1). Given an adaptation corpus of sentences paired with new context types, we take a forward pass for each batch and then backpropagate through the decoder to the contextual encoder. This approach handles any arrangement of new context. Section 6.3 details results evaluating how adaptation benefits over zero-shot approaches with a static model.

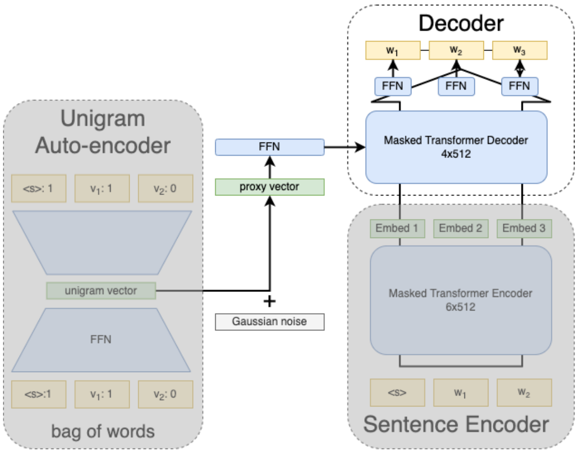

Figure 2: *Priming the decoder with proxy embeddings.* We add noise to an embedding of the target sentence unigram distribution as a proxy for the decoder to learn to attend to context as yet unknown during training. Modules in gray are frozen during decoder training.

4.2 Proxy embeddings

We now consider the scenario where we have no sentences paired with context during training, but want to bias our architecture on context at adaptation time. Since the decoder parameters are frozen during adaptation, we must prime it during training to pay attention to a context embedding, even though we lack the context to generate such an embedding. We tackle this problem by hypothesizing that context plays a role similar to a topic model: it mostly affects the unigram distribution, with small higher-order effects. Thus, we generate proxy embeddings from an oracle encoding the unigrams in the target sentences, described below.

4.2.1 Generate unigram embeddings

We first transform each sentence $W = w_1, \ldots, w_n$ in our training corpus $\mathcal{D}$ into an empirical unigram

---

[1] Out of scope for this paper is missing context at inference time. We assume the same set of contexts at adaptation and testing time.

distribution ("bag of words") over the vocab $\mathcal{V}$,

$$\tilde{P}(W) = \left\{ w \in \mathcal{V} : \frac{\sum_{i=1}^{n} \mathbb{1}(w_i = w)}{n} \right\}. \quad (5)$$

Next, a feed-forward auto-encoder, $\mathcal{F}_\Theta$, reconstructs $\tilde{P}(W)$ through a low-dimensional hidden layer fitted by minimizing reconstruction loss with Kullback–Leibler (KL) divergence,

$$\mathcal{L}(\Theta; \mathcal{D}) = \sum_{i=1}^{N} \mathrm{KL}(\mathcal{F}_\Theta(\tilde{P}_i) || \tilde{P}_i). \quad (6)$$

The layers were 28996×128×16×128×28996 with ReLU non-linearities, and a final softmax layer to generate a distribution over the vocabulary. We swept multiple architecture sizes and saw no gain for more parameters. Reconstruction loss on the test set improved from 5.59 to 1.94 after ten epochs.

4.2.2 Train decoder with proxy embeddings

We then replace the context encoder with this auto-encoder; freeze the sentence encoder and fit the parameters of the decoder on training data that do not have context annotations (see Figure 2). In place of the context embedding, we construct a proxy embedding $\hat{a}$ by adding Gaussian noise to the embedding of the *entire* sentence and re-normalizing.

$$\hat{a} = \mathcal{F}_\Theta(\tilde{P}) + \mathcal{N}(0, \sigma^2) \quad (7)$$

$$\hat{a} = \frac{\hat{a}}{||\hat{a}||^2}, \quad (8)$$

As we increase σ, the information content in $\hat{a}$ decreases, calibrating the information content of the proxy embeddings to match the expected strength of the actual context. Section 6.3 details the importance of this hyperparameter. We then project this low-dimensional embedding to the target contextual embedding (512 in our experiments) through a linear projection and pass it as input to the decoder.

4.2.3 Adapting the context encoder

Once annotated sentences with context are available for adaptation, we train only the context encoder to project available context into an embedding space tuned to the decoder. The decoder was "primed" to attend to an external embedding and the sentence-internal embeddings. We freeze the decoder and sentence encoder weights; backpropagate; and update only the weights of the transformer in the context encoder and the linear projections that scale from DistilBERT embeddings to the context embedding dimension. As mentioned above, our encoder is agnostic to the ordering of the context types and transforms text into an embedding through DistilBERT. Section 6 demonstrates that this approach successfully adapts to unseen context data.

Purpose	#Articles	#Sentence	#Words
Word LM training	250K	8.5M	215M
Context training	55K	1.8M	47M
Context adaptation	60K	2M	41M
Validation	5K	170K	4.3M
Test	5K	166K	4.2M

Table 2: *NYTimes corpora used in this work.* We randomly shuffle all articles before partitioning and use 20% of the entire corpus to reduce experiment turnaround time.

5 Corpus

We used the New York Times Annotated Corpus (Sandhaus, 2008) released through Linguistic Data Consortium (catalog number LDC2008T19) containing over 1.8M English articles spanning 1987 to 2007. This corpus includes a rich collection of contextual annotations for each article, ideal for evaluating our CUE framework. Each article contains up to 47 different metadata types that were labeled by humans (author, title, desk) or algorithmically (locations, topic). We down-selected from 47 to 11 distinct metadata signals after removing redundant or uninformative context. All context types were character sequences and include previous sentence, title, author, entities present in the article, section descriptors, date, and topic descriptors (see Appendix A for details). Articles averaged 32 sentences in length and average sentence length (after tokenization) was 26. We trained the sentence encoder on a large subset of articles; used separate training and adaptation corpora and separate validation and test sets (Table 2).

6 Experimental Results

6.1 Hyper-parameters

Sentences were tokenized first with spaCy (Honnibal and Montani, 2017) and then into word pieces using the DistilBERT tokenizer. We evaluated model performance by computing perplexity (PPL) on the heldout test set. We trained all models for ten epochs using the AdamW (Loshchilov and Hutter, 2017) optimizer and One Cycle learning rate scheduler (Smith and Topin, 2017) with a learning rate of 0.0001, maxing at 0.004; and gradient clip-

Contextual features	Test PPL	Rel. PPL
Sentence-internal only	36.6	-
+ article metadata	35.9	-2.0%
+ previous sentence	29.8	-18.6%
+ previous sentence + metadata	27.4	-25.0%

Table 3: *Reduction in PPL by adding context.* We contrast a sentence-internal transformer LM with four variations of added contextual information. Article metadata (e.g., author, title) is mildly informative, the previous sentence is the most useful. Metadata improves PPL *more* when previous sentence is included.

ping of 0.95. We parallelized batches on 8 V100 GPUs and averaged 75k tokens per second with a per-GPU batch size varying between 64 and 256 sentences depending on the architecture size. The parameters of the sentence encoder and DistilBERT are frozen for all the experiments, greatly speeding up training time with negligible impact on PPL.

6.2 Contextual biasing

We first compare our architecture against a sentence-internal auto-regressive language model. The 6x512, 4-head transformer word language model was trained on the separate 200M-word corpus and used as the sentence-encoder in our full CUE framework. As shown in Table 3, contextual signals reduce PPL by 25% for this corpus and nearly three fourths of that gain is due to the previous sentence. Since the remaining contextual features are at the *article* level, they have a smaller impact on within-sentence likelihoods.[2] This 25% relative gain is the upper bound for adaptation methods since context types are consistent between training and test; and context encoder and decoder are trained jointly.

To evaluate the key elements of our architecture, we conducted an ablation study by disabling various components and measured the relative degradation in perplexity, as shown in Table 4. Removing the transformer after DistilBERT embeddings and using a simple average gives an 8% degradation. Removing the transformer decoder and instead concatenating the CUE vector with each step's hidden state before the logit layer gives a 22% degradation. Replacing DistilBERT with a randomly initialized transformer estimated on the contextual training corpus give the biggest loss of 27%. Finally, using only the context to predict each word (a constant vector at each step) is much worse, but still 45x better than random (which would be equal to the vocab size of 28,996). Context is a useful prior, even though it is constant for all tokens in the sentence.

Module	Test PPL	Rel. PPL
Full architecture	27.4	0%
No context transformer	29.6	+8%
No decoder transformer	33.5	+22%
No DistilBERT	34.8	+27%
No contextual inputs	36.6	+33%
No sentence inputs	643	+2200%

Table 4: *Ablation study on architecture modules.* Refer to Figure 1 for a schematic of the components.

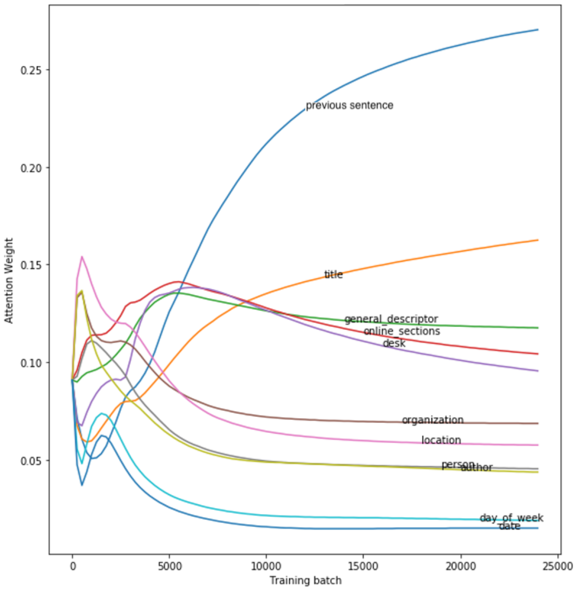

Figure 3: *Change in normalized attention weights over training iterations.* The weights of the self-attention component of the context encoder converge to the relative importance of each contextual category over time, with previous sentence receiving the most weight.

Figure 3 captures the model's attention converging to the relative importance of each context type. The ordering of context types by attention weights is similar to a ranking by perplexity gain given in Appendix B.

6.3 Adaptation

We next evaluate our framework for interchangeability of different forms of context. We randomly partitioned the eleven context types into two sets **A** and **B** and report the average over five separate trials in Table 5. Set **A** is our training set and we experiment with two adaptation scenarios: **B** replaces **A** or **B** is added to **A**.

When *adding* additional context types (**A** → **A**+**B**), adapting the context encoder without retraining the decoder captures 85% of the possible gain for jointly training the context encoder and de-

---

[2] See Appendix B for a breakdown of the relative strength of each contextual type.

Row	Description	Train	Adapt	Test	PPL	Rel. PPL
1	Word-only baseline	-	-	-	36.6	-
2	Proxy training (cheating)	Proxy	-	Proxy	29.7	−19%
3	Context A always available	A	-	A	29.3 ± 1.3	−20 ± 4%
4	No training context	Proxy	B	B	31.8 ± 0.8	−13 ± 2%
5	No adaptation	A	-	B	32.0 ± 0.2	−13 ± 1%
6	Context A replaced by B	A	B	B	30.9 ± 0.7	−16 ± 2%
7	Context B always available	B	-	B	29.9 ± 1.4	−19 ± 4%
8	No training context	Proxy	A+B	A+B	30.4	−20%
9	No adaptation	A	-	A+B	30.1 ± 2.1	−18 ± 6%
10	Context B added after training	A	A+B	A+B	28.8 ± 1.0	−21 ± 3%
11	Context A+B always available	A+B	-	A+B	27.4	−25%

Table 5: *Adaptation results.* Results are averaged over five random partitions of context types into training set **A** and adaptation set **B**. Results without std. dev. are based on a single experiment run. Adding metadata with CUE embeddings outperforms a word-only model (row 1) by 25% (row 11). CUE vectors are robust to evolving context, either without any context in training (rows 4, 8); no adaptation (rows 5, 9); or adapting with new annotated sentences (rows 6, 10). Contrast with lower bound of all context available in training and adaptation (rows 7,11).

coder on all context types (compare rows 1, 10 and 11). Starting at a word-only PPL of 36.6, adaptation to $\mathbf{A}+\mathbf{B}$ reaches 28.8 versus the lower bound of 27.4. When *replacing* context types ($\mathbf{A} \rightarrow \mathbf{B}$), adaptation also achieves 85% of the possible gain (36.6 to 30.9 versus the lower bound of 29.9 in rows 1, 6 and 7). Even without *any* adaptation (rows 5 and 9), our architecture generalizes to new context types (approximately 70% of the possible gain), though not as effectively as with adaptation. This is because we transform context into English text and leverage BERT embeddings as a strong initial embedding for context sequences.

When we train the decoder with proxy embeddings (no real context at all) and adapt to context, the PPL is within 6% to 11% (depending on the context subset) of the lower bound of jointly training the context encoder and decoder. This approach recovers 67% of the gain from jointly training context encoder and decoder for the two scenarios ($\mathbf{A} \rightarrow \mathbf{B}$ and $\mathbf{A} \rightarrow \mathbf{A}+\mathbf{B}$). We find this quite remarkable given that the decoder knows nothing of context during training; the result validates our hypothesis that context encodes the unigram priors.

We tuned the strength of the proxy embedding by sweeping the variance of Gaussian noise added. The sweet spot is where the information content in the proxy embedding is close to the actual context, as shown in Figure 4. This intuitive result provides a sensible recipe for setting this hyperparameter in a production setting.

6.4 Different sentence encoders

Our CUE architecture factors the context encoder from the sentence encoder and decoder. This approach generates one embedding that can be used with multiple decoders and sentence encoder pairs.

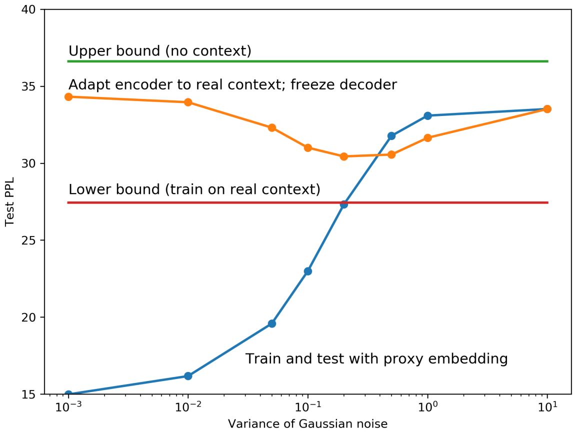

Figure 4: *Varying proxy embedding strength.* The baseline is no context (green line) versus the lower bound of knowing all context in training and test (red line). We sweep the amount of noise added to the oracle unigram vector on the x-axis. When training and testing on only the unigram vector (blue line) the unigram vector is a powerful oracle without noise, but then becomes random as the variance increases. During adaptation (orange line), we discard the unigram embeddings, freeze the decoder parameters, and retrain the context encoder (5% of parameters). The amount of embedding noise is optimal roughly when the proxy embedding is as informative as actual context (where blue and red lines intersect).

To evaluate the generalizability of our CUE framework, we trained a 4x512 LSTM sentence encoder and froze its model parameters for the remaining experiments. We then trained a new decoder using the LSTM sentence encoder and evaluated two different context encoders: 1) randomly initialized and jointly trained with the decoder *or* 2) the pretrained encoder jointly trained with the old, *transformer*-based sentence encoder and frozen parameters. Table 6 shows that the CUE vectors trained with one sentence-LM architecture are useful to the other, with a relative degradation when swapping of 7% and 1%, respectively, between LSTM and transformer sentence encoders.

Row	Sentence Encoder	Context Encoder	PPL
1	Transformer, frozen	jointly trained	27.4
2	Transformer, frozen	frozen from (3)	29.4
3	LSTM, frozen	jointly trained	28.0
4	LSTM, frozen	frozen from (1)	28.2

Table 6: *Swapping context and sentence encoders.* Without fine tuning, frozen context encoders generalize to new sentence encoders and decoders with <7% relative degradation (compare rows 1 and 2; 3 and 4).

These results suggest that our CUE framework can factor the context encoder and decoder training and generalize to multiple decoder architectures. This frequently occurs in operational settings such as the first and second pass LMs in speech recognition or compressed parameter sizes due to memory and latency constraints.

7 Discussion

We analyzed whether a sentence's context behaves like a cache model, since it contains textual data from the previous sentence, title, and other contexts. To better understand this effect, we divided test data tokens into two bins: Those that appeared in the text of the sentence's context and those that did not. We measured the relative gain in log likelihood when conditioning the LM on context versus not. 30% of the tokens appeared in the context (cache) and the relative gain was 74%—there clearly is a strong benefit for recurring tokens and the CUE encoders capture this effect. The 70% of tokens that do not occur in the cache improved their log likelihood by 26% relative. So the cache effect does not explain the entire benefit of CUE vectors and correlations among different token types are captured as well. The top context types that had tokens in the sentence were previous sentence (23%), title (9%) and person (6%).

To verify that the empirical improvements from the previous sections are semantically plausible, we analyzed the context embeddings of the *first sentence* of 5000 heldout articles. These embeddings do not contain information from the previous sentence and thus represent the entire article's metadata. Figure 6 projects these embeddings down to two dimensions with t-SNE. We then clustered the vectors with k-means and aggregated word counts for all articles within a cluster.

Finally, we display the five most salient words (computed with TF-IDF) from the context and, separately, from the article text. Even though the articles were clustered based only on context, the groupings of *article text* are semantically meaningful, with clear clusters related to newspaper sections such as corrections, marriage announcements, sports and other news related topics. Our context embedding is preserving semantic information.

One limitation of the proxy embedding approach is that they may not extend to other NLP tasks, like named entity tagging. Since they are derived from the unigram embedding, they directly encode the targets of the language model task. This may not prove useful for higher-order annotations and further work should look into a multi-task proxy embedding that directly optimizes an "interface" embedding space instead of a unigram distribution.

8 Conclusions

We introduced the CUE framework to factor context encoding and next word prediction of context-aware neural language models. Unlike previous work, we do not assume that the set of context signals is constant between training and test. We optimize the model architecture to reduce the operational burden of managing and retraining of large neural LMs over their life cycle.

Our approach is robust to changing context types; by adapting only 5% of the parameters, we recover 85% of the possible gain from jointly training all components. Furthermore, we introduce *proxy embeddings* to pretrain a decoder to be attuned to external context embeddings even when those are not known at training time. This approach is 67% as good as jointly training with all context.

In future work, we would like to handle missing context at inference time through data imputation or dropout approaches. Furthermore, we plan to extend the proxy embedding approach such that the context encoders can be trained fully independent of the decoder.

B Appendix: Relative strength of context types

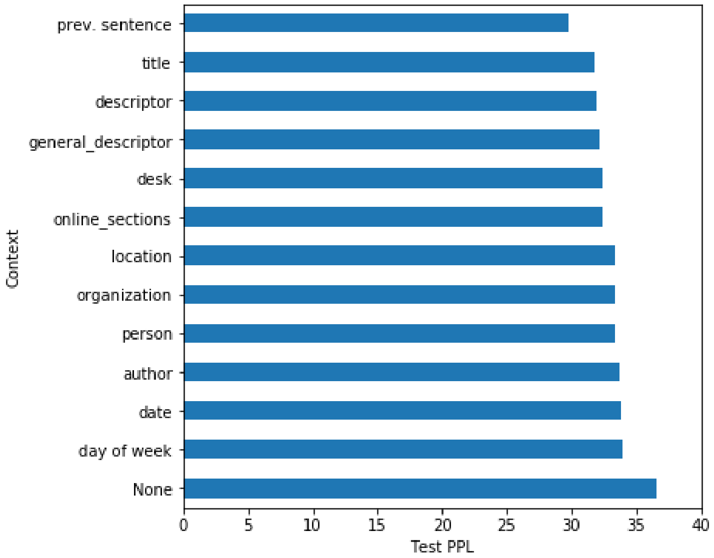

Figure 5: *Relative strength of each contextual type*. We trained the CUE model with only one contextual signal at a time and measured perplexity on the same heldout test set. Textual context types (previous sentence, title, descriptor) are the most powerful.

C Appendix: Qualitative Visualization

Figure 6: *T-SNE plot of context embeddings*. We cluster the *first sentence* embedding of 5000 articles and project the 512-d context vectors to two dimensions with t-SNE. We group context vectors into clusters with k-means and compute TF-IDF scores separately for context (green) and sentence (blue) words and show the top 5 for each. Notice how the set of five green words cohere with the five blue words, indicating the CUE embeddings project context and metadata to a similar space as the article contents. The clustering recovers meaningful news topics, such as company earning reports, obituaries, sports, books and art.

Cross-Lingual UMLS Named Entity Linking using UMLS Dictionary Fine-Tuning

Abstract

We study cross-lingual UMLS named entity linking, where mentions in a given source language are mapped to UMLS concepts, most of which are labeled in English. Our cross-lingual framework includes an offline unsupervised construction of a translated UMLS dictionary and a per-document pipeline which identifies UMLS candidate mentions and uses a fine-tuned pretrained transformer language model to filter candidates according to context. Our method exploits a small dataset of manually annotated UMLS mentions in the source language and uses this supervised data in two ways: to extend the unsupervised UMLS dictionary and to fine-tune the contextual filtering of candidate mentions in full documents. We demonstrate results of our approach on both Hebrew and English. We achieve new state-of-the-art (SOTA) results on the Hebrew Camoni corpus, +8.9 F1 on average across three communities in the dataset. We also achieve new SOTA on the English dataset MedMentions with +7.3 F1.

1 Introduction

Public health practices are becoming increasingly digital, with tools to explore scientific sources of information such as medical literature and online health communities rising in popularity. Such tools are essential in offering insights to researchers, providing information to patients and to their caregivers. Reliable identification of mentions of biomedical concepts in free text is a key technique to enable robust mining of such textual resources. Named-Entity Recognition (NER) is the task of classifying entities in text to high level classes (Person, Organization, Gene, Disease, Treatment, etc.). Named-Entity Linking (NEL) seeks to additionally classify entity mentions in text into specific concepts according to an existing reference list or knowledge base. We focus in this work on biomedical NEL, *i.e.,* identifying mentions referring to biomedical concepts such as disorders and drugs and linking them to normalized concepts, for example, concept unique identifiers (CUIs) listed in the Unified Medical Language System (UMLS) controlled vocabulary. Biomedical NEL has been mostly studied in English. Other languages present additional challenges because terms in the ontology are described in English. We address cross-lingual NEL which consists of mapping mentions in a source language to concepts labeled and described in a different target language. We focus on cross-lingual UMLS NEL, where mentions in the source language (we specifically test Hebrew, see Figure 1 for a Hebrew tagging example) are mapped to UMLS concepts. We aim for a general solution that can be adapted to any source language. We operate in a low resource setting, where the ontology is large, text describing most entities is not available, and labeled data can only cover a small portion of the ontology. We also consider different genres of text to be annotated, ranging from consumer health medical articles in popular web sites to scientific biomedical articles.

Our main contributions are: (1) We provide a general framework for cross-lingual UMLS NEL that can be adapted to source languages with few pre-requisites; (2) Our method exploits a small annotated corpus of documents in the source language and genre annotated manually for UMLS mentions (a few thousands annotated mentions). This training data is split to support (a) the extension of the unsupervised UMLS dictionary with corpus-salient entity names and (b) fine-tune the contextual ranking and filtering of (candidate mentions, concept) pairs. We find that the step of UMLS dictionary fine-tuning boosts NEL performance and identify

a clear tradeoff in allocating training data between lexicon extension and contextual fine-tuning; (3) We demonstrate results of our approach on both Hebrew and English. We achieve new SOTA on the Hebrew Camoni corpus (Bitton et al., 2020) with +8.87 F1 and on the English dataset MedMentions (Mohan and Li, 2019) with +7.3 F1[1].

2 Previous Work

Biomedical NEL is challenging because the underlying ontology (most often UMLS) is extremely large and the acquisition of annotated training data requires rare and expensive expertise. Loureiro and Jorge (2020) presented MedLinker, a tool for improving biomedical NEL by predicting the semantic type of a medical concept mention and filtering out candidates of the wrong type. MedLinker was tested on the MedMentions task of concept linking (Mohan and Li, 2019), improving above TaggerOne (Leaman and Lu, 2016), the baseline model for MedMentions which did not use deep learning. MedLinker splits the end to end task of entity linking into two stages - candidate recognition and linking. For candidate matching, it combines a BiLSTM-CRF model for contextual matching with an approximate dictionary matching method to increase recall. In the cross-lingual setting, dictionary matching is not applicable. We report our results on the same MedMentions dataset in Section 5.2.

Past work has shown that using in-domain text can provide additional gains over general-domain language models (Gu et al., 2020). Therefore, recent work (BioBERT (Lee et al., 2020), SciBERT (Beltagy et al., 2019)) addressed biomedical NEL, focusing on pre-training models on scientific/medical text. Liu et al. (2021) developed SapBERT, a pre-training scheme which exploits the graph structure of the UMLS controlled vocabulary and aims at learning an encoding of medical mentions that can align with synonym relations in the UMLS graph. Combining the SapBERT objective with pre-training on biomedical text of PubMedBERT (Gu et al., 2020) boosts results on NEL. Experimental results demonstrated that SapBERT outperforms many domain-specific BERT-based variants (BioBERT and SciBERT) on the BC5CDR (BioCreative V CDR) corpus. Although our model focuses on cross-lingual NEL, it also applies to English documents. We compare our results to these approaches on BC5CDR and MedMentions (Tables 4 and 3).

Indexing of the abundant biomedical scientific literature requires precise detection of medical concepts. Mohan et al. (2021) developed a low-resource recognition and linking model of biomedical concepts (henceforth referred to as *LRR*) aimed at generalizing to entities unseen at training time, and incorporating linking predictions into the mention segmentation decisions. This BERT-based model achieved SOTA results on the MedMentions task. In our work, we adopt the LRR bottom-up candidate generation approach (see Section 4.2). We address the main drawback of the approach by incorporating a UMLS dictionary fine-tuning technique which extends the list of candidate pairs (source expression, CUI) on a portion of the training data. We elaborate on the motivation for the technique in Section 4.5 and demonstrate its contribution in ablation experiments (see Section 5.4).

Cross-lingual NEL, the problem of grounding mentions of entities in a source language text into a different target language knowledge base (typically English), has been addressed in recent years, with a range of promising techniques. When the source and target languages operate over different alphabets and sound systems, both translation and transliteration of terms (which is a noisy process even when done by people) must be handled. Bitton et al. (2020) curated the Camoni corpus, an annotated resource of Hebrew posts from online health communities (OHCs), where noisy text (as opposed to scientific text) introduces additional challenges. Many user queries mention medical terms, which are very likely to include noisy transliterations. For example, the Hebrew query equivalent to “How do I know I have fibromyalgia?” does not return any results in the search engine of the Camoni online community when ‘fibromialgia’ is transliterated. Bitton et al. (2020) introduced MDTEL (Medical Deep Transliteration Entity Linking) for Hebrew-English NEL on noisy text in OHCs, and tested it on the Camoni corpus. MDTEL adopts a four-step approach - consisting of an offline unsupervised Hebrew UMLS dictionary learning, candidate mention generation, high-recall matching and filtering of matching mentions. We adopt MDTEL’s unsupervised UMLS dictionary matching, which uses an attention-based recurrent neural network encoder-decoder that maps UMLS from English to Hebrew (either a Hebrew translation or translit-

שלום,

לאחרונה חלה החמרה בהליכתי והוצע לי להתחיל טיפול בבוטוקס לשחרור השרירים ומניעת הספסטיות

האם מישהו כאן עבר טיפול כזה ? האם זה עוזר? אין חשש שטיפול כזה יחליש מאוד את השריר ויעשה את הפעולה
הממש הפוכה?

Figure 1: A forum post from the Camoni sclerosis community that translates to: *"Hello, recently, my gait has deteriorated and I was suggested to begin Botox treatment to release the muscles and prevent spasticity. Has anyone here undergone such treatment? does it help? is there a risk that such treatment will greatly weaken the muscle, causing the exact opposite action?"*. The post contains 37 words and 6 spans that link to 4 different CUIs of UMLS concepts. Notice that a span can consist of more than 1 word (such as the term matched with "gait abnormality") and a single CUI can be referenced from several places in the same post (such as the CUI of "General Treatment").

eration of the concept). We introduce new methods for candidate generation, high-recall matching and contextual relevance filtering, relying on multilingual pre-trained language model (mBERT). Our new components lead to significant performance improvement over MDTEL on the Camoni corpus (see Table 2).

3 Task Formulation

Given input language L and target language L_t, a database of medical concepts $C_{L_t} : L_t^* \to CUI$ is a function from concept names in L_t to concept IDs (CUIs). Using C_{L_t}, we want to learn a function F from a span in input language L and its context to a CUI. We identify dictionary $C_L : L^* \to CUI$. C_L is the translated version of the medical concepts database C_{L_t}. We learn C_L by mapping the medical terms in L_t to terms in L. Given mapping C_L, we aim to learn:

$$F : L^* \times L^* \to CUI \cup \{\perp\}$$

where $\perp$ is a special code denoting a non-medical term. F differs from C_L as it addresses the variability and ambiguity of the task by depending on the context as well as the span. Given text $W = (w_1, ..., w_n)$, where $w_i \in L$, for every span $s_{i,j} = (w_i, ..., w_j) \subseteq W$, we would like to compute $F(W, s_{i,j})$, where $0 \leq j - i < k$ (we limit the span sizes to at most k), that is, we want to predict the concept associated with a span under context W in language L. Provided a dataset A_L exposing a subset of F combined with linguistic knowledge and generalization capabilities of neural models, we aim at learning a larger portion of function F.

4 Model Architecture

Our end-to-end cross-lingual UMLS NEL model (Figure 2) consists of four consecutive stages: (1) **multilingual UMLS mapping**: generate UMLS dictionary C_L (see Section 4.1) based on the method of Bitton et al. (2020), and fine-tune it using our UMLS dictionary fine-tuning technique (see Section 4.5); (2) **candidate generation**: consider all spans of up to k words as candidate mentions and compute vector representations for both mentions and concepts (see Section 4.2); (3) **high recall matching**: use a semantic similarity based score function to generate the top matching entities with high recall (see Section 4.3) and (4) **contextual relevance modeling**: encode each candidate into a context-dependent vector representation using a pre-trained transformer-based language model fine tuning process (see Section 4.4).

Our approach attempts to avoid three types of mistakes: (1) **morphological and transliteration noise**, where candidate terms in the source language might be extracted due to a transliteration or morphological error and matched with UMLS entities, (2) **contextual errors**, where candidate terms which are not medical terms when considering the context might be matched with UMLS entities, and (3) **partial UMLS tagging**, where candidate terms

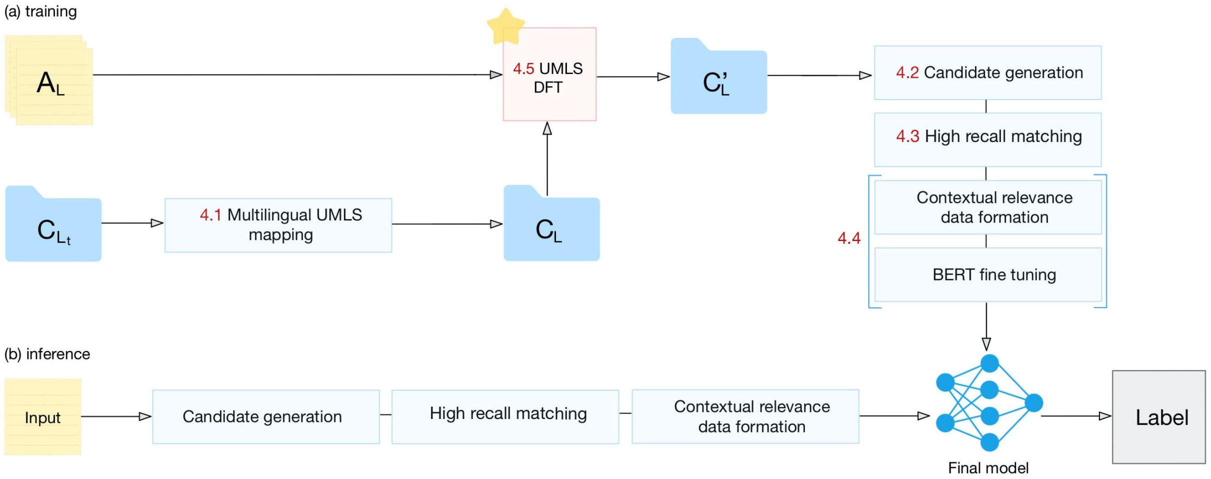

Figure 2: End-to-end pipeline overview. Training process of the model is depicted in section (a), inference process using the final model is depicted in section (b).

which are not the full medical terms in the text but rather more general UMLS mentions might be tagged instead of the full term (*e.g.,* in the mention "flu vaccine", "flu" should not be tagged). The first challenge is addressed by learning a high-recall C_L dictionary with generalization capabilities, trained both on translation and transliteration data; the second, is addressed by an mBERT-based contextual language model; the third, by systematic consideration of all spans up to size k as candidates as part of the candidate generation and contextual relevance components.

4.1 Multilingual UMLS Mapping

The first step of our model is offline, fully unsupervised, and based on the method of (Bitton et al., 2020): we generate a mapping C_L between medical concept names in source language L to their corresponding CUIs. An attention-based character-based recurrent neural network encoder-decoder is used to create a list of *⟨UMLS term in English, term in language L⟩* so that each UMLS term in English is matched with both transliterated and translated forms in L. This is done without the need of manually annotated data and results in a noisy mapping C_L of source language medical terms and their CUIs.

4.2 Candidate Generation

Given a document in L where we want to identify UMLS mentions, the candidate generation step begins with pre-processing: we normalize the source text documents from annotated data A_L and the target UMLS concepts from C_L by transforming all string values to lower case and removing delimiters. We then generate a list of overlapping candidate mention spans, ranging in length according to the max length parameter k (*i.e.,* $1, ..., k$. See Appendix A for details). We exclude spans starting or ending with stop words. We then represent both the spans and the concepts as tf-idf character n-gram (1 to 3-gram) vectors using sklearn's implementation (Pedregosa et al., 2011). Empirical experiments showed that tf-idf encoding improved recall in candidate generation compared to bag of words encoding (see Appendix B for a comparison between the two representations using both Hebrew and English datasets).

4.3 High Recall Matching

The high recall matcher (HRM) receives the vector representations from the candidate generator and computes a similarity score between each span and all concept names in C_L using cosine similarity (see Appendix B for comparison against Manhattan score function). We then select the top m matches per span with score over a threshold th (see Appendix C for hyper-parameters). This results in a high recall list of candidate matches.

4.4 Contextual Relevance Modeling

At this step, we want to predict which spans returned from the high recall matcher are true biomedical concepts. We use multilingual BERT (m-BERT) (Jacob Devlin, 2019), a 12 layer transformer that was trained on the Wikipedia pages of 104 languages (including Hebrew) with a shared word piece vocabulary. M-BERT does not use any marker denoting the input language, and does not include explicit mechanism to encourage translation equivalent pairs to have similar representations. We fine-tune m-BERT on a binary classification task on our training data: each candidate mention span returned from the HRM is centered in its context from the original doc, *i.e.,* W_s words to the right of the span and W_s words to the left of the span, creating a window surrounding the candidate mention. The classifier takes as input the window, the HRM's decision on which concept is represented by the mention in the window, and the true verdict of whether the candidate mention is indeed an occurrence of the concept. We utilize m-BERT's QA format as follows: the question (medical concept c) and the reference text (window w) are packed into the input, and provide the binary label as answer of whether or not c is a medical mention in context w: $[CLS]$ w $[SEP]$ c $[SEP]$. This fine-tuning step consists of adding an additional output layer on top of the pre-trained m-BERT model to adapt it to the biomedical NEL task.

4.5 UMLS Dictionary Fine-Tuning

We introduce a UMLS dictionary fine-tuning (UMLS DFT) technique where some of the data in A_L is removed from the training dataset and used to directly expand the learned dictionary C_L. We reserve $R\%$ of the training data A_L to fine-tune C_L generating C'_L (see Figure 2): from this chunk of A_L, we add each mention in the tagged data as new pairs (mention in L, CUI).

For example, suppose our training data consists of 10 tagged documents and our UMLS dictionary C_L contains 100 concepts. Given $R = 10\%$, our UMLS dictionary fine-tuning technique will require one tagged document d (10% of the 10 docs in the training set) to be used for fine-tuning C_L. We go over every tagged pair (m, c) from doc d, where m is a mention in doc d and c is the UMLS concept the annotators tagged m. If $m \notin C_L$, we add m to C_L with the CUI of c. Suppose doc d contained 15 such tags, we will obtain an augmented C'_L containing $100 + 15 = 115$ concepts. We cannot use this portion of data for later training of our model, since after fine-tuning we are guaranteed to get a perfect match for all the spans in the documents used for fine-tuning (thus creating bias of the HRM). Although this process decreases the overall size of the input dataset for contextual relevance fine-tuning, it improves the recall of the HRM and adds more positive examples for the BERT training process. We elaborate more on this trade-off in Section 5.4.2. This approach allows us to improve recall on synonyms and abbreviations that were not originally in our UMLS dictionary, with genre-specific terminology observed in the training data (as evident from the experiment shown in Table 5).

5 Experiments

We test our approach both on cross-lingual UMLS Linking using the Camoni dataset of Hebrew consumer health data and on English UMLS Linking using MedMentions and BC5CDR, which include scientific papers in the bio-medical field.

5.1 Camoni Corpus

The Camoni corpus was curated by Bitton et al. (2020) for the analysis of the MDTEL system. Camoni is an Israeli social network in Hebrew aimed at patients with chronic diseases and their family members (Camoni). Camoni serves about 20,000 registered members and 100,000 unique visitors per month. The digital platform is organized into 39 disease-specific communities. Bitton et al. (2020) extracted text from three communities (diabetes, sclerosis, and depression), for a total of 55,000 posts and 2.5 million tokens, and constructed an annotated dataset in which 1,000 mentions of UMLS terms were annotated. Bitton et al. (2020) proposed a high recall matcher based on a fuzzy string matching algorithm introduced in prior work to perform the matching between the spans and medical entities. Table 1 compares our HRM results (recall) with MDTEL for each community (diabetes, depression, sclerosis).

We observe that our candidate generation method (adopting the LRR bottom-up approach and mBERT similarity matching) significantly improves the recall of the HRM (average of 74% using MDTEL's approach vs. average of 82% using our method). We believe that the use of the tf-idf character n-gram vectorization before applying the cosine similarity function as means of comparison helped us achieve better results compared to MDTEL's method which only applied the cosine similarity.

In the end to end linking task, our model achieves much higher precision (98% vs. 77%) without affecting the recall (73%), resulting in much improved F-score (84% vs 74%). Table 2 compares the performance of MDTEL with our

Model	Community	Recall %
MDTEL	Diabetes	76.6
Our model	Diabetes	**82.0**
MDTEL	Depression	74.1
Our model	Depression	**83.5**
MDTEL	Sclerosis	70.0
Our model	Sclerosis	**81.0**

Table 1: High recall matcher performance of our model compared to MDTEL (Bitton et al., 2020) on Camoni corpus.

model on the end to end linking task for each community.

5.2 MedMentions

MedMentions (Mohan and Li, 2019) is a corpus of Biomedical papers annotated with mentions of UMLS entities. The corpus consists of 4,392 papers (Titles and Abstracts) randomly selected from papers released on PubMed in 2016, that were in the biomedical field, published in the English language, and had both a Title and an Abstract available. MedMentions contains over 350,000 linked mentions, annotated by a team of professional annotators with rich experience in biomedical content curation. We focus on MedMentions ST21pv (21 Semantic Types and Preferred Vocabularies), a subset of the full annotations containing 203,282 mentions and restricting the concepts to a 2.3M large subset of the full ontology (UMLS ST21pv). Each concept in this subset is associated with one of 21 selected semantic types, or to one of their descendants in the semantic type hierarchy.

We compare our performance to other models' results on MedMentions ST21pv in Table 3. We improve on the latest SOTA LRR (Mohan et al., 2021), achieving +7.3 F1.

Our recall was similar to LRR, however our model achieved highly improved precision, 76.4 compared to 63. We believe this improvement can be attributed to our UMLS dictionary fine-tuning technique, which provides an extended list of candidates and thus more examples for the mBERT fine-tuning process for contextual relevance. Mohan et al. (2021) mention the need to improve recall for cases where the mentions are indirect or too abbreviated to generate a good lexical match from the entity knowledge base, which is exactly what our technique helps improve. For example, our process picked up in the training data that the abbreviation *mrn* is tagged as *messenger rna* (CUI $C0035696$), which was not originally present in the UMLS dictionary for English.

5.3 BC5CDR

The BC5CDR corpus (Li et al., 2016) consists of 1,500 PubMed articles with 4,409 annotated chemicals, 5,818 diseases and 3,116 chemical-disease interactions. Each entity annotation includes both the mention text spans and normalized concept identifiers, using MeSH (Medical Subject Headings) (Lipscomb, 2000) as the controlled vocabulary (MeSH is part of the UMLS controlled vocabulary). Compared to MedMentions which contains annotations of general medical concepts, BC5CDR is topic-specific, containing only annotations of chemicals and diseases. BC5CDR is also much smaller, consisting of just 1,500 articles compared to the 4,392 annotated papers of MedMentions. BC5CDR has a total of 13,343 linked mentions compared to 203,282 in MedMentions ST21pv.

We compare our model's performance to other models using BC5CDR's test set in Table 4. We observe that domain-specific pre-trained transformers help improve results on BC5CDR (93.5 F-measure vs. 73 for our model). The subset of semantic types covered in this dataset is much more technical (chemicals and chemical-disease interactions) than those covered in MedMentions, even though both BC5CDR and MedMentions include documents in the same genre of scientific biomedical articles. This difference is evidenced in the ablation study presented below. It explains why specialized language models trained on the biomedical domain lead to much improved performance compared to our model which uses the general mBERT. We hypothesize that using SapBERT combined with our model could enhance performance on this dataset and leave this for future work.

5.4 UMLS Dictionary Fine-Tuning Ablation Study

In this section, we test several factors impacting the contribution of UMLS dictionary fine-tuning to our tagger's performance. First, we test the technique on two different datasets and evaluate its benefits depending on the dataset size. Next, we test a range of UMLS dictionary fine-tuning percentage values (R) and discuss the trade-off between this value and the end to end performance of our linker.

Model	**Community**	**Precision %**	**Recall %**	**F1 %**
MDTEL	Diabetes	71.0	**75.0**	73.0
Our model	Diabetes	**98.3**	73.8	**84.3**
MDTEL	Depression	77.0	73.0	75.0
Our model	Depression	**97.7**	**76.9**	**86.0**
MDTEL	Sclerosis	82.0	**71.0**	76.0
Our model	Sclerosis	**98.3**	67.8	**80.3**

Table 2: Intrinsic evaluation performance of our model compared to MDTEL (Bitton et al., 2020) on Camoni corpus.

Model	**Precision %**	**Recall %**	**F1 %**
TaggerOne (Leaman and Lu, 2016)	47.1	43.6	45.3
MedLinker (Loureiro and Jorge, 2020)	48.4	50.1	49.2
LRR (Mohan et al., 2021)	63.0	52.0	57.0
Our model	**76.4**	**55.5**	**64.3**

Table 3: Performance of different models on the MedMentions dataset.

5.4.1 Dataset Size Impact

We tested the UMLS dictionary fine-tuning technique on English datasets MedMentions and BC5CDR across 5 random seeds and found that it improved recall on both, but impacting MedMentions much more than BC5CDR due to a much smaller number of added concepts in BC5CDR, 209 compared to 3,294 in MedMentions (see Table 5). The difference in the number of added concepts could be explained by the fact that BC5CDR is much smaller, thus the decrease in training data size counteracts the small number of concepts being added to the UMLS dictionary. To test this hypothesis, we took a subset of MedMentions of the same size as BC5CDR (annotation-wise: 8,575 in total), see Table 6 for results averaged across 5 random seeds. The results suggest that the size of the dataset directly affects the number of concepts added to our UMLS dictionary (227 added in the MedMentions subset, very close to the 209 added in BC5CDR), which in turn impacts the HRM's recall: the improvement in recall is very similar between the two datasets, +1.37 for BC5CDR, +1.7 for MedMentions subset.

5.4.2 The Recall-Accuracy Tradeoff

We first observe that our UMLS dictionary fine-tuning (DFT) technique can only improve the high recall matching performance (Section 4.3) since an annotation that we do not have a good semantic match for from UMLS will be a missed match without UMLS DFT. Similarly, an annotation for which we do have a good semantic match will be found regardless of whether we utilize UMLS DFT or not. Thus, UMLS dictionary fine-tuning helps us find non-semantically similar matches that we would have otherwise missed, meaning that the higher R is - the higher the recall of the HRM should be. However, there is a trade-off between the recall gained from the annotations utilized for UMLS dictionary fine-tuning and the overall performance of the linker, since the annotations used for fine-tuning are examples that the contextual model will be missing during fine-tuning. We explore this trade-off and compare the performance of the high recall matching component with the final tagging results of our model using different values of R on the MedMentions dataset. Figure 3 shows that there is a clear trend of increased recall of the HRM as R increases. However, Figure 4 shows the complexity of the trade-off since the tagger's performance reaches a peak and then begins to drop as R increases. The contextual model fine-tuning improvement plateaus after a certain amount of training examples, demonstrating the benefit of multi-task adaptation of pre-trained models which converge rapidly. The data efficiency of the contextual relevance fine-tuning process allows the UMLS dictionary fine-tuning technique to help improve end to end linking results.

6 Conclusion

In this work we explored the task of cross lingual named entity linking in the biomedical field. We describe a pipeline to detect and link mentions of UMLS concepts in documents in Hebrew or in English, which improves upon existing methods. The

Model	**Dataset**	**F1 %**
BioBERT (Lee et al., 2020)	BC5CDR	88.6
SciBERT (Beltagy et al., 2019)	BC5CDR	90.0
SapBERT (Liu et al., 2021)	BC5CDR-d	**93.5**
Our model	BC5CDR	73.0

Table 4: Performance of different models on the NER task using BC5CDR dataset. Additional evaluation metrics of our model include precision of 88.4% and recall of 62.2%.

Dataset	**UMLS DFT**	**Added Concepts**	**Recall %**
MedMentions	✗	0	63.2
MedMentions	✓	3,294	**71.5**
BC5CDR	✗	0	74.13
BC5CDR	✓	209	**75.5**

Table 5: Number of added concepts per dataset and the average performance of the HRM with and without UMLS dictionary fine-tuning, across 5 random seeds. "✗": UMLS DFT not used, "✓": UMLS DFT used.

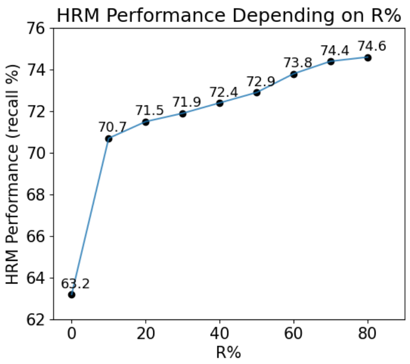

Figure 3: HRM Performance (recall%) on MedMentions dataset depending on the value of R.

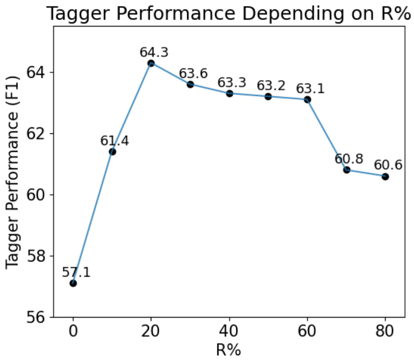

Figure 4: Tagger Performance (F1) on MedMentions dataset depending on the value of R.

key characteristics of our approach are (1) it distinguishes candidate generation from linking; (2) it uses the sophisticated unsupervised UMLS dictionary construction using the character-level RNN model introduced in Bitton et al. (2020) which takes into account both translation and transliteration but extends this dictionary with a portion of the training data mentions; empirical analysis of this dictionary augmentation method demonstrates its importance in end to end linking performance; (3) it adopts the bottom-up systematic generation of candidates from Mohan et al. (2021) and improves it by using a compact tf*idf ranking of the candidates (char n-gram) which helps reduce memory allocation; (4) it uses a multi-lingual pre-trained language model (mBERT) to fine-tune a contextual relevance model to filter a list of high-recall candidate matches. Our framework for cross-lingual UMLS NEL can easily be adapted to any source language and does not rely on any descriptive text for the entities.

We compared our performance to baseline approaches on the Camoni dataset in Hebrew (Bitton et al., 2020), and the MedMentions (Mohan and Li, 2019) and BC5CDR English datasets. Our end-to-end approach achieves SOTA results on Camoni in Hebrew and MedMentions in English with significant improvements. For BC5CDR, we observe that the small size of the dataset prevents our dictionary augmentation technique from reaching its potential and models trained on specialized biomedical text (PubMedBert with SapBert training objective) obtain better coverage. Such specialized training is, however, not available in a multi-lingual setting.

Dataset	UMLS DFT	Added Concepts	Recall %
MedMentions subset	✗	0	62.7
MedMentions subset	✓	227	**64.4**

Table 6: We took a subset of MedMentions the same size as BC5CDR (8,575 annotations). We report the number of added concepts and the average performance of the HRM with and without UMLS DFT across 5 random seeds. "✗": UMLS DFT not used, "✓": UMLS DFT used.

For future work, we intend to test whether utilizing language-specific BERT models instead of multilingual BERT (*e.g.,* swapping m-BERT with the recently released AlephBERT (Seker et al., 2021), a Hebrew version of BERT) could improve results on the Hebrew Camoni corpus. In addition, taking into account the SapBERT objective which exploits the UMLS graph structure as part of either fine-tuning or pre-training in Hebrew could lead to improved generalization capabilities. Finally, exploring datasets with additional source languages will help understand the capabilities of our multilingual pipeline. The CLEF eHealth challenges (Névéol et al., 2017, 2018) are good candidates for such analysis.

A Span Length Selection (k)

Span length k represents the number of words we select from the input text and may or may not represent a medical concept. This definition is used in the candidate generation step (see Section 4.2), where we create representations of all possible spans in the text and match them to top ranking concepts.

In order to define the max span length parameter k of the model, we performed a simple analysis of the annotated span lengths per dataset. As can be seen in Figures 5, 6 and 7, the most common length values tagged are generally 1 or 2. Taking into account computational limitations of using large span lengths, we chose $k = 3$. Note that even if the maximal span length selected is smaller than the maximal medical term length in the target dataset C_L, it is still possible to match source spans to such medical terms since our scoring function does not exclude matches based on length comparison (see Section 4.3).

B Vectorization and Score Function Methods Comparison

We compared the performance (recall %) using two different score functions: (1) cosine similarity and (2) Manhattan distance, and two different vectorization techniques: (1) term frequency (tf) and (2) tf-idf (term frequency * inverse document frequency). We used character unigram, bigram and trigram analysis in all the reported cases (Table 7).

We hypothesize that the improvement stems from idf penalizing frequent words by taking the log of {number of docs in the corpus divided by the number of docs in which the term appears}, where in our context, a 'doc' is either a span of text or a UMLS concept from C_L. Since no stop words can appear at either the start or end of the span/concept, we increase the odds of having meaningful words comprising each 'doc'. The tf-idf method may contribute to this further because it not only focuses on the frequency of words present in the corpus (tf, bag-of-words) but also provides an importance weight to them.

Vectorizer	**Score Function**	**Recall %**
Tf	Cosine	69.3
Tf	Manhattan	68.4
Tf-Idf	Cosine	**70.7**
Tf-Idf	Manhattan	69.7

Table 7: Performance of the HRM using two different vectorization methods and two different score functions on MedMentions dataset.

Vectorizer	**Score Function**	**Recall %**
Tf	Cosine	81.5
Tf	Manhattan	81.8
Tf-Idf	Cosine	**82.0**
Tf-Idf	Manhattan	81.9

Aligned Weight Regularizers for Pruning Pretrained Neural Networks

James O' Neill and **Sourav Dutta** and **Haytham Assem**
Huawei Research Center, Dublin, Ireland
{james.o.neil,sourav.dutta2,haytham.assem}@huawei.com

Abstract

While various avenues of research have been explored for iterative pruning, little is known what effect pruning has on zero-shot test performance and its potential implications on the choice of pruning criteria. This pruning setup is particularly important for cross-lingual models that implicitly learn alignment between language representations during pretraining, which if distorted via pruning, not only leads to poorer performance on language data used for retraining but also on zero-shot languages that are evaluated. In this work, we show that there is a clear performance discrepancy in magnitude-based pruning when comparing standard supervised learning to the zero-shot setting. From this finding, we propose two weight regularizers that aim to maximize the alignment between units of pruned and unpruned networks to mitigate alignment distortion in pruned cross-lingual models and perform well for both non zero-shot and zero-shot settings. We provide experimental results on cross-lingual tasks for the zero-shot setting using XLM-RoBERTa$_{\text{Base}}$, where we also find that pruning has varying degrees of representational degradation depending on the language corresponding to the zero-shot test set. This is also the first study that focuses on cross-lingual language model compression.

1 Introduction

Deep neural networks (DNNs) have grown increasingly large in the recent years. This has led to models requiring more storage requirements, more resources for training and inference (e.g., GPUs and TPUs), longer compute times and larger carbon footprints. This is largely due to the rise of masked self-supervised learning (SSL) which trains DNNs (e.g., Transformers in NLP) on a large collection of samples that do not have task labels but instead use a subset of the inputs as labels. Given the aforementioned challenges, it has become more difficult for machine learning practitioners to use these SSL pretrained models for fine-tuning on downstream tasks. While training tricks such as effective batch sizes, gradient accumulation and dynamic learning rate schedules (Howard and Ruder, 2018) have improved the efficiency of fine-tuning DNNs under resource constraints, it can still come at a cost, e.g. gradient accumulation leads to less updates.

Pruning (LeCun et al., 1990; Reed, 1993) is a type of model compression method (Buciluă et al., 2006) that aims to address these shortcomings by zeroing out a subset of weights in the DNN, while maintaining performance close to the original model. Retraining is often carried out directly after each pruning step to recover from pruning induced performance drops. This process is referred to as *iterative pruning*. Although, iterative pruning has been extensively studied in the SSL setting (Hassibi and Stork, 1993; Han et al., 2016; Ding et al., 2018) and the transfer learning setting (Molchanov et al., 2016; Gordon et al., 2020; Sanh et al., 2020), little is known about pruning DNNs in the zero-shot setting[1] where a model is required to make predictions on a set of samples from classes that are unobserved during training. One salient example is pretrained cross-lingual language models (XLMs) (Conneau and Lample, 2019; Conneau et al., 2020a) whereby the model is trained with a masked/translation language model (MLM/TLM) objective to predict tokens for a large set of different languages whereby the objective forces the XLM model to learn similar representations for different languages. After cross-lingual pretraining, the model is further fine-tuned to a downstream task in one language (e.g., English) and then evaluated on different languages in the zero-shot setting (e.g., Spanish, French, Chinese, etc.). In this context, applying current pruning methods can damage the

---

[1] Here, zero or one-shot is the conventional usage of the meaning (i.e., number of samples per class), not one-shot pruning (2018) which is the number of pruning steps used during retraining.

Findings of the Association for Computational Linguistics: ACL 2022, pages 3391 - 3401
May 22-27, 2022

XLM cross-lingual alignment that has been learned during pretraining. Ideally, we would aim to prune XLMs in such a way that avoids this alignment distortion which effects the zero-shot performance of pruned XLMs. Additionally, overfitting to the language used for fine-tuning becomes more of an issue due to the progressive reduction in parameters throughout iterative pruning as the remaining weights are relatively large, moving away from an “aligned” XLM state.

This is an important problem to address as the application of large pretrained models in the zero shot-setting for natural language and other modalities (e.g images and audio) is of practical importance e.g., using XLMs in production for multiple languages by only requiring annotations in a single language for fine-tuning, making predictions on unseen classes at test time from pretrained visual representations (Bucher et al., 2017) using only semantic descriptions (i.e., label similarity to known classes) or zero-shot predictions in pretrained multimodal models such as CLIP (Radford et al., 2021).

Hence, this work addresses the *alignment distortion* pruning problem by introducing *AlignReg*, a class of weight regularizers for magnitude-based pruning that force pruned models to have parameters that point in a similar direction or have a similar distribution to the parameters of the original pretrained network. To our knowledge, this is the first study on how iteratively pruned models perform in the zero-shot setting and how the solution differs from solutions found in the non-zero shot setting. We believe our findings have a strong practical implication as well-established pruning criteria may not be suitable given the observed discrepancy between zero-shot performance and the typically reported non-zero shot performance. Moreover, our proposed weight regularizer improves overall pruning generalization in zero-shot cross-lingual transfer. Below, we summarize our **contributions**.

- The first analysis of pruning cross-lingual models, how this effects zero-shot cross-lingual transfer and performance differences to pruning in the SSL setup.
- A weight regularizer that mitigates alignment distortion by minimizing the *layer-wise Frobenius norm or unit similarity* between the pruned model and unpruned model, avoiding overfitting to single language task fine-tuning.
- A post-analysis of weight distributions after pruning and how they differ across module types in Transformers.

2 Related Work

Below we describe regularization-based pruning, other non-magnitude based pruning and how masked language modeling (MLM) implicitly learns to align cross-lingual representations.

Regularization-based pruning. Pruning can be achieved by using a weight regularizer that encourages network sparsity. Three well-established regularizers are L_0 (Louizos et al., 2018), L_1 regularization (Liu et al., 2017; Ye et al., 2018) and the commonly used L_2 regularization for weight sparsity (Han et al., 2015, 2016). Wang et al. have proposed an L_2 regularizer that increases in influence throughout retraining and shows the increasing regularization improves pruning performance. For structured pruning where whole blocks of weights are removed, Group-wise Brain Damage (Lebedev and Lempitsky, 2016) and SSL (Wen et al., 2016) propose to use Group LASSO (Yuan and Lin, 2006) to learn structured solutions.

Importance-based pruning. Magnitude-based pruning (MBP) relies on the assumption that weight or gradient magnitudes have correlation with its importance to the overall output of the network. Mozer and Smolensky instead use a learnable gating mechanism that approximates layer importance, finding that weight magnitudes reflect importance statistics. To measure weight importance as the difference in loss between pruned and unpruned network, LeCun et al. approximate this difference with a Taylor series up to the second order. This involves the product of the gradient and weight magnitude in the 1st term and an approximation of the Hessian and the square of the weight magnitude for the second term. However, computing the Hessian and even its approximations (LeCun et al., 1990; Hassibi and Stork, 1993; Dong et al., 2017; Wang et al., 2019; Singh and Alistarh, 2020) can significantly slow down retraining. In our work, we avoid the requirement of computing the Hessian or approximations thereof, as it is not scalable for models such as XLM-R (Conneau et al., 2020a). Park et al. have extended MBP to block approximations to avoid pruning lowest weight magnitudes that may be connected to weights in adjacent layers that have high weight magnitude. Lee et al. have provided a method to automatically choose the sparsity of layers by using the rescaled version of weight magnitude to incorporates the model-level distortion incurred by pruning.

Implicit Alignment in Pretrained MLMs In context of multi-task learning, Chen et al. (2020) minimize the mean squared error between pretrained weights and weights being learned for a set of different source tasks to avoid catastrophic forgetting in the continual learning setting. Conneau et al. (2020b) have found that multilingual MLM (i.e training with an MLM objective with concatenated text for multiple languages) naturally leads to models with strong cross-lingual transfer capabilities. Additionally, they find that this is also found for monolingual models that do not share vocabulary across monolingual corpora and the only requirement is that weight sharing is used in the top layers of the multi-lingual encoder. In the context of our work, we want to bias our fine-tuned and iteratively pruned model to have similar geometric properties and symmetries to these pretrained MLMs to preserve zero-shot cross-lingual transfer.

3 Methodology

In this section, we describe how our proposed *AlignReg* weight regularizers can improve pruning performance in both supervised learning and zero-shot pruning settings. We focus on two regularizers, namely, *a neuron correlation-based regularizer* (cosine-MBP) and *Frobenius layer-norm regularizer* (frobenius-MBP).

Let $\mathcal{D} := \{X_i, y_i\}_{i=1}^{D}$ where each X_i of D training samples consists of a sequence of vectors $X_i := (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ and $\boldsymbol{x}_i \in \mathbb{R}^d$ (e.g., $d = 512$). For structured prediction (e.g., NER and POS), $y_i \in \mathbb{R}^{n \times c}$ and for single and pairwise sentence classification, $y_i \in \mathbb{R}^c$ where c is the number of classes. Let $\theta = (\theta_1, \ldots, \theta_L)$ be the parameters of a pretrained network f with L layers, where θ_l refers to the parameters, including weight matrix $\mathbf{W}_l$ and bias b_l, at layer l. Let $f_{\tilde{\theta}}$ be a network with parameters $\tilde{\theta}$ consisting of weights $\tilde{\mathbf{W}}_l \in \mathbb{R}^{N_{l-1} \times N_l}$ and bias $\tilde{\boldsymbol{b}}_l \in \mathbb{R}^{N_l}$ where N_l is the number of units in the l-th layer. Here, $\tilde{\mathbf{W}}_l := \mathbf{W}_l \mathbf{M}_l$ where $\mathbf{M}$ is the pruned mask. For MBP (Karnin, 1990) we remove weights of $\mathbf{W}_l$, $\forall l \in L$ with the smallest absolute weight magnitude until a specified percentage p of weights are removed. Note that this is a layer-wise process and requires the pruned weights to be masked with $\mathbf{M}_l$ which has 0 entries corresponding to weights to be pruned and 1 entries for unpruned weights $\mathbf{W}_l$. Global MBP can also be used whereby the weights $\{\mathbf{W}_l\}_{l=1}^{L}$ are first vectorized and concatenated prior to choosing p lowest weight magnitudes. Unlike layer-wise MBP, the percentage of weights removed in each layer can vary for global-MBP. Typically, weight regularization is used with MBP to encourage weight sparsity. Thus the objective for iterative pruning can be expressed as,

$$\mathcal{L}_{\theta} := \frac{1}{D} \sum_{i=1}^{D} \ell_{ce}\big(f_{\tilde{\theta}}(\mathbf{X}_i), \boldsymbol{y}_i\big) + \lambda ||\tilde{\theta}||_0 \quad (1)$$

where λ controls the influence of the weight magnitude regularization. We now describe our proposed *AlignReg*.

3.1 *AlignReg* - Pruning-Aware Regularization

AlignReg can be used to align weights unit-wise or layer-wise between unpruned and pruned networks. We initially discuss the cosine-MBP regularizer.

cosine-MBP aims to preserve the inherent cross-lingual alignment, during iterative pruning, by minimizing the angle between parameter vectors of the same unit in the pruned and unpruned network. The intuition is that cross-lingual alignment relies more on parameter vector direction than vector magnitudes. Moreover, as the network is being pruned, the weights will consequently change weight magnitude to account for the information loss. To apply *AlignReg* to linear layers within Transformers, we compute the pairwise cosine similarity between pairs of pruned weights $\tilde{\mathbf{W}}_l \subset \tilde{f}$ and unpruned weights $\mathbf{W} \subset f$ for all l-th layers. For $\mathbf{W}_l \in \mathbb{R}^{N_{l-1} \times N_l}$ of the l-th layer, the average weight correlation is

$$\rho(\tilde{\mathbf{W}}_l, \mathbf{W}_l) = \frac{1}{N_l} \sum_{i=1}^{N_l} \frac{|\mathbf{W}_{li}^{\top} \tilde{\mathbf{W}}_{li}|}{||\mathbf{W}_{li}||_2 ||\tilde{\mathbf{W}}_{li}||_2} \quad (2)$$

where $\mathbf{W}_{li}$ is i-th column of the matrix corresponding to the i-th unit of the l-th layer. Intuitively, $\rho(\mathbf{W}_l, \tilde{\mathbf{W}}_l)$ is the average cosine similarity between weight vectors of the same unit at the l-th layer of the pruned and unpruned network. Adding *AlignReg* to the objective results in Equation (3),

$$\mathcal{L}_{\theta} := \ell_{ce}\big(f_{\tilde{\theta}}(\mathbf{X}), \boldsymbol{y}\big) - \frac{\lambda}{L} \sum_{l}^{L} \rho\big(\tilde{\mathbf{W}}_l, \mathbf{W}_l\big) \quad (3)$$

where $\lambda \in [0, \infty)$ controls the importance of AlignReg relative to the main cross-entropy loss $\ell_{ce}(\cdot, \cdot)$. The gradient of the loss w.r.t to θ is then

Algorithm 1: AlignReg Pruning

```
Input: Weight tensors $\mathbf{W}_1, \ldots, \mathbf{W}_L$ of a fine-tuned network, $p$ percentage of weights to remove per layer
Output: Pruned weight tensors $\tilde{\mathbf{W}}_1, \ldots \tilde{\mathbf{W}}_L$
for $l = 1, \ldots, L$ do
    Compute $\rho(\tilde{\mathbf{W}}_l, \mathbf{W}_l)$ with Eq.2.
    Set $\tilde{\mathbf{W}}_{s_i}$ as $s_l$-th smallest element of $\tilde{\mathbf{W}}$
    Set $\mathbf{M}_l \leftarrow \mathbb{1}\{\mathbf{W}_l - \tilde{w}_{s_l} \geq 0\}$
    Set $\tilde{\mathbf{W}}_l \leftarrow \mathbf{M}_l \odot \mathbf{W}_l$
end for
Compute $\mathcal{L}_\theta$ according to Eq.3
```

expressed as equation (4),

$$\nabla_\theta \mathcal{L}_\theta := \nabla_{\tilde{\theta}} \ell_{ce}(f_{\tilde{\theta}}(\mathbf{X}), \boldsymbol{y}) - \frac{\lambda}{L} \sum_{l}^{L} \frac{\partial \rho(\tilde{\mathbf{W}}_l, \mathbf{W}_l)}{\partial \tilde{\mathbf{W}}_l} \quad (4)$$

where $\frac{\partial \rho(\tilde{\mathbf{W}}_l, \mathbf{W}_l)}{\partial \tilde{\mathbf{W}}_l}$ is a function of the ‘2-norm of the matrices in $\mathbf{W}_l$. For the element $\mathbf{W}_{l,(i,j)}$ of i-th row and j-th column in $\mathbf{W}_l$, we have

$$\frac{\partial \rho(\tilde{\mathbf{W}}_l, \mathbf{W}_l)}{\partial \tilde{\mathbf{W}}_{l,(i,j)}} = \frac{1}{N_l - 1} \sum_{j=1}^{N_l} \Big(\text{sign}(\mathbf{W}_{l,(,j)}^\top \tilde{\mathbf{W}}_{l,(,j)}) \Big[\frac{\tilde{\mathbf{W}}_{l,(i,j)}}{||\mathbf{W}_{l,(,j)}||_2 ||\tilde{\mathbf{W}}_{l,(,j)}||_2} - \frac{\mathbf{W}_{l,(i,j)} \mathbf{W}_{l,(,j)}^\top \tilde{\mathbf{W}}_{l,(,j)}}{||\mathbf{W}_{l,(,j)}||_2^3 ||\tilde{\mathbf{W}}_{l,(,j)}||_2} \Big] \Big) \quad (5)$$

where $\mathbf{W}_{l,(,j)}$ and $\tilde{\mathbf{W}}_{l,(,j)}$ are j-th column in $\mathbf{W}_l$ and $\tilde{\mathbf{W}}_l$, respectively. Thus, this regularization favors solutions with high cosine similarity between units of pruned and unpruned networks. We also consider a layer-wise $\rho(\mathbf{W}, \tilde{\mathbf{W}})$ that relaxes the unit-level alignment to whole layers. This is partially motivated due to the fact neural networks can exhibit similar output activation behavior even when neuron weights have been permuted within the layer (Brea et al., 2019). To perform this we simply apply Equation (2) with vectorized weights $\rho(\text{vec}(\tilde{\mathbf{W}}_l), \text{vec}(\mathbf{W}_l))$ and the subsequent partial derivatives in Equations (4) and (5) are applied for updating $\tilde{\mathbf{W}}_l$. In our experiments we did not see a significant difference using vectorized weights and thus use unit-wise cosine similarity.

Algorithm 1 shows how AlignReg is applied for a single mini-batch update during an iterative pruning epoch.

Relaxing Unit-Wise AlignReg To A Layer-Wise Frobenius Distortion Formulation Thus far we have described the application of cosine similarity as a measure of similarity between unpruned and pruned weights of the same units. However, this may be a strict constraint, particularly at high compression rates where the remaining weights for a unit are forced to have higher norms to allow zeroed weights. Hence, an alternative measure is the layer-wise Frobenius norm (Frobenius-MBP) regularizer based on the difference between weights $||\mathbf{W} - \tilde{\mathbf{W}}||_F$. MBP itself can be viewed in terms of minimizing the Frobenius distortion (Han et al., 2016; Dong et al., 2017) as $\min_{\mathbf{M}:||\mathbf{M}||_0 = p} ||\mathbf{W} - \mathbf{M} \odot \mathbf{W}||_F$ where $\odot$ is the Hadamard product, $||\cdot||_0$ denotes the entrywise 0-norm, and p is a constraint of the number of weights to remove as a percentage of the total number of weights for that layer. In the zero-shot setting, we need to account for out-of-distribution Frobenius distortions, such as *alignment distortion* in XLM due to pruning and overfitting to a single language. Taking the view of Frobenius distortion minimization when using our weight regularizer, we reformulate it to include Frobenius-MBP as,

$$\min_{\mathbf{M}:||\mathbf{M}||_0 = p} \Big[||\mathbf{W}\text{-}\mathbf{M} \odot \mathbf{W}||_F^2 + \lambda ||\mathbf{W}^T\text{-}\mathbf{M} \odot \mathbf{W}||_F^2 \Big] \quad (6)$$

where $\mathbf{W}^T$ are the weights from the pretrained model prior to fine-tuning that is cross-lingually aligned from the masked language modeling (MLM) pretraining objective. In our experiments, $\lambda = 5 \times 10^{-4}$.

***frobenius*-MBP Implicitly Aligns Eigenvectors** To explicitly show that the Frobenius distortion minimization aligns fine-pruned and pretrained parameter vectors we expect their eigenvectors to also be close. We can use the Eckart-Young-Mirsky Theorem (Golub et al., 1987) to express Frobenius distortion minimization as Equation 7,

$$||\mathbf{W}^T - \mathbf{M} \odot \mathbf{W}||_F^2 = ||\mathbf{\Sigma} - \mathbf{U}^\top \mathbf{M} \odot \mathbf{W}\mathbf{V}||_F^2 \quad (7)$$

where the unitary invariance under the 2-norm that $\mathbf{U}$,$\mathbf{V}$ vanishes and singular value matrix is left to approximate $\mathbf{W}^T$, hence the inclusion of $\mathbf{\Sigma}$. We express $\mathbf{X} = \mathbf{U}_k \Sigma_k^{12}$, $\mathbf{Y} = \Sigma_k^{12} \mathbf{V}_k^\top$ and $\mathbf{XY} = \mathbf{A}_k$. Hence, we can further describe the minimization as $||\Sigma - \mathbf{U}^\top \mathbf{W}_k^T \mathbf{V}||_F^2$ and since $\mathbf{X}$, $\mathbf{Y}$ are unitary, $||\Sigma - \Sigma_k||_F^2$.

3.2 Connections to Knowledge Distillation

Knowledge distillation (KD) works by using outputs of the last layer (Hinton et al., 2015) or intermediate layers (Romero et al., 2015) as additional soft targets. *AlignReg* regularizers instead

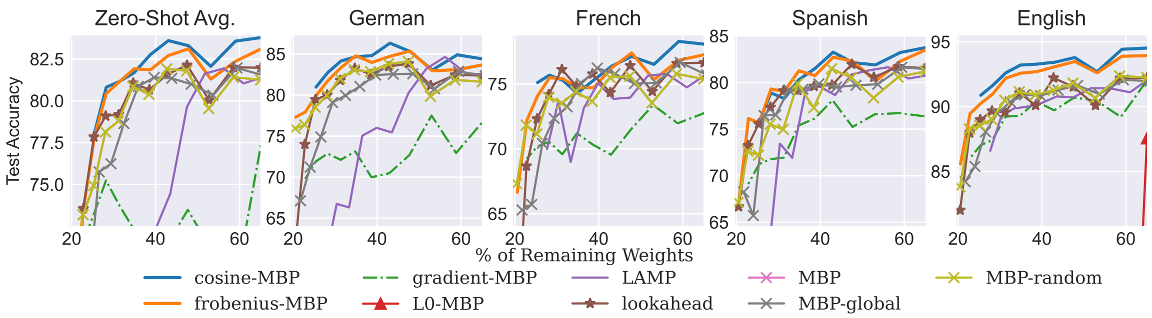

Figure 1: **English and Zero-Shot Test Accuracy on News Classification.**

operate directly on minimizing a divergence or distance between weight tensors as opposed to their corresponding output activations. Hence, *AlignReg* does not necessarily need training data as it operates directly on aligning weight tensors. Since the networks that are used for alignment are architecturally identical, we can show that maximizing weight similarity is equivalent to minimizing distance between their corresponding output activations (Romero et al., 2015) when the norm of input Z is smaller than the output range of σ. For our experiments, we use XLM-RoBERTa$_{\text{Base}}$ which contain Gaussian Linear Error Unit (GeLU) activation functions, which can be formulated as $\sigma(\mathbf{Z}_{li}) := \mathbf{Z}_{li}/2(1.0 + \text{erf}(\mathbf{Z}_{li}/\sqrt{2.0}))$ where erf is an error function, $\sigma(\cdot)$ is a monotonic activation function and $\boldsymbol{Z}_{li}$ is the input vector. The GELU activation has the properties that for $\mathbf{Z}_{li} > 0$ it is equivalent to the ReLU activation and $\mathbf{Z}_{li} \leq 0$ it tends to -1. For $\mathbf{Z}_{li} > 0$, $||\mathbf{Z}_{li}||_2 \leq 1$ and a monotonic piecewise linear function $\sigma(\cdot)$, the inequality in Equation 8 holds.

$$\begin{aligned} &||\mathbf{W}_{li}\text{-}\mathbf{M}_{li} \odot \mathbf{W}_{li}||_F \leq \\ &||\sigma(\mathbf{Z}_l\mathbf{W}_{li}) - \sigma(\mathbf{Z}_{li}\mathbf{M}_{li} \odot \mathbf{W}_{li})||_F \end{aligned} \tag{8}$$

Layer normalization leads to features having zero mean and unit variance and hence $||\mathbf{Z}_{li}||_2 \leq 1$. Hence, minimizing the Frobenius distortion of pruned and unpruned weights is equivalent to minimizing the mean squared error (MSE) between output activations, as is the knowledge distillation method used for FitNets (Romero et al., 2015). In contrast, KD using FitNets encourages the student network to have activation outputs that are the same as the teacher with permutation invariance on the units incoming weights, not restricting the weights to be similar. Unlike KD, this minimization can be performance without any data.

4 Experimental Setup

Datasets. We perform experiments on multilingual tasks from the XGLUE benchmark (Liang et al., 2020) with pretrained XLM-R$_{\text{Base}}$. This covers pairwise classification (QAM, QADSM, WPR, XNLI), sentence classification (NC) and structured prediction (NER and POS) tasks.

Iterative Pruning Details. Texts are tokenized using the SentencePiece BPE tokenizer (Sennrich et al., 2016) with a vocabulary of 250K tokens. For structured prediction tasks (POS and NER), a single layer feed-forward (SLFF) token-level classifier is used on top of XLM-R$_{\text{Base}}$ and for sentence-level task a SLFF sentence-level classifier is used. The batch size is 32, the learning rate is $5 \cdot 10^{-6}$ and the maximum sequence length is set to 256 for all tasks, except for POS in which we use a learning rate of $2 \cdot 10^{-5}$ with the `adam` optimizer (Kingma and Ba, 2015) with weight decay (AdamW) and a max sequence length of 128. We carry out a pruning step after each 15 training epochs, uniformly pruning 10% of the parameters at each pruning step. We omit the pruning of embedding layers, layer normalization parameters and the classification layer as they account for a relatively small number of the total parameter count ($< 1\%$) and play an important role in XLM generalization. Although prior work has suggested non-uniform pruning schedules (e.g., cubic schedule (Zhu and Gupta, 2017)), we did not see major differences to uniform pruning in preliminary experiments. Each task is trained with English data only and evaluated on all available languages for that task. Hence, we expect the percentage of achievable compression to be lower as performance in the zero-shot cross-lingual setting to be more difficult than the monolingual setting (e.g., GLUE tasks).

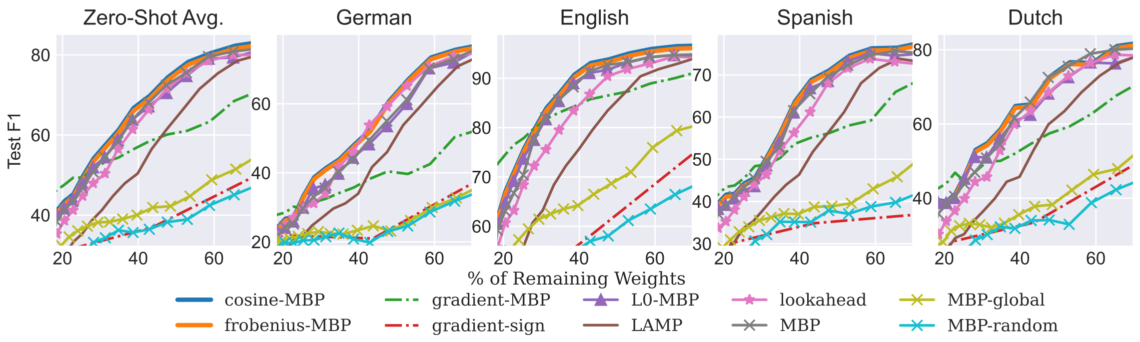

Figure 2: **Zero-Shot Test F1 on Named Entity Recognition.**

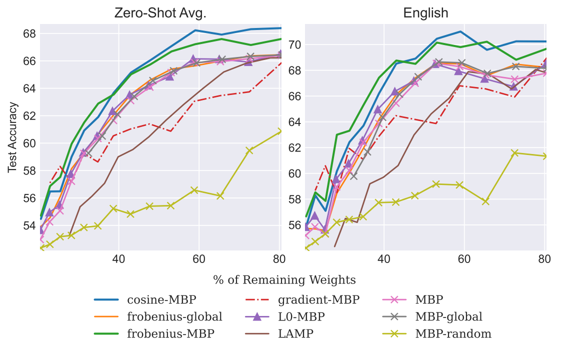

Figure 3: **Question Answer Matching Test Accuracy.**

Pruning Baselines. Below lists our pruning baselines. **Random Pruning** (1997) - weights are pruned uniformly at random across all layers to a chosen fraction.**Layer-wise Magnitude Pruning** (MBP) (Janowsky, 1989; Mozer and Smolensky, 1989) - for each layer, weights with the lowest absolute value (LAV) are pruned. **Layer-wise Gradient Magnitude Pruning** (Sun et al., 2017) - for each layer, prunes the weights with LAV of the accumulated gradients evaluated on a batch of inputs. **Global Magnitude Pruning** (Global-MBP) (Karnin, 1990) - prunes weights with LAV anywhere in the DNN. L_0 **norm MBP** (Louizos et al., 2018) - uses non-negative stochastic gates that choose which weights are set to zero as a smooth approximation to the non-differentiable L_0-norm. **Lookahead pruning (LAP)** (Park et al., 2019) - prunes paths that have smallest weight magnitude across blocks of layers, unlike MBP which treats layers independently. **Layer-Adaptive Magnitude Pruning (LAMP)** (Lee et al., 2020) adaptively sets the pruning ratio of each layer.

5 Empirical Results

We now discuss results on the XGLUE tasks.

News Classification (NC) Figure 1 shows the results on news classification where a category for news article is predicted and evaluated in 5 languages and trained and iteratively pruned on English text. Firstly, we observe the trend in iterative pruning performance degradation is somewhat volatile. From preliminary experiments we found news classification to require only 3 epochs to converge for standard fine-tuning on XLM-RoBERTa$_{\text{Base}}$. We find that this task is relatively "similar" to the pretraining task and therefore able to easier recover from pruning steps. Overall, both Cosine-MBP and Frobenius-MBP consistently lead to the best zero-shot test performance across both pruning steps and languages.

Question Answer Matching (QAM) Figure 3 shows the test accuracy on English and the zero-shot test accuracy on French and German for Question-Answer Matching (QAM). This involves predicting whether a question is answered correctly or not given a question-answer pair. We find that Frobenius-MBP and Cosine-MBP maintain higher accuracy across multiple pruning steps, outperforming baselines. More generally, we see there is close to 2% drop in average test accuracy drop in French and German when compared to testing on samples from the same language used in training.

Named Entity Recognition (NER) The Named Entity Recognition (NER) cross-lingual dataset is made up of CoNLL-2002 NER and CoNLL-2003 NER (Sang and De Meulder, 2003), covering English, Dutch, German and Spanish with 4 named entities. From Figure 2 we find that cross-lingual transfer of pruned models is most difficult in German and Dutch, which both come from the same language family, sharing commonalities such as word order and having similar vocabularies. The primary reason for the difficulty in maintaining per-

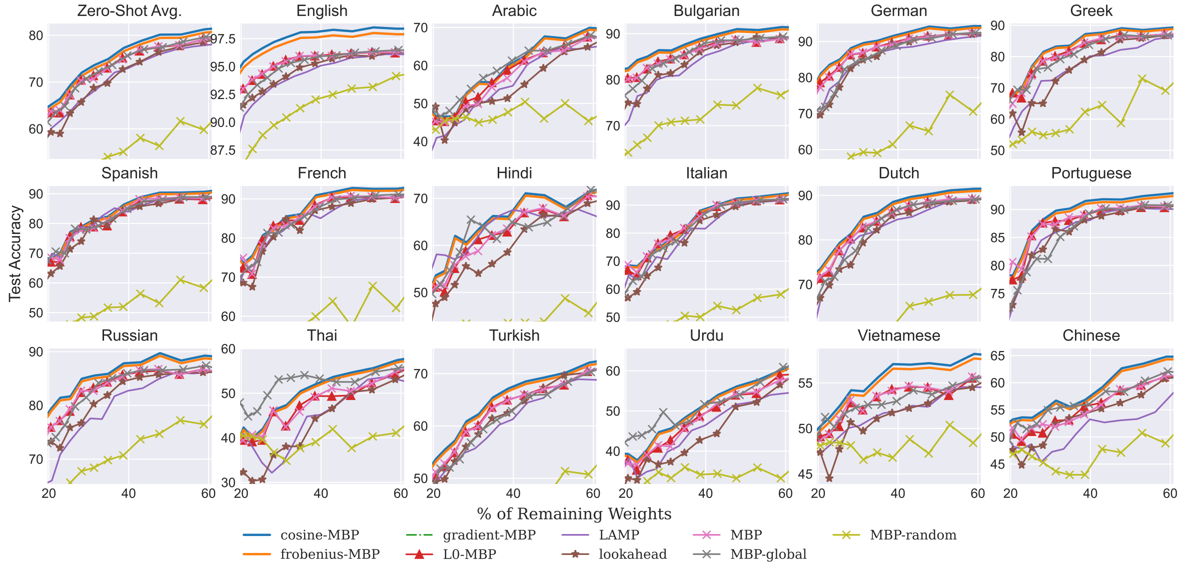

Figure 4: **Part of Speech Tagging Test Accuracy.**

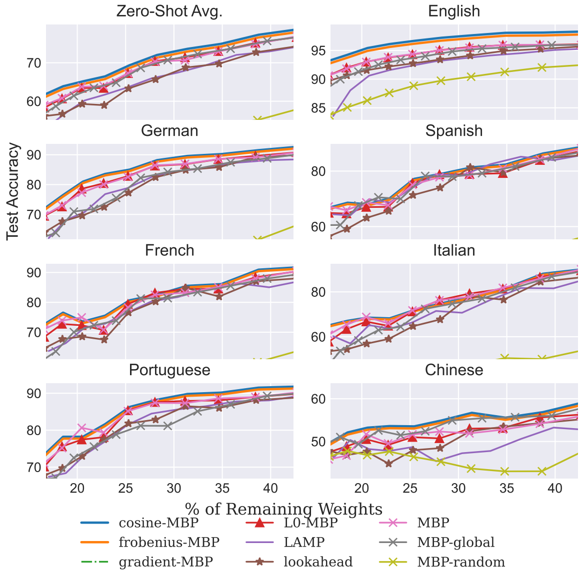

Figure 5: **Web-Page Ranking Test Matthew's Correlation Coefficient.**

formance in high compression rates for this NER dataset is that there is only 15k training samples, being significantly lower than the remaining XGLUE tasks (the majority contains 100k training samples). Thus, not only is there less training data to recover directly after each pruning step, but the pruning step interval itself is shorter. In contrast, English test performance is close to the original performance up until 25% of remaining weights, unlike the remaining languages. We find that gradient-MBP eventually overtakes MBP approaches past 20% remaining weights. However accuracy has reduced too much at this compression level. We find that Cosine-MBP and Frobenius-MBP weight regularizers achieve the best performing pruned model performance above 20% remaining weights, with Lookahead pruning and L_0 regularized MBP being competitive in zero-shot performance.

Part of Speech Tagging (POS) The Part of Speech (PoS) tagging dataset consists of a subset of the Universal Dependencies treebank (Nivre et al., 2020) and covers 18 languages. In Figure 4, we see both Cosine-MBP and Frobenius-MBP tend to outperform baselines, although L_0-based pruning (Louizos et al., 2018) has similar performance to Cosine-MBP for zero-shot accuracy. There is also a clear discrepancy between SSL accuracy (English) versus zero-shot accuracy (Average), the latter following closer to linear decay after 40-50% of weights remaining. Generally, both Cosine-MBP and Frobenius-MBP outperform baselines with the exception of Thai and Urdu at higher compression rates ($< 40\%$), both being some of the most under-resourced languages of all 18 languages.

Web Page Ranking aims to predict whether a web page is relevant (1-5 ratings, "bad" to "perfect") to an input query and it is evaluated for 7 languages using the Normalized Discounted Cumulative Gain (nDCG). From Figure 5, we see that between the 15% - 45% region the average zero-shot performance degrades faster than the English language used for training. In contrast, semantically and syntactically different languages from English, such as Chinese, already suffer from loss of alignment due to pruning as the performance gap between proposed methods (and baselines) and random pruning is shortened.

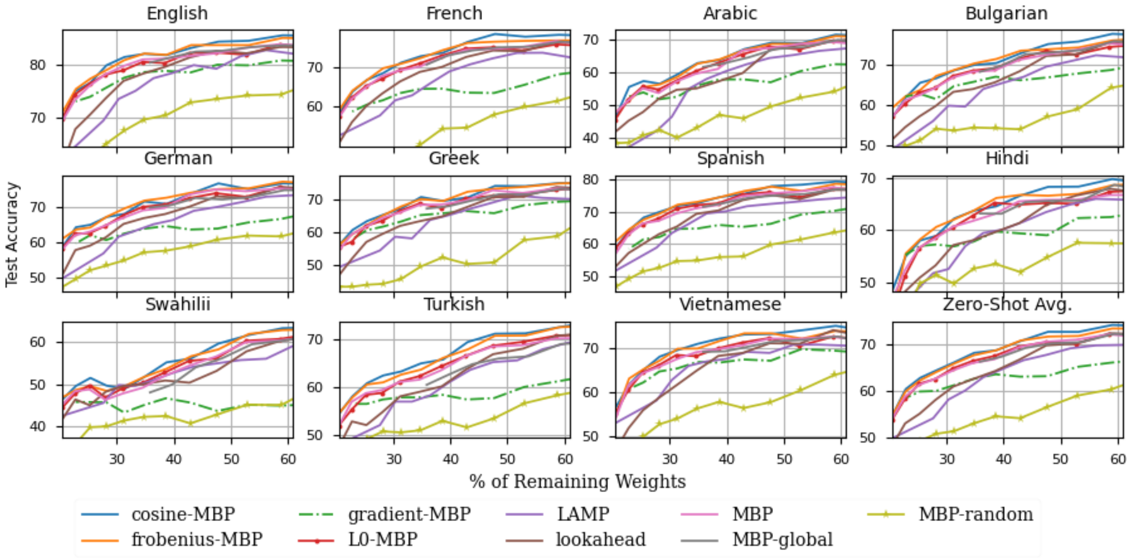

Figure 6: **Zero-Shot XNLI Results Per Language After Iteratively Fine-Pruning XLM-RoBERTa$_{\text{Base}}$**

Cross-Lingual Natural Language Inference (XNLI) Figure 6 shows the zero-shot cross-lingual transfer for various unstructured pruning methods. We find that both the accuracy on the English test (i.e SSL generalization) and the average zero-shot test accuracy are consistently improved using Cosine-MBP and Frobenius-MBP, outperforming L_0 pruning, Lookahead pruning and LAMP. We find that morphologically rich languages such as Arabic, Swahili and Turkish degrade in performance linearly once performance begins to drop after 60% of the remaining weights are pruned. This trend is roughly followed for all MBP-based pruning methods. Additionally, test accuracy on English can be maintained within 10% accuracy drop of the original test accuracy up to 20% of remaining weights for MBP, while Swahili can only be within a 10% accuracy drop up to 55% of the remaining weights. Hence, iterative pruning in the zero-shot setting leads to faster performance degradation for languages that are typologically or etymologically further from the language used for fine-tuning.

When comparing, English and the average zero-shot test accuracy we see that the slope is steeper after the inflection point[2] for all pruning methods, not to mention the greater than 10% accuracy drop across pruning steps.

XGLUE Average Result Finally, in Table 1 we show the overall and average task *understanding* scores on the XGLUE benchmark for our proposed *AlignReg* weight regularizer and the pruning baselines. We find that the use of *AlignReg* Cosine-MBP and Frobenius-MBP better preserves cross-lingual alignment during model pruning, thereby outperform other MBP baselines, including LAMP and Lookahead pruning, based on improved zero-shot cross-lingual performance.

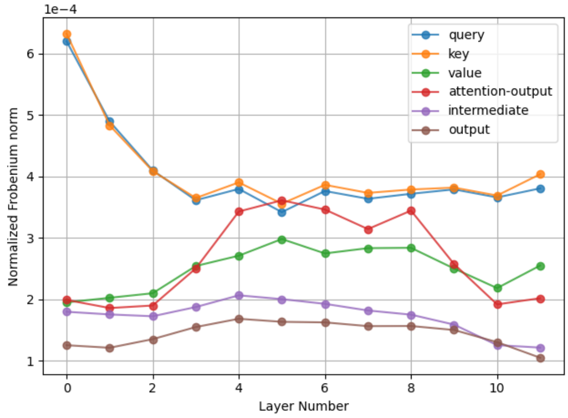

Figure 7: **Pruned Model Weight Norms Per Layer**

Discussion From our experiments, we found that layer-wise pruning tends to outperform global pruning. This can be explained by the clear discrepancy between weight norms of different layer types within each self-attention block. Global pruning chooses the majority of weights to prune from the layer type that has the smallest norm, leading to an information bottleneck, or layer collapse (Lee et al., 2018) for very high compression rates. This effect

---

[2] The point which the performance slope significantly steepens and drops are relatively large to previous pruning steps.

Table 1: **Overall XGLUE Score for Iterative Pruning of XLM-R$_{\text{Base}}$ @ 31% Remaining Weights.**

is due to layer normalization being applied after query, key and value (QKV) parameters, rescaling features such that weight magnitudes remain low. Hence, this motivates why we have focused on the application of *AlignReg* to layer-wise MBP. This is reflected in Figure 7 which shows the weight norm by layer type for each layer for MBP. We see that QKV weight values are distinctly higher than the remaining fully-connected layers (attention output layer, intermediate position-wise feedforward layer and the blocks output layer), with the exception that the output attention layer norm becomes higher between layer 3-8.

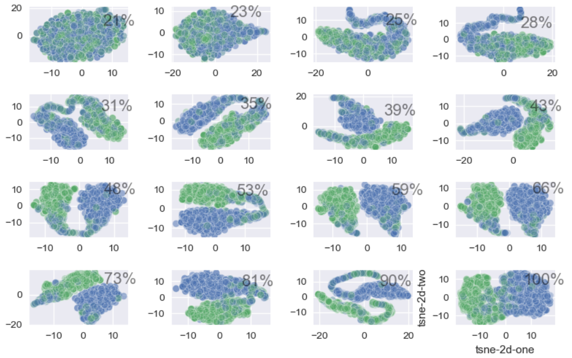

Figure 8: **Class Separability Between Class Representations At Each Iterative Pruning Step on PAWSX.**

For the majority of tasks, the rate of performance drop for zero-shot test performance occurs close to 30% of remaining weights. This is consistent for all pruning methods and therefore the focus of our analysis has been around this operating region.

We also note that the effect of MBP (including our AlignReg regularization-based MBP) on zero-shot performance for different languages heavily depends on the semantic distance of evaluated language to the single language used for training. For example, in Figure 6 Arabic, Bulgarian, Swahili and Hindi have the largest drops in test accuracy around 20-60% remaining weights. Similarly Arabic, Thai and Hindi suffer most around 20% - 60% for PoS tagging in Figure 4. However, we also acknowledge this is partly reliant on the proportion of training data per language used during pretraining the underlying language model, in our case XLM-R$_{\text{Base}}$.

Lastly, to show the representational degradation of pruned networks, in Figure 8 we visualize the class separability via a t-SNE plot of two principal components of the last hidden representation corresponding to the [CLS] token of an iteratively pruned XLM-R$_{\text{Base}}$ for PAWSX. Even from only two principal components of a single token input, we clearly see a change in class separability from 31% to 28% remaining weights, reflecting the lack of linear separation.

6 Conclusion

In this paper, we analysed iterative pruning in the zero-shot setting where a pretrained masked language model uses self-supervised learning on text from various languages but can only use a single language for downstream task fine-tuning. We find that some languages degrade in iterative pruning performance faster than others for some tasks (NER and XNLI) and propose a weight regularizer that biases the iteratively pruned model towards learning weight distributions close to the cross-lingually aligned pretrained state. This improves over well-established weight regularization methods for magnitude-based pruning in both the standard supervised learning setting and the zero-shot setting.

Abstract

Continual relation extraction (CRE) aims to continuously train a model on data with new relations while avoiding forgetting old ones. Some previous work has proved that storing a few typical samples of old relations and replaying them when learning new relations can effectively avoid forgetting. However, these memory-based methods tend to overfit the memory samples and perform poorly on imbalanced datasets. To solve these challenges, a consistent representation learning method is proposed, which maintains the stability of the relation embedding by adopting contrastive learning and knowledge distillation when replaying memory. Specifically, supervised contrastive learning based on a memory bank is first used to train each new task so that the model can effectively learn the relation representation. Then, contrastive replay is conducted of the samples in memory and makes the model retain the knowledge of historical relations through memory knowledge distillation to prevent the catastrophic forgetting of the old task. The proposed method can better learn consistent representations to alleviate forgetting effectively. Extensive experiments on FewRel and TACRED datasets show that our method significantly outperforms state-of-the-art baselines and yield strong robustness on the imbalanced dataset. The code is publicly available at `https://github.com/thuiar/CRL`.

1 Introduction

Relation extraction (RE) is an essential issue in information extraction (IE), which can apply to many downstream NLP tasks, such as information retrieval (Xiong et al., 2017) and question and answer (Tao et al., 2018). For example, given a sentence x with the annotated entities pairs e_1 and e_2, the RE aims to identify the relations between e_1 and e_2. However, traditional relation extraction models (Zhou et al., 2016; Soares et al., 2019a) always assume a fixed set of predefined relations and train on a fixed dataset, which cannot handle the growing relation types in real life well.

To solve this situation, continual relation extraction (CRE) is introduced (Wang et al., 2019; Han et al., 2020; Wu et al., 2021; Cui et al., 2021). Compared with traditional relation extraction, CRE aims to help the model learn new relations while maintaining accurate classification of old ones. Wang et al. (2019) shows that continual relation learning needs to alleviate the catastrophic forgetting of old tasks when the model learns new tasks. Because neural networks need to retrain a fixed set of parameters with each training, the most efficient solution to the problem of catastrophic forgetting is to store all the historical data and retrain the model with all the data each time a new relational instance appears. This method can achieve the best effect in continual relation learning, but it is not adopted in real life due to the time and computing power costs.

Some recent works have proposed a variety of methods to alleviate the catastrophic forgetting problem in continual learning, including regularization methods (Kirkpatrick et al., 2017; Zenke et al., 2017; Liu et al., 2018), dynamic architecture methods (Chen et al., 2015; Fernando et al., 2017), and memory-based methods (Lopez-Paz and Ranzato, 2017; Chaudhry et al., 2018). Although these methods have been verified in simple image classification tasks, previous works have proved that memory-based methods are the most effective in natural language processing applications (Wang et al., 2019; de Masson D'Autume et al., 2019). In recent years, the memory-based continual relation extraction model has made significant progress in alleviating the problem of catastrophic forgetting (Han et al., 2020; Wu et al., 2021; Cui et al., 2021). Wang et al. (2019) proposes a mechanism for embedding sentence alignment in memory mainte-

nance to ensure the stability of the embedding space. Han et al. (2020) introduces a multi-round joint training process for memory consolidation. But these two methods only explore the problem of catastrophic forgetting in the overall performance of the task sequence. Wu et al. (2021) proposes to integrate curriculum learning. Although it is possible to analyze the characteristics of each subtask and the performance of the corresponding model, it still fails to make full use of the saved sample information. Cui et al. (2021) introduce an attention network to refine the prototype to better recover the interruption of the embedded space. However, this method will produce a bias in the classification of the old task as the new task continues to learn the classifier, which will affect the performance of the old task. Although the above method can alleviate catastrophic forgetting to a certain extent, it does not consider the consistency of relation embedding space.

Because the performance of the model of CRE is sensitive to the quality of sample embedding, it needs to ensure that the learning of new tasks will not damage the embedding of old tasks. Inspired by supervised contrastive Learning (Khosla et al., 2020) to explicitly constrain data embeddings, a consistent representation learning method is proposed for continual relation extraction, which constrains the embedding of old tasks not to occur significantly change through supervised contrastive learning and knowledge distillation. Specifically, the example encoder first trains on the current task data through supervised contrastive learning based on memory bank, and then uses k-means to select representative samples to storage as memory after the training is completed. To relieve catastrophic forgetting, contrastive replay is used to train memorized samples. At the same time, to ensure that the embedding of historical relations does not undergo significant changes, knowledge distillation is used to make the embedding distribution of the new and old tasks consistent. In the testing phase, the nearest class mean (NCM) classifier is used to classify the test sample, which will not be affected by the deviation of the classifier.

In summary, our contributions in this paper are summarized as follows: First, a novel CRE method is proposed, which uses supervised contrastive learning and knowledge distillation to learn consistent relation representations for continual learning. Second, consistent representation learning can ensure the stability of the relational embedding space to alleviate catastrophic forgetting and make full use of stored samples. Finally, extensive experiments results on FewRel and TACRED datasets show that the proposed method is better than the latest baseline and effectively mitigates catastrophic forgetting.

2 Related Work

2.1 Continual Learning

Existing continual learning models mainly focus on three areas: (1) Regularization-based methods (Kirkpatrick et al., 2017; Zenke et al., 2017) impose constraints on updating neural weights important to previous tasks for relieving catastrophic forgetting. (2) Dynamic architecture methods (Chen et al., 2015; Fernando et al., 2017) extends the model architecture dynamically to learn new tasks and prevent forgetting old tasks effectively. However, these methods are unsuitable for NLP applications because the model size increases dramatically with increasing tasks. (3) Memory-based methods (Lopez-Paz and Ranzato, 2017; Aljundi et al., 2018; Chaudhry et al., 2018; Mai et al., 2021) saves some samples from old tasks and continuously learns them in new tasks to alleviate catastrophic forgetting. Dong et al. (2021) proposes a simple relational distillation incremental learning framework to balance retaining old knowledge and adapting to new knowledge. Yan et al. (2021) proposes a new two-stage learning method that uses dynamic expandable representation for more effective incremental conceptual modelling. Among these methods, memory-based methods are the most effective in NLP tasks (Wang et al., 2019; Sun et al., 2019; de Masson D'Autume et al., 2019). Inspired by the success of memory-based methods in the field of NLP, we use the framework of memory replay to learn new relations that are constantly emerging.

2.2 Contrastive Learning

Contrastive learning (CL) aims to make the representations of similar samples map closer to each other in the embedded space, while that of dissimilar samples should be farther away (Jaiswal et al., 2021). In recent years, the rise of CL has made great progress in self-supervised representation learning. (Wu et al., 2018; He et al., 2020; Li et al., 2020; Chen and He, 2021). The common point of these works is that no labels are available, so positive and negative pairs were formed through data augmentations. Recently, supervised contrastive learning (Khosla et al., 2020) has received much attention, which uses label information to extend contrastive learning. Hendrycks and Dietterich (2019) compares the supervised contrastive loss with the cross-entropy loss on the ImageNet-C dataset, and verifies that the supervised contrastive loss is not sensitive to the hyperparameter settings of the optimizer or data enhancement. Chen et al. (2020) proposed a contrastive learning framework for visual representations that does not require a special architecture or memory bank. Khosla et al. (2020) extend the self-supervised batch contrastive approach to the fully-supervised setting, which use supervised contrastive loss learning better represetation. Liu and Abbeel (2020) proposed a hybrid discriminant-generative training method based on an energy model. In this paper, contrastive learning is applied to continual relation extraction to extract better relation representation.

3 Methodology

3.1 Problem Formulation

In continual relation extraction, given a series of K tasks $\{T_1, T_2, ..., T_K\}$, where the k-th task has its own training set D_k and relation set R_k. Each task T_k is a traditional supervised classification task, including a series of examples and their corresponding labels $\{(x_i, y_i)\}_{i=1}^{N}$, where x_i is the input data, including the natural language text and entity pair, and $y_i \in R_k$ is the relation label. The goal of continual relation learning is to train the model, which keeps learning new tasks while avoiding catastrophic forgetting of previous learning tasks. In other words, after learning the k-th task, the model can identify the relation of a given entity pair into $\hat{R}_k$, where $\hat{R}_k = \cup_{i=1}^{k} R_i$ is the relation set already observed till the k-th task.

In order to mitigate catastrophic forgetting in continual relational extraction, episodic memory modules have been used in previous work (Wang et al., 2019; Han et al., 2020; Cui et al., 2021), to store small samples in historical tasks. Inspired by (Cui et al., 2021), we store several representative samples for each relation. Therefore, the episodic memory module for the observed relations in $T_1 \sim T_k$ is $\hat{M}_k = \cup_{r \in \hat{R}_k} M_r$, where $M_r = \{(x_i, y_i)\}_{i=1}^{O}$, r represents a certain relation, and O is sample number (memory size).

25:     $M_k \leftarrow M_{k-1} \cup \hat{M}$
26: end if
27: return $\mathbf{E}$, $M_k$, $\hat{R}_k$;
```

3.2 Framework

The consistent representation learning (CRL) in the current task is described in Algorithm 1, which consists of three main steps: (1) **Init training for new task** (line $4 \sim 11$): The parameters of the encoder and projector head are trained on the training sample in D_k with supervised contrastive learning. (2) **Sample selection** (line $12 \sim 13$): For each relation $r \in R_k$, we retrieve all samples labeled r from D_k. Then, the k-means algorithm is used

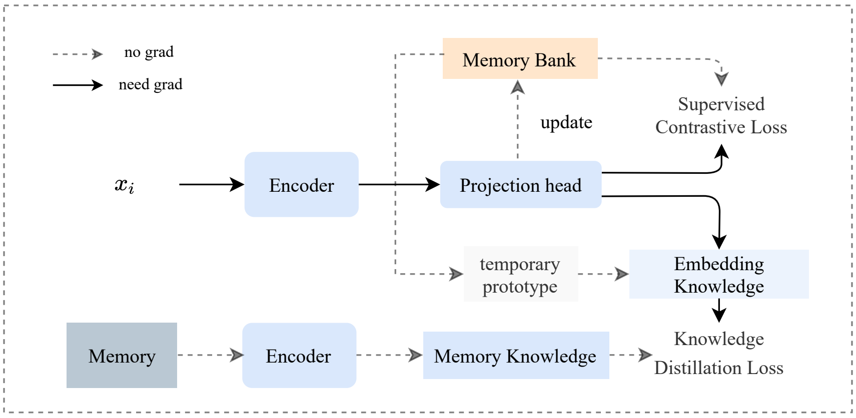

Figure 1: Framwork of consistent representation learning.

to cluster the samples. The relation representation of the sample closest to the center is selected and stored in memory for each cluster. (3) **Consistent representation learning** ($16 \sim 23$): In order to keep the embedding of historical relations in space consistent after learning new tasks, we perform contrastive replay and knowledge distillation constraints on the samples in memory.

3.3 Encoder

The key of CRE is to obtain a better relation representation. The pre-trained language model BERT (Devlin et al., 2019) shows a powerful ability in extracting contextual representation of text. Therefore, BERT is used to encode entity pairs and context information to get the relational representation.

Given a sentence $x = [w_1, \ldots, w_{|x|}]$ and a pair of entities (E1, E2), we follow Soares et al. (2019b) augment x with four reserved word pieces to mark the begin and end of each entity mentioned in the sentence. The new token sequence is fed into BERT instead of x. To get the final relation representation between the two entities, the output corresponding to the positions of E1 and E2 are concatenated, and then map it to a high-dimensional hidden representation $\mathbf{h} \in \mathbb{R}^{d_h}$, as follows:

$$\mathbf{h} = \mathbf{W}[\mathbf{h}_{[\text{E1}]}; \mathbf{h}_{[\text{E2}]}] + \mathbf{b}, \tag{1}$$

where $\mathbf{W} \in \mathbb{R}^{2d_h \times d_h}$ and $\mathbf{b} \in \mathbb{R}^{d_h}$ are trainable parameters. The encoder in which the above-mentioned encoded sentence is a relation representation is denoted as $\mathbf{E}$.

Then, we use a projection head Proj to obtain the low-dimensional embedding:

$$\tilde{\mathbf{z}} = \text{Proj}(\mathbf{h}), \tag{2}$$

where $\text{Proj}(\cdot) = \text{MLP}(\cdot)$ is composed of two layers of neural networks. The normalized embedding $\mathbf{z} = \tilde{\mathbf{z}}/||\tilde{\mathbf{z}}||$ is used for contrastive learning, and the hidden representation is used for classification.

3.4 Inital training for new task

Before training for each new task T_k, we first use Encoder to extract the embedding $\tilde{\mathbf{z}}$ of the relational representation of each sentence in D_k, and use them as the initialized memory bank M_b:

$$M_b \leftarrow \{\mathbf{z}_i\}_{i=1}^{N}. \tag{3}$$

At the beginning of training, relation representation extraction is performed on each batch B. Then the data embedding is explicitly constrained by clustering through supervised contrastive learning (Khosla et al., 2020):

$$\mathcal{L}_{\text{CL}} = \sum_{i \in I} \frac{-1}{|P(i)|} \sum_{p \in P(i)} \log \frac{\exp(z_i \cdot z_p / \tau)}{\sum_{j \in S_I} \exp(z_i \cdot z_j / \tau)}, \tag{4}$$

where $I = \{1, 2, \ldots, |B|\}$ is the set of indices of B. S_I represents the indices set of randomly sampled partial samples from M_b. $P(i) = \{p \in S_I : y_p = y_i\}$ is the indices set that is the same as the z_i label in M_b, and $|P(i)|$ is its cardinality. $\tau \in \mathcal{R}^+$ is an adjustable temperature parameter controling the separation of classes, the $\cdot$ indicates the dot product.

After backpropagating the gradient of loss on each batch, we update the representation in the memory bank:

$$M_b[\tilde{I}] \leftarrow \{\mathbf{z}_i\}_{i=1}^{|B|}. \tag{5}$$

where $\tilde{I}$ is the corresponding index set of this batch of samples in M_b. After *epoch*1 training set training, the model can learn a better relation representation.

3.5 Selecting Typical Samples for Memory

In order to make the model not forget the relevant knowledge of the old task when it learns the new task, some samples need to be stored in M_r. Inspired by (Han et al., 2020; Cui et al., 2021), we use k-means to cluster each relation, where the number of clusters is the number of samples that need to be stored for each class. Then, the relation representation closest to the center is selected and stored in memory for each cluster.

3.6 Consistent Representation Learning

After learning a new task, the representation of the old relation in the space may change. In order to make the encoder not change the knowledge of the old task while learning the new task, we propose two replay strategies to learn consistent representation for alleviating this problem: contrastive replay and knowledge distillation. Figure 1 shows the main flow of consistent representation learning.

Contrastive Replay with Memory Bank After the new task learning is over, we use the new task to train the encoder to further train the encoder by replaying the samples stored in memory M_k. After the learning of the current task is over, we use the same method in Section 3.4 to replay the samples stored in memory M_k.

The difference here is that each batch uses all the samples in the entire memory bank for contrastive learning, as follows:

$$\mathcal{L}_{\text{CR}} = \sum_{i \in I} \frac{-1}{|P(i)|} \sum_{p \in P(i)} \log \frac{\exp\left(z_i \cdot z_p / \tau\right)}{\sum_{j \in \tilde{S}_I} \exp\left(z_i \cdot z_j / \tau\right)}, \tag{6}$$

where $\tilde{S}_I$ represents the set of indices of all samples in $\tilde{M}_b$. $\tilde{M}_b$ is the memory bank, which stores the normalized representation of all samples in M_k.

By replaying the samples in memory, the encoder can alleviate the forgetting of previously learned knowledge, and at the same time, consolidate the knowledge learned in the current task. However, contrastive replay allows the encoder to train on a small number of samples, which risks overfitting. On the other hand, it may change the distribution of relations in the previous task. Therefore, we propose knowledge distillation to make up for this shortcoming.

Knowledge Distillation for Relieve Forgetting We hope that the model can retain the semantic knowledge between relations in historical tasks. Therefore, before the encoder is trained on a task, we use the similarity metric between the relations in memory as **Memory Knowledge**. Then use the knowledge distillation to relieve the model from forgetting this knowledge.

Specifically, the samples in the memory are encoded first, and then the prototype of each class is calculated:

$$p_c = \sum_{i=1}^{O} z_i^c, \tag{7}$$

where O is the number of memory size, z_i^c is the relation representation belonging to class c. Then, the cosine similarity between the classes is calculated to represent the knowledge learned in the memory:

$$a_{ij} = \frac{p_i^T p_j}{\|p_i\| \, \|p_j\|}, \tag{8}$$

where a_{ij} is the cosine similarity between prototype i and j.

When performing memory replay, we use KL divergence to make the encoder retain the knowledge of the old task.

$$\mathcal{L}_{KL} = \textstyle\sum_i KL(P_i || Q_i), \tag{9}$$

where $P_i = \{p_{ij}\}_{j=1}^{|\hat{R}_k|}$ is the metric distribution of the prototype before training, and $p_{ij} = \frac{\exp(a_{ij}/\tau)}{\sum_j \exp(a_{ij}/\tau)}$. Similarly, $Q_i = \{q_{ij}\}_{j=1}^{|\hat{R}_k|}$ is the metric distribution of calculate the temporary prototype from the memory bank during training, and $q_{ij} = \frac{\exp(\tilde{a}_{ij}/\tau)}{\sum_j \exp(\tilde{a}_{ij}/\tau)}$. $\tilde{a}$ is the **Embedding Knowledge** of the memory M_k, which is the cosine similarity between temporary prototypes. The temporary prototype is dynamically calculated in each batch based on the memory bank $\tilde{M}_b$.

3.7 NCM for Prediction

To predict a label for a test sample x, the nearest class mean (NCM) (Mai et al., 2021) compares the embedding of x with all the prototypes of memory and assigns the class label with the most similar prototype:

$$\begin{aligned} p_c &= \frac{1}{n_c} \sum_i \mathbf{E}\left(\bar{x}_i\right) \cdot \nVdash \left\{y_i = c\right\}, \\ y^* &= \underset{c=1,\ldots,k}{\operatorname{argmin}} \left\| f(\mathrm{x}) - p_c \right\|, \end{aligned} \tag{10}$$

where $\bar{x} \in M_k$ is stored sample, and y^* is a predicted label. Since the NCM classifier compares the embedding of the test sample with prototypes, it

Table 1: Accuracy (%) on all observed relations (which will continue to accumlate over time) at the stage of learning current task. The method marked by † represents the results generated from open source code[1] and the other baseline results copied from the original paper (Cui et al., 2021)

does not require an additional FC layer. Therefore, new classes can be added without any architecture modification.

4 Experiments

4.1 Datasets

Our experiments are conducted on two benchmark datasets: in the experiment, the training-test-validation that the split ratio is 3:1:1.

FewRel (Han et al., 2018) It is a RE dataset that contains 80 relations, each with 700 instances. Following the experimental settings by Wang et al. (2019), the original train and valid set of FewRel are used for experimental, which contains 80 classes.

TACRED (Zhang et al., 2017) It is a large-scale RE dataset containing 42 relations (including no relations) and 106,264 samples, built on news networks and online documents. Compared with FewRel, the samples in TACRED are imbalanced. Following Cui et al. (2021), the number of training samples for each relation is limited to 320 and the number of test samples of relation to 40.

4.2 Evaluation Metrics

Average accuracy is a better measure of the effect of catastrophic forgetting because it emphasizes the model's performance on earlier tasks (Han et al., 2020; Cui et al., 2021). This paper evaluates the model by using the average accuracy of K tasks at each step.

4.3 Baselines

We evaluate CRL and several baselines on benchmarks for comparison:

(1) EA-EMR (Wang et al., 2019) introduced a memory replay and embedding alignment mechanism to maintain memory and alleviate embedding distortion during training for new tasks.

(2) EMAR (Han et al., 2020) constructs a memory activation and reconsolidation mechanism to alleviate the catastrophic forgetting problem in CRE.

(3) CML (Wu et al., 2021) proposed a curriculum-meta learning method to alleviate the order sensitivity and catastrophic forgetting in CRE.

(4) RP-CRE (Cui et al., 2021) achieves enhanced performance by utilizing relation prototypes to refine sample embeddings, thereby effectively avoiding catastrophic forgetting.

Figure 2: Comparison of model's dependence on memory size, it shows that our model has a light dependence on memory size. The X-axis is the serial ID of the current task, Y-axis is the accuracy of the standard model on the test set from all observed relations at current stage.

4.4 Training Details and Parameters Setting

A completely random sampling strategy at the relation level is adopted. It simulates ten tasks by randomly dividing all relations of the dataset into 10 sets to simulate 10 tasks, as suggested in (Cui et al., 2021). For a fair comparison, we set the random seed of the experiment to be the same as the seed in (Cui et al., 2021), so that the task sequence is exactly the same. Note that our reproduced model RP-CRE † and CRL use strictly the same experimental environment. In order to facilitate the reproduction of our experimental results, the proposed method source code and detailed hyperparameters are provided on Github[2].

4.5 Results and Discussion

Table 1 shows the results of the proposed methods and baselines ones compared on two datasets, where RP-CRE † is reproduced under the same conditions based on open source code. We also ablated knowledge distillation and contrastive replay for consistent representation learning. CRL (w/o KL) and CRL (w/o CR) respectively refer to removing knowledge distillation loss $\mathcal{L}_{KL}$ and contrastive replay loss $\mathcal{L}_{CR}$ when replaying memory. From the table, some conclusions can be drawn:

(1) Our proposed CRL is significantly better than other baselines and achieves state-of-the-art performance in the vast majority of settings. Compared with RP-CRE, our model also produces apparent advantages. It proves that CRL can learn better consistent relation representations and is more stable in the process of continual learning.

(2) It is observed that all baselines perform worse on the TACRED dataset. The primary reason for this result is that TACRED is an imbalanced dataset. However, our model performs better than RP-CRE's last task on TACRED (3.4% higher than RP-CRE), which is more significant than the improvement (0.5%) on the class-balanced dataset FewRel. It shows that our model is more robust to scenarios with class-imbalanced.

(3) Comparing CRL and CRL (w/o KL), not adopting knowledge distillation during training can cause the model to drop 1% and 0.6% on FewRel and TACRED, respectively. The experimental results show that knowledge distillation can uniformly alleviate the model's forgetting of previous knowledge to learn a better consistent representation.

(4) Comparing CRL and CRL (w/o CR), removing L during memory replay caused the model to drop 2.4% and 4.8% on FewRel and TACRED, respectively. The reason for the significant drop is that only adopting $\mathcal{L}_{KL}$ cannot make the model review the samples of the current task, which leads to overfitting in the historical relations during replay.

4.6 Effect of Memory Size

The memory size is the number of memory samples needed for each relation. In this section, we will study the impact of memory size on the performance of our model and RP-CRE. We compare three memory sizes: 5, 10, and 20. The experimental results are shown in Figure 2.

We choose RP-CRE as the main competitor, where all configurations and task sequence remain unchanged. (1) As the size of the memory decreases, the performance of the model tends to decline, which shows that the size of the memory is a key factor that affects continuous learning and learning. But our model is more stable than RP-CRE (the performance gap in the final task), especially on the TACRED dataset. (2) On both FewRel and TACRED, CRL keeps the best perfor-

mance under different memory sizes and produces obvious advantages in small memory. It indicates that utilizing consistent representation learning is a more effective way to utilize memory than the existing memory-based CRE method.

4.7 Effect of Consistent Representation Learning

In order to explore the long-term effects of consistency representation learning in continual relation extraction, we tested our model and RP-CRE on TACRED to observe the changes in the embedding space of old tasks as new tasks continue to increase. The model performs feature extraction on all samples in the test set in task 1 at the end of tasks 1, 4, 7, and 10. Then t-SNE is used to represent the dimensionality reduction relation representation. All samples on the test set of task 1 are drawn, where different color points represent different ground-truth labels. The visualization results are shown in Figure 3.

From Figure 3, we can see that although the relation embeddings of RP-CRE are clustered and separated in each class after prototype refinement, as new tasks are continuously learned, the data embedding of task 1 is obviously scattered. In contrast, our model retains a good separation between classes, while the data embedding within classes is compact and has a certain diversity. In addition, we can see that our model has relatively stable changes in the distribution of different classes in task 1, and retains the knowledge of historical tasks with training. This is mainly because our model learns through supervised comparison, and explicitly emphasizes that the samples in historical memory are compact within the class and far away from each other. And the knowledge of historical memory is preserved through the distillation of memory knowledge. Because knowledge distillation preserves the distance distribution between classes, it can make up for the contrastive learning to over-optimize the distance between classes to prevent overfitting.

5 Conclusions and Future Work

This paper proposes a novel consistent representation learning method for the CRE task, mainly through contrastive learning and knowledge distillation when replaying memory. Specifically, we use supervised contrastive learning based on a memory bank to train each new task so that the model can effectively learn the feature representation. In addition, in order to prevent the catastrophic forgetting of the old task, we contrast and replay the memory samples, and at the same time, make the model retain the knowledge of the relation between the historical tasks through the knowledge distillation. Our method can better learn consistent representations to alleviate catastrophic forgetting effectively. Extensive experiments on two benchmark data sets show that our method significantly improves the performance of the most advanced technology and demonstrates powerful representation learning capabilities. In the future, we will continue to study cross-domain continual relation extraction to acquire ever-increasing knowledge.

Abstract

Open-ended text generation tasks, such as dialogue generation and story completion, require models to generate a coherent continuation given limited preceding context. The open-ended nature of these tasks brings new challenges to the neural auto-regressive text generators nowadays. Despite these neural models are good at producing human-like text, it is difficult for them to arrange causalities and relations between given facts and possible ensuing events. To bridge this gap, we propose a novel two-stage method which explicitly arranges the ensuing events in open-ended text generation. Our approach can be understood as a specially-trained coarse-to-fine algorithm, where an event transition planner provides a "coarse" plot skeleton and a text generator in the second stage refines the skeleton. Experiments on two open-ended text generation tasks demonstrate that our proposed method effectively improves the quality of the generated text, especially in coherence and diversity. The code is available at: `https://github.com/qtli/EventPlanforTextGen`.

1 Introduction

With the fast development of large-scale pre-trained models, considerable progress has been made in improving the quality of machine generated text (Radford et al., 2019; Rashkin et al., 2019a; Zhang et al., 2020b; Brown et al., 2020; Guan et al., 2021; Bakhtin et al., 2021). Today, machine learning models can do extremely well in generating text that looks human (Clark et al., 2021). The problem is still far from solved, however, as further reading of the machine-generated text often exposes defects such as self-contradiction and topic drifting (Bisk et al., 2020; Gao et al., 2020; Tan et al., 2021; Fan et al., 2019; Dou et al., 2021; Dziri et al., 2021). These issues are particularly serious in open-ended text generation tasks (e.g., story completion), where the model is asked to produce a coherent continuation which often involves multiple events, given limited preceding context.

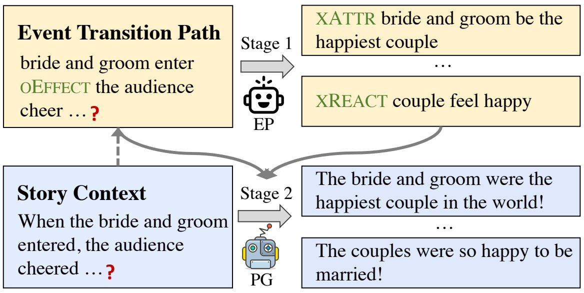

Figure 1: An illustration of our planning based framework in story completion task. Given story context, we extract corresponding event transition path, and use model EP to develop potential ensuing event transition paths. The planned paths accordingly guide the path-aware text generation model PG.

To bridge this gap, we propose a two-stage method which explicitly models the event transitions in open-ended text generation. Multi-step generation has been adopted to control the generated content at a high level (Dong and Lapata, 2018; Ji et al., 2020; Xu, 2021). Different from previous works that rely on inflexible pattern retrieval, we leverage a generative model as an event transition planner in the first stage to boost the high-level coherence and causalities in open-ended text generation.

Specifically, in stage one, an event transition planner (§3.1) outlines a transition path of events starting from the ones extracted from the input context. In stage two, this path is used to ensure a relevant and sound continuation from the actual text generator (§3.2). This method can be understood as a specially-trained coarse-to-fine algorithm, where

Table 1: Examples of event transition paths acquired from downstream tasks, i.e., dialogue generation and story completion. Events are marked in blue box.

an event transition planner provides a "coarse" plot skeleton and a path-aware text generator refines the skeleton. Figure 1 shows an illustration of our approach.

There are two main challenges in this method. First, the planer should produce high-quality and diverse paths that can generalize well to the unseen events at test time. For this challenge, we fine-tune a GPT-2 (Radford et al., 2019) on a large amount of event paths extracted from commonsense graphs (Sap et al., 2019), as well as from the training set of the specific task, aiming to extrapolate to event sequences that never appeared in these sources with the help of general knowledge stored in the large pre-trained model (Petroni et al., 2019; Lee et al., 2021).

For the second challenge, the auto-regressive text generator need to work effectively under the supervision of the even transition path. We thus design an event query layer to absorb information from the planned paths and use the query layer to guide the text generation process.

We validate our method thorough extensive experiments on two standard open-ended text generation tasks, dialogue generation (Rashkin et al., 2019b) and story completion (Mostafazadeh et al., 2016). Our two-stage approach outperforms a strong knowledge enhanced GPT-2 baseline (Guan et al., 2020a) in both automatic and human evaluation metrics. Further analysis shows that the improvements of the event transition planning model come in particular from the high-level consistency and diversity in long and difficult generation cases.

2 Event Transition Path.

In this work, the event transition path is defined as an alternating sequence between events and relations, where an *event* is a subject-verb phrase, a *relation* is chosen from a pre-defined label set (e.g., OREACT - object reaction; XATTR - subject attribute) of a commonsense atlas (Sap et al., 2019). Table 1 shows some text examples and their corresponding event transition paths. We collect event transition paths from a commonsense atlas ATOMIC (Sap et al., 2019), as well as from the training set of the specific task, to train an event transition planner.

Sampling Paths from ATOMIC. We use everyday commonsense atlas ATOMIC (Sap et al., 2019) to acquire plenty event paths. ATOMIC is organized through 9 relations and 877k events (textual descriptions) of inferential commonsense, e.g., if "PersonX pays PersonY a compliment", then "PersonY will likely return the compliment". It has been demonstrated that ATOMIC is useful for open-ended text generation tasks, such as story generation (Guan et al., 2020b).

Besides, to increase the flexibility, we introduce a reverse relation (e.g., _XATTR) for each original relation (e.g., XATTR) so that a sampled path can contain reverse triplets. The intuition is that, in open-ended text generation, the narrative maybe in a reverse order. After explaining the event A, the author may want to introduce the subsequent event B. Meanwhile, if the author introduce the event B first, she/he may want to describe the event A as an explanation for the reason/motivation.

Finally, we collect sufficient event paths of variant lengths from ATOMIC via random walk-

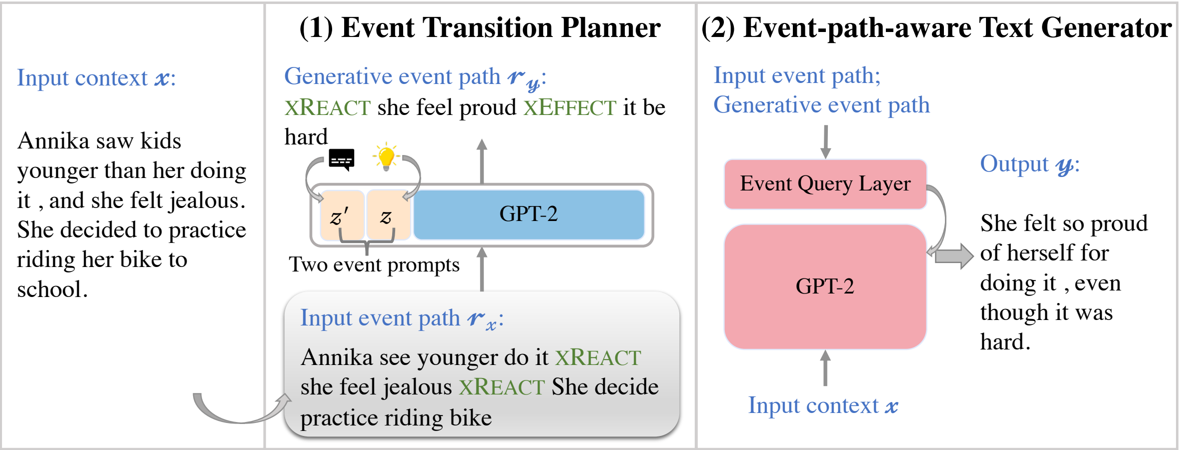

Figure 2: Overall architecture of the proposed coarse-to-fine framework. It consists of two components. (1) **Event Transition Planner**: given a input context, it first extracts corresponding event path and then generates possible ensuing event path. The planner directly inherits the pre-trained parameters from GPT-2; (2) **Event-path-aware Text Generator**: another GPT-2-based generator is applied to generate a natural language sentence by attending to input context and explicit event transition path.

ing[1]. We split the sampled paths into training/validation/test with the ratio of 18:1:1. We use these sampled paths to optimize the event transition planner which is responsible for generative event planning (see §3.1). The statistics of sampled paths are shown in Table 6 of Appendix A. We display several examples of the randomly sampled event transition paths in Table 7 of Appendix A.

Extracting Paths from Specific Dataset. We use two kinds of event transition paths. A general kind is obtained from random walking on a daily commonsense graph, ATOMIC, as mentioned above. Another kind is extracted from the natural language instances of downstream datasets, which is used for the training and prediction stage of task-specific event planning. For example, given the inputs, "When the bride and groom entered, the audience cheered", the extracted event path is "bride and groom enter OEFFECT audience cheer".

In detail, for each sentence, to ensure the extracted events have complete semantics and keep a similar format with the events in ATOMIC, we use ASER event extractor tool[2] to distil events for all sentences of downstream datasets. We further predict the relations between these events, linking these isolated events as event transition paths. Specifically, we train a BERT (Devlin et al., 2019) classifier using event triples and relations in ATOMIC. The sizes of training/validation/test instances are 639,045/35,503/35,502, respectively. We finally achieve a accuracy score of 85% on the test set for the relation prediction.

3 Methodology

We focus on the conditional language modeling problem in open-ended text generation tasks. Formally, given an input context $\boldsymbol{x}$, models are required to generate a sentence $\boldsymbol{y}$ that is consistent with input context and not contradicts itself.

In this work, we propose a two-stage model for the generation process. In the first stage, we extract the starting event sequence $\boldsymbol{r}_x$ from the input context and employ the event transition planer to generates subsequent event transition path $\boldsymbol{r}_y$ based on $\boldsymbol{r}_x$. In the second stage, the output text is generated from an auto-regressive model conditioning on the path and the preceding context $\boldsymbol{x}$.

Figure 2 gives an overview of our coarse-to-fine framework for open-ended text generation. In a nutshell, we first fine-tune a GPT-2 on event transition sequences as an event planner (i.e., a conditional generative model for event paths). This fine-tuning involves event transition sequences extracted from both commonsense graphs and the training set. We then build a path-aware text generator with an event query layer specifically designed to refer to the planned path when generating the output.

3.1 Generative Event Transition Planner

In this section, we describe the event transition planner which completes the partial event path

---

[1] The hops of these sampled paths fall in between 1 and 5.

[2] `https://hkust-knowcomp.github.io/ASER/html/index.html`

given certain input context. Pre-trained language models can be good representation learners of relational knowledge (Petroni et al., 2019; Bosselut et al., 2019). In our model, we choose GPT-2 (Radford et al., 2019) as the backbone of our event transition planner.

Specifically, we first fine-tune GPT-2 with large-scaled event transition paths sampled from ATOMIC (Sap et al., 2019). After that, we fine-tune the resulting model in addition on the event transitions extracted from the training corpus, so that the planner is aware of general transitions in the commonsense while focusing on the transitions in the specific domain in the meantime.

In preliminary experiments, we find that directly running a full fine-tuning (i.e., updating all GPT-2 parameters) leads to a drop in the final performance. We suspect the reason is the full fine-tuning flushes out the original general knowledge from the large-scale pre-training (Chen et al., 2019; Lee et al., 2020; Chen et al., 2020).

To overcome this drawback, we prepend a trainable continuous event prompt $\boldsymbol{z}$ to the input path $\boldsymbol{r} = [\boldsymbol{r}_x; \boldsymbol{r}_y]$ of every transformer layer in event transition planner, as prefix-tuning (Li and Liang, 2021) does. A trainable matrix $\mathbf{U}_\theta$ with parameters θ is randomly initialized to embed event prompt $\boldsymbol{z}$. The aim is to use parameters θ introduced by $\boldsymbol{z}$ to store event transition patterns from ATOMIC. Then the representation of each input event transition path $\boldsymbol{r}$ is prompted as $\boldsymbol{r}' = [\boldsymbol{z}; \boldsymbol{r}]$. To increase training speed and performance robustness, we apply an additional linear reparameterization function on $\mathbf{U}_\theta$.

$$\mathbf{U}_\theta = \mathit{FFN}_\theta\ (\mathbf{U}_\theta^{'}), \tag{1}$$

where $\boldsymbol{U}_\theta^{'}$ is another randomly initialized matrix with smaller dimension, *FFN* is a large feedforward neural network (Vaswani et al., 2017). We perform gradient updates on the following log-likelihood objective:

$$\max_\theta \ \log(\boldsymbol{r}_y \mid [\boldsymbol{z}; \boldsymbol{r}_{<y}]) = \sum_{y \in \boldsymbol{z}_{\text{idx}}} \log \ \mathit{EP}_{\phi,\theta}(\boldsymbol{r}_y \mid \mathbf{h}_{<y}), \tag{2}$$

where ϕ denotes the pre-trained parameters from the backbone LM of event transition planner, θ denotes the newly introduced parameters for the event prompt, $\boldsymbol{z}_{\text{idx}}$ denotes the index sequence of the event prompt, *EP* is short for event transition planner, and $\mathbf{h}_{<y}$ denotes the hidden states calculated by the trainable event prompt matrix and activation layers of the backbone LM:

$$\mathbf{h}_y = \begin{cases} \mathbf{U}_\theta[y, :], & \text{if } y \in \boldsymbol{z}_{\text{idx}}, \\ \boldsymbol{LM}_\phi(\boldsymbol{r}_y \mid \mathbf{h}_{<y}) & \text{otherwise.} \end{cases} \tag{3}$$

Similar to the above event prompting technique, for the paths from downstream dataset, we prepend another event prompt $\boldsymbol{z}'$ to the $\boldsymbol{r}'$ and only optimize the parameters introduced by $\boldsymbol{z}'$. This effectively preserves the newly-learned event transition patterns from ATOMIC and continuously adapts the event transition planner to different downstream event transition patterns.

3.2 Event-path-aware Text Generation

Current state-of-the-art systems for open-ended text generation are based on fine-tuning pre-trained language models with different downstream datasets. Although text generation fluency is usually not a crucial issue nowadays, topic-related mistakes (Dou et al., 2021) such as off-prompt and self-contradiction are common. We therefore integrate the event transition paths produced by the planner into the text generation model via an event query layer using the multi-head attention mechanism (*MHA*).

The event query layer is built on top of the stacked transformer layers, aiming to explicitly induce the expected output with event transition paths. The input of the event query layer is the event transition path $\boldsymbol{r}$ given the current input $\boldsymbol{x}$. $\boldsymbol{r}$ not only summarizes the event transition in $\boldsymbol{x}$, also indicates possible event path following $\boldsymbol{x}$. The structure of the event query layer resembles the transformer layer. Its output serves as the key and value vectors in the multi-head attention mechanism, which computes another attention vector $\mathit{MHA}(\boldsymbol{r})$. We concatenate two multi-head attention vectors and derive the final event-path-aware attention vector $\mathbf{m}$:

$$\mathbf{m} = \mathit{MLP}([\mathit{MHA}(\boldsymbol{x}); \mathit{MHA}(\boldsymbol{r})]), \tag{4}$$

where $\mathit{MHA}(\boldsymbol{x})$ is the output from the multi-head attention function of the original transformer layer, $\mathit{MHA}(\boldsymbol{r})$ is the output from the event query layer. The event-path-aware attention vector $\mathbf{m}$ replaces the original multi-head attention vector $\mathit{MHA}(\boldsymbol{x})$ and participates the remaining calculation of the language model.

The optimization of the event-path-aware text generator is the standard cross-entropy objective: $\mathit{CrossEntropy}(\boldsymbol{y}_j \mid \boldsymbol{y}_{<j}, \boldsymbol{x}, \boldsymbol{r})$.

3.3 Implementation Details

We base our event planner and event-plan-aware text generator on pre-trained GPT-2-small models[3]. The event prompt length during training ATOMIC event transition paths are set to 5 according to pilot study. We inject and optimize the event query layer on the last layer of the stacked Transformers. When training the event-path-aware text generator, event path $\boldsymbol{r}_y$ is derived from the ground truth. During inference, $\boldsymbol{r}_y$ is the prediction from event transition planner given the input event transition path $\boldsymbol{r}_x$. More details are elaborated in Appendix B.

4 Experiments

We conduct experiments on two open-ended text generation tasks, dialogue generation and story completion, to answer the following questions:

- **RQ1**: How to develop a better event transition planner?
- **RQ2**: Whether the integration of event transition paths enhances the open-ended text generation?
- **RQ3**: How do the event transition paths benefit text generation?

4.1 Evaluated Tasks

- **Story Completion** requires models to complete a story given the first few sentences. We evaluated our framework on ROCSTORIES (Mostafazadeh et al., 2016), which contains 98k five-sentence stories. Our default setting is to predict the last sentence given the first four ones.
- **Dialogue Generation** aims to generate reasonable and human-like responses given the dialogue history. We evaluated our framework on EMPATHETICDIALOGUES (Rashkin et al., 2019b) which consists of 25k conversations grounded in pre-specified situations.

4.2 Event Transition Planning (RQ1)

We compare our event transition planner, named as PLANGENERATION, with fine-tuned pre-trained GPT-2 (Radford et al., 2019) and several ablation settings, investigating *how to develop a better event transition planner*.

Specifically, the compared settings include:

- **GPT-2** is a pre-trained GPT-2 model (Radford et al., 2019) directly fine-tuned on the event paths extracted from specific tasks, i.e., dialogue generation or story completion in our work.
- **PLANGENERATION** is our proposed event planning method, which explores a two-stage fine-tuning on event transition paths from ATOMIC (Sap et al., 2019) and the downstream task, equipping with the proposed event prompting module.
- **w/o PROMPT** is our proposed method without the event prompting module, but still using the two-stage fine-tuning strategy.
- **w/o TUNING ON ATOMIC** is our proposed method without the first-stage fine-tuning on the event paths extracted from external commonsense atlas ATOMIC.
- **PLANRETRIEVAL** is a retrieval based planning methods, which employs the BM25 ranking function (ROBERTSON et al., 1995) to retrieve from the paths extracted from the training sets according to the given context.

Results. We use **BLEU** (Papineni et al., 2002) and **DIST** (Li et al., 2016) as the automatic metrics to evaluate the generated sentences in terms of the coherence and diversity, respectively. BLEU evaluates n-gram overlap between generation and ground truth. BLEU scores will become extremely low for large n. We thus experiment with $n \in \{1, 2, 4\}$. DIST measures the ratio of distinct n-grams to all the generated n-grams from the perspective of the generation diversity. For DIST metric, we adopt $n \in \{1, 2\}$. The experimental results are shown in Table 2. The dataset needed in this section consists of event transition paths sampled from ATOMIC and extracted from downstream datasets. i.e., ROCSTORIES and EMPATHETICDIALOGUE. The details of event transition paths are shown in §2 and Appendix A.

On both dialogue generation and story completion tasks, our proposed PLANGENERATION greatly outperforms baseline GPT-2 on event planning coherence (BLEU) and event path diversity (DIST). Specifically, on two downsteam tasks, our event transition planner PLANGENERATION surpasses the fine-tuned GPT-2 by 3.09 and 3.53 on BLEU-1, 0.31 and 0.30 on DIST-1. This improvement indicates that (1) the two-stage event prompting module could endow event transition planner powerful abilities on predicting the ensuing event paths; (2) enhanced with the large-scale event transition patterns from ATOMIC, our event transition

planner becomes more creative and produces more diverse outcomes.

Considering the ablation settings, without tuning on ATOMIC (w/o TUNING ON ATOMIC) or without the event prompting module (w/o PROMPT), the method performs worse on both tasks and across almost all metrics. The limited performance of w/o TUNING ON ATOMIC suggests the necessity and effectiveness of learning general event transition patterns from ATOMIC before optimizing on task-specific event paths. Tuning on ATOMIC event patterns could make event transition planner get familiar with the event-path-like language and generalize well on unseen event patterns. Compared to ablation model w/o PROMPT, EVENTPLANNING is comparatively more effective. This is because when optimizing on event paths of target tasks, the proposed event prompt protects the parameters of pre-trained language model from drastic change when training with event transition paths. This comparison confirms our intuition that event prompting module could improve event planning performance without destroying the eventual commonsense stored in pre-trained parameters. It provides a more flexible approach to blend the event transition patterns in both ATOMIC and specific tasks with the pre-trained GPT-2 model.

We also attempt a variation of our PLANGENERATION method, i.e., PLANRETRIEVAL. We can see that the BELU scores of PLANRETRIEVAL are substantially lower that the generation based methods. The main reason is that the target event paths are flexible, infinite, and task-related. Many transition patterns are not seen in the training data or external commonsense graph.

4.3 Event-path-aware Text Generation (RQ2)

In this section, we compare our overall framework EP-PG with several baselines to investigate *whether the integration of generative event transition paths benefits the open-ended text generation.*

We consider the following settings:

- **GPT-2** is a pre-trained GPT-2 model (Radford et al., 2019) fine-tuned on the task-specific dataset.
- **GPT-2-CS-FT** is a commonsense-enhanced GPT-2 model. By following Guan et al. (2020b), we conduct a first-stage post-training on the ATOMIC commonsense triples and then fine-tuning on task-specific dataset.
- **EP-PG** is our proposed framework, which is a fine-tuned GPT-2 model integrated with the event transition path produced from event transition planner PLANGENERATION via an event query layer.
- **R-EP-PG** is another version of **EP-PG** to explore the proposed event query layer. The input event transition paths are produced by PLANRETRIEVAL in a retrieval way.

Results. We consider the same evaluation metrics as in §4.2. As demonstrated in Table 3, EP-PG achieves the most satisfying performance among all settings on both tasks[4]. Integrated with the explicit guidance of the event transition paths, EP-PG produces more accurate open-ended generations with higher diversity.

Particularly, our proposed framework EP-PG consistently and significantly improves GPT-2 baseline for all tasks on content quality (BLEU) and diversity (DIST), showcasing the advantage of injecting event query layer on fine-tuned GPT-2. Without the explicit modeling of event transition

[4] P-value < 0.05 on BLEU-1, according to Padó (2006).

Tasks	Models	BLEU-1	BLEU-2	BLEU-4	DIST-1	DIST-2
Dialogue Generation	GPT-2	16.07	6.41	2.13	2.06	7.70
	GPT-2-CS-FT (Guan et al.)	16.43	6.83	2.31	2.16	8.28
	R-EP-PG	16.68	6.71	2.27	**2.21**	**8.44**
	EP-PG (Ours)	**16.74**	**6.94**	**2.39**	2.19	8.25
Story Completion	GPT-2	25.03	9.58	2.70	8.38	31.33
	GPT-2-CS-FT (Guan et al.)	25.09	9.64	2.72	8.07	30.68
	R-EP-PG	24.72	9.27	2.63	7.01	26.49
	EP-PG (Ours)	**25.47**	**9.71**	**2.74**	**8.99**	**34.48**

Table 3: Results of experiments on open-ended text generations. For detailed information about each compared model, please refer to §4.3.

paths, GPT-2-CS-FT which post-trains on commonsense triples only obtains a slight improvement or even performs comparable with GPT-2 model. EP-PG further improves generation performance from GPT-2-CS-FT across all metrics on the two tasks, highlighting the efficacy of long-range event planning via an additional event query layer.

Particularly remarkable are the relative differences between R-EP-PG and EP-PG. Although R-EP-PG manages to bring generations more diversity, but in most cases, EP-PG is more effective on content planning and informativeness due to generative event transition patterns in higher qualities. Moreover, R-EP-PG performs even worse than GPT-2 on story completion. This implies that low-quality event paths even damage the generations. Thus, a reliable event path is a key guarantee for effective downstream text generation.

4.4 Analysis: Event Transition Planning for Different Generation Scenarios (RQ3)

To further investigate *how do the event paths benefit text generation*, we analyse the effectiveness of event paths on differently difficult levels of generation, i.e., token-level and sentence-level.

Token-level. We first separate the test set into 5 groups according to the averaged target sentence lengths, and then observe the improvements of our proposed EP-PG over GPT-2 on BLUE-1 score. We find that our framework gains more on the longer instances in both story completion (from 0.4 to 1.3 on instances with more than 15 non-stop-words) and dialogue generation (from 0.3 to 0.9 on instances with more than 5 non-stop-words). We argue that the longer targets imply more sophisticated upcoming event transitions, where the guidance from the event transition planner becomes more important.

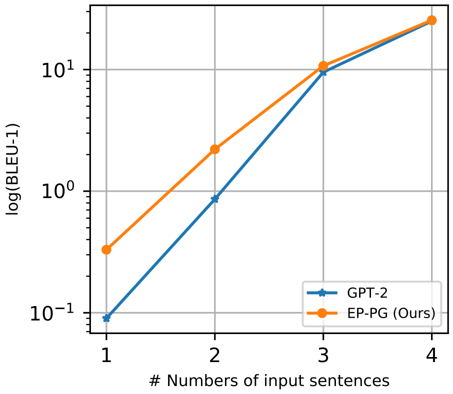

Figure 3: The log of BLEU-1 scores on story completion with different numbers of sentences as input.

Sentence-level. For story completion on five-sentence story dataset ROCSTORIES, we further conduct experiments on EP-PG with various input sentences and output sentences, i.e., the numbers of input (output) sentence are 1 (4), 2 (3), 3 (2), and 4 (1), respectively. Figure 3 shows that, compared to GPT-2, the relative improvement proportion of EP-PG is nearly doubled on the most difficult setting where there is only one sentence as input. This improvement is much larger than the easiest situation where 4 sentences are input to the model. Despite less input context, EP-PG with event transition planning manages to performs better with smaller performance drop.

4.5 Human Evaluation

We set up a human evaluation as a complementary evaluation beyond automatic evaluation. For both tasks, we randomly select 100 samples from test set. For each sample, we compare three pairs of models: EP-PG versus GPT-2, GPT-2-CS-FT, and R-EP-PG. Each comparison is rated by three crowd workers, who are asked to give a preference (win, lose or tie) from two perspectives:

Tasks	Models	Coherence				Diversity			
		Win	Lose	Tie	κ	Win	Lose	Tie	κ
Dialogue Generation	Ours vs. GPT-2	45%	11%	44%	0.290	71%	10%	19%	0.226
	Ours vs. GPT-2-CS-FT	34%	10%	56%	0.286	54%	7%	39%	0.288
	Ours vs. R-EP-PG	32%	8%	60%	0.472	67%	11%	22%	0.291
Story Completion	Ours vs. GPT-2	45%	12%	42%	0.397	59%	10%	31%	0.220
	Ours vs. GPT-2-CS-FT	47%	17%	36%	0.387	56%	17%	27%	0.210
	Ours vs. R-EP-PG	43%	17%	40%	0.393	61%	6%	33%	0.340

Table 4: Manual evaluation results on downstream text generation. The scores indicate the percentages of Win, Lose or Tie when our model is compared with other baselines. κ denotes Fleiss' kappa (all are *fair agreement* or *moderate agreement*).

• **Coherence.** It indicates whether the inference is natural, relevant, and follows logically from the given context.

• **Diversity.** Particularly, for baseline models, we use beam search decoding with a top-k ($k = 5$) sampling scheme (Fan et al., 2018) and a softmax temperature τ ($\tau = 0.7$) to generate three inferences per sample. For our method EP-PG, its event transition planner first predicts three paths via the same beam decoding, then its text generator uses greedy decoding based on the generated three paths to produce three inferences per sample. During pair-wise comparison, we ask annotators to evaluate which model's predictions contain more reasonable and coherent event transition patterns.

The two aspects are independently evaluated and results are shown in Table 4. According to human evaluations, our proposed EP-PG significantly outperforms compared baselines in terms of both criteria on the test set of all datasets. Overall inter-rater agreement measured by Fleiss' kappa (Fleiss, 1971) and all the results show fair agreement ($0.2 \leq k \leq 0.4$) or moderate agreement ($0.4 \leq k \leq 0.6$). The results indicate that explicit incorporating event transition patterns yields significant improvement in generating coherence texts given the input context. Specifically, with guidance from different event transition paths, our method could produce more diverse and reasonable inferences.

4.6 Qualitative Study

Table 5 illustrates how our model tends to produce more contentful and coherent predictions compared to the other systems. In this story completion case, the generated event path successfully captures the correlations between *working out* and *pass physical test*, which further helps our model produce the most reasonable output, *Alex was able to pass the physical exam.* For the baseline without commonsense knowledge, GPT-2, is instead not related to the core context *failed the physical assessment*. Tuning on commonsense atlas Atomic, GPT-2-CS-FT produces informative inference but contradicts the context. The retrieval-based model R-EP-PG searches a related event transition *police officer*. However, its flexibility is limited by search space and cannot maintain a long-range event path, which is easy to produce hallucinated inference. More case analysis are stated in the Appendix C.

Story Context:
Alex was in training to be a police officer.
He was not in the best shape.
Alex failed the physical assessment.
Alex started working out.

Golden Event Path:
xEffect he take the test again xEffect he pass
Retrieved Event Path:
wants to be best police officer xWant tells person to stop
Generated Event Path:
xEffect Alex able get good shape xEffect Alex able pass physical test

Reference:
He took the test again and passed .
GPT-2:
Alex was able to get a good job.
GPT-2-CS-FT:
Alex made the squad.
R-EP-PG:
Alex was able to become a police officer.
EP-PG:
Alex was able to pass the physical exam.

Table 5: Case study on story completion. The three sections from top to bottom are the input context, the event transition plans, and inferences from our model and baseline models, respectively.

5 Related Work

Recent advances in pre-trained language models have resulted in impressive performances on open-domain text generation, such as story completion (See et al., 2019; Yao et al., 2019; Fan et al., 2019; Ippolito et al., 2020), dialogue generation (Rashkin et al., 2019b; Zhang et al., 2020b; Li, 2020; Vulić et al., 2021), question generation (Cheng et al., 2021; Wang et al., 2021), and so on. For example, in dialogue generation, Zhang et al. (2020b) design a trainable generative pre-trained transformer by training an autoregressive language model on large-scale Reddit context-response pairs with a maximum mutual information scoring function to improve diversity. Goldfarb-Tarrant et al. (2020) integrate semantic role labels and prompts into pre-trained BART (Lewis et al., 2020) during fine-tuning for prompt based story telling. In this paper, we focus on story completion and dialogue generation and build a generative coarse-to-fine method to generate open-ended text with explicit event transition paths.

Despite the success of generative pre-trained language models on a series of open-ended text generation tasks, they still suffer in maintaining coherence throughout multiple sentences due to the left-to-right word-by-word generation style (Fan et al., 2019; Yu et al., 2020). To alleviate this problem, one research direction adopts coarse-to-fine progressive text generation (Tan et al., 2021). This generation paradigm has been studied in many text generation systems for specific tasks, such as data-to-text generation (Moryossef et al., 2019; Puduppully and Lapata, 2021), storytelling (Goldfarb-Tarrant et al., 2020; Orbach and Goldberg, 2020), and dialogue generation (Xu et al., 2020a). Our work adopts a generative event transition planner that is trained on a large amount of event transition paths, aiming to arrange the ensuing events in open-ended text generation.

Another research direction incorporates external entities to guide the open-ended text generation (Guan et al., 2019; Zhang et al., 2020a; Dziri et al., 2021; Li et al., 2020; Peng et al., 2021). Ji et al. (2020) and Xu et al. (2020b) retrieve entities from knowledge bases to control the generated content. However, the retrieval-based methods also suffer from the sparsity problem and the domain shift between external sources and downstream tasks (Wang et al., 2020). Guan et al. (2020b) integrate entity relations into pre-trained language model via additional tuning on entity triples. Even with such specialized learning, the resulted model still often stuck in logical errors or repeats pieces of narratives (Guan et al., 2020b; Peng et al., 2021). This phenomenon demonstrates the need for an intact inductive bias on organizing event transition patterns for open-ended text generation. Different from using event triples as additional training instances, our method explicitly maintains generative event transition paths to make the generation process more explainable and improve the coherence.

6 Conclusion

In this paper, we propose a novel two-stage method to improve high-level consistency and diversity in open-ended text generation. We design a special-trained event transition planner to explicitly arrange the ensuing events and introduce an event-path-aware text generator to exploit the event transition guidance for language generation. We investigate two open-ended text generation tasks, i.e., story completion and dialogue generation. Thorough experiments demonstrate that the explicit arrangement of event transition path indeed facilitate models to generate more coherent and diverse text in open-ended scenery. Besides, with the proposed event prompt and event query layer, our method could be extended to any other language models and open-ended generation tasks. A future line of investigation is to explore the effect of the proposed method on other open-ended tasks, such as commonsense question answering.

[2] PersonX asks PersonY to join oWANT PersonY wants to be friends xREACT PersonY feels loved
[3] PersonX is inebriated _xATTR PersonX loses control of PersonX's car xREACT PersonX feels scared _oREACT PersonY takes PersonX by force xREACT PersonY feels triumphant

Table 7: Event transition paths sampled from daily commonsense reasoning atlas ATOMIC (Sap et al., 2019).

B Implementation Details

For all the systems, including the event transition planner and text generator in our proposed method, we employ the small version of GPT-2 model[5] which is a Transformer with 12-head, 12-layer, and hidden size of 768. The total parameter scalse is 117M. We use pre-trained GPT-2 Byte Pair Encoding (BPE) tokenizer with an extended vocabulary of 50,282 tokens to tokenize texts.

The event prompt length during training ATOMIC event transition paths, EMPATHETICDIALOGUES paths, and ROCSTORIES paths are 5, 5, and 10, respectively. The dimension of the randomly initialized smaller matrix $\mathbf{U}'_\theta$ in Eq.1 is 512.

The batch size is 128 using AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of 5e-5. We select the best checkpoint according to the perplexity on the development set of each task and apply early stopping on training where the patient value is set to 2. We adopt the pre-trained BERT-base model[6] to train the event relation classifier. All experiments are implemented by PyTorch framework (Paszke et al., 2017) and run on NVIDIA V100 GPUs. The training time of the event transition planner and event-path-aware text generator are less than 5 hours and 3 hours with 8 GPUs.

C Case Study

We qualitatively analyze our model predictions and find that although the proposed model outperforms the state-of-the-art baselines, many of predictions are still wrong. Table 8 shows several satisfying and unsatisfying predictions on the two datasets. One significant error originates from the weak alignment between event transition path and final prediction. For example, in the second case, despite "xEFFECT tommy be happy" is imperfect, the prediction "bought it" do not convey its information and makes co-reference mistake (the expected output is "bought them"). Another serious error type is event transition hallucination, where both the predicted event path and its corresponding

---

[5] `https://huggingface.co/gpt2`

[6] `https://huggingface.co/bert-base-uncased`

inference fail to maintain the logic coherence, such as the fourth case. These problems could be alleviated if we design a better format of event transition path which is easier to learn or improve the relation modeling between events and sentences.

	Input	**Corresponding Event Transition Path**
Good Case on Story Completion	**Context**:	
	Our granddaughter is two.	Our granddaughter be two
	Today she went to the doctor for a blood draw.	xEFFECT she go doctor for draw
	She did very well.	xEFFECT she do well
	Our daughter sent a photo of her licking a lollypop afterward.	oREACT we daughter send a photo xEFFECT she lick lollypop
	Target:	
	We were very proud of her.	oEFFECT we be proud
	Prediction:	
	We were amused by the photo.	xEFFECT we get good photo xEFFECT we be happy
***Bad* Case on Story Completion**	**Context**:	
	Tommy wanted to buy a new computer.	tommy want buy new computer
	After some research he decided to build a PC himself.	xEFFECT After research decide build PC
	He found a site that spelled out compatible parts lists.	xEFFECT he find site
	He shopped around for the cheapest parts he could get.	xEFFECT he shop around part _xEFFECT he could get
	Target:	
	The PC he made was more powerful than computers twice its price.	xEFFECT he make powerful computer
	Prediction:	
	He finally found the perfect parts list and bought it.	xREACT he find part xEFFECT tommy be happy
Good Case on Dialogue Generation	**Context**:	
	Hi, I joined a firm 6 months ago and then I got a promotion for Junior Manager.	i join firm ago xEFFECT i get promotion for manager
	Target:	
	Congratulations. That sounds like the fast track.	oREACT that like fast track
	Prediction:	
	That's awesome! I bet you are excited!	oREACT that be great xEFFECT you must be proud
***Bad* Case on Dialogue Generation**	**Context**:	
	I got my four year old daughter her first tricycle yesterday.	i get my daughter tricycle yesterday
	Target:	
	thats so sweet of you.	oREACT that sweet
	Prediction:	
	Wow, that's a lot of fun. What kind of tricycle?	oEFFECT that be great xEFFECT what be tricycle

Comprehensive Multi-Modal Interactions for Referring Image Segmentation

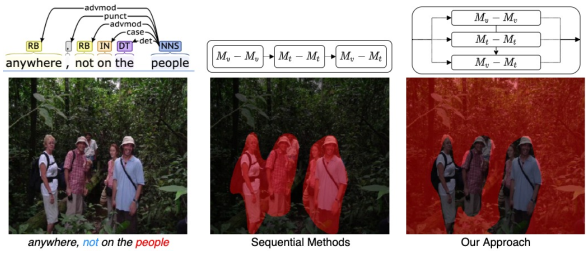
Kanishk Jain and **Vineet Gandhi**
CVIT, KCIS, IIIT Hyderabad, India
`kanishk5991@gmail.com`, `vgandhi@iiit.ac.in`

Abstract

We investigate Referring Image Segmentation (RIS), which outputs a segmentation map corresponding to the natural language description. Addressing RIS efficiently requires considering the interactions happening *across* visual and linguistic modalities and the interactions *within* each modality. Existing methods are limited because they either compute different forms of interactions *sequentially* (leading to error propagation) or *ignore* intramodal interactions. We address this limitation by performing all three interactions *simultaneously* through a Synchronous Multi-Modal Fusion Module (SFM). Moreover, to produce refined segmentation masks, we propose a novel Hierarchical Cross-Modal Aggregation Module (HCAM), where linguistic features facilitate the exchange of contextual information across the visual hierarchy. We present thorough ablation studies and validate our approach's performance on four benchmark datasets, showing considerable performance gains over the existing state-of-the-art (SOTA) methods.

1 Introduction

Traditional computer vision tasks like detection and segmentation have dealt with a pre-defined set of categories, limiting their scalability and practicality. Substituting the pre-defined categories with natural language expressions (NLE) is a logical extension to counteract the above problems. Indeed, this is how humans interact with objects in their environment; for example, the phrase "the kid running after the butterfly" requires localizing only the child running after the butterfly and not the other kids. Formally, the task of localizing objects based on NLE is known as Visual Grounding. Existing works either approach the grounding problem by predicting a bounding box around the referred object or a segmentation mask corresponding to the referred object. We focus on the latter approach, as a segmentation mask can effectively pinpoint the exact location and capture the actual shape of the referred object. The task is formally known as Referring Image Segmentation (RIS).



anywhere, not on the people Sequential Methods Our Approach

Figure 1: Unlike existing methods which model interactions in a sequential manner, we synchronously model the Intra-Modal and Inter-Modal interactions across visual and linguistic modalities. Here, M_v and M_t represent Visual and Linguistic Modalities, and {-} represents interactions between them.

RIS requires understanding both visual and linguistic modalities at an individual level, specifically word-word and region-region interactions. Additionally, a mutual understanding of both modalities is required to identify the referred object from the linguistic expression and localize it in the image. For instance, to ground a sentence "whatever is on the truck", it is necessary to understand the relationship between words as grounding just the individual words will not work. Similarly, region-to-region interactions in visual modality help group semantically similar regions, e.g., all regions belonging to the truck. Finally, to identify the referent regions, we need to transfer the distinctive information about the referent from the linguistic modality to the visual modality; this is taken care of by the cross-modal word-region interactions. The current SOTA methods (Yang et al., 2021; Feng et al., 2021; Huang et al., 2020; Hui et al., 2020; Hu et al., 2020) take a modular approach, where these interactions happen in parts, sequentially.

Different methods differ in how they model these interactions. (Huang et al., 2020) first perform a

Findings of the Association for Computational Linguistics: ACL 2022, pages 3427 - 3435
May 22-27, 2022

region-word alignment (cross-modal interaction). The second stage takes these alignments as input to select relevant image regions corresponding to the referent. (Yang et al., 2021) and (Hui et al., 2020) use the dependency tree structure of the referring expression for the reasoning stage instead. (Hu et al., 2020) select a suitable combination of words for each region, followed by selecting the relevant regions corresponding to referent based on the affinities with other regions. The performance of the initial stages bounds these approaches. Furthermore, they ignore the crucial intra-modal interactions for RIS.

In this paper, we perform all three forms of interactions simultaneously. We propose a Synchronous Multi-Modal Fusion Module (SFM) which captures the inter-modal and intra-modal interactions between visual and linguistic modalities in a single step. Intra-modal interactions handle the cases for identifying the relevant set of words and semantically similar image regions. Inter-modal interactions transfer contextual information across modalities. Additionally, we propose a novel Hierarchical Cross-Modal Aggregation Module (HCAM) to exchange contextual information relevant to referent across visual hierarchies and refine the referred object's segmentation mask.

We motivate the benefits of simultaneous interactions over sequential in Figure 1 by presenting a failure case of the latter. For the given referring expression "anywhere, not on the people", sequential approaches fail to identify the correct word to be grounded, and the error gets propagated till the end. CMPC (Huang et al., 2020) which predicts the referent word from the expression in the first stage, identifies "people" as the referent (middle image in Figure 1) and completely misses "anywhere" which is the correct entity to ground. Similarly, (Yang et al., 2021), and (Hui et al., 2020), which utilize dependency tree structure to govern their reasoning process, identify the referred entity "anywhere" as an adverb from the dependency tree. However, considering the expression in context with the image, the word "anywhere" should be perceived as a "pronoun". The proposed SFM module successfully addresses the aforementioned limitations. Overall, our work makes the following contributions:-

1. We propose SFM to reason over regions, words, and region-word features in a synchronous manner, allowing each modality to focus on relevant semantic information to identify the referred object.
2. We propose a novel HCAM module, which routes hierarchical visual information through linguistic features to produce a refined segmentation mask.
3. We present thorough quantitative and qualitative experiments to demonstrate the efficacy of our approach and show notable performance gains on four RIS benchmarks.

2 Related Work

Referring Expression Comprehension: Localizing a bounding box/proposals based on an NLE is a task commonly referred to as Referring Expression Comprehension (REC). The majority of methods for REC learn a joint embedding space for visual and linguistic modalities and differ in how joint space is computed and how it is used. Earlier methods, (Hu et al., 2016b; Rohrbach et al., 2016; Plummer et al., 2018) used joint embedding space as a metric space to rank proposal features with linguistic features. Later methods like (Yang et al., 2019; Deng et al., 2018; Liu et al., 2020) utilized attention over the proposals to select the appropriate one. More Recent Methods like (Lu et al., 2019; Chen et al., 2020) utilize transformer-based architecture to project multi-modal features to common semantic space. Specifically, they utilize a self-attention mechanism to align *proposal-level features* with linguistic features. In our work, we utilize *pixel-level image features* which are crucial for the task of RIS. Additionally, compared to (Lu et al., 2019), we *explicitly* capture inter-modal and intra-modal interactions between visual and linguistic modalities.

Referring Image Segmentation: Bounding Box-based methods in REC are limited in their capabilities to capture the inherent shape of the referred object, which led to the proposal of the RIS task. It was first introduced in (Hu et al., 2016a), where they generate the referent's segmentation mask by directly concatenating visual features from CNN with tiled language features from LSTM. (Li et al., 2018) generates refined segmentation masks by incorporating multi-scale semantic information from the image. Since each word in expression makes a different contribution in identifying the desired object, (Shi et al., 2018) model visual context for each word separately using query attention. (Ye et al., 2019) uses a self-attention mechanism to capture long-range correlations between visual and textual

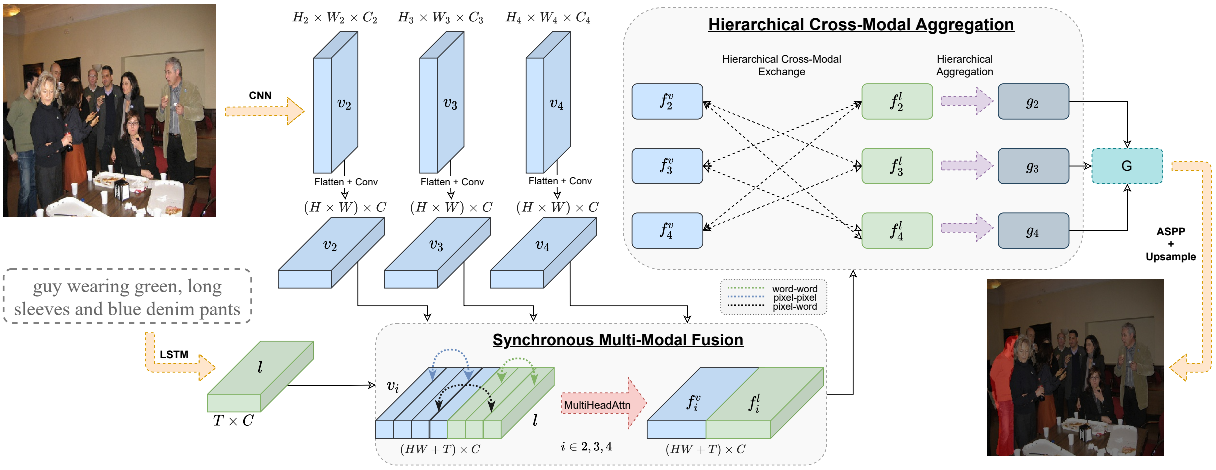


Figure 2: The proposed network architecture. Synchronous Multi-Modal Fusion captures pixel-pixel, word-word and pixel-word interaction. Hierarchical Cross-Modal Aggregation exchanges information across modalities and hierarchies to selectively aggregate context relevant to the referent.

modalities. Recent works (Hu et al., 2020; Huang et al., 2020; Hui et al., 2020) utilize cross-modal attention to model multi-modal context, (Hui et al., 2020; Yang et al., 2021) use dependency tree structure and (Huang et al., 2020) use coarse labelling for each word in the expression for selective context modelling. Most of the existing works capture Inter and Intra modal interactions separately to model the context for referent. In this work, we *concurrently* model the comprehensive interactions across visual and linguistic modalities.

3 Method

Given an image and a natural language referring expression, the goal is to predict a pixel-level segmentation mask corresponding to the referred entity described by the expression. The overall architecture of the network is illustrated in Figure 2. Visual features for the image are extracted using a CNN backbone, and linguistic features for the referring expression are extracted using a LSTM. A Synchronous Multi-Modal Fusion Module (SFM) simultaneously aligns visual regions with textual words and jointly reasons about both modalities to identify the multi-modal context relevant to the referent. SFM is applied to hierarchical visual features extracted from CNN backbone since hierarchical features are better suited for segmentation tasks (Ye et al., 2019; Chen et al., 2019; Hu et al., 2020). A novel Hierarchical Cross-Modal Aggregation module (HCAM) is applied to effectively fuse SFM's multi-level output and produce a refined segmentation mask for the referent. We describe the feature extraction process in the next section, and both SFM and HCAM modules are described in the subsequent sections.

3.1 Feature Extraction

Our network takes an image and a natural language expression as input. We extract hierarchical visual features for an image from a CNN backbone. Through pooling and convolution operations, all hierarchical visual features are transformed to the same spatial resolution and channel dimension. Final visual features for each level are of shape $\mathbb{R}^{C_v \times H \times W}$, with H, W and C_v being the height, width, and channel dimension of the visual features. Final visual features are denoted as $\{V_2, V_3, V_4\}$, corresponding to layers 2, 3 and 4 of the CNN backbone. For ease of readability, we denote the visual features as V. GloVe embeddings for each word in the referring expression are then passed as input to LSTM. The hidden feature of LSTM at i^{th} time step $l_i \in \mathbb{R}^{C_l}$, is used to denote the word feature for the i^{th} word in the expression. The final linguistic feature of the expression is denoted as $L = \{l_1, l_2, ..., l_T\}$, where T is the number of words in the referring expression.

3.2 Synchronous Multi-Modal Fusion

In this section, we describe the Synchronous Multi-Modal Fusion Module (SFM). To successfully segment the referent, we need to identify the semantic information relevant to it in both the visual and linguistic modalities. We capture comprehensive intra-modal and inter-modal interactions explicitly in a synchronous manner, allowing us to jointly reason about visual and linguistic modalities while considering the contextual information from both.

Hierarchical visual features $V \in \mathbb{R}^{C_v \times H \times W}$ and linguistic word-level features $L \in \mathbb{R}^{C_l \times T}$ are passed as input to SFM, with $C_v = C_l = C$. We flatten the spatial dimensions of visual features and perform a lengthwise concatenation with linguistic feature, followed by layer normalization to get multi-modal feature X of shape $\mathbb{R}^{C \times (HW+T)}$. We then add separate positional embedding P_v and P_l to visual $X_v \in \mathbb{R}^{C \times HW}$ and linguistic $X_l \in \mathbb{R}^{C \times T}$ part of X to distinguish between visual and linguistic part. Finally, we apply multi-head attention over X to capture the inter-modal and intra-modal interactions between visual and linguistic modalities. Specifically, pixel-pixel, word-word and word-pixel interactions are captured. Pixel-pixel and word-word interactions help in independently identifying semantically similar pixels and words in their respective modalities, pixel-word interaction helps in identifying corresponding pixels and words with similar contextual semantics across modalities.

$$\begin{aligned} X &= \text{LayerNorm}(V \odot L) \\ X &= X + (P_v \odot P_l) \\ F &= \text{MultiHead}(X) \end{aligned} \tag{1}$$

Here, $\odot$ is length-wise concatenation, F is the final output of SFM module having same shape as X. We process all hierarchical visual features $\{V_2, V_3, V_4\}$ individually through SFM, resulting in hierarchical cross-modal output $\{F_2, F_3, F_4\}$.

3.3 Hierarchical Cross-Modal Aggregation

Hierarchical visual features of CNN capture different aspects of images. As a result, depending on the hierarchy, visual features can focus on different aspects of the linguistic expression. In order to predict a refined segmentation mask, different hierarchies should be in agreement regarding the image regions to focus on. Therefore, all visual hierarchical features should also focus on image regions corresponding to linguistic context from other hierarchies. This will ensure that all hierarchical features are focusing on common regions. We propose a novel Hierarchical Cross-Modal Aggregation (HCAM) module for this purpose. HCAM includes two key steps: (1) **Hierarchical Cross-Modal Exchange**, and (2) **Hierarchical Aggregation**. Both steps are illustrated in Figure 3.

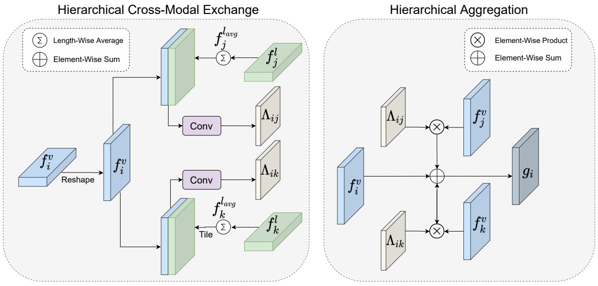

Figure 3: Our Novel Hierarchical Cross-Modal Aggregation Module consisting of Hierarchical Cross-Modal Exchange and Hierarchical Aggregation steps.

Hierarchical Cross-Modal Exchange: During the HCME step, we calculate the affinity weights Λ_{ij} between the j^{th} layer's linguistic context f_j^l and the spatial regions for i^{th} layer's visual features f_i^v, where f_i^v and f_i^l are the visual and linguistic part of i^{th} layer's output of SFM F_i.

$$\Lambda_{ij} = \sigma(Conv([f_i^v; f_j^{l_{avg}}])) \tag{2}$$

Here $\Lambda_{ij} \in \mathbb{R}^{C \times H \times W}$, $f_j^{l_{avg}} \in \mathbb{R}^C$ is the global linguistic context for j^{th} layer and is computed as length-wise average of linguistic features f_j^l, σ is the sigmoid function. Here, $f_j^{l_{avg}}$ act as a bridge to route linguistic context from j^{th} layer to spatial regions of i^{th} layer's visual hierarchy. Similarly, Λ_{ik} is computed with $i \neq j \neq k$, allowing for cross-modal exchange between all permutations of visual and linguistic hierarchical features.

Hierarchical Aggregation: After computing the affinity weights Λ_{ij}, we perform a layer-wise contextual aggregation. For each layer, visual context from other hierarchies is aggregated in the following way:

$$\begin{gathered} g_i = f_i^v + \sum_{j \neq i} \Lambda_{ij} \circ f_j^v \\ G = Conv3D([g_2; g_3; g_4]) \end{gathered} \tag{3}$$

Here, $\circ$ is element-wise product and $[;]$ represents stacking features along length dimension, ie:- $\mathbb{R}^{3 \times C \times H \times W}$ dimensional feature. $g_i \in \mathbb{R}^{C \times H \times W}$ contains the relevant regions corresponding to the linguistic context from the other two hierarchies. Finally, we use 3D convolution to aggregate g_i's to include the common regions corresponding to the linguistic context from all visual hierarchies. G is the final multi-modal context for referent.

3.4 Mask Generation

Finally, G is passed through Atrous Spatial Pyramid Pooling (ASPP) decoder (Chen et al., 2018) and Up-sampling convolution to predict final segmentation mask S. Pixel-level binary cross-entropy loss is applied to predicted segmentation map S and the ground truth segmentation mask Y to train the entire network end-to-end.

4 Experiments

4.1 Experimental Setup

We conduct experiments on four Referring Image Segmentation datasets. **UNC** (Yu et al., 2016) contains 19,994 images taken from MS-COCO (Lin et al., 2014) with 142,209 referring expressions corresponding to 50,000 objects. Referring Expressions for this dataset contain words indicating the location of the object. **UNC+** (Yu et al., 2016) is also based on images from MS-COCO. It contains 19,992 images, with 141,564 referring expressions corresponding to 50,000 objects. In UNC+, the expression describes the object based on their appearance and context within the scene without using spatial words. **G-Ref** (Mao et al., 2016) is also curated using images from MS-COCO. It contains 26,711 images, with 104,560 referring expressions for 50,000 objects. G-Ref contains longer sentences with an average length of 8.4 words; compared to other datasets which have an average sentence length of less than 4 words. **Referit** (Kazemzadeh et al., 2014) comprises of 19,894 images collected from IAPR TC-12 dataset. It includes 130,525 expressions for 96,654 objects. It contains unstructured regions (e.g., sky, mountains, and ground) as ground truth segmentations.

4.2 Implementation details

We experiment with two backbones, DeepLabv3+ (Chen et al., 2018) and Resnet-101 for image feature extraction. Like previous works (Ye et al., 2019; Chen et al., 2019; Hu et al., 2020), DeepLabv3+ is pre-trained on Pascal VOC semantic segmentation task while Resnet-101 is pre-trained on Imagenet Classification task, and both backbone's parameters are fixed during training. For multi-level features, we extract features from the last three blocks of CNN backbone. We conduct experiments at two different image resolutions, 320×320 and 448×448 with $H = W =$ 18. We use GLoVe embeddings (Pennington et al., 2014) pre-trained on Common Crawl 840B tokens to initialize word embedding for words in the expressions. The maximum number of words in the linguistic expression is set to 25. We use LSTM for extracting textual features. The network is trained using AdamW optimizer with batch size set to 50; the initial learning rate is set to $1.2e^{-4}$ and weight decay of $9e^{-5}$ is used. The initial learning rate is gradually decreased using polynomial decay with a power of 0.7. We train our network on each dataset separately.

Evaluation Metrics: Following previous works (Ye et al., 2019; Chen et al., 2019; Hu et al., 2020), we evaluate the performance of our model using overall Intersection-over-Union (overall IoU) and Precision@X as metrics. Overall IoU metric calculates the ratio of the intersection and the union computed between the predicted segmentation mask and the ground truth mask over all test samples. Precision@X metric calculates the percentage of test samples having IoU greater than the threshold X, with $X \in \{0.5, 0.6, 0.7, 0.8, 0.9\}$.

4.3 Comparison with State of the Art

We evaluate our method's performance on four benchmark datasets and present the results in Table 1. Since three of the datasets are derived from MS-COCO and have significant overlap with each other, pre-training on MS-COCO can give misleading results and should be avoided. Hence, we only compare against methods for which the backbone is pre-trained on Pascal VOC. Unless specified, all the approaches in Table 1 are at 320×320 resolution. Our approach, SHNet (SFM+HCAM), achieves state-of-the-art performance on three datasets without post-processing. In contrast, most previous methods present results after post-processing through a Dense Conditional Random Field (Dense CRF).

The expressions in UNC+ avoid using positional words while referring to objects; instead, they are more descriptive about their attributes and relationships. Consistent performance gains on the UNC+ dataset at all splits showcases the effectiveness of utilizing comprehensive interactions simultaneously across visual and linguistic modalities. Similarly, our approach gains 1.68% over the next best performing method EFN (Feng et al., 2021) on the Referit dataset, reflecting its ability to ground unstructured regions (e.g., the sky, free space). We also achieve solid performance gains on the UNC dataset at both resolutions, indicating that our method can effectively utilize the positional

Method	UNC			UNC+			G-Ref	Referit

8	SHNet	**75.18**	**69.36**	**61.21**	**46.16**	**16.23**	**63.98**

Table 2: Ablation Studies on Validation set of UNC, SHNet is the full architecture with both SFM and HCAM modules. The input image resolution is 320 × 320 in each case.

words to localize the correct instance of an object from multiple ones. EFN (Feng et al., 2021) (underlined in Table 1) gives the best performance on G-Ref dataset; however, it is fine-tuned on the UNC pre-trained model. With similar fine-tuning, SHNet achieves 56.44% overall IoU, surpassing EFN by a large margin. However, such an experimental setup is incorrect, as there is a significant overlap between G-Ref test and UNC training set. Hence, in Table 1 we report performance on a model trained on G-Ref from scratch. Performance of SHNet is marginally below BusNet on the G-Ref dataset. Feature maps in SHNet have a lower resolution of 18 × 18 compared to 40 × 40 resolution used by other methods and that possibly leads to a drop in performance on G-Ref, which has extremely small target objects. We could not train SHNet on higher resolution feature maps due to memory limits induced by multi-head attention (on RTX 2080Ti GPU); however, training on higher resolution input improves results.

4.4 Ablation Studies

We perform ablation studies on the UNC dataset's validation split. All methods are evaluated on Precision@X and Overall IoU metrics, and the results are illustrated in Table 2. Unless specified, the backbone used for ablations is DeepLabv3+ trained at 320 × 320 resolution. The feature extraction process described in Section 3.1 is used for all ablation studies. ASPP + ConvUpsample decoder is also common to all the experiments.

Baseline: The baseline model involves direct concatenation of visual features with the tiled textual feature to result in multi-modal feature of shape $\mathbb{R}^{(C_v+C_l)\times H\times W}$. This multi-modal feature is passed as input to ASPP + ConvUpsample decoder.

HCAM without SFM: “Only HCAM" network differs with baseline method only on the fusion process of hierarchical multi-modal features. Introducing the HCAM module over baseline results in 4.83 % improvement on the Overall IoU metric and an improvement of 2.5 % on the $prec$@0.9 metric (illustrated in Table 2), indicating that the HCAM module results in refined segmentation masks.

SFM without HCAM: Similarly, the “Only SFM" network differs from the baseline method in how different types of visual-linguistic interactions are captured. We observe significant performance gains of 7.46 % over the baseline, indicating that simultaneous interactions help identify the referent.

SFM + X: We replace HCAM module with other multi-level fusion techniques like ConvL-

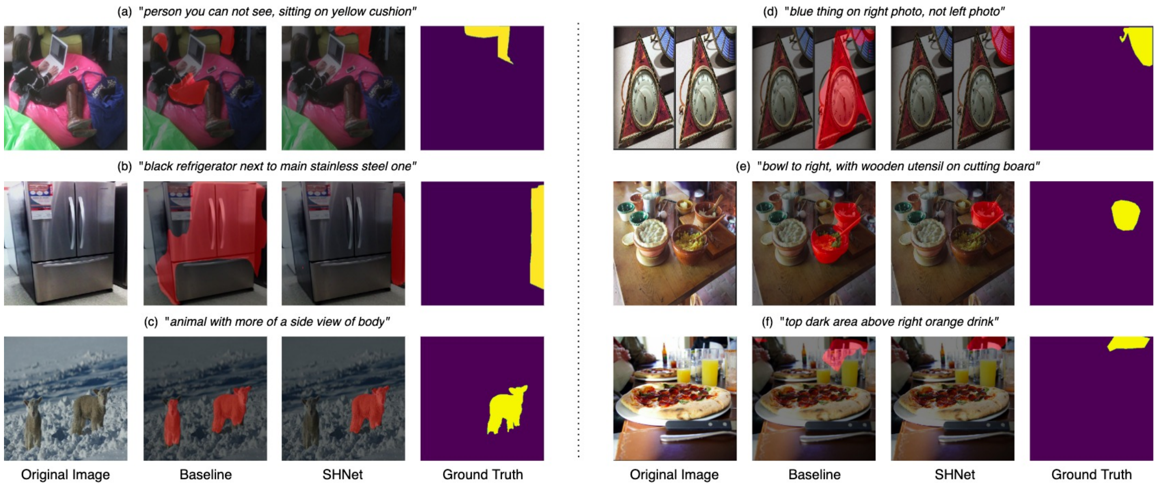

Figure 4: Qualitative results comparing the baseline against SHNet.

(a) Original Image (b) Only HCAM module (c) Only SFM module (d) SHNet (e) Ground Truth

Figure 5: Qualitative results corresponding to combinations of proposed modules. In (b) we show results when only HCAM module is used, (c) result with only SFM module being used, (d) output mask when both SFM and HCAM modules are used

STM and Conv3D. Comparing the performance of SFM+ConvLSTM with SHNet (SFM+HCAM), we observe that HCAM is indeed effective at fusing hierarchical multi-modal features (Table 2). For SFM+Conv3D, we stack multi-level features along a new depth dimension resulting in 3D features, and perform 3D convolution on them. The same filter is applied to different level features that result in each level feature converging on a common region in the image. SFM+Conv3D achieves a similar performance as SFM+ConvLSTM while using fewer parameters. Using Conv3D achieves higher Precision@0.8 and Precision@0.9 than ConvLSTM, suggesting that it leads to more refined maps. It is worth noting that HCAM also uses Conv3D at the end, and the additional gains of SHNet over SFM+Conv3D suggest the benefits of hierarchical information exchange in HCAM.

Glove and Positional Embeddings: We verify Glove embeddings' significance by replacing it with one hot embedding. We also validate the usefulness of Positional Embeddings (P.E.) by training a model without them. Both variants observe a drop in performance (Table 2), with the drop being more significant in the variant without Glove embeddings. These ablations suggest the importance of capturing word-level semantics and positional-aware features.

In Table 3, we present ablations with different backbones at different resolution. The results demonstrate that our approach does not heavily rely on backbone for its performance gains, as even with a vanilla Imagenet pre-trained Resnet101 backbone, not fine-tuned on segmentation task, we outperform existing methods at both resolutions. Predictably, using a backbone fine-tuned on a segmentation task gives further performance gain.

backbone	resolution	val	testA	testB
Resnet101	320 x 320	63.76	67.05	60.15
	448 x 448	64.88	68.08	60.82
DeepLabv3+	320 x 320	63.98	67.51	60.48
	448 x 448	65.29	68.56	62.04

Table 3: Result with different backbone at different input resolutions on UNC dataset.

We also present ablations with different aggregation modules in Table 4. We use the modules presented in MGATE (Ye et al., 2019), TGFE (Huang

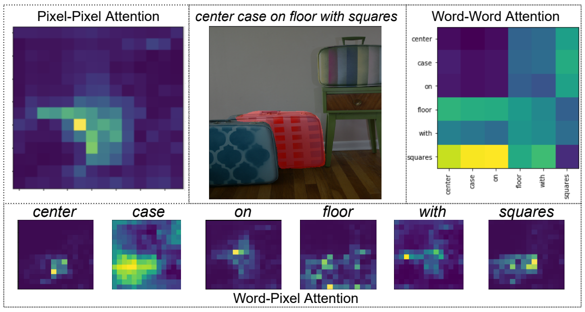

Figure 7: Visualization of Inter-modal and Intra-modal interactions in SFM.

et al., 2020) and GBFM (Hui et al., 2020), for which codes were publicly available. HCAM consistently outperforms other methods by clear margins at both resolution.

4.5 Qualitative Results

Figure 4 presents qualitative results comparing SHNet against the baseline model. SHNet localizes heavily occluded objects (Figure 4 (a) and (b)); reasons on the overall essence of the highly ambiguous sentences (e.g. “person you cannot see", “right photo not left photo") and; distinguishes among multiple instances of the same type of object based on attributes and appearance cues (Figure 4 (b), (c), and (e)). While, without any reasoning stage, the baseline model struggles to segment the correct instance and confuse it with similar objects. Figure 4 (d) and (f) illustrate the ability of SHNet to localize unstructured non-explicit objects like “dark area" and “blue thing". The potential of SHNet to perform relative positional reasoning is highlighted in Figure 4 (b), (e), and (f).

We outline the contributions of both SFM and HCAM modules in Figure 5. “Only HCAM" network does not involve any reasoning, however, it manages to predict the left sandwich with refined boundaries. “Only SFM" network understands the concept of “the right half of the sandwich" and leads to much better output; however, the output mask bleeds around the boundaries, and an extra small noisy segment is visible. The full model benefits from the reasoning in “SFM," and when combined with HCAM facilitates information exchange across hierarchies to predict correct refined mask as output. In Figure 6, we anchor an image and vary the linguistic expression. SHNet is able to reason about different linguistic expressions successfully and ground them. Inter-modal and Intra-modal interactions captured by SFM are illustrated in Figure 7. Pixel-pixel interactions highlight image regions corresponding to the referent. For the given expression, “squares" contains the differentiating information and is assigned high importance for different words. Additionally, for each word appropriate region in the image is attended.

Additional qualitative examples with success and failure cases are provided in the supplementary material.

5 Conclusion

In this work, we tackled the task of Referring Image Segmentation. We proposed a simple yet effective SFM to capture comprehensive interactions between modalities in a single step, allowing us to simultaneously consider the contextual information from both modalities. Furthermore, we introduced a novel HCAM module to aggregate multi-modal context across hierarchies. Our approach achieves strong performance on RIS benchmarks without any post-processing. We present thorough quantitative and qualitative experiments to demonstrate the efficacy of all the proposed components.
