The articulation of mathematical arguments is a fundamental part of scientific reasoning and communication. Across many scientific disciplines, expressing relations and inter-dependencies between quantities is at the centre of its argumentation. One of the particular linguistic elements used for such argumentation is *variables*: they are essential for expressing complex mathematical ideas, allowing scientists to refer to a set of values compactly and rigorously. Given the essential nature of variables, models that perform inference over scientific and mathematical text should be able to meaningfully represent and leverage such elements to understand mathematical language and improve downstream inference performance.

While there is still debate on a universally accepted definition for variables, their functional aspects within mathematical text are well established. A variable is usually defined as a symbol standing as a referent for a set consisting of at least two elements (Philipp, 1992). Given their nature of abstract and dynamic referents, two aspects make the representation of variables particularly challenging in the field of NLP: (i) The meaning of a variable is exclusively determined by its context (Schoenfeld and Arcavi, 1988), a variable carries no meaning when considered in isolation, behaving unlike any word in English; (ii) The same variable symbol (e.g., the variable x) can be reused in an unlimited number of sentences and expressions, possibly assuming different meanings and referring to different sets of values while keeping the same name. While a similar problem can also be found for the representation of words (i.e., word sense disambiguation), the scale of ambiguity is more marked, due to the fact that variable names, unlike words, are not grounded a priori to any particular set of concepts.

In order to understand mathematical text, the meaning of variables (i.e., their type) needs to be implicitly or explicitly inferred at some point from the text. Identifying and qualifying the binding between variables and their types, therefore, is crucial for reasoning with mathematical text, given that any form of inference on a variable is fundamentally constrained by the possible values it can take, and those values are uniquely determined by its type. For example, we can only correctly predict the entailment between two sentences containing variables if we infer their types beforehand.

As a benchmark for variable comprehension in mathematical text, the variable typing task (Stathopoulos et al., 2018) requires finding the connections between variables and their respective types in a sentence. Despite its importance for scientific inference, the task is still widely unex-

Findings of the Association for Computational Linguistics: ACL 2022, pages 938 - 948
May 22-27, 2022

plored. Most of the existing work focusing on the representation of mathematical elements, in fact, has been carried out in a non-textual setting, where the mathematical elements are represented independently from any textual content (Aizawa and Kohlhase, 2021). While some expressions and formulas are universal enough to be encoded without context (e.g., Pythagoras theorem), variables have no meaning in isolation and different symbols can be arbitrarily chosen to indicate variables with the same meaning. Therefore, an important principle for designing and evaluating a variable representation is that such a representation should be agnostic to the specific symbols adopted as referents in the text – i.e., the variable names. This is because the variable names contained in a generic passage can be opportunely renamed without altering the sentences' meaning. For instance, a robust variable representation should be able to encode the sentences "Let x be an integer" and "Let y be an integer" in exactly the same way, if they are inserted in the same context.

However, while this characteristic seems to be intrinsic in the nature of variables, it has been largely ignored by current evaluation frameworks, where there is no agnostic way to verify the quality of the generated variable representation independently of their surface form. To move a step forward towards more robust and generalisable representations, this work proposes a new testing and modelling framework based on the property of *generalisation to variable renaming*. Specifically, we define a model to be generalisable to variable renaming if the model's performance does not decrease when renaming variables in the test set with variable names never seen during training. Through testing such a property, since the renaming of variables does not alter the context or meaning of the sentences, we are verifying whether the context is correctly moulding the variable encoding and, at the same time, whether the performance is not due to overfitting to the surface form of the text.

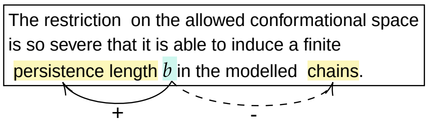
To address and study generalisation to variable renaming, this work proposes **VarSlot** (Variable Slot), a model for variable typing that represents variables in a surface agnostic way. To achieve a generalisable representation, VarSlot initialises variables as blank slots and employs a multi-slot mechanism, extending from slot attention (Locatello et al., 2020), to iteratively specialise the representation. Specifically, VarSlot leverages self-attention to conform the representation of each variable to its context (i.e., its surrounding words and other variables), where each surrounding element has a different influence on the final representation. Experiments adopting VarSlot to extend sentence embeddings based on Transformers (Devlin et al., 2019) demonstrate not only that the proposed framework is able to achieve state-of-the-art results on the variable typing task, but also, in contrast with previous work, that VarSlot allows for better generalisation to variable renaming. To the best of our knowledge, this is the first work that focuses on generalisation and robustness for variable representation in mathematical text, providing, at the same time, a critical analysis of large language models (LLMs) targeting the scientific domain. To summarise, the contributions of this paper are as follows:

- We propose a new evaluation framework for testing the property of generalisation to variable renaming;
- We systematically analyse the understanding of variables in large language models, demonstrating their limitations when handling variable renaming;
- We propose a state-of-the-art model for the variable typing task, demonstrating, at the same time, that it significantly outperforms large language models when analysing the property of generalisation to variable renaming;

2 Variable Typing problem

This work follows the same definition of a variable used in (Stathopoulos et al., 2018), considering as variables *simple expressions* composed of a single, possibly scripted, base identifier. The *variable typing task* requires the assignment between variables in the sentence and its respective types. We use the same setting as (Stathopoulos et al., 2018) for this task: given a sentence s with a pre-identified set of variables V and types T, the task is defined as a binary classification of all edges $V \times T$, where a positive edge means that the variable is assigned that type and negative otherwise. Figure 1 introduces an example of a mathematical statement, containing one variable b with type *persistence length*. The edge linking to this type is a positive one, while the one linking to type *chains* is a negative edge.

While the task carries some similarity to two other well-known tasks in NLP, *Coreference Res-*



The restriction on the allowed conformational space is so severe that it is able to induce a finite persistence length b in the modelled chains.

Figure 1: Example of a mathematical statement containing one variable. This example shows two different edges (variable→type), with a positive and a negative binding.

olution and *Relation Extraction*, there are some fundamental differences. Variables have a particular behaviour, where there is a disconnection between the variable name and its meaning. Also, the variable typing task mainly involves intra-sentence dependencies and does not rely on a predicate-argument relation.

3 Our Approach: Variable Slots (VarSlot)

Following the recent literature (Stathopoulos et al., 2018), this work frames the variable typing problem as binary classification, where each variable is tested against all possible types. Given a sentence s from a mathematical text containing known variables $V = \{v_1, v_2, \ldots, v_{n_v}\}$ and types $T = \{t_1, t_2, \ldots, t_{n_t}\}$, VarSlot aims at finding a function such that $f(v_i, t_j) = 1$ if v_i has type t_j and $f(v_i, t_j) = 0$ otherwise. In this section we detail our approach, **VarSlot**, illustrated in Figure 2.

3.1 From types and expressions to hypotheses

A novel framing for the variable typing problem is proposed in this work. Instead of treating sentences, types and variables as different features of the problem (Stathopoulos et al., 2018), each sentence s_i is converted to a set of hypotheses $H_{s_i} = \{h_{(v_1,t_1)}, h_{(v_1,t_2)}, \ldots, h_{(v_{n_v},t_{n_t})}\}$ of size $n_v \times n_t$ by adding to the end of the sentence, the following phrase: "Then [variable] is of type [type]" where *variable* and *type* are replaced by the ones being evaluated at that instance. For example, if one wants to test if the variable x is of type *integer* in the sentence "Let x be an integer and y be a real", it can be converted to a hypothesis by adding "Then x is of type *integer*" after the initial sentence. This modification will allow our approach to leverage pre-trained sentence encoders, obtaining enriched representations.

3.2 Encoding the sentences

Previous research has shown that LLMs struggle to understand concepts such as numeracy (Spithourakis and Riedel, 2018) and solving math word problems (Piękos et al., 2021), but there is still no research on the representation of variables inside the mathematical text for such models, despite their higher performance for different inference tasks (Rogers et al., 2020).

We hypothesise that it is possible to leverage pre-trained sentence representations to obtain an initial encoding for each hypothesis. By using an encoder, each hypothesis h of size N is mapped to a representation $E \in \mathbb{R}^{N \times D}$, where each token is assigned a vector of size D, regardless of being a variable or a word. At this point, the representation is unable to distinguish between both modalities of elements.

3.3 Representing Variables with Multi-Slots

Variables represent a set of possible values, acting as a place-holder element for any possible value inside that set (Schoenfeld and Arcavi, 1988). This set of values is attached to the type corresponding to that variable; for example, if a variable is typed as an integer, we expect it to take values from that set only. A variable with the symbol x can refer to completely different sets depending on its context. Therefore, when representing a variable, its *surface form* (or symbol) should not interfere with its representation; the semantics of the variable should be guided exclusively by the defined type. We aim to approximate this behaviour by representing each variable using slots (Locatello et al., 2020). Slots use a common representational format, where each slot can store any object from the input, rendering it a suitable candidate for obtaining a latent representation of variables since the same variable name can take many different contexts and possible types. We extend previous work by designing an approach that combines the representations obtained from different slots (multi-slot).

Given a hypothesis $h_{(v_i,t_j)}$ containing the variables $V = \{v_1, \ldots, v_{n_v}\}$, a pre-trained sentence embedding is used to obtain a representation E for this hypothesis. In order to obtain a representation that can better distinguish from symbol and abstraction of the variables, we generate a new representation $E_{(v_i-)} \in \mathbb{R}^{N \times D}$ for each variable in the sentence, where the vectors representing the variables are all replaced by zeroes. For each variable, the representation obtained from the encoder is dropped, preserving only the other tokens. This step allows our model to learn the representation of

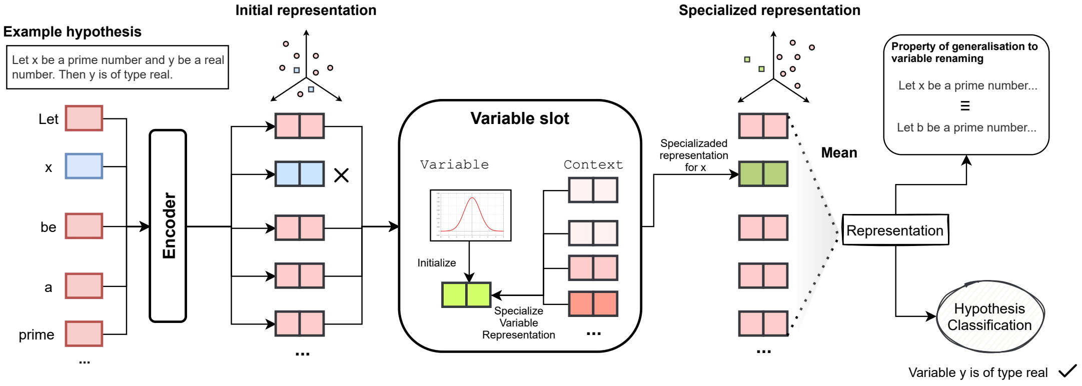


Figure 2: Our model takes as input a statement containing words and variables. These tokens are encoded using a pre-trained language model. Then, the variables' representation is enriched using slot attention. The final representation is obtained as the mean of all tokens. In the end, we obtain the classification of the hypothesis.

the variables based on their context and abstraction, diminishing the weight from its surface features.

A representation $e_{(v_i)} \in \mathbb{R}^D$ is obtained for each variable through iterative Scaled Dot-Product Attention. First, in order to obtain an initial representation, we initialise $e_{(v_i)}$ by sampling from a Gaussian distribution $\mathcal{N}(\mu, \sigma)$, with learnable parameters $\mu \in \mathbb{R}^D$ and $\sigma \in \mathbb{R}^D$. This will generate an empty slot, which will be iteratively conformed into a representation for the variable v_i.

Previous work has shown that having a separated representation for mathematical elements and words can be beneficial for performing inference over mathematical text (Ferreira and Freitas, 2021). We hypothesise that allowing our model to learn a new representation for variables will naturally separate it from other elements.

We apply the linear transformation k and v over $E_{(v_i-)}$ and q over $e_{(v_i)}$ to compute the Scaled Dot-Product Attention (Vaswani et al., 2017):

$$\texttt{Att} = \texttt{softmax}(\frac{q(e_{(v_i)})k(E_{(v_i-)})^T}{\sqrt{D}})v(E_{(v_i-)}) \tag{1}$$

The obtained attention is applied to a Gated Recurrent Unit (Cho et al., 2014) with hidden size D and transformed with a multi-layer perceptron (MLP) with ReLU activation in order to obtain the new value for $e_{(v_i)}$. This process is repeated for T iterations, for each variable in the sentence.

After obtaining the representation for each variable $e_{(v_i)}$, we need to match it again with the original representation. This is achieved by mapping the obtained variable representations to their original positions in $E_{(v_i-)}$. The final matrix is encoded by a BiLSTM layer, obtaining a final enriched representation $\mathcal{E}$ for the sentence. The algorithm describing this process can be found in Appendix C.

3.4 Classifying hypotheses

Finally, we obtain a representation for the hypothesis as a single vector of dimension D by computing the mean over the rows of $\mathcal{E}$. In order to obtain the classification for each hypothesis, we use a final linear layer, with as training objective function the *Binary Cross-Entropy Loss*.

4 Experiments

This section presents the experiments performed to evaluate the performance of VarSlot for the variable typing task. The models and datasets used are made available in our repository[1]. As the encoder for the model, we use the Sentence Transformers (Reimers and Gurevych, 2019) version of SciBERT (Beltagy et al., 2019) pre-trained for NLI tasks (SciBERT-NLI)[2]. We compare our approach with previous research and standard pre-trained language models. The evaluation is conducted in two different settings:

1. **Classic Variable Typing**: This setting represents the canonical evaluation of variable typing task, as it was initially described in (Stathopoulos et al., 2018).
2. **Variable Typing with Renaming**: In order to evaluate the model's ability to abstract from the surface form of the variables and generalise to variable renaming, we replace all the

---

[1] Anonymous repository.

[2] The model `gsarti/scibert-nli` from Hugging Face is used.

variables in the test set with new symbols, unseen in the Train and Dev set without modifying the sentence's meaning.

4.1 Dataset

The dataset used in this work to evaluate the performance of the proposed model is the Variable Typing Dataset (Stathopoulos et al., 2018). This dataset was manually curated and annotated from mathematical statements contained in scientific papers.

For the **Renaming** setting, the Train and Dev set is the same as the previous setting, but the Test set contains only variable names in the format $x_1, x_2, x_3, ..., x_n$. The Test set in both settings has the same hypotheses with identical semantic meaning but different variable names. For example, the fragment "Let b be ..." becomes "Let x_1 be ..." in the Renaming setting. For reproducibility purposes, we make this expanded dataset available in our repository.

4.2 Baselines

We compare our approach to the following models:

- **(Stathopoulos et al., 2018)**: This architecture is based on a Bidirectional LSTM. The model uses one string feature, which is referred to as *supertype*. If the token is a type, then this feature is the string key of the embedding vector of its supertype or *NONE* otherwise. These features are mapped to a separate embedding space and then concatenated with the word embedding to form a single task-specific word representation.
- **BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), SciBERT (Beltagy et al., 2019) and MathBERT (Peng et al., 2021)**: To assess the understanding of variables in pre-trained language models, we use the mentioned models as baselines for the Variable Typing task. For all models we use the `base` and `uncased` version. The models are fine-tuned as a classic NLI model, using a `[SEP]` token to separate the original sentence with our new typing sentence. All models are fine-tuned with batch size of 32, for 10 epochs. The full list of used hyper-parameters can be found in the Appendix A.

4.3 Quantitative results

We present the results for the Variable Typing task in both the classic setting (Table 1) and the renaming setting (Table 2). We include here our approach with $T = 3$ and $T = 2$. We will start our discussion with the results from the classic setting and then move to the renaming setting.

4.3.1 Classic Setting

Considering first the classic setting (Table 1), we can observe that both BERT and RoBERTa achieve good results, outperforming the approach proposed by (Stathopoulos et al., 2018), which was designed explicitly for variable typing and uses specific typing embedding. Such performance does not come as a surprise since, as discussed previously, variable typing carries some similarity to tasks that these models have excelled in the past. However, such performance does not imply that these models have a good understanding of the meaning of variables; most likely, they are leveraging the syntactic knowledge they possess to connect types and variables.

Model	**Test (Classic)**		
	P	**R**	**F1**
Stathopoulos et al. (2018)	83.10	74.70	78.90
BERT	77.8	82.98	80.31
RoBERTa	82.32	80.13	81.21
MathBERT	81.85	73.76	77.59
SciBERT	77.26	87.54	82.08
VarSlot (T=3)	83.18	81.36	**82.26**
VarSlot (T=2)	83.95	79.08	81.44

Table 1: Comparison of our approach with different baselines for Variable Typing for classic setting. We present the values for precision (P), recall (R) and F1-score.

MathBERT and SciBERT are models specialised in scientific and mathematical knowledge. While SciBERT is pre-trained using corpora from several scientific disciplines, MathBERT was exclusively trained on mathematical text. We initially expected both models to excel on this task since they have been previously exposed to mathematical notation. However, as seen from our results, MathBERT was the worst-performing model from our baselines, while SciBERT was the best performing one. While we cannot establish the reasons for MathBERT's lower performance, since this is outside the scope of this work, we hypothesise that training a model with a large amount of mathematical notation without explicitly designing an encoding which reflects its abstract semantics can be damaging to a model's performance. For example, many variable names are reused across different mathematical disciplines, and as we will see in the renaming setting, most models cannot abstract variable meaning from their surface form. SciBERT has been exposed to a smaller mathematical corpus, and usually inside non exclusively mathematical contexts (e.g., computer science papers). Therefore, it is able to achieve higher performance. Given the results obtained from SciBERT, we decided to use the Sentence-Transformers version of this model as our encoder.

We can see that for $T = 3$, VarSlot can outperform all of the models for the classic setting. Even though VarSlot uses SciBERT as part of its model, we can still see an improvement when combining it with multi-slots. For $T = 2$ we still obtain competitive results, being outperformed only by SciBERT.

4.3.2 Renaming setting

In this setting (Table 2), we have the same sentences as in the previous setting, but the variables in the Test split have now different names. Considering the semantic of variables, the previous results should not change, considering the sentence's meaning remains untouched; only the surface of the variables have been altered. However, the obtained results prove otherwise. For all the approaches, there is a decrease relative to the results obtained in the classic setting. Such results hint at the fact that the models still do not encode the expected variable behaviour.

Model	Test (Renaming)				Average (C+R)
	P	**R**	**F1**	**Decrease**	**F1**
BERT	54.00	78.23	63.89	20.44%	72.1
RoBERTa	55.43	68.34	61.21	24.62%	71.21
MathBERT	54.37	44.29	48.82	37.07%	63.21
SciBERT	30.25	93.15	45.67	44.35%	63.88
VarSlot (T=3)	60.86	73.47	66.58	19.06%	74.42
VarSlot (T=2)	69.80	79.04	**71.86**	**11.76%**	**76.65**

Table 2: Results for VarSlot and baselines for Variable Typing for renaming setting. We include here also the decrease in score relative to the classic setting and the average score for both classic and renaming setting.

Looking at the obtained results, we can notice that the results obtained using SciBERT suffers from a more remarkable decrease, with a 44.35% (82.08→45.67) decrease in performance for this new setting, even though it was the best performing model for the previous setting. These results hint that SciBERT is overfitting to the names of the variables instead of abstracting from its symbols and adapting from context. A significant decrease can also be seen for MathBERT. The best performing baseline for this setting is BERT, which is likely, as previously mentioned, using syntactical cues to obtain the correct types.

We can see that VarSlot with $T = 2$ is more robust to this transition, having a less prominent decrease when compared to the other results (81.44→71.86), while we see a slight larger decrease for $T = 3$. The results suggest that our model better understands the difference in behaviour between variables and words and the surface agnostic aspect of variables, not over-fitting as much as the baselines for names of the variables. The results also hints that our model can correctly obtain the meaning of the variables from the context.

4.4 Robustness to substitution

In a more practical scenario, a model should harmonise a combination of the classic and renaming settings. During inference time, a mixture of seen and unseen variables is likely to be present. In this section, we evaluate the robustness of the model for the duplication of hypotheses with substituted variable names.

We add n repetitions of the same hypothesis in the test set for this experiment but with different variable names. For $n = 0$, the Test set is the same as the classic setting. For $n > 0$, we follow the same procedure as the renaming setting; however, we change the letter being used when adding more repetitions. For instance, for $n = 1$ the variables have format $x_{[variable\_index]}$, while for $n = 2$ we use the format $y_{[variable\_index]}$. For $n = 10$, we will have the same hypothesis appear ten times, but all with different variable names.

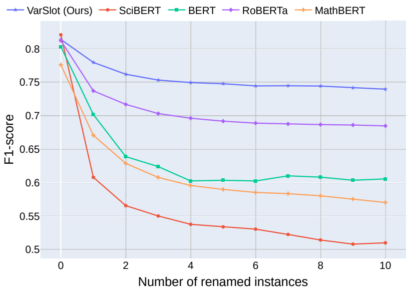

Figure 3: F1 score obtained for different models when adding the same hypotheses with different variable name substitutions.

This test allows us to compare the robustness of each model to the addition of different variables names. Figure 3 presents the performance of the different models in this task, considering the F1 score and number of added substitutions n. For $n = 0$ the results are the same as the ones present in Table 1.

We can observe that all the models suffer degradation in the performance as we add more duplicated modified hypotheses. While the models start at a close point, we can notice that as we increase the value of n, the gap between the proposed approach and the others models increases. Again, we note a big decrease in SciBERT's performance. The performance obtained for VarSlot shows how using multi-slots for representation of variables can increase the robustness of the model for variable name substitution through the test set.

4.5 Ablation Studies

In order to establish what components are impacting on VarSlot comprehension of variables, we perform different ablation studies. Table 3 presents the F1 score for different tests. The first row shows the results for considering only the encoder of our approach (SciBERT-NLI), removing the enriched variable representations and fine-tuning for the classification task. We can notice that our approach improves on top of the sentence representation, with significantly better results on the Renaming setting, showing that multi-slots plays a crucial role on that task.

Ablation	**Classic**	**Renaming**
1. Encoder only (SciBERT-NLI)	80.92	58.88
2. Encoder only (BERT-NLI)	80.67	66.63
3. Using BERT-NLI as encoder	81.24	69.19
4. VarSlot ($T = 1$)	79.52	68.03
5. VarSlot ($T = 2$)	81.44	**71.86**
6. VarSlot ($T = 3$)	**82.26**	66.58
7. VarSlot ($T = 4$)	80.42	65.88

Table 3: Comparison of our approach for the different settings.

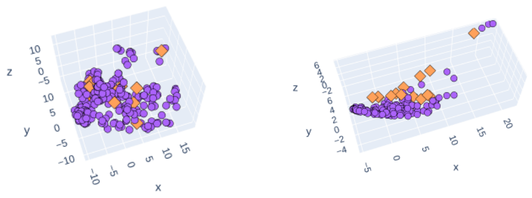
We also tested the generalisability of our approach to different encoders. Row 2 presents the results for the hypothesis classification only using BERT-NLI[3], and Row 3 presents our approach combined with BERT-NLI. We found that by using BERT-NLI instead of SciBERT-NLI for encoding our hypothesis, we could still observe an increase in performance for both classic and renaming settings. The proposed model consistently increases the understanding of variables for different sentence representation models.

The number of iterations T can also have an impact on the generalisation abilities of VarSlot. Rows 4-7 presents how its performance changes as the number of iterations increases. We can notice that we can obtain best results for the renaming setting with $T = 2$, while the best performance for the classic setting comes for $T = 3$. Our model requires a few iterations to conform the variable representation into the correct shape. When adding more iterations, VarSlot is more likely to overfit, leading to a degradation in performance with increasing number of iterations.

4.6 Qualitative Analysis

Previous work (Ferreira and Freitas, 2021) has found that having separate embedding spaces for mathematical elements and natural language when representing mathematical text can be beneficial for performance in other mathematical language processing tasks. We initially hypothesised that by allowing our model to learn the representation of variables, such separation would naturally happen when starting from a Gaussian initialised slot.

In order to verify if the model can discriminate between variables and natural language, we compare the embedding of words obtained from SciBERT-NLI (fine-tuned for the Variable Typing task) and our approach. We selected ten random sentences from the test set, obtained their embedding using both and reduced them to three dimensions using Principal component analysis[4]. The results are presented in Figure 4.



(a) SciBERT-NLI

(b) VarSlot

Figure 4: Embedding of the words and variables obtained from the test set for SciBERT-NLI and VarSlot.

The embeddings for the variables are represented here using the yellow diamond. From the figure,

---

[3] Model obtained from Hugging Face: `bert-base-nli-mean-tokens`

[4] We use the PCA implementation from `Scikit-learn` library with the default parameters.

we can immediately observe that our model easily distinguishes between words and variables, creating a clear separation. The same is not observed for SciBERT-NLI: there is no sharp separation between words and variables, suggesting that the model might not recognise the distinct semantic behaviour.

We also designed a probing test to quantify which model generates a more separable representation for variables. We obtained the representations for every token present in the test set, generating a representation for each word and variable using VarSlot and SciBERT-NLI. Then, given each representation, we trained a Linear Model to classify these representations into variables or non-variables. For the Linear Model, we use the standard configurations from the Probe-Ably[5] (Ferreira et al., 2021) probing framework. The results can be observed in Figure 5. In terms of accuracy, we can notice that the representation generated by our model allows for an easier disentanglement between variables and words, with a Linear model achieving maximum accuracy for linear models with different complexity (evaluated in terms of the norm). Following the classic probing protocol (Hewitt and Liang, 2019; Rozanova et al., 2021), we also provide the results for the Probing selectivity in Appendix B.

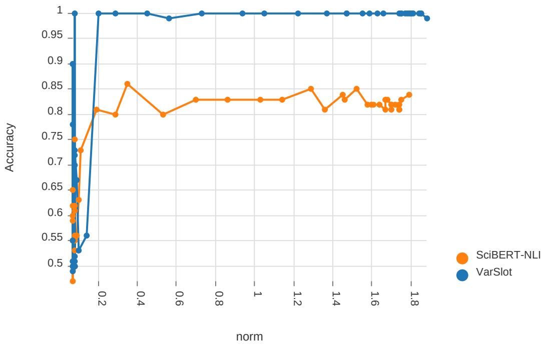


Figure 5: Results for the probing task, where we compare the representations generated from SciBERT-NLI (yellow) and VarSlot (blue).

Such finding reinforces the idea that variables requires a specialised representation. The slots for variables could have potentially relearned to replicate the original representations obtained from the encoder, however, a natural separation has been obtained between variables and words without explicitly being trained for that. This hints to the fact that such separation is beneficial for a better performance on tasks involving mathematical knowledge and models dealing with mathematical knowledge could benefit from explicitly defining such property.

5 Related Work

Even though mathematical text is often a crucial element of scientific discourse, the area of mathematical language processing is still widely unexplored (Ferreira and Freitas, 2020b,a). While initial efforts have focused on rule-based and bag of words-based approaches (Pagael and Schubotz, 2014; Schubotz et al., 2016; Alexeeva et al., 2020; Kristianto et al., 2012), recent work transitioned to supervised-learning methods. (Stathopoulos et al., 2018) presents three different models for addressing this problem, framing it as a binary classification between a variable and a type. The models proposed are an SVM model using features that are type and variable-centric, a ConvNet using pre-trained embeddings to represent the input tokens and a Bidirectional LSTM model that takes as input the full sentence along with the pairs for classification. (Stathopoulos et al., 2018) shows that neural models vastly outperform models with manual feature engineering. The authors also introduce a dataset for the task.

6 Conclusion

In this paper, we introduced VarSlot, a model for solving the task of variable typing generating a more generalisable representation of variables. In order to evaluate the proposed encoding, with a particular emphasis on variable semantics, we propose a new setting for the variable typing task, where during inference type, the model is only exposed to new variable names. We observed that in this setting, there is a decrease in performance for all tested models; however, VarSlot was the most robust model. As future work, we leave the application of these specialised embeddings for different downstream tasks, similar to the work done in (Stathopoulos et al., 2018). We expect that generating better representations for variables will enable an increase in performance across different mathematical language inference tasks.

A Hyperparameters

The list of used hyper-parameters, which are shared across baselines and our approach are as follows:

- Seed: 42
- Batch size: 32
- Train Epochs: 10
- Learning Rate: 1e-5 (5e-5 for MathBERT)
- Gradient Accumulation Steps: 1
- Weight Decay: 0.0
- Adam Epsilon: 1e-8
- Warmup Steps: 0
- Max Grad Norm: 1.0

For fine-tuning all the models, we used 4 Tesla 16GB V100 GPUs.

B Probing Selectivity

The selectivity score, namely the difference in accuracy between the representational probe and a control probing task with randomised labels, serves as an indicator that the probe architectures used are not expressive enough to "memorise" unstructured labels. Ensuring that there is no drop-off in selectivity increases the confidence that we are not falsely attributing strong accuracy scores to the representational structure where they could have been explained by over-parameterized probes.

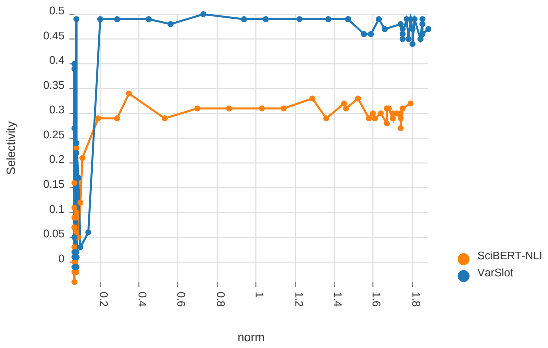

Figure 6: Results for the probing task, where we compare the representations generated from SciBERT-NLI (yellow) and VarSlot (blue), evaluating in terms of selectivity

Figure 6 presents the selectivity results for our probing task. We can notice that the selectivity remains stable for more complex probes, indicating that these are in fact, probes that are more reliable.

C VarSlot approach algorithm

This section presents Algorithm 1 used for obtaining the encoded representations of each hypothesis.

Algorithm 1: Learning the representation of mathematical statements with variables.

```
Input: Encoded representation of the hypothesis $E$,
       variables in the hypothesis $v_1, v_2, ..., v_{n_v}$, and
       positions of each variable in the hypothesis
       $P_{v_1}, P_{v_2}, ...P_{v_{n_v}}$.
Output: New hypothesis representation $\mathcal{E}$.
$E_{(v_i-)} \leftarrow E$
for $j \leftarrow P_{v_0}$ to $P_{v_n}$ /* Discard variable
    representations */
 do
    $E_{(v_i-)_j} \leftarrow [0\ 0\ \dots\ 0\ 0]$
end
for $i \leftarrow 0$ to $n_v$ /* For all variables */
 do
    $e_{(v_i)} \sim \mathcal{N}(\mu, \sigma)$; /* Initialise new
        representation */
    for $t \leftarrow 0$ to $T$ /* Iterate over
        representation $T$ times */
     do
        $e_{(v_i)_{t-1}} \leftarrow e_{(v_i)}$
        $e_{(v_i)} \leftarrow \texttt{LayerNorm}(e_{(v_i)})$
        $K \leftarrow k(E_{(v_i-)})$
        $Q \leftarrow q(e_{(v_i)})$
        $V \leftarrow v(E_{(v_i-)})$
        $A \leftarrow \texttt{Att}(Q, K, V)$
        $e_{(v_i)} \leftarrow \texttt{GRU}(e_{(v_i)_{t-1}}, A)$
        $e_{(v_i)} \leftarrow e_{(v_i)} + \texttt{MLP}(\texttt{LayerNorm}(e_{(v_i)}))$
    end
    for $j \leftarrow P_{v_{i0}}$ to $P_{v_{in}}$ /* Replace with
        new representation */
     do
        $E_{(v_i-)} \leftarrow e_{(v_i)}$
    end
end
$\mathcal{E} \leftarrow \texttt{BiLSTM}(E_{(v_i-)})$
return $\mathcal{E}$
```

GRS: Combining Generation and Revision in Unsupervised Sentence Simplification

Abstract

We propose GRS: an unsupervised approach to sentence simplification that combines text generation and text revision. We start with an iterative framework in which an input sentence is revised using explicit edit operations, and add paraphrasing as a new edit operation. This allows us to combine the advantages of generative and revision-based approaches: paraphrasing captures complex edit operations, and the use of explicit edit operations in an iterative manner provides controllability and interpretability. We demonstrate these advantages of GRS compared to existing methods on the Newsela and ASSET datasets.

1 Introduction

Text simplification is the task of reducing the complexity and improving the readability of text while preserving its meaning. This is beneficial for persons with reading disabilities (Evans et al., 2014), non-native speakers, people with low literacy, and children. Furthermore, other NLP tasks can use simplification as a pre-processing step, such as summarization (Klebanov et al., 2004), parsing (Chandrasekar et al., 1996), and machine translation (Štajner and Popovic, 2016).

Sentence simplification models can be categorized into *generative* and *revision-based*. Generative approaches produce a simple sentence from a complex sentence in one step, in an auto-regressive way (Zhang and Lapata, 2017; Guo et al., 2018; Kriz et al., 2019; Surya et al., 2019; Martin et al., 2020a). Revision-based methods iteratively edit a given sentence using a sequence of edit operations such as word deletion (Alva-Manchego et al., 2017; Dong et al., 2019; Kumar et al., 2020; Agrawal et al., 2021). While generative models learn complex edit operations implicitly from data, the explicit edit operations performed by revision-based approaches can provide more control and interpretability.

Simplification methods can also be categorized as supervised or unsupervised. Supervised methods tend to have better performance, but require aligned complex-simple sentence pairs for training (Zhang and Lapata, 2017; Guo et al., 2018; Kriz et al., 2019; Martin et al., 2020a,b; Maddela et al., 2021). Unsupervised methods do not need such training data but do not perform as well (Surya et al., 2019; Kumar et al., 2020; Zhao et al., 2020).

We propose GRS: a new approach to bridge the gap between generative and revision-based methods for unsupervised sentence simplification. The insight is to introduce *paraphrasing* as an edit operation within an iterative revision-based framework. For paraphrasing, we use a fine-tuned BART model (Lewis et al., 2020) with lexically-constrained decoding (Hokamp and Liu, 2017; Post and Vilar, 2018; Hu et al., 2019a). This decoding technique allows us to select words from the initial sentence that must be changed in the paraphrased sentence (otherwise, paraphrasing an entire sentence reduces to a pure generative model). To avoid the computational overhead of repeatedly performing constraint-based decoding using various combinations of words to paraphrase, GRS includes a complex component detector to identify the most appropriate words to paraphrase. The code is available at `https://github.com/imohammad12/GRS`.

GRS is unsupervised in the sense that it does not require aligned complex-simple sentence pairs, but it uses supervised models. The paraphrasing model requires paraphrasing corpora, and the complex component detector requires two unlabeled corpora, one containing more complex sentences than the other. However, collecting paraphrasing data and unaligned simplification data is simpler than collecting aligned complex-simple pairs.

2 Related Work

Early work on simplification relied on rules, e.g., to split or shorten long sentences (Chandrasekar and

Findings of the Association for Computational Linguistics: ACL 2022, pages 949 - 960
May 22-27, 2022

Srinivas, 1997; Carroll et al., 1998; Vickrey and Koller, 2008). Later work treated simplification as a monolingual phrase-based machine translation (MT) task (Coster and Kauchak, 2011; Wubben et al., 2012), with syntactic information added, such as constituency trees (Zhu et al., 2010). Recent work, reviewed below, leverages neural models in a *generative* and *revision-based* manner.

Supervised Generative Methods employ Seq2Seq models to learn simplification operations from aligned complex-simple sentence pairs (Nisioi et al., 2017). Building on a Seq2Seq model, Zhang and Lapata (2017) used reinforcement learning to optimize a reward based on simplicity, fluency and relevance. Recent methods build on transformer (Vaswani et al., 2017) models, by integrating external databases containing simplification rules (Zhao et al., 2018), using an additional loss function to generate diverse outputs (Kriz et al., 2019), combining syntactic rules (Maddela et al., 2021), and conditioning on length and syntactic and lexical complexity features (Martin et al., 2020a).

Unsupervised Generative Methods rely on non-aligned complex and simple corpora. Zhao et al. (2020) adopted a back-translation framework, whereas Surya et al. (2019) used an unsupervised style transfer paradigm. Martin et al. (2020b) used a pre-trained BART model fine-tuned on paraphrased sentence pairs.

Controllable Generative Methods produce outputs at specified grade levels (Scarton and Specia, 2018; Nishihara et al., 2019), or apply syntactic or lexical constraints on the generated sentences (Martin et al., 2020a,b). However, these models do not provide any insights into the simplification process.

Supervised Revision-Based Methods use complex-simple sentence pairs to learn where to apply edit operations. Alva-Manchego et al. (2017) use keep, replace, and delete operations. Some recent work used iterative non-autoregressive models to edit sentences by either predicting token-level edit-operations (Omelianchuk et al., 2021) or using a fixed pipeline of edit operations (Agrawal et al., 2021). Dong et al. (2019) proposed a hybrid method with explicit edit operations in an end-to-end generative model.

Unsupervised Revision-Based Methods such as Narayan and Gardent (2016) apply a pipeline of edit operations in a fixed order. Kumar et al. (2020) presented an unsupervised revision-based approach by modelling text simplification as an unsupervised search problem. While GRS also uses a revision-based framework and an unsupervised search strategy, we integrate a generative paraphrasing model into the framework to leverage the strengths of both text generation and text revision approaches.

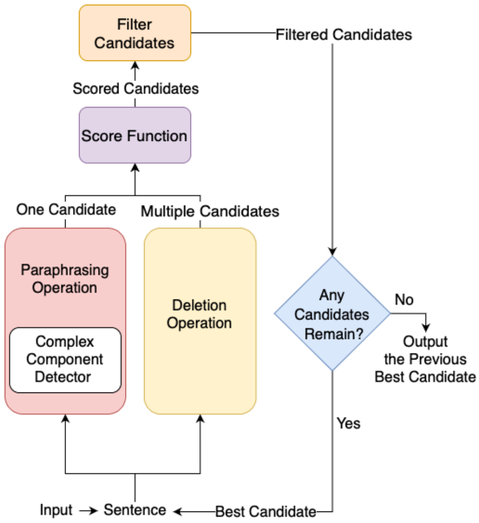

Figure 1: An overview of GRS. Given a complex input sentence, simplifications are iteratively produced via paraphrasing and deletion, with paraphrasing guided by the complex component detector. Sentences passing a filter (Equation 4) are candidates for input to the next iteration.

3 GRS Model

3.1 Overview

Our solution, GRS, iteratively revises a given complex sentence by applying edit operations on sentence fragments. In each iteration, multiple candidate simplifications are produced and evaluated using a scoring function (Section 3.5), and the best candidate is selected (Section 3.6). The selected sentence acts as the input to the next iteration. This process continues until none of the candidate sentences are simpler than the input sentence.

GRS uses two edit operations: *paraphrasing* (Section 3.2; guided by the complex component detector described in Section 3.3) and *deletion* (Section 3.4). The scoring function (Section 3.5) guides our search for best simplfication, using soft and hard constraints on simplicity, linguistic acceptability, and meaning preservation.

In Section 3.6, we explain how paraphrasing and deletion work in an iterative search framework, how candidate sentences are selected, and when the algorithm terminates. Figure 1 gives an overview of GRS, which is explained further in Section 3.6.

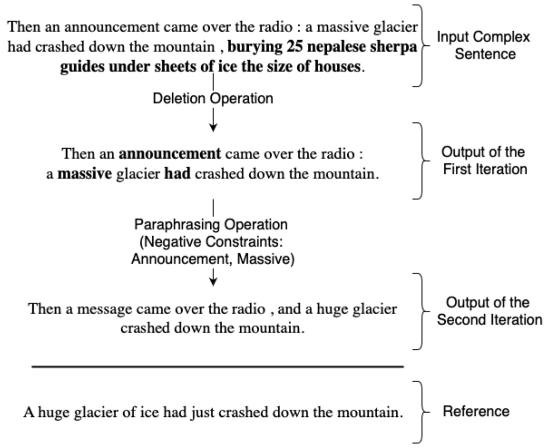

Figure 2: Two iterations of edit operations: deletion, then paraphrasing to simplify the complex fragments ("announcement" and "massive") identified by the complex component detector and given as negative constraints to the paraphrasing model. This example demonstrates the interpretability of GRS through building a simplification path leading to the final sentence.

3.2 Paraphrasing Operation

We use a pre-trained BART model (Lewis et al., 2020), fine-tuned on a small subset of ParaBank 2 paraphrasing dataset (Hu et al., 2019b); however, any paraphrasing auto-regressive model can be used instead. During inference, we use lexical-constrained decoding (Hokamp and Liu, 2017; Post and Vilar, 2018; Hu et al., 2019a) to place negative constraints on complex words and phrases in the input sentence. Negative constraints are words that the paraphrasing model is forced not to generate during decoding. Figure 2 shows an example in which an input sentence was paraphrased to exclude two complex words (negative constraints): "massive" and "announcement". We explain how to choose negative constraints below, with the help of the complex component detector.

3.3 Complex Component Detector

Constrained decoding is computationally more expensive than greedy and beam search decoding. In GRS, before paraphrasing a sentence, the complex component detector predicts the best negative constraints; then the sentence and the predicted negative constraints are given to the paraphrasing model to generate a new candidate sentence. As a result, the paraphrasing operation is called only once per iteration of GRS, using the predicted negative constraints, avoiding the expensive process of repeatedly paraphrasing the input using different combinations of negative constraints.

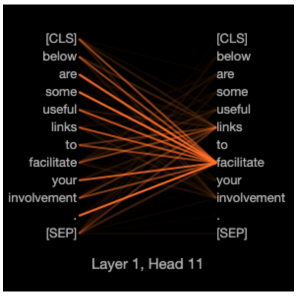

Figure 3: One of the attention matrices of the DeBERTa complex-simple classifier (head 11 of the second layer). Attention weights are reflected by color intensity. The input sentence in this example is "below are some useful links to facilitate your involvement." We used BertViz (Vig, 2019) to visualize attention weights.

We implemented the complex component detector as a complex-simple classifier that gives a simplicity probability to a given sentence. We only require two corpora with different complexity levels to train this classifier. Since aligned complex-simple sentence pairs are not required, this classifier can be trained on any pair of corpora with different complexity levels. Reid and Zhong (2021) showed that it is possible to extract style-specific sections of a sentence using the attention layers of a style classifier. Similarly, we use the attention layers of our complex-simple classifier to extract the complex components from a given input sentence.

We fine-tune the pre-trained DeBERTa model (He et al., 2020) as our complex-simple classifier. Figure 3 illustrates one of the attention heads of the second layer of DeBERTa. This visualization shows that the word "faciliate" was attended to more than the other words in the given sentence. We use this intuition and devise a formula (Equations 1 and 2 below) to detect complex words by analyzing attention weights.

BERT (Devlin et al., 2019) and its extensions (e.g. DeBERTa) add a [CLS] token to the beginning and a [SEP] token to the end of each sentence (as shown in Figure 3). In these models, the hidden states of the [CLS] token in the last layer are used for classification tasks. In our complex-simple classifier, we found that the attention paid by the [CLS] token in the second layer to other words in the sentence can help us detect complex components. Equations 1 and 2 demonstrate how we extract complex components from attention head matrices of the second layer of the classifier. Here, $\mathbf{A}_{h,i}^{[CLS]}$ refers to the amount of attention the [CLS] token in the hth attention head of the second layer pays to the ith token of the input sentence. N and H refer to the length of the input sentence and the number of attention heads, respectively. c_i defines whether the ith token is complex or not. If $c_i = 1$, then this token will be set as a negative constraint. $\bar{T}$ is a threshold used for finding complex tokens. In the example demonstrated in Figure 3, only c_8, which refers to the word "facilitate", is a complex token.

$$\bar{T} = \frac{\sum_{h=0}^{H-1} \sum_{i=0}^{N-1} \mathbf{A}_{h,i}^{[CLS]}}{N} \tag{1}$$

$$c_i = \begin{cases} 1, & \text{if } \sum_{h=0}^{H-1} \mathbf{A}_{h,i}^{[CLS]} \geq \bar{T} \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

3.4 Deletion Operation

Deletion aims to remove peripheral information to make sentences simpler, and is composed of two sub-operations: removal and extraction. Inspired by Kumar et al. (2020), we use the *constituency tree* of the input sentence to obtain all constituents from different depths of the parse tree. These constituents can be deleted (removal) or selected as a simplified candidate sentence (extraction). The removal sub-operation creates new candidate sentences by removing each of these phrases from the input sentence. The extraction sub-operation selects phrases as candidate sentences, which helps the model extract the main clause and drop peripheral information. The example in Figure 2 drops the phrase *"burying 25 nepalese sherpa guides under sheets of ice the size of houses"* from the complex sentence since it is not the main clause.

3.5 Scoring Function

Candidates generated by our two edit operations may not be correct in terms of linguistic acceptability. Furthermore, important information from the original sentence may have been removed. We use a score function to filter out non-grammatical candidates or sentences that are not conceptually similar to the original sentence. The score function is composed of three important components.

Meaning Preservation (H_{mp}): First, we use the method proposed in Reimers and Gurevych (2019) to obtain the semantic representations of the sentences. We then use the cosine similarity measure between the representations of the original and the generated candidate sentence. Our meaning preservation measure acts as a hard filter. A hard filter assigns a zero score to candidate sentences that do not pass a certain threshold.

Linguistic Acceptability (H_{la}): By removing some components of a complex input sentence, the output sentence may become nonsensical. To check the linguistic acceptability of the generated sentences, we train a classifier on the CoLA (the corpus of linguistic acceptability) (Warstadt et al., 2019) dataset. This classifier measures the probability that a given sentence is grammatical. This module, like the meaning preservation module, is used as a hard filter in the score function.

Simplicity (S_{simp}): This is a soft constraint, for which we use the complex-simple classifier mentioned in Section 3.3, which computes the simplicity probability of a sentence.

These three measures together evaluate the quality of each candidate sentence, as shown in Equation 3. In this equation, S, S_{simp}, H_{la}, H_{mp}, c, and o refer to the score function, simplicity module, linguistic acceptability hard filter, meaning preservation hard filter, candidate sentence, and the original sentence, respectively.

$$S(c) = S_{simp}(c) * H_{mp}(c, o) * H_{la}(c) \tag{3}$$

3.6 Simplification Search

Our unsupervised search method is inspired by Kumar et al. (2020), but with different simplification operations and a different score function. Given a complex input sentence, paraphrasing and deletion operations generate candidate sentences separately. In each iteration, the paraphrasing operation creates only one candidate sentence, as described in Section 3.2, whereas the deletion operation generates multiple candidate sentences (Section 3.4). Candidates sentences are then evaluated according to the scoring function. Given a score for each candidate sentence, we filter out those candidates that do not improve the score of the input sentence by some threshold. The threshold depends on the edit operation that the candidate sentence has been created from. In equation 4, t_{op} is the threshold associated with operator op. S, c, and c' refer to the score function, the candidate sentence, and the input sentence in the current iteration, respectively.

$$S(c) > S(c') * t_{op} \tag{4}$$

Finally, at the end of each iteration, out of the remaining sentences (that are not filtered out), we select the one with the highest score.

4 Experiments

This section discusses the experimental setup (Sections 4.1 through 4.4), a comparison of GRS with existing approaches (Section 4.5), a controllability study (Section 4.6), an evaluation of the complex component detector (Section 4.7), an analysis of the simplification search (Section 4.8), and a human evaluation (Section 4.9).

4.1 Data

We use the Newsela (Xu et al., 2015) and ASSET datasets (Alva-Manchego et al., 2020) to evaluate GRS against existing simplification methods. Newsela contains 1840 news articles for children at five reading levels. We use the split from Zhang and Lapata (2017), containing 1129 validation and 1077 test sentence pairs. ASSET includes 2000 validation and 359 test sentences pairs. Each sentence has ten human-written references.

4.2 Training Details

Paraphrasing Model: We fine-tune a pre-trained BART model (Lewis et al., 2020) implemented by Wolf et al. (2020). To do this, we use a subset of the ParaBank 2 paraphrasing dataset (Hu et al., 2019b) containing 47,000 pairs. We observe that a conservative paraphrasing model helps us to control the generated output. This is because such a model is better at specifically changing only words provided as negative constraints. Thus, for fine-tuning the BART model, we select paraphrasing sentence pairs that are semantically similar to each other. For calculating the semantic similarity of sentence pairs, we use the model from Reimers and Gurevych (2019) to obtain sentence embeddings, and then we use cosine-similarity to find the most similar sentence pairs.

The BART model is composed of a 12-layer encoder and a 12-layer decoder, each layer containing 16 attention heads. The model's hidden size is 1024, and the tokenizer vocabulary size is 50265. We use a batch size of 8 (per device). It took approximately 1.5 hours to fine-tune the model using three NVIDIA 2080 Ti GPUs.

Complex-Simple Classifier: We use a pre-trained DeBERTa (He et al., 2020) model implemented by Wolf et al. (2020). This model is composed of a 12-layer self-attentional encoder, each layer containing 12 attention heads. The model's hidden size is 768, and the tokenizer vocabulary size is 30522. To fine-tune the DeBERTa model for the binary classification task, we use the Newsela-Auto dataset (Jiang et al., 2020). To train the classifier, we use the AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of 5×10^{-5} and a batch size of 16. Note that we do not use the alignment between complex-simple sentence pairs in the Newsela-Auto dataset. Thus, our complex-simple classifier can be trained on any text corpora with different complexity levels. It took approximately one hour to fine-tune the classifier using a single NVIDIA 2080 Ti GPU. The accuracy of this classifier is 78.46.

Meaning Preservation Module of the Scoring Function: To obtain contextual embeddings of sentences, we use the SentenceTransformers (Reimers and Gurevych, 2019) framework, specifically, the paraphrase-mpnet-base-v2 pre-trained model.

Linguistic Acceptability Module of the Scoring Function: To score the linguistic acceptability of a sentence, we fine-tune a pre-trained DeBERTa model (He et al., 2020) for a binary classification task on the CoLA (the corpus of linguistic acceptability) (Warstadt et al., 2019) dataset. It contains 10,657 sentences, each labelled either as grammatical or ungrammatical. The configuration and training hyperparameters of this classifier are the same as the complex-simple classifier explained above. It took approximately 30 minutes to fine-tune the model using a single NVIDIA 2080 Ti GPU. On the validation set, the accuracy of the model is 79.33.

Simplification Search and Score Function: The threshold associated with paraphrasing (t_{par}) is 0.8, and the thresholds related to the removal (t_{dl-rm}) and extraction (t_{dl-ex}) sub-operations of the deletion operation are 1.1, and 1.25, respectively. The score function's meaning preservation (H_{mp}) and linguistic acceptability (H_{la}) thresholds are 0.7 and 0.3, respectively. We obtained these values using the validation set. These values are used for both ASSET and Newsela datasets.

4.3 Evaluation Metrics

To evaluate GRS and other models, we use SARI (Xu et al., 2016) as our primary metric. SARI (System output Against References and against the Input sentence) evaluates the quality of the output text by calculating how often the output text correctly keeps, inserts, and deletes n-grams from

Model	SARI ↑	Add ↑	Delete ↑	Keep ↑	FKGL ↓	Len
Identity Baseline	12.24	0.00	0.00	36.72	8.82	23.04
Unsupervised Models						
Zhao et al. (2020)	37.20	1.51	73.53	36.54	3.80	11.78
Kumar et al. (2020)	38.36	1.01	77.58	36.51	**2.81**	9.61
Martin et al. (2020b)	38.29	**4.44**	76.02	34.42	4.65	12.49
GRS: DL (RM + EX)	37.52	0.66	69.45	**42.44**	3.93	12.64
GRS: PA	36.42	3.44	69.55	36.28	5.79	19.08
GRS: PA + DL (RM + EX)	**40.01**	3.06	**80.43**	36.53	3.20	11.72
Supervised Models						
Narayan and Gardent (2014)	34.73	0.77	73.22	30.21	4.52	12.40
Zhang and Lapata (2017)	38.03	2.43	69.47	**42.20**	4.78	14.36
Dong et al. (2019)	39.28	2.13	77.17	38.53	3.80	10.92
Zhao et al. (2020)	39.14	2.80	74.28	40.34	4.11	11.63
Martin et al. (2020b)	**41.20**	**6.02**	**81.70**	35.88	**2.35**	9.22

Table 1: Comparison of supervised and unsupervised simplification models on the Newsela test set. PA and DL refer to paraphrasing and deletion, respectively. RM and EX refer to the removal and extraction sub-operations of the deletion operation. ↑ denotes the higher the value, the better. ↓ denotes the lower the value, the better.

the complex sentence, compared to the reference text, where $1 \leq n \leq 4$. We report the overall SARI score, as well as individual SARI scores corresponding to n-grams correctly added (ADD), deleted (DELETE) and kept (KEEP); the overall SARI score is the mean of these three scores. We also report the FKGL score, which only considers the output sentence, not the source and reference sentences. It is computed based on sentence length and the number of syllables for each word in the sentence. We use the EASSE package (Alva-Manchego et al., 2019) to calculate SARI and FKGL. We do not use the BLEU (Papineni et al., 2002) metric since Sulem et al. (2018) showed that BLEU does not correlate well with simplicity.

4.4 Models Tested

We evaluate GRS with different configurations: only deletion - GRS: DL(RM+EX), only paraphrasing - GRS: PA, and both deletion and paraphrasing - GRS: PA+DL(RM+EX). We also consider the complex sentence itself as a trivial baseline, denoted by 'Identity Baseline'. The ASSET dataset contains multiple references for a sentence, so we also calculate an upper bound for a given evaluation metric, which we denote as 'Gold Reference'. To calculate the 'Gold Reference' score, each reference is selected once, and the scores are calculated against others. Finally, we average across all the reference scores to obtain the final 'Gold Reference' score.

We also compare GRS with existing approaches. From unsupervised methods, we select unsupervised generative models that use Seq2Seq models Surya et al. (2019); Zhao et al. (2020). We also compare with Martin et al. (2020b), which leverages pretrained language models and a large paraphrase pair dataset, and Kumar et al. (2020), an iterative revision-based method with several explicit edit operations (deletion, lexical substitution and reordering).

From supervised methods, we start with Narayan and Gardent (2014) and Xu et al. (2016), which use phrase-based MT models. We also consider Seq2Seq generative methods: Zhang and Lapata (2017), which uses reinforcement learning, and Zhao et al. (2020); Martin et al. (2020a,b), which use Seq2Seq transformer models. Next, we select Omelianchuk et al. (2021), a recent supervised revision-based method. Finally, we consider Dong et al. (2019), a hybrid approach using explicit edit operations in a generative framework.

4.5 Evaluation Results

Tables 1 and 2 illustrate the results on Newsela and ASSET, respectively. We report the overall SARI score, the individual scores of three operations used in SARI score, the FKGL score, and the average length of the output sentences. To evaluate previous methods, we obtained their output sentences on ASSET and Newsela from the respective project Github pages or by contacting the respective authors, followed by calculating the SARI and FKGL scores using the EASSE package (described in Section 4.3). One exception is Omelianchuk et al. (2021): since they also used the EASSE package, we copied their reported ASSET scores in Table 2, but they did not report the average sentence length.

For Newsela, using paraphrasing and deletion

Model	SARI ↑	Add ↑	Delete ↑	Keep ↑	FKGL ↓	Len
Identity Baseline	20.73	0.00	0.00	62.20	10.02	19.72

1.0	39.42	2.69	75.03	40.54	3.84	12.99
1.1	38.55	1.97	70.47	43.23	4.11	13.50
Effect of the Linguistic Acceptability Threshold (H_{la})						
0.6	39.42	3.06	78.19	37.00	3.65	12.54
0.7	39.52	3.00	77.98	37.57	3.68	12.67
0.8	39.69	3.08	77.60	38.40	3.79	12.85
0.9	38.41	2.93	76.87	38.42	4.04	13.04

Table 3: Impact of paraphrasing, deletion, meaning preservation, and linguistic acceptability thresholds on the Newsela dataset.

together (GRS: PA + DL(RM+EX)) gives the best performance on the SARI metric. On the Newsela dataset, our best model outperforms previous unsupervised methods and achieves +1.6 SARI improvement. It also outperforms all supervised methods except Martin et al. (2020b).

For ASSET, even though Martin et al. (2020b) perform better than our best model, we improve the performance over Kumar et al. (2020) by +3.6 SARI points and close the gap between revision-based and generative approaches. Compared to supervised models, our unsupervised model again outperforms others except Martin et al. (2020b) and Omelianchuk et al. (2021). For the ASSET dataset, we observe that our model with only paraphrasing (GRS (PA)) has the best SARI score.

Analyzing the results, we observe that simplification is done differently by human annotators in Newsela than in ASSET. In Newsela, removal of peripheral information through content deletion happens more aggressively. The average reference sentence length is 12.75 compared to 23.04 for the source sentences. However, in ASSET, content removal is conservative and can be handled by paraphrasing alone. The average reference sentence length is 16.54 compared to 19.72 for the source sentences. Simplifications in ASSET focus on lexical simplification, sentence splitting and word reordering.

Martin et al. (2020b) leverage a pretrained BART model (Lewis et al., 2020) and fine-tune it on a paraphrasing dataset containing 1.1 million sequence pairs. Unlike traditional paraphrasing datasets that are structured at the sentence level, their paraphrasing dataset contains multiple sentences in a sequence, thus allowing the model to learn a sentence splitting operation as well. Thus, they outperform

CCD-module	Acc ↑	Rec ↑	Prec ↑	F1 ↑
LS-CCD	84.67	37.36	70.51	48.84
Att-Cls	84.58	47.95	72.59	57.75

Table 4: Performance of different Complex Component Detectors (CCD) on the Complex Word Identification (CWI) task. CWIG3G2 dataset has been used for this evaluation. LS-CCD and Att-Cls refer to the CCD module obtained from Lexical Simplification edit operation of Kumar et al. (2020) and the original CCD module used in GRS design explained in Section 3.3, respectively. ↑ denotes the higher value, the better.

the previous best unsupervised models on ASSET. On Newsela, both GRS and the model from Kumar et al. (2020) perform better than Martin et al. (2020b) since they include an explicit removal edit operation. Martin et al. (2020b) instead do not explicitly perform content removal and only do content deletion by way of paraphrasing. Finally, Kumar et al. (2020) does not perform well on ASSET since they do not perform paraphrasing. Our new design thus combines the advantages of both revision-based and generative approaches.

4.6 Controllability

By manipulating the thresholds for the components of the score function and the edit operations, we can control the amount of deletion, paraphrasing, and the trade-off between simplicity and meaning preservation. We show the results in Table 3 using the GRS (PA + DL) model and the Newsela test set. The column labels have the same meaning as in Tables 1 and 2.

Meaning Preservation Threshold: As mentioned in Section 3.5, meaning preservation is a hard filter in our score function. As the meaning preservation threshold increases, candidate sentences less similar to the original sentence are pruned. Sentences more similar to the original sentence have higher Keep and lower Delete SARI scores. The SARI Add score increases since paraphrasing is prioritized over deletion. Finally, the length of the output sentences increases since the model becomes more conservative.

Removal Threshold of Deletion Operation: By increasing this threshold, the SARI Keep score increases and the SARI Delete score decreases, which also results in increased average length. The SARI Add score increases as well since a higher deletion threshold makes the model conservative on deletions and thus candidates from the paraphrasing operation are more likely to be selected.

Paraphrasing Threshold: Reducing this threshold results in more aggressive paraphrasing. Thus, we observe an increase in the SARI Delete and Add scores since paraphrasing replaces complex words and phrases with simpler ones.

Linguistic Acceptability Threshold: Like meaning preservation, linguistic acceptability is a hard filter in our score function (Section 3.5). As the linguistic acceptability threshold increases, more candidate sentences receive a zero score. This results in a more conservative model that makes fewer changes to the input sentences because the original sentences are already linguistically acceptable. By increasing the linguistic acceptability threshold, the SARI Deletion score drops and the SARI Keep score increases. Also, this results in longer sentences.

4.7 Complex Component Detector Evaluation

To show the effectiveness of the proposed Complex Component Detector (CCD) mentioned in Section 3.3, we evaluate the CCD module on the Complex Word Identification (CWI) task. The task is defined as a sequence tagging problem in which each word in a sentence is tagged as complex or not complex. We use the test set of CWIG3G2 (Yimam et al., 2017), a professionally written news dataset. As explained in Section 3.3, the CCD module used in GRS (denoted by Att-Cls) operates by interpreting the attention matrix of the second layer of the complex-simple classifier. We also compare with the lexical simplification operation of Kumar et al. (2020), denoted by LS-CCD. It uses the IDF scores to find complex words in a sentence.

Table 4 shows the complex word identification performance of the two CCD modules on CWIG3G2. Att-Cls outperforms LS-CCD in recall, precision, and the F1 score. Tables 5 demonstrates the performance of GRS with different CCD modules on ASSET (Alva-Manchego et al., 2020) and Newsela (Xu et al., 2015) test sets. On both datasets, the GRS model using Att-Cls has higher deletion and addition scores compared to the GRS model using LS-CCD. The overall SARI score is considerably higher when using Att-Cls on ASSET.

4.8 Simplification Search Analysis

GRS is an interpretable unsupervised simplification method in which we can trace the simplification process. That is, we know which edit operation is applied on a given complex sentence in each

Model	**SARI** ↑	**Add** ↑	**Delete** ↑	**Keep** ↑	**FKGL** ↓	**Len**
			ASSET			
Identity Baseline	20.73	0.00	0.00	62.20	10.02	19.72
Gold Reference	44.89	10.17	58.76	65.73	6.49	16.54
GRS(PA, CCD:LS-CCD)	37.80	5.59	57.39	50.44	7.17	18.75
GRS(PA, CCD:Att-Cls)	**40.41**	**7.00**	**62.37**	**51.88**	**6.70**	17.94
			Newsela			
Identity Baseline	12.24	0.00	0.00	36.72	8.82	23.04
GRS(PA+DL(RM), CCD:LS-CCD)	39.30	2.87	78.18	**36.85**	**3.39**	13.54
GRS(PA+DL(RM), CCD:Att-Cls)	**39.61**	**3.18**	**79.13**	36.52	3.45	13.43

Table 5: Comparison of GRS versions that use different Complex Component Detectors (CCD) on ASSET and Newsela. PA and DL refer to paraphrasing and deletion, respectively. RM refers to removal, which is the sub-operation used in deletion operation. ↑ denotes the higher value, the better. ↓ denotes the lower value, the better.

Model	**Iterations/Sent** (all-Operations)	**PA-iterations**	**DL-iterations**	
			RM	EX
		Newsela		
GRS: PA	4.72	4.72	–	–
GRS: DL	0.79	–	0.46	0.33
GRS: PA + DL	4.40	3.72	0.37	0.31
		ASSET		
GRS: PA	4.18	4.18	–	–
GRS: DL	1.05	–	0.54	0.51
GRS: PA + DL	3.79	2.94	0.39	0.45

Table 6: Analysis of edit operation used during simplification search, showing the average number of simplification iterations of GRS and the average share of each edit operation. PA and DL refer to paraphrasing and deletion, respectively. RM and EX refer to the removal and extraction sub-operations of the deletion operation.

iteration. Table 6 demonstrates how many simplification iterations were needed to simplify a complex sentence, on average, in the Newsela and ASSET datasets. We also show the average frequency of each operation to simplify a given sentence.

Table 6 illustrates that when both edit operations are allowed (GRS:PA+DL), almost four simplification iterations are applied to a sentence, and paraphrasing is generally more common than deletion.

4.9 Human Evaluation

We selected 30 sentences from the ASSET test set for human evaluation. Following (Kriz et al., 2019), we measure Fluency (whether the sentence is grammatical and well-formed), Simplicity (whether it is simpler than the complex sentence), and Adequacy (whether it keeps the meaning of the complex sentence). We asked four volunteers to assess the sentences based on these metrics and evaluate the performance of various models, including GRS. Results are shown in Table 7. All models are unsupervised except Dress-Ls (Zhang and Lapata, 2017).

CCD-module	**Adequacy** ↑	**Simplicity** ↑	**Fluency** ↑	**Average** ↑
Reference	4.29	4.08	4.76	4.37
GRS(PA)	**3.98**	4.04	4.47	4.17
(Surya et al., 2019)	3.57	3.48	4.32	3.79
(Zhao et al., 2020)	3.89	3.27	4.54	3.89
(Martin et al., 2020b)	3.95	**4.17**	**4.78**	**4.30**
(Kumar et al., 2020)	3.15	3.56	4.15	3.62
(Zhang and Lapata, 2017)	3.67	3.64	4.69	4.00

Table 7: Human evaluation on the ASSET dataset. Adequacy, simplicity, and fluency are human evaluation metrics, and in the fourth column, the average of these metrics is shown. Each row represents a simplification model. Human evaluation scores are based on a 1–5 Likert scale. ↑ denotes the higher value, the better.

The fourth column in Table 7 shows the average score of all three metrics used in the human evaluation. According to the average scores, MUSS (Martin et al., 2020b) has the best performance, followed by GRS. The human evaluation demonstrates that the automatic evaluation (SARI scores shown in Table 2) is aligned with human evaluation scores. GRS has the best performance in meaning preservation (Adequacy). This may be because we have a relatively conservative paraphrasing model. Also, GRS evaluated in this study is only leveraging paraphrasing, and this version is the most conservative.

5 Conclusion

We proposed GRS, a controllable and interpretable method for unsupervised text simplification that bridges the gap between previous unsupervised generative and revision-based approaches. We combined the two approaches by incorporating an explicit paraphrasing edit operation into an iterative simplification search algorithm. Empirically, we showed that GRS has the advantages of both approaches. GRS outperformed state-of-the-art unsupervised methods on the Newsela dataset and reduced the gap between generative and revision-based unsupervised models on the ASSET dataset.

Abstract

Morphologically-rich polysynthetic languages present a challenge for NLP systems due to data sparsity, and a common strategy to handle this issue is to apply subword segmentation. We investigate a wide variety of supervised and unsupervised morphological segmentation methods for four polysynthetic languages: Nahuatl, Raramuri, Shipibo-Konibo, and Wixarika. Then, we compare the morphologically inspired segmentation methods against Byte-Pair Encodings (BPEs) as inputs for machine translation (MT) when translating to and from Spanish. We show that for all language pairs except for Nahuatl, an unsupervised morphological segmentation algorithm outperforms BPEs consistently and that, although supervised methods achieve better segmentation scores, they under-perform in MT challenges. Finally, we contribute two new morphological segmentation datasets for Raramuri and Shipibo-Konibo, and a parallel corpus for Raramuri–Spanish.

1 Introduction

Polysynthetic languages are known because of their rich morphology, that encodes most parts of the semantics into verbs, leading to a high morpheme-per-word rate. The resulting combinations of morphemes and roots result in extreme type sparsity. Thus, polysynthetic languages represent a challenging environment for NLP methods (Klavans, 2018). Subword segmentation has been a common method to reduce sparsity (Vania and Lopez, 2017). Moreover, as these languages are mostly extremely low-resource (ELR), the challenge is even harder. Some of the reasons behind this is that most of them are endangered and spoken by minority groups (Mager et al., 2018; Littell et al., 2018).

But what impact does morphological segmentation have on downstream tasks like machine translation (MT), when translating from or into fusional languages? Linguistically inspired segmentation was considered to be the best option to handle rich morphology (Koehn et al., 2005; Virpioja et al., 2007) until the appearance of Byte-Pair Encodings (BPEs; Sennrich et al., 2016) and has been adopted as the default segmentation technique. BPEs earned this status for its good results, unsupervised training and language independence. Salleva and Lignos (2021) show that there is no significant gain when using an unsupervised morphological segmentation for the input over BPEs when evaluating those methods in moderate LR scenarios for Nepali–English and Kazakh–English, contradicting initial findings of Ataman and Federico (2018). However, how would BPEs perform for polysynthetic languages in ELR scenarios? Schwartz et al. (2020) compare BPE, with Morfessor (Smit et al., 2014) and Rule-Based morphological analyzers for medium resourced Inuktitut–English, and for the ELR Yupik–English and Guarani–Spanish. Their results show that BPEs outperform Morfessor and the morphological analyzer in all MT cases (but with better Language Modeling capabilities of morphological models over BPEs). However, most of these studies only rely on the usage of a limited set of segmentation methods and do not consider the quality of the used morphological segmentation methods.

This study aims to answer the following research questions: i) is morphological segmentation beneficial for MT where one language is polysynthetic and ELR?; and ii) is higher morphological segmentation quality correlated with higher MT scores?

To answer these questions, we perform segmentation experiments on four polysynthetic languages:[1] Nahuatl (`nah`), Raramuri (`tar`), Shipibo-Konibo (`shp`) and Wixarika (`hch`) and apply those segmentations to MT paired with Spanish (`spa`). First, we revisit a wide set of supervised and unsupervised methods and apply them to the input of MT transformer models. This study is the first

---

[1] We choose the languages for this study based on the availability of a morphological segmentation dataset.

to show that strong unsupervised morphological approaches outperform BPEs consistently on ELR polysynthetic languages, except for `nah`. These results are related to Ortega et al. (2020), that found that a morphologically guided BPE can improve the MT performance for Guarani–Spanish. On the other hand, even when supervised morphological segmentation methods achieve better results for the segmentation task, when it comes to MT systems they under-perform all other approaches. We hypothesize that this might be due to overfitting the clean and out-of-domain morphological training set. To make all these experiments possible we introduce additionally two new morphologically annotated datasets for `tar` and `shp`; and one parallel dataset for `spa–tar`[2].

Polysynthetic languages. A polysynthetic language is defined by the following linguistic features: the verb in a polysynthetic language must have an agreement with the subject, objects and indirect objects (Baker, 1996); nouns can be incorporated into the complex verb morphology (Mithun, 1986); and, therefore, polysynthetic languages have agreement morphemes, pronominal affixes and incorporated roots in the verb (Baker, 1996), and also encode their relations and characterizations into that verb.

2 Descriptions of Novel Datasets

2.1 Raramuri–Spanish Parallel Dataset

For the dataset, we manually extract phrases that had a translation into Spanish from the Brambila (1976) dictionary. Additionaly, given that the orthography in this book is out of use, we normalized it to a modern version used in (Caballero, 2008). The book does not specify the dialect of the sentences. Table 1 shows the characteristics of the dataset, and the dataset splits.

2.2 Morphological Segmentation Datasets

We also introduce two new morphologically annotated datasets. For Raramuri we manually extracted segmented morphemes from a specialized linguistics paper (Caballero, 2010) and thesis (Caballero, 2008) that contain segmented and non-segmented words. Both sources annotate the Raramuri variant of the village of Choguita.

For Shipibo-Konibo, we adapted annotated sentences for lemmatization and part-of-speech tagging (Pereira-Noriega et al., 2017), and from a treebank (Vasquez et al., 2018), which was segmented in morphemes due to a particular phenomenon for clitics in the dependencies annotation.

3 Experimental Setup

3.1 Resources

For the machine translation experiment we use the following parallel datasets: the `hch–spa` translation of the fairy tales of Hans Christian Andersen (Mager et al., 2017); the Shipibo-Konibo–Spanish

---

[2] The datasets are available under `http://turing.iimas.unam.mx/wix/mexseg`

translations from a bilingual dictionary and educational material (Galarreta et al., 2017); and for `nah–spa`, the Axolotl dataset (Gutierrez-Vasques et al., 2016). This dataset contains several variants of Nahuatl. On top of that we also use our collected `tar–spa` Parallel corpora (§2.1). The details of the data splitting are described in Table 5 in the appendix. For morphological segmentation we use the `nah` and `hch` annotated datasets from Kann et al. (2018b) and additionally we use the `shp` and `tar` datasets introduced in section 2.2. We use the same splits as reported by the original sources.

3.2 Metrics

For machine translation we use the standard BLEU (Papineni et al., 2002) and chrF (Popović, 2015) metrics from the SacreBLEU implementation (Post, 2018). To evaluate morphology, we compare all outputs against the gold annotated test sets calculating accuracy and the EMMA F1 metric (Spiegler and Monson, 2010).

3.3 Subword Segmentation

BPEs (`BPEs`; Sennrich et al., 2016) is our reference system we use the sentence piece implementation (Kudo and Richardson, 2018) of BPEs. We tune the vocabulary size on a vanilla transformer small for each language, and take the best model evaluated on the development set.

Morfessor (`Morfessor`; Smit et al., 2014) As an unsupervised method we use Morfessor 2.0, that is a statistical model for the discovery of morphemes using minimum description length optimization.

FlatCat (`FC`; Grönroos et al., 2014), is a variant of Morfessor. It consists of a category-base hidden Markov model and a flat lexicon structure for segmentation.

LMVR (Ataman et al., 2017) modify the `FC` implementation by adding a lexicon size restriction and increase the tendency of the model to increase segmentation of commonly seen words.

CRFs (`CRFs`) As our first supervised model we use the conditional random fields (CRFs; Lafferty et al., 2001) segmentation model of Ruokolainen et al. (2014). We also investigate the capabilities of `semiCRFs` (Sarawagi and Cohen, 2005) for this particular task. For this, we use the Chipmunk implementation (Cotterell et al., 2015).

Seq2seq We also use a vanilla RNN sequence-to-sequence model with attention. The first variant (`s2s`) employs a supervised neural model. Additionally, we use the most promising extension proposed by Kann et al. (2018b) adding random generated strings in an auto-encoding fashion (`s2s+multi`).

Pointer–Generator Networks (`PtrSeg`; See et al., 2017) are commonly used in task where copying part of the input to the output is part of the task. This model has been used successfully for canonical segmentation (Mager et al., 2020).

3.4 NMT System

As our translation models, we use an encoder-decoder transformer model (Vaswani et al., 2017) with the hyperparameters proposed by Guzmán et al. (2019) as a baseline for low-resource languages. We use the vanilla version of this transformer without any further back-translation or other enhancements, so that we can remove any additional variables from the experiment, and focus only on the input segmentation. We use a 5k[3] vocabulary size for all sides using BPE. We use fairseq (Ott et al., 2019) for all translation experiments. The polysynthetic languages are segmented with the different investigated segmentation methods and Spanish always uses BPE in both translation directions.

4 Results

Morphology Table 3 shows that `BPEs`, a model that is not intended for morphological segmenta-

system	`hch`	`nah`	`tar`	`shp`
`BPEs`	53.17	53.38	62.54	71.41
`Morfessor`	61.51	60.48	59.05	59.45
`FC`	62.28	58.94	64.65	67.95
`LMVR`	61.27	60.55	65.46	67.58
`semiCRFs`	68.10	81.92	81.22	-
`CRFs`	82.43	**87.83**	89.79	-
`s2s`	82.42	84.62	88.47	82.25
`s2s+multi`	**83.75**	84.90	88.37	**85.99**
`PtrSeg`	65.60	83.85	**90.13**	78.22

Table 3: Test results of surface segmentation for `hah`, `nah` and `tar`, and canonical segmentation for `shp`. Values are F1 scores, bold numbers are the best systems overall, underscored are the best unsupervised systems.

---

[3] We searched for the best vocabulary size using 2k, 4k, 5k, 6k and 8k.

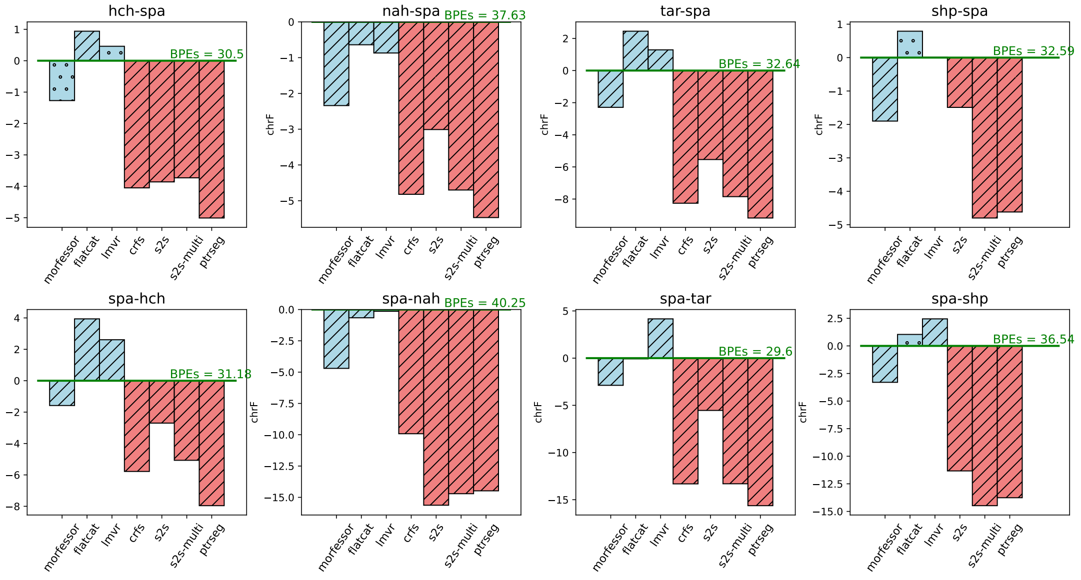

Figure 1: chrF score difference for all morphological segmentation when compared to `BPEs` on the test sets for both translation directions. We run a paired approximation test with 10000 trials using the `BPEs` system output as the baseline. Diagonals indicates a p-value ≤ 0.05, while stars indicates a p-value > 0.05. Blue systems are unsupervised, while Red ones are supervised.

tion, perform worst on all languages as expected, with exception of `tar`. The unsupervised morphological segmentation models (`Morfessor`, `FC` and `LMVR`) are consistently the worst performing models among the morphologically inspired models. The best performing systems are supervised, with `s2s+multi` showing best results for `hch` (83.7 F_1) and `shp` (85.99 F_1). `CRFs` achieved the best result for `nah` with 87.8 F_1 and `PtrSeg` achieved the best scores for `tar` with 90.13 F_1.

4.1 Discussion

MT Figure 1 shows the chrF score difference against the `BPEs` baseline in all directions[4]. We first observe that the supervised segmentation approaches under-perform in contrast with the unsupervised ones in all the settings.

Moreover, with the polysynthetic languages in the source side, `FC` has a significantly higher score for `hch-spa` and `tar-spa`, and a statistical tie in `shp-spa`; whereas `LMVR` obtains similar results to `BPEs` in `hch-spa` and `shp-spa`. In the other direction, with the polysynthetic languages as targets, `LMVR` is the method that significantly surpasses the baseline for more language pairs: `spa-hch`, `spa-tar` and `spa-shp`; whereas `FC` obtains the maximum score in `spa-hch` and statistical ties in `spa-tar` and `spa-shp`. We conclude that both methods are robust alternatives for translating from and to a polysynthetic language.

Despite the good results of `s2s`, `s2s+multi` or `PtrSeg` in morphological segmentation, for MT they have the worst performance. We argue that these kind of methods innovate new subwords in their output, which can aid for morphological segmentation, but for MT only adds noise in the input for the model.

Overall, we notice that in contrast to other languages (Saleva and Lignos, 2021), segmentation methods matter for polysynthetic ones. Poor suited methods can strongly decrease the performance of down-stream tasks like MT. However, the question on which segmentation method is better for MT is still open.

4.2 Analysis

To better understand the current results, we explore the outputs of different systems. For simplicity, we choose the best performing segmentation system for each of the segmentation paradigms. For unsupervised morphological inspired segmentation, we use `LMVR`, `s2s+multi` for supervised morphological segmentation, and `BPEs` for frequency-based segmentation.

First, we explore the impact of morphological richness on each of the systems. We use

---

[4] See Table 6 for the specific scores, BLEU ones included.

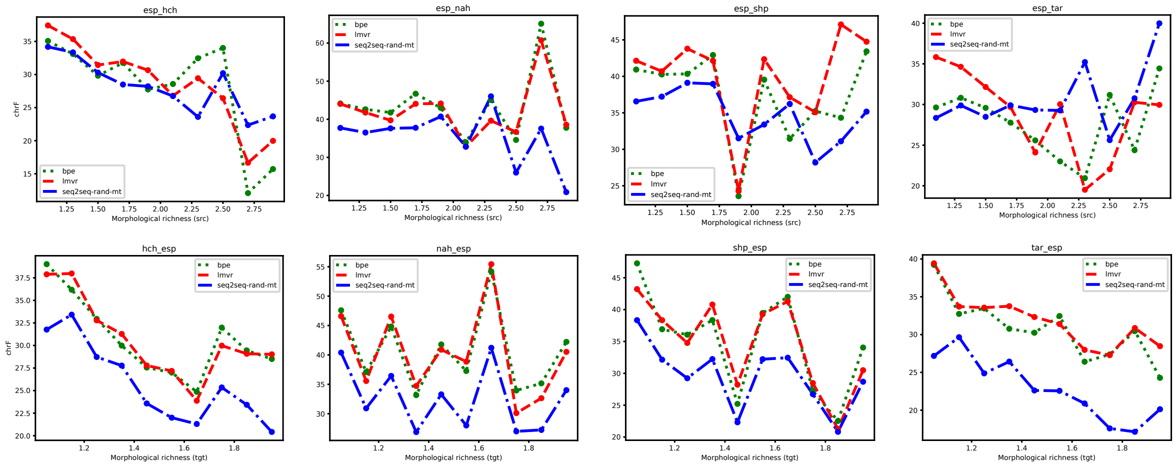

Figure 2: Relation between morphological richness of each polysyntetic language with relation to its chrF score, in each translation direction. The scores are analysed for `BPEs`, `LMVR` and `s2s+multi`.

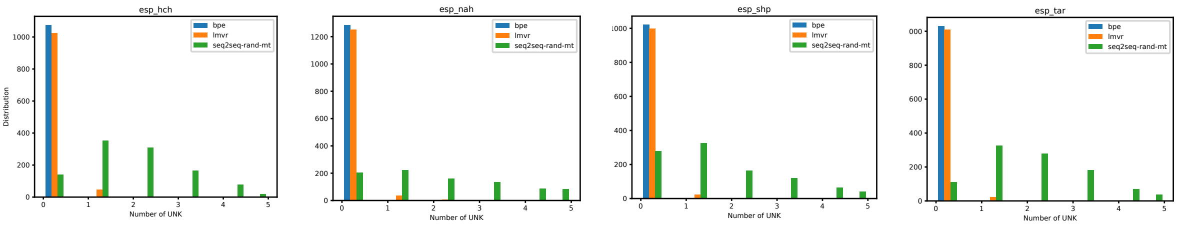

Figure 3: Number of out-of-vocabulary tokens (UNK) found for each polysynthetic language classified by system. The scores are analysed for `BPEs`, `LMVR` and `s2s+multi`.

`Morfessor` to infer the segmentation for each polysynthetic language data point and divide the number of found morphemes by the total number of tokens. Figure 2 shows that there is no clear correlation between morphological richness and systems' performance for `nah` and for `shp`. However, for `hch` we observe that a richer morphology implies a loss in translation quality. The same correlation can be seen for the `tar-esp` direction. This correlation is stronger when the polysynthetic language is in the source and weaker when it is in the target. Overall, a similar behavior can be observed between `LMVR` and `BPEs`.

Second, we explore the impact of out-of-vocabulary (UNK) tokens that each segmentation model introduces because having a high number of UNK tokens can negatively influence the MT results. In figure 3, we show the number of UNK tokens that each segmentation has when used with the dictionary of an MT system. The supervised `s2s+multi` has the highest amount of UNK symbols. We suggest that the reasons behind this phenomena could be the strong generative power of such systems and well-known artifacts that such models introduce (i.e., string repetitions). However, `LMVR` has a slightly higher number of UNK tokens, leaving `BPEs` the best vocabulary coverage. This can explain the surprisingly low performance of supervised models.

5 Conclusion

In this paper, we compared a wide set of morphological segmentation models with BPEs when applied to the input of Neural Machine Translation systems for extreme low-resource polysynthetic languages. We found that unsupervised morphological segmentation outperformed BPEs significantly on 5 out of 8 language pairs, setting a consistent overall performance. Surprisingly SOTA supervised morphological segmentation achieved the lowest performance of all systems. In future, we will explore Adaptor-Grammars (Johnson et al., 2006; Narasimhan et al., 2015; Eskander et al., 2020) for segmentation, and also the way to make unsupervised segmentation more robust and suitable for MT including the reduction of produced UNK symbols.

Ethical Considerations

The datasets introduced in this paper for machine readable training and evaluations are extracted from previous specialized linguistic work. We stick to the ethical standards giving credit to the original author in the spirit of *fair scientific usage*. We further strongly encourage future work that use these resources to cite also the original sources of the data. Additionally we found another ethical risks of this work: for the down-stream task of MT, a translation system should not be deployed with low quality translations, as it can mislead the user, and have implicit biases. Finally, want to state that the authors of this paper have a long record of working with the studied indigenous languages. Some have conducted field studies with the communities in the past, and Manuel Mager is part of the Wixarika community. This allows the authors to have a better understanding of the concerns of the communities that speak the discussed languages.

Acknowledgments

We want to thank all the anonymous reviewers as well as Pavel Denisov for their helpful comments and suggestions. This project has benefited from financial support to Manuel Mager by a DAAD Doctoral Research Grant.

`nah–spa`	14208	644	1291
`tar–spa`	12987	582	1021
`shp–spa`	13102	587	1030

Table 5: Data splitting (in number of phrases) used for out Machine Translation experiments, from and to Spanish.

A.2 The Languages of new collected datasets

Raramuri (also known as Tarahumana) is a Yuto-Aztecan language, spoken in the northern part of the Mexican Sierra Madre Occidental by 89,503 speakers (INEGI, 2020). Raramuri is a polysynthetic and agglutinative language and has a Subject-Object-Verb (SOV) word order with morphonological fusion indicated by verbal suffixes (Caballero, 2008).

Shipibo-Konibo is a Panoan language spoken by around 26,000 people in the Amazonian region of Perú. This language is polysynthetic, with a strong tendency to agglutination, but also with certain degree of fusion. Its word order is mainly SOV (Dixon and Aikhenvald, 1999).

A.3 Additional related work

Morphological segmentation was firs introduced by Harris (1951). Unsupervised methods are popular with the Morfessor (Creutz and Lagus, 2002, 2007; Poon et al., 2009) family of segmentors. They also have a semi-supervised version (Kohonen et al., 2010; Grönroos et al., 2014). Recently Adaptor Grammars have been applied with great success to the task (Eskander et al., 2019, 2020). Supervised methods have achieved the best results with methods like CRFs (Ruokolainen et al., 2013), LSTM taggers (Wang et al., 2016), seq2seq RNNs (Kann et al., 2018a), CNNs (Sorokin, 2019), pointer networks (Yang et al., 2019), and pointer generator networks (Mager et al., 2020).

For the MT down-stream task, few research has been done (Schwartz et al., 2020; Roest et al., 2020). New research has been done in context of the WMT 2020 shared task on Inuktitut-English Bawden et al. (2020); Kocmi (2020); Knowles et al. (2020); Roest et al. (2020).

Distributed NLI: Learning to Predict Human Opinion Distributions for Language Reasoning

Xiang Zhou* **Yixin Nie*** **Mohit Bansal**
Department of Computer Science
University of North Carolina at Chapel Hill
`{xzh, yixin1, mbansal}@cs.unc.edu`

Abstract

We introduce distributed NLI, a new NLU task with a goal to predict the *distribution* of human judgements for natural language inference. We show that by applying additional distribution estimation methods, namely, Monte Carlo (MC) Dropout, Deep Ensemble, Re-Calibration, and Distribution Distillation, models can capture human judgement distribution more effectively than the softmax baseline. We show that MC Dropout is able to achieve decent performance without any distribution annotations while Re-Calibration can give further improvements with extra distribution annotations, suggesting the value of multiple annotations for one example in modeling the distribution of human judgements. Despite these improvements, the best results are still far below the estimated human upper-bound, indicating that predicting the distribution of human judgements is still an open, challenging problem with a large room for improvements. We showcase the common errors for MC Dropout and Re-Calibration. Finally, we give guidelines on the usage of these methods with different levels of data availability and encourage future work on modeling the human opinion distribution for language reasoning.[1]

1 Introduction

Natural Language Understanding (NLU) and Reasoning play a fundamental role in Natural Language Processing (NLP) research. It has almost become the de facto rule that newly proposed generic language models will be tested on NLU tasks and progress obtained on general NLU often bring potential improvement on other aspects of NLP research (Wang et al., 2019). The well-known NLU tasks include Sentiment Analysis (Socher et al., 2013), Natural Language Inference (NLI) (Bowman et al., 2015; Nie et al., 2020a), Commonsense Reasoning (Talmor et al., 2019), etc., covering a representative set of problems for NLP.

One common practice shared by most of the language understanding and reasoning tasks is that they are formalized as a classification problem, where the model is required to predict a single most preferable label from a predefined candidate set, and the goal is to reverse-engineer how a reasonable human chooses the best one. This simplification not only helps standardize the evaluation, i.e., accuracy could become the canonical measure, but also help make the annotation task more straightforward during crowdsourcing data collection.

However, recent findings suggest that inherent disagreements exist in both the Natural Language Inference (NLI) and Commonsense Reasoning datasets (Pavlick and Kwiatkowski, 2019; Chen et al., 2020; Nie et al., 2020b) and advocate that NLU evaluation should explicitly incentivize models to predict distributions of human judgments. Similarly, Gantt et al. (2020) suggest that NLI should account for annotator random effects. This is intuitive since there might be different subjective views of the world and people might think differently given the same reasoning task especially those involving pragmatic reasoning (Potts et al., 2016). Modeling the distribution of human opinions provides a higher level "meta-view" of the collective human intelligence which would be valuable for all aspects of NLP applications.

In this work, as a case study for learning the distribution of human judgements on NLU, we extend the NLI task to distributed NLI – a new task in which models are required to predict the distribution of human judgements for natural language inference. We introduce the new task based on the data from prior works (Pavlick and Kwiatkowski, 2019; Nie et al., 2020b) with new experimental guidelines designed for the distribution annotations. Standard NLP models are trained towards predicting single labels, while in theory models

Findings of the Association for Computational Linguistics: ACL 2022, pages 972 - 987
May 22-27, 2022

trained on single labels should still be able to capture the whole label distribution (see Appendix E.3 for a more detailed discussion), their predicted distribution may not be reliable (Guo et al., 2017). To achieve better distribution estimation and to maintain the merits of SOTA models, we consider four distribution estimation methods that do not need major architecture changes, namely, MC Dropout (Gal, 2016), Deep Ensemble (Lakshminarayanan et al., 2017), Re-Calibration (Guo et al., 2017), and Distribution Distillation for distributed NLI. These methods have achieved empirical success in estimating the aleatoric uncertainty (Gal, 2016), calibrating the neural network prediction confidence (Guo et al., 2017), and neural network knowledge distillation (Hinton et al., 2015), respectively. We show that all four methods can substantially outperform the baseline and that Re-Calibration and Distribution Distillation can provide further improvement by making use of additional distribution annotations. Specifically, our primary contributions are:

- We introduce and define the distributed NLI task with the goal to model the distribution of human opinions on NLI. We also elaborate the motivation, feasibility (Sec. 2) and the experiential design (Sec. 3) for the task, serving as common ground for future research on the topic.

- We test 4 methods (MC Dropout, Deep Ensemble, Re-Calibration, Distribution Distillation) for predicting the distributions over human judgments on NLI according to our experimental design, and find: (1) all methods bring substantial improvements over baseline; (2) Re-Calibration, MC Dropout, and Distribution Distillation are able to further improve the performance by using additional distribution annotations (3) the best results are still far below the estimated human performance. (4) MC Dropout and Re-Calibration can achieve decent generalization performance on out-of-domain distributed NLI test set without in-domain training data (Sec. 6).

- Despite the improvement, we showcase common errors of MC Dropout and Re-Calibration and give guidelines on selecting methods and setting hyperparameters in different scenarios and argue for future work on modeling human opinions on language reasoning (Sec. 7).

2 Distributed NLI

2.1 Natural Language Inference

NLI was first introduced and mostly formulated as a 3-way classification problem. The input is a premise paired with a hypothesis. The output y is a discrete and mutually exclusive label that can be entailment, neutral, or contradiction, indicating the truthfulness of the hypothesis given the premise. Some works advocated a shift for NLI from the 3-way discrete labeling schema to a graded schema due to the probabilistic nature of entailment inference (Zhang et al., 2017; Chen et al., 2020). Following such schema, models were instead required to produce a continuous score representing how likely the premise is true given the hypothesis. No matter whether the label is discrete or graded, the conventional goal of NLI in most recent literature is to develop models to make the inferences that an *individual* would naturally make with an implicit assumption that there is only one true label.

2.2 Task Definition

We introduce distributed NLI by extending the conventional NLI label to be a distribution representing collective human opinions on the example. Specifically, the goal of distributed NLI is to ***develop NLI models that can predict a categorical distribution similar to the real human opinion distribution obtained from a large population.*** In the following subsection, we explain the motivation and importance of distributed NLI.

2.3 Motivation and Positioning

Advocated by Manning (2006), annotation tasks of NLI should be "natural" for untrained annotators, and that the role of NLP should be to model the inferences that humans make in practical settings without imposing a prescriptivist definition of what types of inferences are licensed.[2] Maintaining the "naturalness" of inference instead of referring to a strict definition of logic entailment facilitates the practical usage of NLI, however, it unfortunately brings a degree of uncertainty to the inference among different individuals. Recent findings reveal that inherent disagreements exist in a noticeable amount of examples in oft-used NLI

---

[2] There has been a gravitation towards the preference of natural inference over rigorous annotation guidelines based on a prescriptive definition of entailment relation in logic. We refer readers to (Pavlick and Kwiatkowski, 2019) for a more comprehensive discussion on the topic.

Premise	**Hypothesis**	**Labels**	**Hypothetical Reason for the Disagreement**
To savor the full effect of the architect's skill, enter the courtyard through the gate which opens onto the Hippodrome.	The gate to the Hippodrome is an example of the architect's skill.	$E^{(76)}$ $N^{(22)}$ $C^{(2)}$	Annotators might have different judgements on what is demonstrating the architect's skill. The gate is highly possible for some annotators but it is not certain for others.
Look, there's a legend here.	See, there is a well known hero here.	$E^{(57)}$ $N^{(42)}$ $C^{(1)}$	Whether "a legend" refers to a "well known hero" is debatable and subjective.
While it's probably true that democracies are unlikely to go to war unless they're attacked, sometimes they are the first to take the offensive.	Democracies probably won't go to war unless someone attacks them on their soil	$E^{(66)}$ $N^{(31)}$ $C^{(3)}$	The words like "probably" and "sometimes" make it hard to determine whether the "democracies" will be the first to attack or not.

Table 1: We show 3 examples from ChaosNLI-M with their distribution labels and our hypothesis regarding how the disagreement arises.

datasets (Pavlick and Kwiatkowski, 2019; Nie et al., 2020b). Hence, the conventional goal of NLI (i.e., to model the natural thinking process of a single human) may have a risk of ill-definition because a consensus on the label cannot be reached for some cases.[3] Examples are shown in Table 1. Moreover, with such label agreements, traditional evaluation methods using a single label may also become unreliable (Gordon et al., 2021). Our proposed distributed NLI resolves such a risk without compromising the naturalness of the inference.

An alternative approach toward the inherent disagreements is to narrow the task to model only the majority label. This is the default setup for most prior studies where multiple labels were collected for the examples in the development and test sets and the majority label will be chosen as the gold label upon which the accuracy will be calculated. We argue that such a practice is insufficient. With the advancement in general language modeling for NLU, we could envision NLI models having a potential influence on AI-aided critical decision making. Such decisions may be involved when assisting a jury's verdict of a lawsuit given the vocal and textual reports about the case (Surden, 2019; Armour and Sako, 2020), providing automated opinions for company recruiting or university admissions based on personal information (Ochmann and Laumer, 2020; Newman et al., 2020), or even helping governments make decisions (Eggers et al., 2017) (see the Appendix E.1 for potential NLI inputs for these applications). Hence, it would be important for the system used in such a decision-making process to be aware of different opinions and to pass the distribution of the collective opinions to either the actual decision maker or any downstream models.

Merits of Distribution Labels. The Distributed NLI and the traditional format of NLI seem to be two similar tasks with a major difference as using the distribution labels instead of the one-hot labels. However, we argue that these distribution labels can capture more fine-grained and subtle semantics that may have a great impact on downstream applications, which is ignored in the traditional one-hot labeling schema. Firstly, *distribution modeling captures more semantic subtleties.* Three examples are shown in Table 1. In order to predict the corresponding label correctly, the model needs to understand all these challenging language properties, including ambiguous relationships between phrases (e.g. "legend" vs. "well known hero" in the second example), sentences with subjective understandings (the first example), sentences with more complicated relationships hard to attribute any of the three classes conclusively (the third example). These challenges are not visible in the traditional one-hot label schema, but become essential to solving the distributed NLI task. Additionally, *capturing these semantic ambiguities can also lead to great impact in downstream tasks and real-life applications*. NLI models are widely used in various downstream tasks either to conduct a sub-step and to provide rewards (Pasunuru and Bansal, 2017; Falke et al., 2019), where the data distribution can be diverse and noisy (e.g. model-generated sentences are usually imperfect), which leads to more complex and ambiguous labels. Models capturing better label distribution can be more useful in these downstream applications, as well as in the potential decision-making applications.

Remark on Labeling Schema. For the study of distributed NLI in this work, we maintain the discrete labeling schema rather than the graded labeling schema because this is the default format by which most of the natural data is recorded. The discrete label is also more straightforward for annotation, since annotators are accustomed to providing their discrete judgement (yes or no, true or false) in daily life, but usually not a real value indicating

---

[3] In such cases, we cannot coerce a most legitimate label by giving a prescriptivist definition of the inference since it will contradict the "naturalness" of the task described above.

how confident (or strong) their feelings are. Note that despite the schema choice in this work, the concept of distributed NLI can be easily generalized to graded-label settings where the target is to fit a distribution of the continuous grade score. Finally, there can be a connection between the distributed NLI categorical distribution and the graded score annotated by an individual human. Despite their different meanings, the judgement of individual humans can sometimes be influenced by their belief of other people's thoughts (Kovács et al., 2010).

Remark on Future Directions. Additionally, an ideal model should also be able to capture the detailed thought process behind the prediction of each label and provide corresponding explanations. Such interpretability will make the model more reliable in critical applications, but is generally beyond the capability of current models and hard to evaluate under current datasets. While related information can be extracted from current models by using post-hoc interpretability tools (e.g. LIME (Ribeiro et al., 2016)), we encourage future works to build more interpretable models and collect datasets suitable for more fine-grained evaluations.

Remark on Annotation Quality. Evaluation of distributed NLI compares model prediction to the opinion distribution estimated by multiple annotations. We noticed that examples with a high-level of disagreement usually require more mental effort to annotate. While previous work (Pavlick and Kwiatkowski, 2019; Nie et al., 2020b) have conducted analyses showing these collected label distribution contain genuine intrinsic disagreement, we also notice unreasonable labels that may just come from annotation noises. So far, it is still unclear whether the collected distribution labels are *high-quality* and *clean* enough to serve as evaluation datasets. Therefore, to ensure that the evaluation is valid, it is crucial to maintain the quality of annotations such that the label distribution will indeed represent opinion diversity rather than annotation errors. As an example, we use ChaosNLI (Nie et al., 2020b) in our experiments, which is collected with careful quality control.[4] Furthermore, we conducted a manual quality check on 100 examples from the ChaosNLI-M (the D_s^{dev} subset later to be introduced in Sec. 3). Each example has 100 three-way annotated NLI labels, and we examine whether any of the 100 annotations for each example will be an absolute error in almost all scenarios. In total, only 4 (out of 100) examples contain more than 10 error annotations and no example contain more than 16 error annotations. Quantitatively, we have also verified that these errors do not substantially impact the findings and comparisons in this paper. More detailed results and examples on annotation quality analysis are in the Appendix E.2.

3 Dataset and Experiment Design

In this section, we describe a typical design of dataset and experiment of the distributed NLI task, and is used in later experiments in this work. For a typical NLI task, the dataset is split into train, development, and test set where each example is associated with one ground truth label. The model will be trained using examples in the training set. Accuracy on the development set is used for model selection, and accuracy on the test set will be reported as the final metric. For distributed NLI, in order to develop models that can predict the label distribution, we assume that each example in the test set will also have a sufficient amount of human labels to approximate the real human label distribution to evaluate the model's prediction.

Let us define the D^{train}, D^{dev}, D_s^{dev}, and D_s^{test} to be the different splits of the dataset. The subscript s in D_s^{dev} and D_s^{test} indicates that the examples in these two splits have soft labels representing the human label distribution, while there is no such label in D^{train} and D^{dev}. D_s^{dev} is a very small set of examples with soft-labels besides the test set. This gives a good simulation for real production because in practice, D_s^{dev} will be extremely scarce. The goal of the distributed NLI is to develop models that can predict human label distributions and minimize the average divergence between predicted label distributions and approximated human label distributions on the test set using examples in D^{train}, D^{dev}, and D_s^{dev}. [5] Even though obtaining these soft label distributions is expensive, our design can generalize to the situation where we can also have enough training data with soft-label by simply making a new split D_s^{train} on which the model can be trained.

---

[4] Note that despite the three-way discrete label schema choice in this work, the concept of distributed NLI can be easily generalized to other datasets, including graded-label settings where the target is to fit a distribution of the continuous grade score. More discussion is in the Appendix E

[5] Although D_s^{dev} is also called development set, there is no strict relation between examples in D_s^{dev} and D^{dev}. They could share some examples or can be mutually exclusive.

4 Distribution Estimation

The output of a typical NLI classifier is a vector $\mathbf{z} \in \mathbf{R}^3$ whose elements z_i represent the unnormalized scores (or logits) for each of the three labels (Parikh et al., 2016; Nie and Bansal, 2017). In modern NLI models, the classifier is usually a deep neural network and the final output is:

$$\hat{\mathbf{y}} = \mathrm{Softmax}(\mathbf{z}), \quad \hat{c} = \arg\max(\mathbf{z})$$

where $\hat{\mathbf{y}}$ is the normalized label distribution whose element $\hat{y}_i = e^{z_i} / \sum e^{z_i}$, and $\hat{c}$ is the predicted label. Prior works (Pavlick and Kwiatkowski, 2019; Nie et al., 2020b) revealed that the distribution $\hat{\mathbf{y}}$ produced by the softmax layer gives a poor estimation on the real human label distribution.

In this work, we experiment on using distribution estimation methods for predicting human opinion distribution on NLI, and we show that they can achieve better performance than the softmax output. These methods have been used in uncertainty estimation and confidence calibration with some empirical success. Although the problem of uncertainty estimation is different from opinion distribution estimation, the essence of the two are the same – the estimation of a distribution.[6]

4.1 Bayesian Inference

The Bayesian view of neural networks (MacKay, 1992; Neal, 1995) offers a mathematically grounded framework to produce a distribution for the end task. From a Bayesian perspective, we have a prior over possible models $p(\theta)$, a likelihood of the data $p(D|\theta)$, and we can use the expected posterior prediction as the final prediction distribution:

$$p(\hat{y}|x) = \int_\theta p(\hat{y}|x, \theta) p(D|\theta) p(\theta) d\theta$$

In practice, the integral over θ is intractable. We can approximate it by Monte Carlo sampling (Metropolis and Ulam, 1949) θ from an approximated posterior $p(\theta|D) \propto p(D|\theta)p(\theta)$ and then averaging their outputs.

$$p(\hat{y}|x) = \mathbb{E}_{p(\theta|D)} [\![p(\hat{y}|x, \theta)]\!] \approx \frac{1}{k} \sum_i^k p(\hat{y}|x, \theta_i)$$

where θ_i is one of the k models sampled from the posterior $p(\theta|D)$. The calculation of the real posterior $p(\theta|D)$ is also intractable and there are multiple ways to approximate the model parameters sampled from the posterior. In this work, we consider two simple and empirically effective methods.

Deep Ensemble. The ensemble of neural networks (Lakshminarayanan et al., 2017) has an intuitive Bayesian interpretation: network initialization is a sample from the prior $p(\theta)$ and network training is maximizing the data likelihood $p(D|\theta)$. Hence, sampling k models from posterior $p(\theta|D)$ can be approximated by training k models with different initialization and example ordering.

Monte Carlo Dropout. Sampling models by ensemble is computationally expensive because in total, k models need to be trained, and even training one single model is already expensive for some tasks. Alternatively, Gal and Ghahramani (2016) proposed an efficient method that directly draws the samples by making k stochastic forward passes with dropout in one single fully trained neural network. Loosely speaking, this is similar to obtaining samples by adding noise to a fully trained network (Srivastava et al., 2014): $p(\hat{y}|x, \theta_i) = p(\hat{y}|x, \theta + \sigma_i)$. The method was shown to have good performances on neural network uncertainty estimation, and we refer the readers to the original paper for a detailed theoretic description.

Remark. The Bayesian approach for the estimation of the NLI human label distribution has an appealing analogy to collective thinking. Sampling θ_i from parameter space can be seen as sampling an individual person from a large population with potentially diverse opinions. The stochasticity in personal experience is analogous to the randomness of network initialization and training dynamics.

4.2 Re-Calibration

The Bayesian method has a nice theoretical ground and does not require additional soft-labeled data D_s^{dev}. However, the empirical performance of Bayesian methods can be suboptimal due to overly idealized approximation. Therefore, we also consider the method of calibration for distribution estimation which makes empirical post-editing on the output of the network by explicitly taking advantage of additional soft-labeled data D_s^{dev}. The core of calibration is to seek a proper scaling of $\mathbf{z}$ such that the calibrated output $\hat{y}$ can better present the objective distribution.In our work, the calibrated predicted distribution is:

$$\hat{y}_i = \frac{z_i/T}{\sum_i z_i/T}$$

---

[6] Conceptually, capturing the distribution label in NLU tasks is similar to modeling the aleatoric uncertainty (Kendall and Gal, 2017). And the uncertainty estimation of the opinion distribution can be itself a new task out of this paper's scope.

Experiments	D^{train}	D^{dev}	D_s^{dev}	D_s^{test}
ChaosNLI-α	169,654	3,059	100	1,432
ChaosNLI-S	942,854	10,000	100	1,414
ChaosNLI-M	942,854	10,000	100	1,499
UNLI	-	-	-	2,998
PK2019	-	-	-	297

Table 2: The size of each data split in this work.

The method is called temperature scaling and T is a hyper-parameter that will be tuned on the hold-out validation set D_s^{dev} by minimizing the summation of the KL-divergence between the predicted distribution and the true distribution for the examples in the set: $\sum \mathrm{KL}\,(\mathbf{y}\|\hat{\mathbf{y}})$. Note that the method is proposed to be used in confidence calibration (Guo et al., 2017), whereas we use it for calibrating the model outputs to the human label distribution.

4.3 Distribution Distillation

Both the Bayesian Inference and Re-Calibration methods do not involve a supervised learning process that is often effective for training models. Here, we consider another method that involves direct training of neural networks called Distribution distillation (reminiscent of model distillation (Hinton et al., 2015)). Distribution distillation consists of three steps. Firstly, we use a "teacher method", which can be the Bayesian Inference or Re-Calibration method explained above, to obtain high-quality distribution estimation using D^{train}, D^{dev}, D_s^{dev}. Secondly, we re-label the training set D^{train} with the "teacher method" so every example in the training set will be associated with a pseudo soft-label. Finally, we train a new "student model" using the relabeled training set. The method is similar to distilling the distribution knowledge of the "teacher method" to the final "student model" through a large-scale diverse training set.

5 Experimental Setup

5.1 Datasets

We consider the following two NLI-related tasks in our experiments: NLI, and abductive commonsense reasoning. As described in Sec. 3, we need to make the split for D^{train}, D^{dev}, D_s^{dev}, and D_s^{test} for each task. We use ChaosNLI (Nie et al., 2020b) as the data source for D_s^{dev} and D_s^{test} since every example in ChaosNLI are associated with high quality 100 human-annotated labels.[7] Following (Nie et al., 2020b), for each task, we calculate the soft-label for D_s^{dev} and D_s^{test} by using the 100 labels for each example in ChaosNLI. We sampled 100 examples from ChaosNLI and use them for D_s^{dev} and all the other example in ChaosNLI are used for D_s^{test}. We use the training set of SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) as D^{train} for the NLI task and the training set of αNLI (Bhagavatula et al., 2020) as D^{train} for the abductive reasoning task. We use SNLI-test, MNLI-dev-mismatch, and αNLI-test as the D^{dev}.[8] Additionally, we use the dataset (PK2019) collected in Pavlick and Kwiatkowski (2019) as a generalization test set since it contains NLI examples from a different set of domains from MNLI and SNLI.[9] Note that each example in PK2019 is labeled by 100 annotators with graded labeling schema and we converted the graded labels to 3-way labels (the same format as ChaosNLI) following the conversion guidelines in Pavlick and Kwiatkowski (2019). The sizes of each split are in Table 2, and another Table summarizing the split details here is in the Appendix A. Moreover, to understand how well the distribution estimation method can capture individual graded plausibility judgements, we also test our methods on UNLI (Chen et al., 2020) where each example is annotated with one single graded label denoting a continuous plausibility score. For both UNLI and PK2019, we again removed the examples that appeared in our training or development set. The resulting PK2019 dataset used in this work only contains examples from RTE2 (Dagan et al., 2005), DNC (Poliak et al., 2018) and JOCI (Zhang et al., 2017).

5.2 Metrics

We report the accuracy on the majority label and the KL-divergence and JS-distance (JSD) between the predicted distribution and the soft distribution. On UNLI, we report the Pearson correlation r and the Spearman correlation ρ between the provided graded label and the predicted entailment probability, following the original UNLI setup.[10] On PK2019, we report the same metrics as ChaosNLI.

---

[7] As explained in Sec. 2.3, ChaosNLI is collected with rigid quality control and manual examination reveals that most annotation disagreement results in the actual opinion discrepancy between annotators rather than errors.

[8] The examples in ChaosNLI used in D_s^{test} are mostly from the development splits of the original dataset. Therefore, we need to modify the original dev and test split in this work.

[9] There is no official name for the data in (Pavlick and Kwiatkowski, 2019). For simplicity, we name it PK2019.

[10] We do not report the MSE metric for UNLI since their label represents slightly different meanings as our output, our model is not expected to predict the same value as the target.

5.3 Implementation Details

All the models in this work are built on RoBERTa-Large (Liu et al., 2019). We use the accuracy on the development set (D^{dev}) for model selection. We run each model with 10 seeds and report the mean. Additionally, for the baseline experiments, we also report the best performance over 10 different runs. All models are trained using the default dropout rate (0.1) for RoBERTa-Large models. Hyperparameter details are in the Appendix B.

6 Results

The performances of different distribution estimation methods are shown in Table 3. The first group (row 2-5) presents the results that do not make use of the soft-labeled data D_s^{dev}, while the second group (row 6-8) uses D_s^{dev}. Table 4 shows the performance of distribution estimation methods on the out-of-domain test set and the performance of predicting individual graded plausibility judgments. In what follows, we explain the main findings.

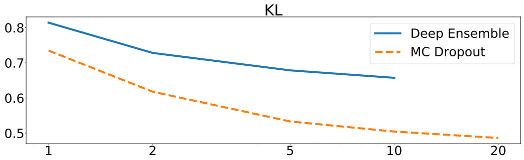

Figure 1: KL divergence of MC Dropout and Deep Ensemble with different numbers of model samples.

MC Dropout is the most preferable method without additional soft-labeled data. The first thing we can observe from the first group (row 2-5) in Table 3 is that both MC Dropout and the Deep Ensemble outperform baselines on all the metrics. More importantly, MC Dropout substantially outperforms Deep Ensemble in all KL and JSD columns, with a slight drop on Accuracy. Notice that the MC Dropout results reported in this group are obtained by using the default dropout rate of RoBERTa-Large models (0.1), without tuning on any additional data. The advantage of MC Dropout over Deep Ensemble is different from previous works (Lakshminarayanan et al., 2017), and we suspect that this is attributed to the fine-tuning regime of BERT-based models, causing the models in the ensemble to be less diverse. Note that compared to Deep Ensemble, MC dropout does not require training multiple models.

Further improvement can be obtained by using soft-labeled data, but still below estimated human upper-bound.[11] From the second group (row 6-8) of Table 3, we can see further improve-

---

[11] We refer the readers to Nie et al. (2020b) for details about the estimation of human upper-bound performance.

ment over the Bayesian methods by using additional 100 soft-labeled data D_s^{dev}. For example, on ChaosNLI-α, Re-Calibration achieves 0.1615 KL (MC Dropout get 0.5045) and 0.1663 JSD (MC Dropout 0.1882). We also include an upper-bound Re-Calibration result by directly applying this method on the test set (> 1000 examples), but get very close performance to the result with only 100 labels, showing that Re-Calibration is label-efficient. With an additional set of soft-labeled data D_s^{dev}, we can also tune the optimal dropout rate of MC Dropout.[12] The results are shown in the table with name MC Dropout (Opt. Rate). The JSD and KL performance after tuning are substantially higher than the original MC Dropout, however, there is also a substantial decrease on the overall accuracy, and overall this method does not outperform Re-Calibration. Additionally, Distribution Distillation[13] only gives slightly better JSD than Re-Calibration, with additional computational cost of retraining the model on the whole relabeled training set, indicating that directly applying Re-Calibration is more efficient. Lastly, the best results here are still below estimated human upper-bound, leaving huge room for improvements.

In-domain improvements hold on the out-of-domain set. Table 4 shows the direct generalization results on PK2019 of the models trained on SNLI and MNLI. All the improvements on the in-domain test sets, including MC Dropout over the baseline and the Re-calibration over the MC Dropout, still hold on the out-of-domain examples in the PK2019 test set. Although the out-of-domain scores are generally lower than the in-domain scores in Table 3, MC Dropout and Re-Calibration can still bring substantial improvements over the baselines without any PK2019 training data.

Correlation exists between opinion distribution and graded individual judgement. As explained in Sec. 2.3 and 5.1, the distribution of human opinions on NLI examples is different from the individual graded plausibility judgement. In Table 4, we compare the entailment probability output by the distribution estimation method with the graded plausibility scores in UNLI. Although MC dropout and Re-Calibration method underperform the baseline on Spearman correlation, Re-Calibration can still greatly improve the Pearson correlation r. More importantly, our best distribution estimation method without using any UNLI data is noticeably comparable to the reported numbers in UNLI (Chen et al., 2020) using a fine-tuned model on in-domain UNLI data. This hints at a certain correlation between opinion distributions and graded individual judgements, consistent with our intuition regarding the interpretation of the labels.

7 Ablation & Analysis

7.1 Ablations for Re-Calibration

In the previous section, we showed the effectiveness of Re-Calibration in predicting human opinion distribution by explicitly utilizing extra soft-labeled data D_s^{dev}. To get a better sense of what contributes to the performance, we make two ablations on D_s^{dev}: (1) reducing the size of D_s^{dev} from 100 to 10; (2) using only the majority class as hard labels in D_s^{dev} rather than the whole label distribution as soft labels for Re-Calibration. Table 5 shows the results.[14] We can observe that with only 10 examples, Re-Calibration can already achieve good performance, with slightly worse KL but slightly better JSD.[15] However, using only the hard labels gives significantly worse scores than using the soft labels on ChaosNLI-M, indicating the necessity of extra annotations in human distribution modeling.

7.2 Sample Sizes in Bayesian Method

In both MC Dropout and Deep Ensemble methods, the distribution is approximated by sampling. To understand how the number of samples will influence the results, we present the result for both methods with different numbers of samples (k) on ChaosNLI-α in Figure 1. We can see that while a larger number of samples will lead to better distribution estimation results on KL, the gain is gradually diminished (even with the log-scale x-axis in Figure 1). Similar trends can also be seen on JSD and Accuracy and the figures are in the Appendix D. Considering practical constraints on inference time and computational budget that prohibit a very large number of samples, in our experiments, numbers around 10 is a sweet point between good performance and an acceptable computational budget.

---

[12] In this experiment, the tuning is done by a linear search through 0.0 to 1.0 with step size 0.05. For ChaosNLI-α, the searched optimal dropout rate is 0.25, and the value for ChaosNLI-S and ChaosNLI-M is 0.25 and 0.3 respectively.

[13] We use Re-Calibration as its teacher method.

[14] See Appendix C for full results including ChaosNLI-S.

[15] The diverse trend is because that the re-calibration is conducted only using the KL metric, but the temperature with the best KL metric does not lead to the best JSD.

Premise	Professor Rogers began her career by clerking for The Honorable Thomas D. Lambros of the United States District Court for the Northern District of Ohio.
Hypothesis	Her career benefited from being a clerk to Thomas.
	Prediction (Entailment / Neutral / Contradiction)
Human Distribution	0.33 / 0.66 / 0.01
MC Dropout	0.1617 / 0.8362 / 0.0021
Re-Calibration	0.3063 / 0.5902 / 0.1035

Table 6: An example of prediction distribution and human ground truth in MNLI.

7.3 Distribution Prediction Example

Table 6 shows an example from MNLI with the prediction distribution from both MC Dropout and Re-Calibration. We can see that one-third of humans believe the label should be entailment and two-third as neutral. It is commonsense that clerking for an honorable District Court can be a really rewarding experience, though the premise does not explicitly say so. The MC Dropout method underestimates such a factor and gives more than 80% for the neutral label. Notably, although Re-Calibration method predicts a smoother distribution that resembles human distribution more, it ends up erroneously increasing the probability for the inexplicable contradiction label. Such observation that MC Dropout tends to overlook the disagreement and Re-Calibration can sometimes produce smooth distribution but with erroneously high probabilities is common and should be taken into consideration before practical deployment. More error-analysis examples and a more detailed comparison of the predictions of distribution prediction methods on the whole-dataset level is in the Appendix F, G.

8 Related Work

Inherent disagreement and ambiguity in NLP annotations has a long history (Poesio and Artstein, 2005; Zeman, 2010) involving tasks like coreference resolution (Poesio et al., 2008, 2019; Li et al., 2020), POS-tagging (Zeman, 2010; Plank et al., 2014, 2016), semantic frame disambiguation (Dumitrache et al., 2019), humorousness prediction (Simpson et al., 2019), etc. Most previous works design methods to predict one single gold label by aggregating the noisy information (Dawid and Skene, 1979; Hovy et al., 2013; Rodrigues et al., 2017; Paun et al., 2018; Braylan and Lease, 2020; Fornaciari et al., 2021). On the contrary, following the recent definition in NLI works (Chen et al., 2020; Pavlick and Kwiatkowski, 2019; Nie et al., 2020b), we directly try to predict distribution labels that accurately reflect the opinion of a large population. Peterson et al. (2019) is most similar to us in label definition, and studied the advantage of using distribution labels in image classification.

Uncertainty and calibration have also been studied in various NLP models, from traditional structured prediction models (Nguyen and O'Connor, 2015), to seq-to-seq models (Ott et al., 2018; Kumar and Sarawagi, 2019; Xu et al., 2020) and transformers (Desai and Durrett, 2020). Gantt et al. (2020) suggests a constructive view of NLI modeling in which the prediction is explicitly grounded on annotator identifiers, incorporating the annotator random effects. Zhang and de Marneffe (2021) propose an ensemble-based framework that can identify examples with high label disagreement. Xiao and Wang (2019) shows that explicitly modeling the uncertainty can improve performance, and Wang et al. (2020) propose a label smoothing method that improves calibration for NMT. Instead of aiming for a better uncertainty, our work uses multiple uncertainty estimation methods for more accurate distribution prediction. Concurrently, Meissner et al. (2021) explores training models directly on the multiple labels from each annotator in SNLI and MNLI, Zhang et al. (2021a,b) also leverage distribution labels in the model development process and explore training methods combining the supervision signal of one-hot and distributional labels. In comparison, our work studies additional Bayesian estimation methods and provides a detailed discussion on why and how modeling distribution labels is beneficial for NLU, including the motivation, nuances, and evaluation standardization.

9 Conclusion

We introduce distributed NLI – an extension of NLI with a new goal of predicting human opinion distribution. We show that several distribution estimation methods can capture such distributions more effectively than softmax, but the best results are still far below the estimated upper-bound. We analyze the properties and weaknesses of the methods, highlight the importance of the task, and encourage future work on developing better models for estimating the human opinion distribution.

10 Ethical Considerations

The main target of this paper is to propose a new extension of the NLI task that focuses on predicting the whole distribution instead of one single label. Our new formalization can potentially make the related application of NLI more reliable in the practice, as the models trained on our proposed task will focus more on minority opinions which may be ignored in the traditional formalization. Nonetheless, we are strongly against the use of current NLI models in any critical applications (e.g. admission, jury, etc.). While NLP models can use to help human judgment (and the results should be verified by a human), their robustness and fairness are still an unsolved issue, and cannot replace the work of human experts.

A Dataset Split Details

The details of dataset split, including the source of the data and the corresponding size in Table 7. The UNLI data can be downloaded at `https://nlp.jhu.edu/unli/`. The PK2019 data is at `https://github.com/epavlick/NLI-variation-data`. The ChaosNLI data is at `https://github.com/easonnie/ChaosNLI`.

B Hyperparameter Details

All the models in this work are built on RoBERTa-Large (Liu et al., 2019). For both NLI and αNLI tasks, we fine-tune our model with peak learning rate 5e-6, warm-up ratio 0.1 and linear learning rate decay. We use a batch size of 32. We train the NLI model for 2 epochs, and the αNLI model for 3 epochs. We always use the accuracy on the development set (D^{dev}) for model selection. All our experiments are conducted on a single server with 4 GTX 1080Ti GPUs.

C Full Re-Calibration Ablation

The full results of Re-Calibration ablations is shown in Table 8. We can see on all three subsets of ChaosNLI, Re-Calibration always achieves good performance even with as few as 10 additional distribution labels; and using 100 distribution labels always significantly outperforms using 100 hard labels without any distribution information.

D The Effect of Sample Size

Figure 2 shows model performances on all three metrics (JSD, KL and Accuracy) with different sample sizes. We can observe similar trends on the KL metric as discussed in the main paper. While a larger number of samples usually leads to better performance, the gain is gradually diminished.

E Additional Motivation and Positioning of Distributed NLI

E.1 Potential Applications of Distributed NLI

In order for NLU models to aid humans in decision-making, it is important for NLI models to output a valid distribution and to capture the opinions of the minority sub-populations. We include two example inputs in such situations in Table 9.

E.2 Analysis of Annotation Quality

We manually examined the label correctness of the 100 examples in the D_s^{dev} split of ChaosNLI-M.

Experiments	**Train** D^{train}	**Dev** D^{dev}	**Soft Dev** D_s^{dev}	**Test** D_s^{test}
ChaosNLI-α	αNLI$^{\text{train}}$ (169654)	αNLI$^{\text{Test}}$ (3059)	αNLI$^{\text{dev}}$ (100)	ChaosNLI-α- D_s^{dev} (1432)
ChaosNLI-S	SNLI$^{\text{train}}$ + MNLI$^{\text{train}}$ (942854)	SNLI$^{\text{Test}}$ (10000)	SNLI$^{\text{dev}}$ (100)	ChaosNLI-S- D_s^{dev} (1414)
ChaosNLI-M	SNLI$^{\text{train}}$ + MNLI$^{\text{train}}$ (942854)	MNLI$^{\text{dev}}_{\text{mismatch}}$ (10000)	MNLI$^{\text{dev}}_{\text{match}}$ (100)	ChaosNLI-M- D_s^{dev} (1499)
UNLI	-	-	-	UNLI (2998)
PK2019	-	-	-	PK2019 (297)

Table 7: Data sources for each split. The corresponding size of each split is shown in the bracket after the source.

	ChaosNLI-α		**ChaosNLI-S**		**ChaosNLI-M**	
	JSD↓	**KL**↓	**JSD**↓	**KL**↓	**JSD**↓	**KL**↓
$D_s^{dev} = 100$	0.1663	**0.1615**	0.1889	**0.1733**	0.2015	**0.1873**
$D_s^{dev} = 10$	**0.1570**	0.1973	**0.1744**	0.1977	**0.1962**	0.1940
No soft label	0.1738	0.1630	0.2008	0.3667	0.2347	0.3704

Table 8: Re-calibration performances with different types of labels. ↓ indicates smaller value is better. ↑ indicates larger value is better. For each column, the best values are in bold.

Premise	**Hypothesis**
Case Description: Some dark night a policeman walks down a street, apparently deserted; but suddenly he hears a burglar alarm, looks across the street, and sees a jewelry store with a broken window. Then a gentleman wearing a mask comes crawling out through the broken window, carrying a bag which turns out to be full of expensive jewelry.[16]	The gentleman is dishonest and guilty for stealing.
The *Off Fossil Fuels for a Better Future Act* lays out that by 2035: (1) 100% of electricity must be generated from clean energy resources, (2) 100% of vehicle sales from manufacturers must be zero-emission vehicles, and (3) 100% of train rail lines and train engines must be electrified.	Passing the bill means embracing clean energy sources for the good of sustainable development.

Table 9: Examples where AI-aided human decision making can be formulated as an NLI problem.

Due to the careful quality control over label collection, only a very limited set of the labels are incorrect. Out of the 100 examples in the examined subset, only 4 examples contain more than 10 error annotations and no example contain more than 16 error annotations. In Table 10, we show two examples of incorrect label annotations in the D_s^{dev} split of ChaosNLI-M. While both examples do contain a certain level of semantic ambiguities, with careful reasoning, we do not find sufficient evidence to make the "contradiction" or "entailment" judgement in those cases respectively, hence we view these labels as error annotations.

We also verified these incorrect labels will not substantially impact the results in this paper. For these 100 examples, we removed all the incorrect labels with more than 5 annotations and created a **corrected** label set. The performance difference between the **original** annotations and the **corrected** annotations can be seen in Table 12. We can see only marginal performance difference is shown for the Baseline, MC Dropout and Deep Ensemble variants. The performance difference for the Re-Calibration variant is slighter larger due to the fact that these labels are also directly used in the temperature calibration process, but it also only leads to a relatively small difference around 0.01. Furthermore, using either the original or the corrected labels, the order of more effective methods (Re-Calibration > MC Dropout > Deep Ensemble > Baseline) always holds.

E.3 Predicting Label Distribution from Deterministic Labels

Another question around the feasibility of the Distributed NLI is whether model can learn label distributions if only deterministic labels are possible. Here we prove it is definitely possible if the deterministic labels are annotated by individual annotators.[17] Specifically, if we assume all the training inputs x are randomly sampled from a dataset D, and each corresponding label y is provided from a random annotator a from a set of annotators A. Then, on the training set, the model is trained to minimize $\underset{x \in D}{\mathbb{E}} \underset{a \in A}{\mathbb{E}} \text{KL}\left(y_a(x) \| P(x)\right)$. Specifically, assuming the model parameter is θ, the optimiza-

---

[17] Annotations from datasets like MNLI and SNLI can still be roughly viewed as labels from individual annotators with an additional voting-based filtering methods that filters out noisy labels using voting among 5 annotators.

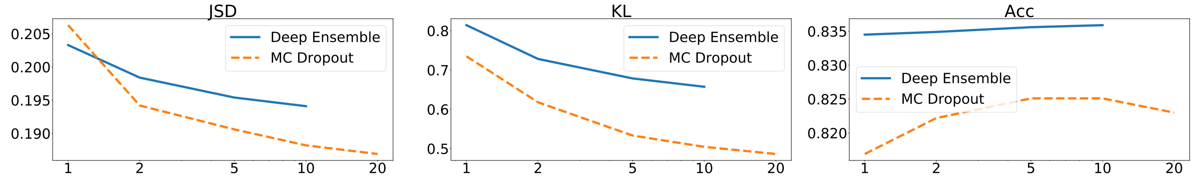

Figure 2: Performances of MC Dropout and Deep Ensemble with different numbers of model samples.

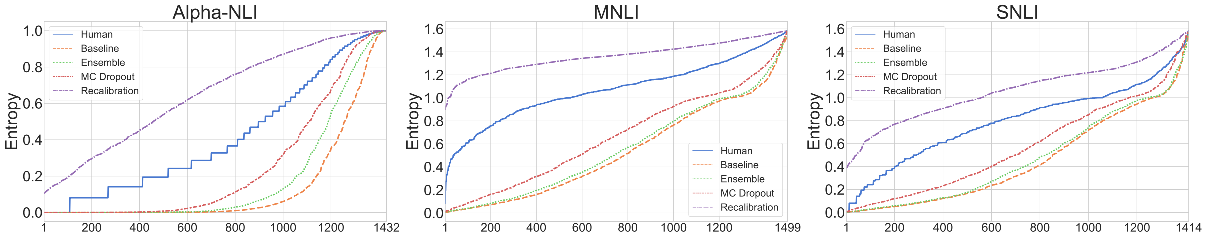

Figure 3: Entropy quantile curve on ChaosNLI. Each point in this figure represents model's prediction on one example. y-axis is the entropy value, and x-axis is the prediction's index in a sequence of examples sorted in the increasing-entropy order.

tion target is:

$$
\begin{aligned}
&\arg\min_{\theta} \mathop{\mathbb{E}}_{x\in D} \mathop{\mathbb{E}}_{a\in A} \mathrm{KL}\left(y_a(x)\|P_\theta(x)\right) \\
=&\arg\min_{\theta} \mathop{\mathbb{E}}_{x\in D} \mathop{\mathbb{E}}_{a\in A} \sum_j y_a(x)_j \frac{\log y_a(x)_j}{\log P_\theta(x)_j} \\
=&\arg\min_{\theta} \mathop{\mathbb{E}}_{x\in D} \mathop{\mathbb{E}}_{a\in A} \sum_j -y_a(x)_j \log P_\theta(x)_j \\
=&\arg\min_{\theta} \mathop{\mathbb{E}}_{x\in D} \sum_j -(\mathop{\mathbb{E}}_{a\in A} y_a(x))_j \log P_\theta(x)_j \\
=&\arg\min_{\theta} \mathop{\mathbb{E}}_{x\in D} \sum_j (\mathop{\mathbb{E}}_{a\in A} y_a(x))_j \frac{\log(\mathbb{E}_{a\in A}\, y_a(x))_j}{\log P_\theta(x)_j} \\
=&\arg\min_{\theta} \mathop{\mathbb{E}}_{x\in D} \mathrm{KL}\left(\mathop{\mathbb{E}}_{a\in A} y_a(x)\|P_\theta(x)\right)
\end{aligned}
$$

, where j is each dimension of the output label. Hence, even with deterministic labels, the model still achieves the best performance if and only if when given an example x, $P_\theta(x) = \mathop{\mathbb{E}}_{a\in A} y_a(x)$, where the model correctly predicts the distribution of all labels.

F More Analysis on Distribution Prediction Examples

In this section, we provided more prediction examples and a more comprehensive analysis in addition to the examples shown in the Ablation & Analysis section in the main paper. Specifically, we focus on analyzing what are the worst-prediction examples produced by current models.

For each model variant, we checked the performance on the D_s^{dev} split on ChaosNLI-M and focused on the examples with the largest KL-divergence (worst-prediction examples). For the baseline, we again noticed the trend that models being over-confident on examples with substantial ambiguity. We show two examples in Table 11. In both of these cases, the model fails to capture the label distribution caused by subtle phrase relationships or under-specified meaning depending on the context, etc. As shown in the results section in the main paper, Such over-confidence can be partially alleviated by the Bayesian uncertainty estimation methods (e.g., MC-Dropout and Deep Ensemble) and by the Re-calibration methods. However, most of the top 10 worst-prediction examples of the baseline variant still remain in the top 10 worst-prediction list of the Bayesian and Re-calibration approaches. This observation is possibly due to the limited improvement of Bayesian approaches and the incapability of Re-calibration methods to correct totally wrong predictions, hence showing current models' inherent incapability to capture these distributions. We also encourage future work to explore the connection between the model's incapability to capture distribution labels and the model's tendency to focus on artifact features.

G Prediction Difference in Bayesian Inference and Re-Calibration

We show that both Bayesian Inference and Re-Calibration can achieve better JSD and KL scores

---

[17] The example is from Jaynes (2003).

Premise	you want to punch the button and go
Hypothesis	You don't want to push the button lightly, but rather punch it hard.
	Prediction (Entailment / Neutral / Contradiction)
Original Annotation	0.48 / 0.45 / 0.07
Incorrect Labels	Contradiction
Reasons for Incorrect Labels	There is no sufficient evidence in the premise indicating "you also want to push the button lightly".
Premise	The tomb guardian will unlock the gate to the tunnel and give you a candle to explore the small circular catacomb, but for what little you can see, it is hardly worth the effort.
Hypothesis	The tomb garden can give you a thorough tour of the catacombs.
	Prediction (Entailment / Neutral / Contradiction)
Original Annotation	0.10 / 0.14 / 0.76
Incorrect Labels	Entailment
Reasons for Incorrect Labels	The premise mentions "tomb guardian" instead of "tomb garden", so it should not be entailment.

Table 10: Examples of wrong annotations on the D_s^{dev} split of ChaosNLI-M.

Premise	They said that (1) agencies need to be able to design their procedures to fit their particular circumstances (e.g.
Hypothesis	The authors of the recently introduced bill stated each agency would be required to match their operational methods to their particular situations.
	Prediction (Entailment / Neutral / Contradiction)
Human Distribution	0.58 / 0.30 / 0.12
Baseline	0.002 / 0.997 / 0.001
Reasons for Ambiguity	Based on different understanding of the phrases "need to be able to" in the premise, this sentence pair can have different labels.
Premise	What changed?
Hypothesis	Nothing changed.
	Prediction (Entailment / Neutral / Contradiction)
Human Distribution	0.04 / 0.76 / 0.20
Baseline	0.001 / 0.007 / 0.992
Reasons for Ambiguity	In different contexts, the question in the premise can imply different meanings.

Table 11: Examples of prediction distribution of the baseline model and human ground truth in MNLI.

Model	**JSD↓**		**KL↓**	
	Original	**Corrected**	**Original**	**Corrected**
Baseline (Mean)	0.3053	0.3039	0.8383	0.8343
MC Dropout	0.2649	0.2653	0.5851	0.5839
Deep Ensemble	0.2956	0.2941	0.7775	0.7709
Re-Calibration	**0.1983**	**0.2079**	**0.1859**	**0.1983**

Table 12: Performances difference on the D_s^{dev} split of ChaosNLI-M.

in the main paper. In order to investigate the difference between the predictions produced by the two methods, we conduct the following analysis. Firstly, for each example in the test set, we calculate the entropy for the models outputs as $\mathbf{H}(\mathbf{p}) = -\sum_{i \in \{e,n,c\}} p_i \log(p_i)$ where p_i is the probability for entailment, neutral, or contradiction. We also calculate the entropy for human using the annotations in ChaosNLI. We then sort the entropy and plot their entropy values for each model. The plot is shown in Fig. 3.[18] We can see a large gap between the blue line representing human distribution and the orange dashed line representing the baseline, consistent with previous quantitative findings. While Bayesian inference methods can slightly reduce this gap, there is still large room for improvements. Moreover, the distribution predicted by the Re-Calibration method is noticeably different from the ones given by the MC Dropout, Ensemble, and the baseline method, while the latter three are very similar to each other. Finally, it is worth noting that the line for the Re-Calibration method is above the human line while the other three methods are below the human line. This suggests that Re-Calibration method tends to over-predict the disagreement among humans whereas the Bayesian method and the baseline fail to capture some inherent disagreements.

---

[18] The design of the figure is similar to the Q–Q (quantile-quantile) plot (Gnanadesikan and Wilk, 1968), a visualization method to compare two probability distributions by plotting their quantiles against each other. We modify the plot to give an intuitive comparison for all the distribution estimation methods in our study.

Morphological Processing of Low-Resource Languages: Where We Are and What's Next

Abstract

Automatic morphological processing can aid downstream natural language processing applications, especially for low-resource languages, and assist language documentation efforts for endangered languages. Having long been multilingual, the field of computational morphology is increasingly moving towards approaches suitable for languages with minimal or no annotated resources. First, we survey recent developments in computational morphology with a focus on low-resource languages. Second, we argue that the field is ready to tackle the logical next challenge: understanding a language's morphology from raw text alone. We perform an empirical study on a truly unsupervised version of the paradigm completion task and show that, while existing state-of-the-art models bridged by two newly proposed models we devise perform reasonably, there is still much room for improvement. The stakes are high: solving this task will increase the language coverage of morphological resources by a number of magnitudes.

1 Introduction

Automatic morphological processing tools have the potential to drastically speed up language documentation (Moeller et al., 2020) and thereby help combat the language endangerment crisis (Austin and Sallabank, 2011). Explicit morphological information also benefits myriad NLP tasks, such as parsing (Hohensee and Bender, 2012; Seeker and Çetinoğlu, 2015), language modeling (Blevins and Zettlemoyer, 2019; Park et al., 2021; Hofmann et al., 2021), and machine translation (Dyer et al., 2008; Tamchyna et al., 2017).

For low-resource languages, valuable morphological resources are typically small or non-existent. Of late, the field of computational morphology has increased its efforts to extend the coverage of multilingual morphological resources (Kirov et al., 2016, 2018; McCarthy et al., 2020a; Metheniti and Neumann, 2020). Simultaneously, there has been a revival of minimally supervised and unsupervised models for morphological tasks, such as segmentation (Eskander et al., 2019), inflection (Kann et al., 2017b), and lemmatization (Bergmanis and Goldwater, 2019). Given the speed of recent developments, it is important to reflect on where we are as a field and what future challenges lie ahead.

To this end, we survey recent computational morphology: we review existing multilingual resources (§2) and tasks and systems (§3), with a focus on low-resource languages. Given recent developments in unsupervised segmentation, low-resource morphological inflection, and unsupervised morphological paradigm completion (Jin et al., 2020; Erdmann et al., 2020)—which we argue is not fully unsupervised—we believe the community is poised for the next logical step: inferring a language's morphology purely from raw text.

In §4, we formalize a new task: *truly unsupervised morphological paradigm completion* (*t*UMPC). We then introduce a pipeline with two novel components (§4.3): one model for aligning paradigm slots across lexemes and another for predicting the slots of observed forms. With these, we assess several state-of-the-art models and the influence of different types of unlabeled corpora within the framework of *t*UMPC. While existing methods leave room for improvement, they perform reasonably enough to support our argument that inferring a language's morphology from raw text is within reach and worthy of community efforts.

To summarize, we present the following contributions: (i) a survey of tasks and systems in computational morphology with a focus on low-resource languages; (ii) models for the tasks of paradigm slot alignment and slot prediction, (iii) a formalization of the task of truly unsupervised morphological paradigm completion and (iv) an evaluation of state-of-the-art approaches and differ-

ent corpora within the framework of this task. Our code and data are publicly available.[1]

2 Morphological Resources

Manually created resources are necessary for developing and evaluating NLP systems. They also serve as a basis for research questions in a multilingual context (Pimentel et al., 2019; Wu et al., 2019).[2] Below, we review the two largest active multilingual resources for morphology and a number of language-specific resources.

Background and Notation The canonical form of a word is called its *lemma*, and the set of all surface forms of a lemma is referred to as that lemma's *paradigm*. As is common, we formally write the paradigm of a lemma ℓ as:

$$\pi(\ell) = \left\langle f(\ell, \vec{t}_\gamma) \right\rangle_{\gamma \in \Gamma(\ell)}, \tag{1}$$

with $f : \Sigma^* \times \mathcal{T} \to \Sigma^*$ defining a mapping from a tuple consisting of the lemma and a vector $\vec{t}_\gamma \in \mathcal{T}$ of morphological features to the corresponding inflected form. Σ is an alphabet of discrete symbols: the characters used in the language of lemma ℓ. $\Gamma(\ell)$ is the set of slots in ℓ's paradigm.

UniMorph The UniMorph project (Sylak-Glassman et al., 2015a,b; Kirov et al., 2016) is a database of triples organized into paradigms, where each triple represents a word as its lemma ℓ, morpho-syntactic description $\vec{t}_\gamma$, and surface form $f(\ell, \vec{t}_\gamma)$. An English example triple is:

mutate	mutates	V;3;SG;PRS

This structure provides training data for inflection generation, lemmatization, or paradigm completion. The most recent version of UniMorph (McCarthy et al., 2020a) includes 118 languages and 14.8 million triples, with more languages under development. As it is semi-automatically created, issues have been noted—particularly, it is a convenience sample across languages (Gorman et al., 2019; Malouf et al., 2020). Still, related efforts validate themselves using UniMorph, including Metheniti and Neumann (2020)—another Wiktionary-derived resource for morphology. Wikinflection captures segmentation information (§3.2) from Wiktionary templates, though the authors note some limits in the morphological tags that are extracted to accompany these.

Universal Dependencies Whereas UniMorph contains type-level annotations, the Universal Dependencies project (UD) is a resource of token-level annotations. As of writing, the latest release (v2.8; Zeman et al., 2021) spans 114 languages, typically semi-automatically extracted from existing corpora, sometimes with less comprehensive annotations (Malaviya et al., 2018). The structure is useful for morphological tagging (§3.1) at the sentence level (Goldman and Tsarfaty, 2021), and several languages have parallel text, enabling evaluation of projection-based approaches for morphology induction, parsing, and other tasks (Yarowsky et al., 2001; Rasooli and Collins, 2017).

Mapping between UniMorph and Universal Dependencies The UD2 morphological annotations borrow several features from UniMorph.[3] Consequently, there is great harmony between the two schemas. A deterministic mapping (McCarthy et al., 2018) has shown the synergy; for instance, Bergmanis and Goldwater (2019) augment a contextual tagger with UniMorph inflection tables.

Language-Specific Resources Throughout the years, many language-specific morphological resources have been created. These include corpora and treebanks like the morphologically annotated corpus for Emirati Arabic by Khalifa et al. (2018). Resources also come in the form of morphological databases, such as CELEX for Dutch, English and German (Baayen et al., 1996), or morphological analyzers, such as the Paraguayan Guaraní analyzer presented by Zueva et al. (2020).

Creation of morphological resources is an ongoing effort which in recent years has increasingly focused on low-resource languages. Several conferences and workshops like LREC (Calzolari et al., 2020), SIGMORPHON (Nicolai et al., 2021), ComputEL (Arppe et al., 2021), AmericasNLP (Mager et al., 2021), PYLO (Klavans, 2018) and FSMNLP (Maletti and Constant, 2011) have presented and continue to present language-specific tools and datasets for computational morphology.

3 Where We Are: Tasks and Systems

3.1 Morphological Tagging

Morphological tagging is a sequence-labeling task similar to part-of-speech (POS) tagging. As a token-level task, it considers words in context.

---

[1] `https://github.com/Adamits/tUMPC`

[2] This approach has been criticized by Malouf et al. (2020) due to incompleteness and quality of existing resources.

[3] `http://universaldependencies.org/v2/features.html#comparison-with-unimorph`

Given a sentence, it consists of assigning to each word $f(\ell, \vec{t_\gamma})$ a morphosyntactic description (MSD), i.e., a tag representing the morphological features $\vec{t_\gamma}$ it expresses. For instance, in the sentence *The virus mutates*, the word *mutates* would be assigned the tag V;3;SG;PRS. Morphological tagging was featured in the SIGMORPHON 2019 shared task (McCarthy et al., 2019).

Systems A leading non-neural morphological tagger is MARMOT (Mueller et al., 2013), a higher-order conditional random field (CRF; Lafferty et al., 2001) tagger. Of late, LSTM (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017) models have been used for tagging (Heigold et al., 2016, 2017; Nguyen et al., 2021).

For low-resource languages, both projection-based approaches (Buys and Botha, 2016) and cross-lingual transfer approaches via multitask training (Cotterell and Heigold, 2017) have been developed. 16 systems were submitted to the SIGMORPHON 2019 shared task[4] (McCarthy et al., 2019), which featured 66 languages. The winning team (Kondratyuk, 2019) built a tagger based on multilingual BERT (Devlin et al., 2019), thus employing cross-lingual transfer; for other systems, we refer the reader to the shared task overview. The largest multilingual morphological tagging effort to date is that by Nicolai et al. (2020) who build morphological analyzers for 1108 languages using projection from a high-resource to a low-resource language via the aligned text in the JHU Bible Corpus (McCarthy et al., 2020b).

3.2 Morphological Segmentation

The goal of morphological segmentation (Goldsmith, 2010) is to split words into their smallest meaning-bearing units: morphemes. We discuss both surface and canonical segmentation here.

3.2.1 Surface Segmentation

During surface segmentation, a word is split into morphemes in a way such that the concatenation of all parts exactly results in the original word. An example (with "*" marking boundaries) is:

$$\text{mutates} \rightarrow \text{mutate} * \text{s}$$

Surface segmentation was the focus of the Morpho Challenge from 2005 to 2010 (Kurimo et al., 2010). The competition featured datasets in Finnish, Turkish, German, English, and Arabic. Additionally, segmentation was a track (alongside morphological analysis and generation) of LowResourceEval-2019 (Klyachko et al., 2020), a shared task which featured four low-resource languages from Russia. The shared task overview lists morphological resources for other Russian languages.

Systems Many approaches to this task are unsupervised. Harris (1970) identifies morpheme boundaries in English based on the frequency of characters at the end of a word. LINGUISTICA (Goldsmith, 2001) finds sets of stems and suffixes that represent the minimum description length of the data. MORFESSOR (Creutz and Lagus, 2002) introduces a family of probabilistic models for identifying morphemes, which have seen wide use, including variations of the original model (Virpioja et al., 2009; Smit et al., 2014). Lignos et al. (2009) learn rewrite rules that can explain many types in the corpus. Poon et al. (2009) apply a CRF to unsupervised segmentation by learning parameters with contrastive estimation (Smith and Eisner, 2005). Incorporating semantic similarity between related words that form ”chains” has also been shown to be effective (Narasimhan et al., 2015). Monson et al. (2007) propose a segmentation algorithm that exposes the properties of partial morphological paradigms in order to learn segments. Xu et al. (2018) iteratively refine segments according to their distribution across paradigms. They filter unreliable paradigms with statistically reliable ones, and induce segments with the proposed partial paradigms. Both systems can only model suffix concatenation. Xu et al. (2020) follow a similar strategy, but incorporate language typology, expanding beyond suffixes, and outperform Xu et al. (2018). MorphAGram (Eskander et al., 2020) is a publicly available tool for unsupervised segmentation based on adaptor grammars (Johnson et al., 2007).

Supervised (Creutz and Lagus, 2005; Ruokolainen et al., 2013; Cotterell et al., 2015) and semi-supervised systems (Ruokolainen et al., 2014) also exist. Non-neural systems are often based on CRFs. Ruokolainen et al. (2013) focus explicitly on low-resource settings and perform experiments on Arabic, English, Hebrew, Finnish, and Turkish with training set sizes as small as 100 instances.

Neural models have also been applied to surface segmentation: Wang et al. (2016) obtain strong re-

---

[4] The task is concerned with joint lemmatization and tagging, but systems can be used for separate tagging as well.

sults with window LSTM neural networks in the high-resource setting, Seker and Tsarfaty (2020) introduce a pointer network (Vinyals et al., 2015) for segmentation and tagging, and Micher (2017) propose a segmental RNN (Kong et al., 2015) for segmentation and tagging of Inuktitut. Kann et al. (2018b) explore LSTM-based sequence-to-sequence (seq2seq) models for segmentation in combination with data augmentation, multitask and multilingual training; they evaluate on datasets they introduce for four low-resource Mexican languages. Eskander et al. (2019) apply an *unsupervised* approach based on adaptor grammars to the same languages; it outperforms supervised methods in some cases. Sorokin (2019) show that CNNs outperform RNN-based models on that data as well as on North Sámi (Grönroos et al., 2019).

Additional contributions have been made by Yarowsky and Wicentowski (2000), Schone and Jurafsky (2001), and Clark (2001). Linguistically informed approaches show demonstrable value compared to approaches like BPE; see Church (2020) and Hofmann et al. (2021). Still, not all morphological phenomena are suited for a segmentation-based analysis, as in fusional morphology that sometimes leaves ambiguity as to where a morpheme boundary lies; indeed in some cases there is no consensus among linguists as to the proper segmentation of a word. Therefore, (especially surface) segmentation is not necessarily meaningful for all languages.

3.2.2 Canonical Segmentation

Canonical segmentation is more complex: its aim is to jointly split a word into morphemes and to undo the orthographic changes which have occurred during word formation. As a result, each word is segmented into its *canonical* morphemes. While often not being modeled this way in practice, the task can be seen as the following two-step process:

manic → maniaic → mania * ic

Systems The state-of-the-art pre-neural system is the CRF-based model by Cotterell et al. (2016c), which is jointly trained on segmentation and restoration of orthographic changes. The unsupervised system of Bergmanis and Goldwater (2017) builds upon MorphoChains (Narasimhan et al., 2015). Neural models are typically based on seq2seq architectures: Kann et al. (2016) use a seq2seq GRU and a feature-based reranker. Like Cotterell et al. (2016c), they evaluate on German, English, and Indonesian. Ruzsics and Samardžić (2017) use a similar system, but add a language model over canonical segments and do not require external resources. In addition to German, English, and Indonesian, they evaluate on Chintang, a truly low-resource language spoken in Nepal. Wang et al. (2019) use a character-level seq2seq model for (surface and) canonical segmentation in Mongolian. Mager et al. (2020) show the benefit of copy mechanisms and introduce datasets for two low-resource Mexican languages. Moeng et al. (2021) show that Transformers outperform RNNs for canonical segmentation in four Nguni languages.

3.3 Lemmatization, Inflection, Reinflection

Inflection and reinflection have recently gained popularity in computational morphology by being featured in yearly SIGMORPHON shared tasks (Cotterell et al., 2016b). They are concerned with generating inflected forms $f(\ell, \vec{t_\gamma})$ of a lemma ℓ; the target inflected form can be specified in different ways, depending on the exact task formulation. While the terms *inflection* and *reinflection* are sometimes used synonymously in the literature, *inflection* refers to generating a word form from a given *lemma*, while *reinflection* refers to generation from an *arbitrary* given form in the paradigm. Lemmatization is a special case of reinflection: instead of generating an indicated inflected form, a lemma is produced. As the target form is implicitly determined by the task definition, lemmatization generally does not require tags to indicate which form to generate.

3.3.1 Type-level Versions

Most commonly, lemmatization, inflection and reinflection are type-level tasks. The input consists of an input form together with the target MSD (which can be omitted for lemmatization). The output is the corresponding inflected form, for instance:

mutated V;3;SG;PRS → mutates

The version of reinflection featured in the SIGMORPHON 2016 shared task also provides the MSD of the *source form*, but performance improvements are usually minor (Cotterell et al., 2016a).

Systems Pre-neural systems for the task include those by Durrett and DeNero (2013) and Nicolai et al. (2015). These systems align lemmas and inflections before extracting character-level transductions for training CRF-inspired models. Faruqui et al. (2016) propose the first neural model for morphological inflection, an RNN seq2seq model, but fail to outperform prior approaches on some of the datasets they evaluate on. The breakthrough for neural models was the SIGMORPHON 2016 shared task (Cotterell et al., 2016a), with about one third of the systems being neural: the winning system (Kann and Schütze, 2016a,b) used multitask training by encoding MSDs together with the character sequence of the source word. This approach has now become the standard for the task, and while a multilingual version of the model by Kann and Schütze (2016a) was submitted to the SIGMORPHON 2021 shared task (Pimentel et al., 2021; Szolnok et al., 2021), the same multitask approach has since been used with other seq2seq models such as Transformers (Wu et al., 2021). Ensembles have been shown to improve performance for inflection (Kann and Schütze, 2016a) and have been systematically studied for the task by Kylliäinen and Silfverberg (2019).

The SIGMORPHON shared tasks on morphological inflection have focused increasingly on low-resource settings. Seq2seq models with hard monotonic attention (Aharoni and Goldberg, 2017), a copy mechanism (Sharma et al., 2018; Singer and Kann, 2020), or both (Makarov et al., 2017; Makarov and Clematide, 2018a,b) obtain great results for training sets as small as 100 examples. Cross-lingual transfer via multitask training was proposed by Kann et al. (2017b) for GRU seq2seq models and has later been used with other architectures, e.g., in the SIGMORPHON 2019 shared task on cross-lingual transfer (McCarthy et al., 2019).

Another approach suitable for low-resource languages is data augmentation. For morphological inflection, this was suggested by several contemporaneous works (Kann and Schütze, 2017; Bergmanis et al., 2017; Silfverberg et al., 2017). In the following years, other augmentation strategies have been developed (Anastasopoulos and Neubig, 2019). The success of data augmentation is mixed, as it is largely dependent on the architecture (*Does it have to learn how to copy or is there a copy mechanism?*) as well as on the quality of the original data, which influences the quality of artificially generated examples.

3.3.2 Token-level Versions

The token-level version of the task is often referred to as lemmatization or inflection *in context*. Here the information about which form to generate is explicitly given via a sentence context in which the target word should be embedded, e.g.:

mutate – The virus [MASK]. → mutates

A drawback of this formulation is that typically many different inflected forms are possible within the same context: in the given example, *mutates* is the gold solution, but *mutated* would be equally grammatical. To overcome this, multiple gold solutions can be provided (Cotterell et al., 2018). It might be impossible to unambiguously define the target form for some languages if the speaker's intention is unknown.

Systems Lemmatization in context is arguably easier than inflection or reinflection, as the target form for generation is implicitly defined. Neural models for inflection are seq2seq architectures: Bergmanis and Goldwater (2018) propose Lematus, a character-level LSTM, which they later extend to the low-resource setting by training on labeled data in combination with raw text (Bergmanis and Goldwater, 2019). They explore data settings as small as 1k types each from UD and UniMorph. Zalmout and Habash (2020) use a similar architecture to Lematus but add subword features. Malaviya et al. (2019) present a joint model for tagging and lemmatization and show that joint training benefits low-resource languages. They evaluate on 20 languages, using data from UD. The best lemmatizer in the SIGMORPHON 2019 shared task (McCarthy et al., 2019), UDPipe (Straka et al., 2019), is based on BERT (Devlin et al., 2019).

Inflection in context can be tackled by neural seq2seq models too. Models typically either see a context window around the target word (Makarov and Clematide, 2018c; Kann et al., 2018a; Ács, 2018) and then are optionally trained via multitask training (Kementchedjhieva et al., 2018) or predict the MSD of the form to generate as a first step (Liu et al., 2018). Kementchedjhieva et al. (2018) show that a multilingual model can aid low-resource languages via cross-lingual transfer.

3.4 Paradigm Completion

The paradigm cell filling problem (Ackerman et al., 2009) – also called supervised paradigm completion (Cotterell et al., 2017a) – is yet another inflection task, but differs from the above ones in that the inflected forms for *all* slots $\Gamma(\ell)$ of lemma ℓ's paradigm need to be generated and that the input can consist of *one or more* forms.

Systems Many approaches for the paradigm cell filling problem are effectively systems for morphological reinflection and generate all forms of a paradigm individually and from a single input form, e.g., Silfverberg et al. (2017); Silfverberg and Hulden (2018); Moeller et al. (2020). Kann et al. (2017a) propose a model for multi-source inflection, showing that multiple available forms per paradigm can be beneficial for generation, but do not evaluate on paradigm completion. Two notable exceptions which design approaches explicitly for the paradigm cell filling problem are Cotterell et al. (2017b) and Kann and Schütze (2018). Cotterell et al. (2017b) rely on the notion of principal parts (Finkel and Stump, 2007) to jointly generate all forms in the paradigm. Kann and Schütze (2018) use a transductive training approach, fine-tuning on a paradigm's *input* forms before generating missing target forms. The latter shows good performance for training sets with as few as 10 paradigms.

3.5 Paradigm Clustering

Paradigm clustering can be seen as a first step towards the unsupervised analysis of a language's morphology and is typically part of pipelines for unsupervised paradigm completion (§3.6). The goal of paradigm clustering is to group all types in a corpus into (partial) morphological paradigms. For example, the input *The*, *virus*, *mutates*, *after*, *it*, *has*, *mutated* should result in the paradigm cluster (*mutates*, *mutated*) and 5 singleton clusters. Systems for the task can be evaluated using best-match F1 (BMF1; Wiemerslage et al., 2021).

Systems Perhaps the seminal work in distributionally-based paradigm clustering is the work of Yarowsky and Wicentowski (2000). Their work predates embedding-based approaches while leveraging both distributional features of context and relative frequency, along with early statistical models of inflection-to-lemma string transduction. For instance, the work succeeds in identifying that the past tense of 'sing' is not 'singed' but 'sang', based on both the distributional signatures of music vs. fire terms in context, as well as the distribution of observed tense *frequency ratios*, where the regular *sing:singed* pairing can also be rejected given its frequency ratio is several standard deviations off of expectation, while the irregular *sing:sang* pairing occurs at nearly exactly the ratio expected. While contextual information has been incorporated in follow-up works (Schone and Jurafsky, 2001) and in recent approaches by means of word embeddings, we do not see much follow-on use of the frequency ratio features, which remain ripe for disambiguation of paradigm members.

Segmentation approaches like Goldsmith (2001), developed to segment words into stems and affixes, can also be used to induce paradigm clusters. Chan (2006) formalizes the notion of a probabilistic paradigm — modeling conditional probabilities of suffixes given paradigms and paradigms given stems. However, they that a segmentation is given, and only model regular morphology for unambiguous words, or those with a known POS. Some segmentation algorithms induce paradigms as a byproduct, as in Monson et al. (2007), Xu et al. (2018) and Xu et al. (2020). These can also be employed as paradigm clustering systems.

Several systems have been proposed for the SIGMORPHON 2021 shared task (Wiemerslage et al., 2021). The best performing system (McCurdy et al., 2021) segments input types with MorphAGram (Eskander et al., 2020), then groups the resulting stems into paradigm clusters. Yang et al. (2021) learn frequent transformation rules and cluster types together that result from rule application.

3.6 Unsupervised Paradigm Completion

Due to the recent progress on supervised morphological tasks, unsupervised paradigm completion (UMPC; or the *paradigm discovery problem* (Elsner et al., 2019)) has recently (re)emerged as a promising way to automatically extend morphological resources such as UniMorph to more low-resource languages. Similar to the supervised version of the task, the goal is to generate the inflected forms corresponding to *all* slots $\Gamma(\ell)$ of lemma ℓ's paradigm. However, no morphological annotations are given during training. Two independent works propose similar unsupervised paradigm completion setups. In Jin et al. (2020), the basis of the SIGMORPHON 2020 shared task (Kann et al., 2020), the input consists of 1) a corpus in a low-resource language and 2) a list of lemmas from one POS in that language. In Erdmann et al. (2020), the inputs are 1) a corpus and 2) a list of word forms belonging to a single POS. For both, the expected output is the paradigms for the words in the provided list.

As systems are trained without supervision, they cannot output human-readable MSDs and, instead, assign uninterpretable slot identifiers to generated forms. Thus, evaluation against gold standard data from UniMorph is non-trivial. Jin et al. (2020) propose to evaluate systems via best-match accuracy (BMAcc): the best accuracy among all mappings from pseudo tags to paradigm slots.

Systems State-of-the-art systems for paradigm completion follow a pipeline approach similar to that by Jin et al. (2020): 1) based on the given input forms, they detect transformations which happen during inflection (and sometimes new lemmas), 2) the paradigm structure is detected based on the transformations, and 3) an inflection model is trained to generate missing surface forms. Jin et al. (2020) employ the inflection model by Makarov and Clematide (2018a), while Mager and Kann (2020) use the LSTM pointer-generator model from Sharma et al. (2018), and Singer and Kann (2020) implement a Transformer-based pointer-generator model. The performance across languages is mixed (Kann et al., 2020).

Is the Task Truly Unsupervised? Existing versions of the unsupervised paradigm completion task make small concessions to supervision requirements by providing lists of lemmas or surface forms from a single POS. This simplifies a difficult task, but also makes it less realistic. From the point of view of data availability, this method is not language-agnostic, as many languages do not have the required documentation: many of the world's languages have fuzzy POS definitions, and no annotated POS corpora. From a language learning perspective, existing methods are closer to L2 than to L1 learning.

Under this framing, UMPC requires only discovering the set of inflection slots for a single paradigm, of a single POS that must be known a priori. The presence of a word list also allows systems to anchor to a privileged form and simplifies paradigm clustering to a retrieval task.

4 What's Next: Truly Unsupervised Paradigm Completion

4.1 Motivation

We introduce a version of UMPC that more strictly removes human intervention. By removing the input lexicon and evaluating more than one POS, we minimize any prior human involvement with the data and better evaluate a system's ability to generalize. This means that our only input is a raw text corpus, and it introduces two challenges. 1) We must model the entire training corpus, rather than a filtered set of words. 2) We must predict which slots to generate at test time. We design test sets to evaluate these problems, ensuring they include paradigms from at least two POS, and prompt for input forms in context, half of which are unseen in the training corpora, so systems can infer the input word POS. We refer to this version of the task as *truly* unsupervised paradigm completion (*t*UMPC).

4.2 Data and Languages

Languages We select three development languages (English, Finnish, and Swedish) and four test languages (German, Greek, Icelandic, and Russian). We select our test languages to maximize orthographic and typological diversity, given three constraints: (1) a large number of available paradigms in UniMorph, (2) two or more POS in UniMorph, and (3) no known issues with the UniMorph data such as large numbers of missing forms. (We exclude all paradigms containing multiword forms.) We note that this yields a set of test languages that are all Indo-European, though it spans three different orthographies.

Raw Text Corpora We experiment on two corpora: the JHU Bible Corpus (McCarthy et al., 2020b) and a child-directed corpus we create by digitizing children's books. While many studies in computational morphology focus on transcripts of child-directed speech from databases like CHILDES (MacWhinney, 2014), child-directed books are part of parent's child-directed talk, and are thus an important source of language for many children (Montag et al., 2015). We translate the child-directed corpus into all of our languages from English using the Google Translate API following Dou and Neubig (2021). We tokenize with spaCy.[5] Details are given in Table A.1.

Test Data Our test data consists of words in context from two different corpora – Wikipedia (Ginter et al., 2017) and JW300 (Agić and Vulić, 2019) –, plus their gold paradigms from UniMorph. A detailed description of the preparation of the test data can be found in Appendix C.2.

4.3 Models

To use existing state-of-the-art approaches and to evaluate them within the framework of *t*UMPC,

---

[5] `https://spacy.io`

we tackle the task with a pipeline approach, conducting 4 steps: 1) paradigm clustering, 2) slot alignment, 3) slot prediction, and 4) inflection generation. State-of-the-art models exist for Steps 1 and 4, and we propose systems for Steps 2 and 3 here, together with descriptions of those subtasks. Hyperparameters for all models are in Appendix B.

Paradigm Clustering The first step for *t*UMPC is clustering words into paradigms. We compare 3 paradigm clustering algorithms: McCurdy et al. (2021, `McC`), Xu et al. (2018, `Xu`), and the baseline from Wiemerslage et al. (2021, `SIG`). We modify `SIG` so it does not predict clusters which are subsets of other clusters, which improves precision. For reference, we provide those systems' paradigm clustering results in Table A.2. In some clustering systems, each type appears in only one paradigm, which confounds our task for types that can instantiate more than one POS, and thus more than one inflectional paradigm, depending on the context.

Slot Alignment Slot alignment is concerned with identifying which words across paradigms express the same inflectional information.

The system we propose for the task first removes all singleton paradigm clusters from the input, as they contain no inflection pairs to learn from, and converts all remaining clusters into abstract paradigms $c_i \in C$ (Hulden et al., 2014) by computing the longest common substring (LCS) for each cluster. For example, the LCS of the (true) paradigm of *walk* is *walk*, and the abstract paradigm is *X0*, *X0+ed*, *X0+ing*, *X0+s*. We filter abstract forms that appear less than $\beta = 50$ times.

Next, we assign a POS tag to each cluster. With a set of latent tags Z, we define a Bayesian model:

$$P(k, c_i) = P(k) \prod_{f_j \in c_i} P(f_j \mid k) \tag{2}$$

$$P(c_i) = \sum_{k \in Z} P(c_i, k) \tag{3}$$

We then maximize the likelihood of the paradigm clusters $c_i \in C$ with an expectation maximization algorithm (Dempster et al., 1977). The POS assignment for each c_i is thus $\text{argmax}_k(P(k, c_i))$, and $|Z|$ is a hyperparameter which we set to 3.

We now have sets C^k. We assign a slot to each form in an abstract paradigm, considering one C^k at a time. To this end, we compute a fastText (Bojanowski et al., 2017) embedding for each type in the corpus and compute the embedding for an abstract form a as the average fastText embedding of all types whose abstract form is a. We define the similarity of two abstract forms a and a' as

$$\text{sim}(a, a') = \cos(a, a') \times (1 - J(a, a')), \tag{4}$$

where $\cos(a, a')$ is the cosine similarity, J is the Jaccard similarity

$$J(a, a') = \frac{|C^a \cap C^{a'}|}{|C^a \cup C^{a'}|}, \tag{5}$$

and C^a is the set of abstract paradigms containing a. Finally, we apply agglomerative clustering over the abstract forms with (4) as our similarity metric and a distance threshold of 0.15.

Slot Prediction Given a test form $f(\ell, \vec{t_\gamma})$, the goal of slot prediction is to predict the source slot $\vec{t_\gamma}$ and target slots $\Gamma(\ell)$. We treat this as a simplified POS tagging task and use a character-level Transformer seq2seq model to predict a word's POS tag and source slot. The model is trained on the results of the slot alignment step. For every word from the raw-text corpus that was assigned a slot, we sample up to 5 unique contexts. A given target word is input with its left and right neighbors; context words that occur fewer than $\alpha = 50$ times in the training data are replaced with OOV. The outputs are the POS tag and the source slot generated by slot alignment. We train our model in FAIRSEQ (Ott et al., 2019); hyperparameters are in Appendix B.

At test time, the model predicts $f(\ell, \vec{t_\gamma})$ and the (pseudo) POS tag. Because the slot alignment step associates each POS tag with a unique set of slots, we can perform a simple lookup to find the slots that $f(\ell, \vec{t_\gamma})$ inflects for.

Morphological Inflection To generate missing forms, we train state-of-the-art inflection models on the results of the slot alignment step and generate surface forms according to the slot prediction. We experiment with the following three models: Makarov and Clematide (2018a, `M&C`), Wu et al. (2021, `Wu`), and Kann and Schütze (2016b, `K&S`).

4.4 Non-neural Baseline

We compare against a rule-based system (`baseline`) that heuristically predicts the same set of slots for all words, and inflects by applying edit trees to input words. A detailed description is in Appendix D, together with a comparison between `baseline` and our proposed POS-based system

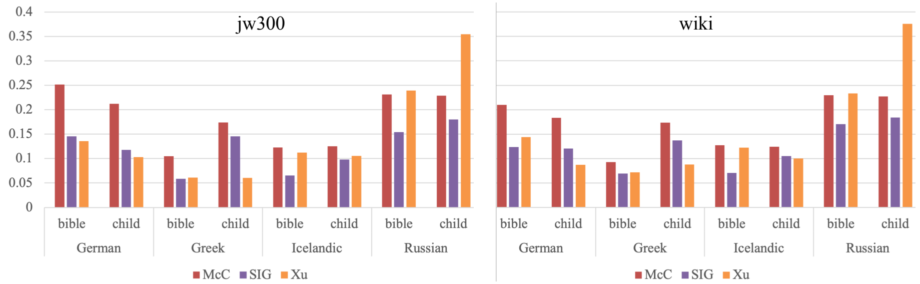

Figure 1: BMAcc for each paradigm clustering system for the POS-based slot aligner; averaged over inflectors.

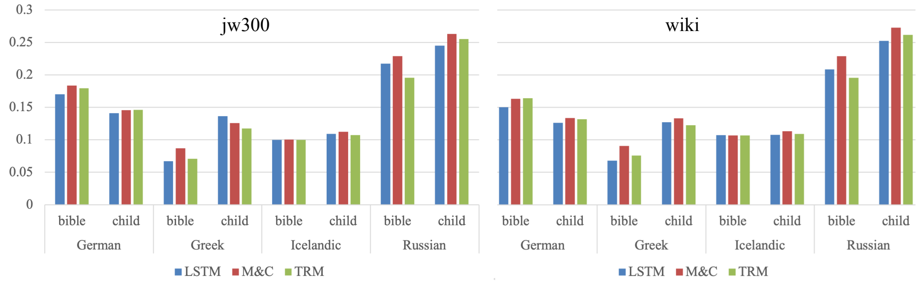

Figure 2: BMAcc for each inflector for the POS-based slot aligner; averaged over paradigm clusters.

for slot alignment and slot prediction. As the POS-based system clearly outperforms `baseline`, we focus the remainder of this paper on the former.

4.5 Results and Discussion

We present results from all experiments in terms of BMAcc (Jin et al., 2020). Overall, *t*UMPC is difficult, though the variance in results over different components of our pipeline implies that there is a great deal of room for the community to innovate. We see the lowest scores for our Greek and Icelandic corpora. These have far fewer tokens than German and Russian, plus higher type–token ratios, which likely makes the task more challenging.

Impact of the Clustering System Figure 1 shows that the choice of paradigm clustering strategy strongly affects our pipeline's downstream performance. `McC`, the best performing clustering system on the paradigm clustering task, frequently outperforms the other two strategies. The exception to this is Russian, where `Xu` gives the best results—by a large margin when learning from the child-directed training corpora.

Impact of the Inflection System From Figure 2 it is obvious that the choice of inflection model does *not* have a large effect on downstream results. All three systems we compare are known to be extremely competitive on the supervised inflection task, so it is reasonable to assume that they fit the generated training data relatively similarly. Future work can assess how inflection generation can best account for the noisy nature of the data in this task, akin to Michel and Neubig (2018).

Impact of the Corpus The consilience of our results suggests that the child-directed corpus leads to slightly better downstream performance, except in German. Notably, the German Bible contains far more tokens and far fewer types than the corresponding child-directed corpus (Table A.1), which may significantly simplify the learning task.

5 Conclusion

Thanks to strong systems for inflection, segmentation, and paradigm completion, computational morphology is ripe to contribute to the large number of the world's languages with very few digital resources. We explore this through the novel task *t*UMPC—which presents several challenges. We believe that truly unsupervised morphology is an important direction, and it can have a large impact on language technology for thousands of languages. With the goal of preserving endangered languages, we note that more than half the world's languages have no writing system (Harmon, 1995). A frontier for this task would process speech as a strategy for language documentation in unwritten languages.

A Remaining Results from Main Text

The statistics of the data used in our experiments is given in Table A.1. Paradigm clustering BMF1 is given in Table A.2. Additionally, BMAcc on the two test corpora is given in Figure A.1.

B Hyperparameters

B.1 Morphological Inflection

Training We train all inflection models on the (word, source slot, target slot) triples produced by the slot alignment. Each inflection system considers the word as an input form, and the slots as the tags. We take the hyperparameters from (Makarov and Clematide, 2018a), and (Wu et al., 2021) exactly for each language. For the LSTM, we train a single layer bidirectional encoder with embedding size 100, and LSTM hidden size of 100. The decoder is also a single layer LSTM with hidden size 100. We employ a soft-attention mechanism (Bahdanau et al., 2015), and optimize with Adam (Kingma and Ba, 2014) with a learning rate of 0.001, and a gradient clip of 1.0. We train for up to 30 epochs, and a batch size of 16. We employ a soft attention mechanism (Bahdanau et al., 2015).

B.2 Slot Prediction

The slot prediction model is a character-level Transformer encoder-decoder, where both the encoder and decoder have 3 layers and 4 attention heads. We optimize with Adam with a learning rate of 0.0001, and a clip norm of 0.2 for up to 5 epochs.

C Additional Details Regarding our Datasets

C.1 Statistics of Our Raw-text Corpora

We give dataset statistics in Table A.1, including type–token ratios. Bible sizes vary depending on whether or not the Old Testament is included. In the case of smaller Bibles, we down-sample the child-directed corpus to have a roughly equal number of tokens.

C.2 Test Set Creation

We use lemmas and POS tag annotations to match words from the test corpora with UniMorph entries. We sample sentences from the annotated Wikipedia corpora (Ginter et al., 2017) from the ConLL 2017 shared task on Multilingual Parsing (Hajič and Zeman, 2017). For Icelandic, which is not included in this dataset, we use wikiextractor (Attardi, 2015) to get the raw Wikipedia text, and acquire lemma and POS annotations with Stanza (Qi et al., 2020). We hypothesize that systems trained on the Bible corpus may not generalize well to the modern language in Wikipedia. We thus additionally sample test sentences from the JW300 corpus, which is more likely to include religious language that resembles that of the bible. For JW300 we rely on the tokenization provided by the authors, but we again use Stanza for lemma and POS annotations.

For a given language and test corpus, we group gold paradigms by POS, and whether at least one form from the paradigm is attested in both training corpora. This means we have two categories for each POS: *seen*, wherein at least one form is attested in both training corpora, and *unseen*, wherein no forms are attested in either training corpus. We sample up to 200 paradigms from each category, ensuring that each category contributes an equal number of paradigms to the gold set. Then one surface form for each gold paradigm is sampled at random, in context, from the test corpus to serve as input to the systems at test time.

D Non-Neural Baseline for *t*UMPC

Given the set of word form clusters $c_1, ..., c_k$, where each cluster $c_i = \{f_1, ..., f_n\}$ is a collection of forms f_j. We start by extracting all edit trees $t = \mathrm{EditTree(f, f')}$ (Chrupała, 2008), where f and f' belong to the same cluster. Let $\mathrm{Count}(t)$ be the count of tree t across the entire training set. Further, let $\mathrm{MLen}(t)$ be the total number of characters which have to match in the input string, when we apply edit tree t. For example, for an edit tree t which maps **walking** to **walks**, a suffix **ing** must match, so $\mathrm{MLen}(t) = 3$. Finally, let $\mathrm{MStr}(t) = u$ be the string consisting of all insertions performed by the edit tree. For the given example t, $\mathrm{MStr}(t) = \mathbf{s}$

When generating outputs for a given form f, we first form the set of all edit trees which can be applied to f. We then order them in the following way: $t > t'$ if $\mathrm{MLen}(t) > \mathrm{MLen}(t')$, or if the precondition lengths are equal, $\mathrm{Count}(t) > \mathrm{Count}(t')$. We then apply the top-$N$ trees to f to generate all remaining forms in the inflectional paradigm of f. We set N to the 95th percentile of paradigm sizes in our input cluster data, not counting singleton paradigms. Each slot labed is assigned based on t as $\mathrm{MStr}(t)$. Note that this will typically not generate a slot label for the input form

Corpus	Language	Lines	Tokens	Types	Type–Token Ratio
`Bible`	German	31102	813317	20644	0.025
	Greek	7914	194135	15541	0.080

`Child Directed`	German	26592	633229	31384	0.050
	Greek	8513	196344	18424	0.090
	Icelandic	8380	181687	17767	0.101
	Russian	26592	586274	44823	0.077

Table A.1: Statistics for raw text corpora used for morphology learning

	Bible					Child-Directed				
System	DEU	ELL	ISL	RUS	Average	DEU	ELL	ISL	RUS	Average
`McC`	**79.19**	**81.91**	**81.66**	**82.01**	**81.19**	**87.72**	**73.68**	**84.65**	**86.28**	**83.08**
`Xu`	63.90	65.14	67.81	52.80	63.91	70.02	46.14	55.22	63.48	58.72
`SIG`	46.04	57.22	47.24	45.10	48.90	45.69	47.04	43.08	47.80	45.90

Table A.2: Paradigm clustering BMF1 scores for a sample of clusters attested in UniMorph.

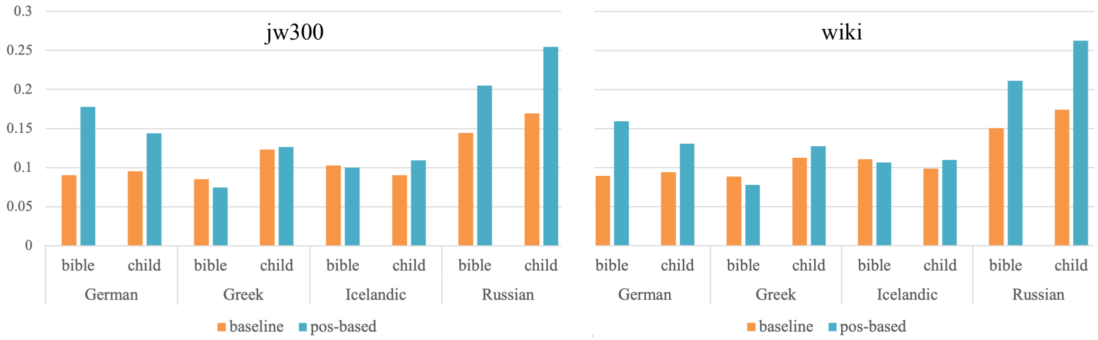

Figure A.1: BMAcc for both slot alignment systems on each test corpus, averaged over results for all input clusters. The POS-based system is also averaged over each inflection system.

f. We, therefore, find the maximal edit tree t (in the sense that it has maximal precondition length and count) which translates one of the generated forms f' back into the original input form f. The slot label for form f is then $\mathrm{MStr}(t)$.

A comparison between `baseline` and our proposed POS-based system is shown in Figure A.1. The latter outperforms `baseline` in the majority of settings, often by a large margin.

Learning and Evaluating Character Representations in Novels

Naoya Inoue, Charuta Pethe, Allen Kim, Steven Skiena
Stony Brook University
`{ninoue,cpethe,allekim,skiena}@cs.stonybrook.edu`

Abstract

We address the problem of learning fixed-length vector representations of characters in novels. Recent advances in word embeddings have proven successful in learning entity representations from short texts, but fall short on longer documents because they do not capture full book-level information. To overcome the weakness of such text-based embeddings, we propose two novel methods for representing characters: (i) graph neural network-based embeddings from a full corpus-based character network; and (ii) low-dimensional embeddings constructed from the occurrence pattern of characters in each novel. We test the quality of these character embeddings using a new benchmark suite to evaluate character representations, encompassing 12 different tasks. We show that our representation techniques combined with text-based embeddings lead to the best character representations, outperforming text-based embeddings in four tasks. Our dataset is made publicly available to stimulate additional work in this area.

1 Introduction

High-quality distributed representations of characters (henceforth, *character embeddings*) play an important role for the computational analysis of narrative texts (Iyyer et al., 2016; Xanthos et al., 2016; Skorinkin, 2017; Azab et al., 2019; Labatut and Bost, 2019; Kubis, 2021; Brahman et al., 2021).

Ideally, characters who share similar properties such as job, gender and a relationship to other characters, should possess similar character embeddings even if they are in different stories (e.g. *Cinderella* and *Juliet*, both young women in forbidden romance situations). This paper aims for learning such fixed-length, distributed representations from novels.

The core problem of learning character embeddings is how to aggregate and embed the contextual information of characters into distributed representations. Conventionally, this has been extensively studied in word embeddings, including static word embeddings such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), and in contextualized word embeddings such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019). All these methods follow the Distributional Hypothesis: “words that occur in the same context tend to have similar meanings” (Harris, 1954).

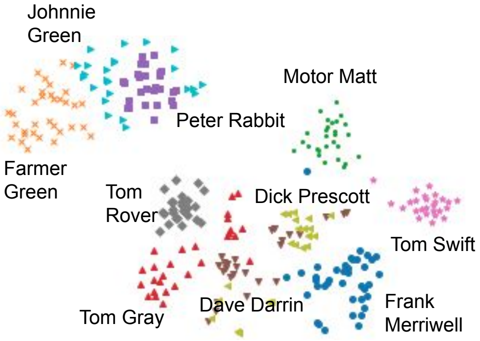

Figure 1: t-SNE visualization of our character embeddings for ten characters. Each character is sampled from more than 24 different books. The proposed method assigns similar representations to each character even though they exist in different books. The proposed method uses no surface form matching.

One limitation of these approaches is that they represent word embeddings by local context: they split documents into individual sentences or small chunks, ignoring the document information of each input. To learn character embeddings, however, it is desirable for an embedding algorithm to be aware of document-level information. This enables us to extend the Distributional Hypothesis to more global context: *characters that occur in the same books/authors tend to have similar or related properties* (e.g. the Sherlock Holmes series tend to have detectives, policemen, criminals, etc.).

To overcome the weakness of such text-based embeddings, we propose two novel methods to learn character embeddings using document-level

Findings of the Association for Computational Linguistics: ACL 2022, pages 1008 - 1019
May 22-27, 2022 ©2022 Association for Computational Linguistics

information. First, we propose *graph-based embeddings*, where we build a full corpus-based character network accompanied with full book-level information and then use a graph neural network to learn character embeddings. Second, we propose *positional embeddings*, where we create low-dimensional embeddings from the occurrence pattern of characters in each novel.

To evaluate the quality of character embeddings, we construct a new character embedding benchmark (*CEB*) consisting of 12 different tasks. At training time, one is allowed to learn fixed-length character embeddings from novels. The learned embeddings are then tested if the important properties of characters such as gender can be recovered *solely* based on them, similar to recent work on probing pretrained language models (Hewitt and Manning, 2019; Voita and Titov, 2020, etc.).

The contribution of this paper can be summarized as follows:

- *New methods for character embeddings* – We propose two novel methods for learning character embeddings leveraging full book-level information (§4).

- *Evaluation of character embeddings* – We create a novel benchmark suite (CEB) for testing the quality of character embeddings, consisting of 12 different tasks (§5). The dataset and evaluation script are publicly available at `https://github.com/naoya-i/charembench`.

  Our experiments show that the proposed embedding methods combined with text-based embeddings leads to the best character embeddings, outperforming text-based embeddings in six CEB tasks (§6.3).

- *Corpus-level views of character embeddings* – We show that character embeddings cluster across large corpora by gender, protagonist status, profession/role, thus demonstrating the versatility of the techniques we employ (§7). Fig. 1 shows the key result, indicating that similar character representations are assigned to each cluster of character, even though they exist in different books.

2 Related work

There is a growing interest in computational narrative analysis, ranging from analyzing the structure of narratives (Kim et al., 2020, 2021; Pethe et al., 2020), identifying important events in stories (Wilmot and Keller, 2020, 2021; Papalampidi et al., 2020; Otake et al., 2020) to analyzing the relationship between characters in novels (Iyyer et al., 2016; Xanthos et al., 2016; Skorinkin, 2017; Azab et al., 2019; Labatut and Bost, 2019; Kubis, 2021; Brahman et al., 2021). The most relevant work to ours is Azab et al. (2019), who apply word2vec (Mikolov et al., 2013) to learn character embeddings from movie scripts. However, they do not use full document-level information such as the author of documents for learning character embeddings. They also experiment on a small-scale dataset–18 movie scripts, while we experiment on 17k novels. Brahman et al. (2021) propose two benchmark tasks for character-centric narrative understanding, namely character identification and character description generation. We extend their benchmark by introducing additional 12 character-related tasks.

Character embeddings are closely related to both static word embeddings such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), and contextualized word embeddings such as dynamic entity embeddings (Kobayashi et al., 2016), ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019). As discussed in §1, these methods follow the Distributional Hypothesis (Harris, 1954), encoding the local context of words into distributed representations. We intend to complement this weakness by taking book-level context into account in the graph neural network-based embedding methods.

The task setting of CEB shares the similar spirit to a recent paradigm on probing pretrained language models (Hewitt and Manning, 2019; Petroni et al., 2019; Voita and Titov, 2020; Shin et al., 2020). The LAMA dataset (Petroni et al., 2019), for example, creates a sentence with blanks, e.g. ___ *was born in*, and ask language models to predict words in the blanks *solely based on* the learned model parameters. Our benchmark also follows this task setting, where one learns character embeddings on a particular corpus and is asked to recover information solely based on the learned embeddings in 12 different tasks.

3 Baseline text-based methods

3.1 Static embeddings

One simple way to learn character embeddings is to treat each character name as one unique token at the document-level and apply standard word embedding algorithms. Given a corpus, we convert all character mentions including pronouns to special tokens consisting of its document ID and character name (e.g. *When* 113_Mary *was sent to...*). To identify character mentions and coreference relations between them, we use Stanford CoreNLP (Manning et al., 2014). See §5.1 for further details.

We then apply word2vec (Mikolov et al., 2013). Because a corpus of novels alone may not provide enough data to learn non-character word vectors, we initialize non-character word vectors with GloVe pretrained embeddings (Pennington et al., 2014).[1] Henceforth, we call this method `w2v`.

We also apply doc2vec (Le and Mikolov, 2014) to the preprocessed corpus, where we treat each character as one document and sentences that mention this character as the content of this document. Henceforth, we call this method `d2v`.

3.2 Context-aggregated embeddings

Another simple way to learn character embeddings is to aggregate contextual information of characters (Ethayarajh, 2019; Bommasani et al., 2020). Given a character c, we extract set $S(c)$ of sentences that mention c and generate a sentence representation $\mathbf{s}_i$ for each $s_i \in S(c)$. We then aggregate them via averaging: $\mathbf{c} = \frac{1}{|S(c)|} \sum_{s_i \in S(c)} \mathbf{s}_i$.

To generate $\mathbf{s}_i$, we explore two methods. The first method is `w_ag`, which simply averages word embeddings learned in Sec. 3.1: $\mathbf{s}_i = \frac{1}{|s_i|} \sum_{w_j \in s_i} \mathbf{w}_j$. We also make `gl_ag`, a variation of this model using vanilla GloVe pretrained embeddings (Pennington et al., 2014).

Another method is `rb_ag`, which uses contextualized word embeddings of characters generated by RoBERTa (Liu et al., 2019). Given $s_i \in S(c)$, we first replace character mentions of c with mask tokens. For example, suppose $c = $ *Mary* and $s_i =$ *Mary was most attracted by the mother and Dickon*. The sentence is then converted to *[MASK] was most attracted by the mother and Dickon*. To generate $\mathbf{s}_i$, we extract contextualized word embeddings of [MASK] tokens at the final layer.

3.3 Name embeddings (`nam`)

Ye et al. (2017) represent common first/last names using a vector representation that encodes gender, ethnicity, and nationality which is readily applicable to building classifiers and other systems. Name embeddings exploit the phenomenon of homophily in communication, specifically that people tend to associate with similar people or popularly that "birds of a feather flock together." These embeddings are constructed from email contact lists of email, rosters of friends on social media, or followers on Twitter. The homophily-induced coherence of these contact lists enables us to derive meaningful features using word embedding methods. We used 100 dimensional embeddings from (Ye and Skiena, 2019).

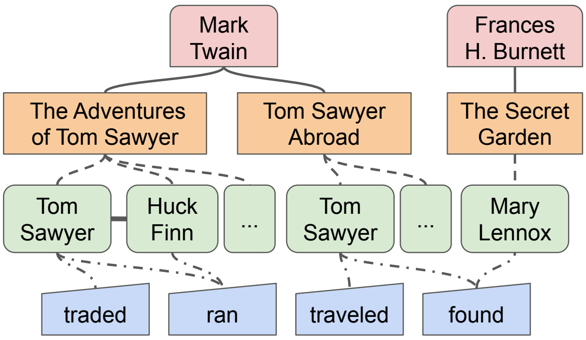

Figure 2: Example of character network. Characters (green) are connected through book-level information, i.e. books (orange) and authors (red). Context information (green) captures the attributes of characters.

4 Proposed methods

While text-based embeddings introduced in §3 can be expected to capture the local context of characters such as gender, they do not take into account full book-level information, such as the author. Intuitively, characters from the same book should have more relatively similar embeddings than those from different books, but the text-based embedding methods cannot use this kind of information. To address this weakness, we propose two methods for character embeddings: (i) `gr`: we build character network across books and then learn character embeddings using Graph Neural Networks (§4.1); and (ii) `pos`: we encode the occurrence pattern of characters into low-dimensional embeddings (§4.2).

4.1 Graph-based embeddings

4.1.1 Character network

Our character network is an undirected graph consisting of four types of nodes and four types of unlabeled edges as shown in Fig. 2.

Nodes. First, we introduce (i) *book nodes* (e.g. *The Adventures of Tom Sawyer*), (ii) *author nodes* (e.g. *Mark Twain*), and (iii) *character nodes* (e.g.

---

[1] CommonCrawl-840B-300d at `https://nlp.stanford.edu/projects/glove/`.

Node type	# nodes	Edge type	# edges
Book	17,275	Bk-Au	17,514
Character	718,324	Bk-Chr	712,332
Author	4,422	Chr-Con	30,934,451
Context	147,000	Chr-Chr	446,917

Table 1: Statistics of character network.

Tom Sawyer), each of which represents individual book, author, and character in the corpus. Note that we keep characters with the same name as separate nodes in the network (e.g. *Tom Sawyer*) because it is not obvious if these characters are indeed the same character or not at this point. As described later, if characters are inferred to be the same from book-level information, these embeddings become similar given the network configuration.

Second, we introduce (iv) *context nodes* which represent the local context information of characters (e.g. *traded*). Following Bamman et al. (2014), we extract words that are connected with a character name in agent, patient, possessive, or predicative dependency relations as context.

Edges. We introduce (i) *book-author edges* connecting book node n_b with author node n_a if n_a is the author of n_b (e.g. *The Adventures of Tom Sawyer–Mark Twain*), and (ii) *book-character edges* connecting book node n_b with character node n_c if n_c appears in n_b (e.g. *The Adventures of Tom Sawyer–Tom Sawyer*). To associate context with characters, we have (iii) *character-context edges* connecting context nodes with character nodes if they have a dependency relation described above (e.g. *Tom Sawyer–traded*). To capture the interaction between characters, we introduce (iv) *character edges* connecting two character nodes n_{c_1}, n_{c_2} if c_1 and c_2 occur within 10 tokens of each other at least 10 times (e.g. *Tom Sawyer–Huck Finn*).

Table 1 shows the statistics of our character network constructed from 17,275 books from Project Gutenberg (see §5.1 for the details of dataset).

4.1.2 Learning embeddings

We use DeepWalk (Perozzi et al., 2014), which is a representation learning algorithm for graph-structured data. It samples graph paths by random walk and then applies word2vec algorithm (Mikolov et al., 2013) to the sampled paths, treating each node as one word.

The main advantage over the text-based methods is as follows. In the text-based methods, two characters from different novels never appear in the same sentence. In contrast, in the graph-based method, two characters may appear in the same sentence (or path) if they are connected via book nodes or author nodes, which makes two character embeddings closer (e.g. two *Tom Sawyer* via *Mark Twain* in Fig. 2). In other cases, two characters from different novels may appear in the same sentence (or path) if they share context nodes (e.g. *Tom Sawyer* and *Mary Lennox* via *found* in Fig. 2), which makes two characters with similar properties closer. This means that we inject document-level information into character embeddings.

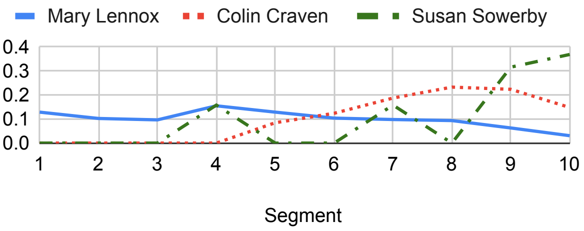

Figure 3: Positional embeddings for characters from *The Secret Garden*. *Mary* and *Colin*, the main characters, indicate continuous appearance throughout the book, while *Susan*, one of the minor characters, indicates discontiguous appearance.

4.2 Positional embeddings

The main character in novels is likely to always appear throughout the story, while a minor character may appear a few times in one chapter and disappear. Such document-level occurrence patterns are not captured by text-based methods, but they may encode useful information about characters.

We thus propose `pos` embeddings purely based on the pattern of mention positions of characters. We divide a novel into 10 segments and count the occurrences of each character i in each segment j (denoted $c_{i,j}$). As exemplified in Fig. 3, we then create two 10-dimensional embeddings by (i) normalizing $c_{i,j}$ across characters, i.e. $\mathbf{c}_i^c = \mathbf{c}_i / \sum_i c_{i,j}$, denoting how important the character is for the segment; (ii) normalizing $c_{i,j}$ across segments, i.e. $\mathbf{c}_i^s = \mathbf{c}_i / \sum_j c_{i,j}$, denoting how important the segment is for the character. Finally, we concatenate these, i.e. $[\mathbf{c}_i^c; \mathbf{c}_i^s]$, to form 20-dimensional embeddings. We repeat the same procedure with pronoun mentions, and concatenate these vectors to obtain final 40-dimensional positional embeddings for each character.

Task	Input	Output	Source	Size
Gender	One char	Male/Female	Heurstics (§5.2)	5,000
Role	One char, Four choices of roles	Role of a character (e.g. schoolmaster)	Reference books	484
Protagonist	One char	Protagonist/Other	Frequency	5,000
Identity	Two chars from different books	Yes/No (if two chars are same)	Metadata	5,000
Cloze	Sentence w/ blank (e.g. ___ *is born in India*), Four choices of chars	A character in the blank	Book content	5,000
Speaker	Quote, Four choices of chars	Speaker of the quote	Book content	2,879
Summary Cloze	Sentence w/ blank from chapter summary, Four choices of chars	A character in the blank	Literature websites	1,361
Desc	Description (e.g. *A simple , but honest and loyal black worker..*.), Four choices of chars	A character that is best described by the given description	Literature websites	551
QA	Question (e.g. *Who does Mary Lennox accept an invitation from?*), Four choices of chars	Answer	Kočiský et al. (2017); Angelidis et al. (2019)	587
Author	Two chars	Yes/No (if two chars are from the same author's books)	Metadata	5,000
Book	Two chars	Yes/No (if two chars are from the same books)	Metadata	5,000
Genre	One char, Genre	Yes/No (if the character belongs to a book with the given genre)	Metadata	44,152

Table 2: Overview of CEB, a benchmark suite for character embeddings.

5 CEB: Character Embedding Benchmark

To test the quality of character embeddings, we construct a new benchmark suite of character embeddings, as summarized in Table 2. The benchmark probes what kind of character-related information, ranging from gender to authors, is embedded in character embeddings. It consists of 12 different tasks categorized into three levels: (i) *character-level tasks*: identifying character attributes (§5.2), (ii) *context-level tasks*: identifying the correct character that best describes a given context (§5.3), and (iii) *book-level tasks*: identifying the attributes of books where characters come from (§5.4).

5.1 Dataset

We extract 17,275 books from Project Gutenberg[2], a publicly available library of free eBooks. We use Stanford CoreNLP (Manning et al., 2014) for NER (Named Entity Recognition). We use the named entities of type `PERSON` as potential character mentions, and follow a rule-based approach similar to Vala et al. (2015) for clustering variants of the same name, and obtaining a final list of characters for each book. To ensure that tested character embeddings have sufficient information, we discarded characters with less than 100 mentions.

5.2 Character-level tasks

Gender Identify the gender of a given character c (female or male). To identify the gold-standard gender of a character, we count the number of male and female pronouns referring to each character (as annotated by CoreNLP), and take a majority vote. If the male pronoun count outnumbers the female pronoun count by at least 10%, we consider the character to be male, and vice versa for female.

Role Identify the role of a given character c. We extract gold-standard character roles from two reference books of English literature (Magill, 1968, 1952), where character roles are represented by simple natural language phrases such as *a French aristocrat*. We extract only head nouns by the dependency parse given by Spacy.[3]

Protagonist Identify whether a given character c is a protagonist or not. As approximation, we identify the most frequent characters as the gold-standard protagonist.

Identity Given two characters c_1, c_2 from different books, identify whether c_1 is the same character as c_2 or not. We use characters with the same full name and the same author as a positive instance.

---

[2] `http://www.gutenberg.org/`

[3] `https://spacy.io/usage`

5.3 Context-level tasks

Cloze Given a sentence S with a blank (e.g. ___ *stood up and tried to keep her eyes open while Mrs. Medlock collected her parcels.*) from book b and four candidate characters from b, choose the character c that best fits into the blank. To sample difficult wrong candidates, we sample characters with similar frequency in all the context-level tasks. Specifically, we use characters c' s.t. $r(c) - 2 \leq r(c') \leq r(c) + 1$, where r is the rank of frequency.

Speaker Given a quote Q (e.g. *"Well, it was this way. I was leaning on the stile..."*) from book b ($\geq$ 50 words) and four candidate characters from b, choose the character that spoke this quote.

Summary Cloze Similar to Cloze, given a sentence S with a blank from a chapter summary of book b and four candidate characters from b, choose the character that best fits into the blank. We extract chapter summaries from LitCharts, an online guide for English literature.

Desc Given a character description snippet D (e.g. *A simple , but honest...*) and four candidate characters from the same book, choose the character that is best described by D. We extract character descriptions from five reliable web sources.[4]

QA Given a question about characters (e.g. *Who brings Mary Lennox the garden tools?*) and four candidate characters from the same book b, choose the character that best fits as the answer. We extract character-related questions (Angelidis et al., 2019) from NarrativeQA (Kočiský et al., 2017).

5.4 Book-level tasks

Author Given two characters from two different books b_1, b_2, identify whether the authors of b_1 and b_2 are the same or not.

Book Given two characters from two books b_1, b_2, identify whether b_1 and b_2 are the same.

Genre Identify the book genre of a given character c. Because one book can belong to more than one genre, we manually selected 11 frequent subjects from Project Gutenberg's metadata and turn them into 11 binary classification tasks[5] and report an average accuracy.

6 Evaluation

6.1 Setup

We follow recent work on probing word embeddings, which report that one should employ less expressive classifiers in order to prevent the classifier itself from learning to solve the probe tasks (Voita and Titov, 2020). At training time, one has access to all books and learns fixed-length character embeddings of each character. At test time, we freeze the learned character embeddings and train task-specific linear classifiers using the learned embeddings as a feature vector.

To solve classification tasks, we train a linear classifier that uses learned character embeddings as a feature vector. For pairwise classification, we merge two character embeddings by element-wise multiplication and absolute element-wise difference, i.e. $[\mathbf{c}_1 \odot \mathbf{c}_2; |\mathbf{c}_1 - \mathbf{c}_2|]$. In our experiments, we employ Support Vector Machines (Cortes and Vapnik, 1995). To solve multiple-choice tasks with context x and characters $\{c_i\}_{i=1}^{4}$, we train a scorer $f(x, c_i) = (W\mathbf{x} + \mathbf{b}) \cdot \mathbf{c}_i$ with a cross entropy loss, where $W, \mathbf{b}$ is a learned projection from the embedding space of context to characters. We use Sentence Transformers (Reimers and Gurevych, 2019)[6] to encode x into $\mathbf{x}$.[7]

The test instances with binary classification tasks are all balanced. Therefore, we use an accuracy as evaluation measure for all the tasks. To see overall picture, for each task category we calculate a *final score* by an average of task accuracies. We use 5-fold cross validation for evaluation and report an average accuracy. For the task with less than 2,000 instances (i.e. Role, Summary Cloze, Desc, QA), we use 10-fold cross validation to secure more training data.

6.2 Hyperparameters

For static embeddings, we use gensim implementation of word2vec (CBOW) and doc2vec.[8] We kept only top one million words in the vocabulary and trained 300-dimensional vectors with 5 epochs, 10 context words, and 10 negative examples.

---

[4] GradeSaver, LitCharts, CliffsNotes, Schmoop, SparkNotes.

[5] Selected subjects are: 19th century, adventure stories, detective and mystery stories, fiction, historical fiction, humorous stories, juvenile fiction, love stories, science fiction, short stories, western stories.

[6] We use all-MiniLM-L12-v2, a publicly available pretrained model of Sentence Transformers at `https://www.sbert.net/docs/pretrained_models.html`.

[7] For the role task, x is a character embedding, and c_i is a Sentence Transformer embedding of a role.

Table 3: Results on CEB. Text-based embeddings capture character-level information better, while graph-based methods capture book-level information better. Combining these two methods leads to the best embeddings.

For graph-based embeddings, we use the original implementation of DeepWalk[9] with 100-dimensional embeddings. We set the length of random walk path to 50 nodes and the number of random walks to start at each node to 20, and kept other hyperparameters as the default values.

We train the multiple-choice classifier for 10 epochs, using AdamW with batch size of 16, learning rate of 1e-3, and weight decay of 1e-2.

6.3 Results and discussion

The results are shown in Table 3. It shows that text-based methods perform better on character-level tasks and context-level tasks, while the graph-based method performs better on book-level tasks. This suggests that text-based methods can capture the local context of characters such as gender better, but it does not take into account document-level context discussed in §4.1. Name embeddings prove effective only at capturing gender.

Despite its simplicity, positional embeddings show surprisingly good performance on the character-level tasks (protagonist, identity) and context-level tasks (QA). This indicates that the occurrence patterns are deeply related to determining the importance of characters in books and that if the same character appears in different books, the occurrence patterns are also similar to each other. The good performance of QA indicates that the relationship between two characters are captured to some extent only by the occurrence patterns.

We then combined the best text-based embedding, `rb_ag`, with `gr` and `pos` (the last row).[10] The results indicate that they complement each other's strength and weakness. For example, `rb_ag`'s low performance on the author and book tasks and `gr`'s low performance on the protagonist and cloze tasks improved. Overall, the proposed methods using book-level information outperformed the text-based methods in four tasks, indicating the importance of book-level information in character representations.

In order to investigate the effect of introducing global edges, we ablate author-book edges (a,b) and character-character edges (c,c) from the proposed graph embedding method. The results are shown in Table 4. '-(c,c)' experiences more performance degradation in context-level tasks and book-level tasks than '-(a,b)', which indicates that character interaction provides useful information especially for these tasks. When both edges are removed, we observe performance drop in nine tasks, again indicating their need for character representations.

7 Qualitative analysis

To obtain further insights on the learned character embeddings, we visualize `rb_ag+gr+pos` by using t-SNE (van der Maaten and Hinton, 2008) with default hyperparameters.

7.1 Universality across books

In Fig. 1, we intend to check the universality of the learned character embeddings across books. We sampled characters with the same name and the same author from different books and plotted 281 samples of their character embeddings. This identifies characters that appear in a series of books, e.g.

---

[9] https://github.com/phanein/deepwalk

[10] We simply concatenated three embeddings, which yields 908-dimensional (768 + 100 + 40) embeddings.

	Character-level				Context-level					Book-level

Table 4: Ablation study of character network embeddings.

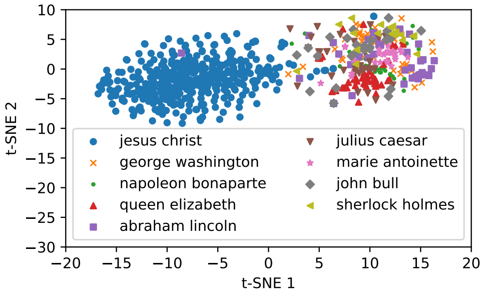

Figure 4: Character embeddings of historical figures.

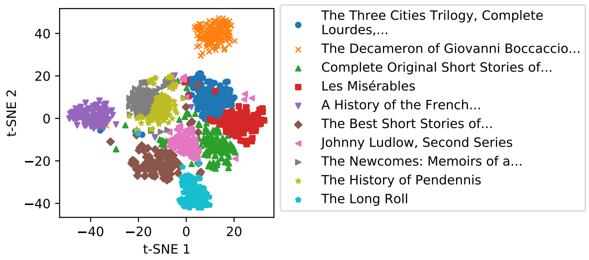

Figure 6: Plot of character embeddings colored by book.

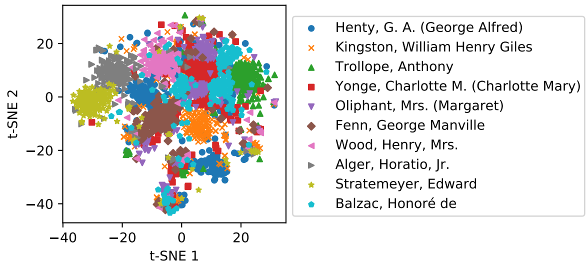

Figure 5: Character embeddings colored by author.

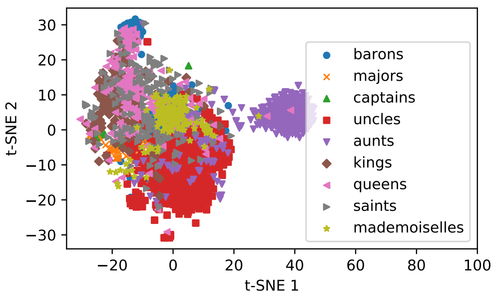

Figure 7: Character embeddings colored by titles.

Peter Rabbit in *The Tale of Peter Rabbit*. Interestingly, Fig. 1 shows that even though such characters appear in different books, the learned embeddings are close to each other. This suggests that the proposed method can capture the book-independent, universal property of characters.

To further confirm the universality of character embeddings, we manually identified 662 famous, historical figures such as *Jesus Christ* and *George Washington* in Project Gutenberg books and plotted character embeddings in Fig. 4. Similar to Fig. 1, it shows one big cluster for Jesus Christ and small clusters for the rest of historical figures, again indicating the universal property of our character embeddings.

While our goal is to learn book-independent universal character embeddings, we check to see if the character embeddings also preserve book-level information. Fig 5 shows character embeddings colored by the author of the book that each character came from. Fig. 6 visualize the learned character embeddings, where the datapoints are labeled by books. The results suggest that character embeddings also encode book-level information.

7.2 Character property

When characters have similar property (e.g. profession), it is desirable to have similar embeddings even though they exist in different books. This section studies the following three properties.

Profession/role Fig. 7 visualizes 2,232 characters that have manually specified titles (e.g. kings, aunts) across different books. We see a clear cluster for each title, and queens, kings and barons being close to each other (left). This indicates another book-independent, universal property of our embeddings from the profession/role's perspective. Note that our training methods do not exploit the titles for learning character embeddings: they convert the whole character name including the title as one unique special token (see §3).

Distance	Name	Gender	Book title	Book author	Juvenile?
0.00	Mary Lennox	Female	The Secret Garden	Burnett, Frances Hodgson	Y
1.44	Sibyl Ogilvie	Female	Daddy's Girl	Meade, L. T.	Y
1.56	Margaret Montfort	Female	Margaret Montfort	Richards, Laura Elizabeth Howe	Y
1.60	Betty Randall	Female	The Children on the Top Floor	Rhoades, Nina	Y
1.61	Carol	Female	Sunny Slopes	Hueston, Ethel	N
1.62	Matilda Laval	Female	Trading	Warner, Susan	Y

Table 5: Five nearest neighbors for *Mary Lennox* from *The Secret Garden.*

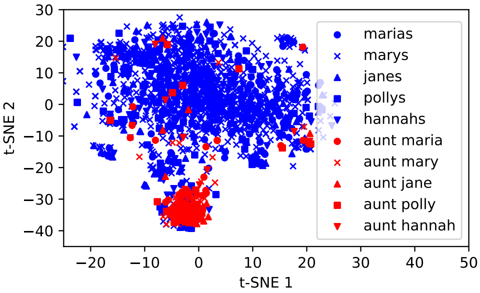

Figure 8: Character embeddings colored by aunts (red) and non-aunt characters (blue).

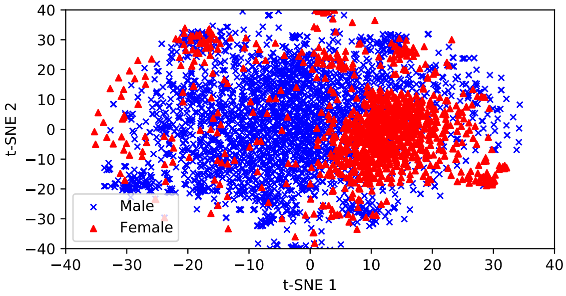

Figure 9: Character embeddings colored by gender.

To see if characters playing a specific role are separated from ordinary characters in our embedding space, we extracted 1,360 characters with the name *aunt X* and *(non-aunt) X* across books and plotted their character embeddings in Fig. 8. We see that aunts and non-aunts form separate clusters. This again supports that our character embeddings also capture the profession/role of characters.

Gender Fig. 9 visualizes 4,000 random samples of character embeddings across books, each of which is labeled with their gender. This clearly shows the clusters of female, indicating that the character embeddings have learned their gender.

Protagonist status Fig. 10 visualizes 4,000 protagonists and non-protagonists across books (4.9% of them are the protagonist). This clearly indicates that the character embeddings have learned protagonist status.

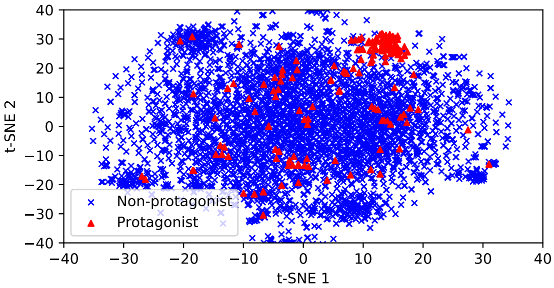

Figure 10: Character embeddings colored by protagonist status.

7.3 Nearest neighbors

To give a closer inspection, we show the list of nearest neighbor characters for *Mary Lennox*, the main female character from *The Secret Garden*, in Table 5. It successfully lists characters with similar attribute at a both character-level and book-level. For example, *Sibyl Ogilvie*, *Betty Randall* are female children of age similar to Mary from juvenile books.

8 Conclusions

We have addressed the problem of learning fixed-length, dense character representations from book-length narrative texts. To overcome the weakness of the text-based embeddings, we have proposed graph-based embeddings and positional embeddings. To test the quality of character embeddings, we have also constructed CEB, a novel benchmark suite for evaluating character embeddings, consisting of 12 different tasks. Our experiments have demonstrated that the proposed embeddings combined with text-based embeddings lead to the best character embeddings, outperforming text-based embeddings in four tasks. We also showed that character embeddings capture both character-level and book-level information across books, demonstrating the versatility of the techniques we employed.

Answer Uncertainty and Unanswerability in Multiple-Choice Machine Reading Comprehension

Abstract

Machine reading comprehension (MRC) has drawn a lot of attention as an approach for assessing the ability of systems to understand natural language. Usually systems focus on selecting the correct answer to a question given a contextual paragraph. However, for many applications of multiple-choice MRC systems there are two additional considerations. For multiple-choice exams there is often a negative marking scheme; there is a penalty for an incorrect answer. This means that the system is required to have an idea of the uncertainty in the predicted answer. The second consideration is that many multiple-choice questions have the option of *none of the above* (NOA) indicating that none of the answers is applicable, rather than there always being the correct answer in the list of choices. This paper investigates both of these issues by making use of predictive uncertainty. It is shown that uncertainty does allow questions that the system is not confident about to be detected. Additionally we show that uncertainty outperforms a system explicitly built with an NOA option for the ReClor corpus.

1 Introduction

Machine reading comprehension (MRC), where the correct answer must be deduced for a question from a context paragraph, plays a crucial role in developing systems for natural language processing and understanding. In recent years, popular MRC datasets (Richardson et al., 2013; Chen et al., 2016; Lai et al., 2017; Trischler et al., 2017; Rajpurkar et al., 2018; Yang et al., 2018; Yu et al., 2020) have consistently observed increasingly competitive systems topping public leaderboards (Trischler et al., 2016; Dhingra et al., 2017; Zhang et al., 2021; Yamada et al., 2020; Zaheer et al., 2020; Wang et al., 2021) and surpassing human performance. However, systems in deployment should not necessarily always aim to answer a posed reading comprehension question. There are two modes of interest in which an MRC system may choose to abstain from giving an answer: *answer uncertainty* and *unanswerability*. If a system is uncertain about its prediction, it is likely that the predicted answer will be incorrect. In particular, negative marking schemes, which are shown to improve the reliability of multiple-choice assessment as guessing is deterred (Holt, 2006), penalise a system for predicting an incorrect answer while abstaining carries no penalty, and of course the correct answer has a positive reward. In such cases, it would be sensible for a system to abstain from answering if there is answer uncertainty in the prediction. Unanswerability is where the answer to a question is not deducible from the associated context. Consequently, a system should abstain from answering a question if it believes the answer is not present in the context. Answer uncertainty is when the system is unsure about its prediction while unanswerability is where the system (confidently) believes the question cannot be answered.

A fair amount of work has investigated the challenge of tackling unanswerability in span-based reading comprehension (Rajpurkar et al., 2018) with the hope of encouraging systems to truly understand the comprehension task beyond simple word matching with remarkable success (Sun et al., 2018; Hu et al., 2019; Zhang et al., 2021). However, limited work has been completed with regard to unanswerability for multiple-choice reading comprehension datasets, where most work focuses on developing state-of-the-art systems on the default task such as Wan (2020); Jiang et al. (2020). This work investigates both answer uncertainty and unanswerability in multiple-choice MRC.

One challenge for this problem is that unanswerable examples are often not available at training time, and the possible range of incorrect answers even to valid questions is vast. Uncertainty measures have been demonstrated to be effective at out-of-distribution detection across a wide range

Findings of the Association for Computational Linguistics: ACL 2022, pages 1020 - 1034
May 22-27, 2022

of tasks (Amodei et al., 2016; Gal, 2016; Malinin, 2019; Malinin et al., 2021). This work studies the potential viability of using uncertainty measures at test time to identify examples for which the system should abstain for both settings of answer uncertainty for optimising performance with a negative marking scheme and handling unanswerability.

2 Multiple-Choice MRC

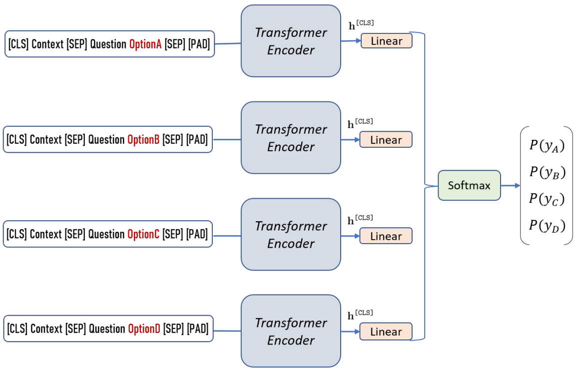

Figure 1: Model architecture.

In the multiple-choice reading comprehension task, the system is given a question, a context passage and multiple possible answer options. The system must be able to select the correct answer option. State-of-the-art for machine comprehension is largely dominated by pre-trained language models (PrLMs) (Devlin et al., 2018; Yang et al., 2019; Liu et al., 2019; Lan et al., 2020; Clark et al., 2020; Radford and Narasimhan, 2018; Radford et al., 2019; Brown et al., 2020; Lewis et al., 2020; Raffel et al., 2020) based upon the transformer encoder architecture (Vaswani et al., 2017). Figure 1 depicts the typical model structure of systems for multiple-choice MRC (Yu et al., 2020). In order to use the transformer architecture, the input to the transformer is constructed as follows [1]:

`[CLS] Context [SEP] Question Option [SEP] [PAD] ...`

The transformer models are usually trained with pairs of sentences separated by the `[SEP]` token. The context is used as the first sentence and the question concatenated with an option is used as the second sentence. The construct is repeated for each of the four options. These four pairs of sentences are passed in parallel to the transformer encoder architecture where the weights are shared for each of the inputs. The hidden state embedding associated with the `[CLS]` token is passed to a final linear head (with a non-linear activation) at the end of the transformer encoder that calculates output scores for each answer option which is then converted to a discrete probability distribution over the four answer options using the Softmax activation. Typically, at test time, the predicted answer option is the one with the greatest probability mass.

The work in this paper focuses on ReClor (A Reading Comprehension Dataset Requiring Logical Reasoning) introduced by Yu et al. (2020) that encourages the development of MRC systems beyond a superficial understanding of the context as the dataset was designed to focus on more challenging logical reasoning questions compared to previous multiple-choice datasets including DREAM (Sun et al., 2019), MCTest (Richardson et al., 2013), ARC (Clark et al., 2018) and RACE (Lai et al., 2017). Results are presented on RACE for comparison against ReClor. Additional numbers are provided on COSMOSQA (Huang et al., 2019) in the Appendix A.3.

The architecture of Figure 1 based on the baseline systems introduced by Yu et al. (2020) is used for simplicity as the focus here is on answer uncertainty and unanswerability. The selected model in this paper deviates from the baseline systems as ELECTRA is specifically selected as the PrLM given that it has been proven to achieve state-of-the-art results in other forms of MRC (Zhang et al., 2021) whilst also being smaller than equivalently competitive ALBERT (Lan et al., 2020) systems.

2.1 Answer uncertainty

In the default setting of multiple-choice reading comprehension task, systems are encouraged to always select one of the available answer options for each of the questions. However, there are many multiple-choice tests, such as the UKMT Senior Mathematics Challenge (Pargeter, 2000), that penalise a candidate for selecting the wrong answer, reward the correct answer and give no penalty for not answering the question. Such scoring systems discourage candidates from guessing if they are not confident about the answer. Similarly, multiple-choice MRC systems must also be able to abstain from giving an answer if there is answer uncertainty present in the prediction. Therefore, it is important to develop robust measures of answer uncertainty where the system chooses to only tackle questions that it is able to answer correctly.

Let the total number of questions in a multiple-

---

[1] Other permutations of the context, question and answer options were trialled but they give worse performance.

choice test be denoted $N = N_{\text{correct}} + N_{\text{wrong}} + N_{\text{abstain}}$ where N_{correct}, N_{wrong} and N_{abstain} respectively denote the questions that the system answered correctly, answered incorrectly and abstained from answering. For a penalty, p and reward, r, the overall test score, S, becomes,

$$S = rN_{\text{correct}} - pN_{\text{wrong}} \tag{1}$$

where the aim is to maximise the score. Therefore, the ratio p/r dictates the degree of aggression in the negative marking scheme where a larger ratio encourages a system to abstain from answering a greater number of questions to avoid the harsh penalty of selecting the incorrect answer option.

2.2 Unanswerability

Typically, multiple-choice MRC datasets assume that the question for a given example can be answered using one of the answer options. However, several real multiple-choice tests (Odegard and Koen, 2007) exist where none of the answer options address the posed question in relation to the contextual paragraph. An artificial answer option, *none of the above* (NOA), is usually present in such tests for candidates to be able to indicate the unanswerable questions. Unanswerability is further possible in an educational setting for automatic question generation (Kriangchaivech and Wangperawong, 2019) where new questions are automatically generated. Such question generation systems require a verification stage to automatically filter out the questions that are unanswerable in relation to a passage. Therefore, it is important for MRC systems to detect unanswerable questions and only answer the answerable questions.

In this work, two modes of unanswerability are explored. First, the simple set-up is considered where a multiple-choice MRC system is trained with a mixture of answerable and unanswerable examples and then evaluated on in-domain data that has the same proportion of answerable and unanswerable examples. Second, a more challenging mode of operation is considered where only answerable examples are present at training time but a mixture of answerable and unanswerable examples at test time. In this setting, the MRC model must be able to identify unanswerable examples at test time without encountering any such examples for the learning of its parameters. Hence, the test data is distributionally shifted with respect to the training data. In the first mode, the architecture from Figure 1 can be directly used to handle unanswerability as an additional artificial answer option, NOA, can exist for each example with a positive label for this option for all unanswerable examples.

3 Uncertainty

Research in uncertainty estimation is popular in recent years with model averaging (Gal and Ghahramani, 2016; Lakshminarayanan et al., 2017; Ashukha et al., 2020; Ovadia et al., 2019) as the standard approach. In particular, ensemble-based and sampling-based uncertainty estimates have demonstrated effectiveness for both identifying misclassifications and out-of-distribution inputs (Malinin et al., 2021). This work focuses on ensemble-based approaches for multiple-choice MRC as ensembles consistently outperform single models (Ganaie et al., 2021) and offer interpretable uncertainty estimates.

For multi-class classification, various measures of predictive uncertainty can be calculated using the predicted probability distributions over the classes from each of the ensemble members. Measures of knowledge uncertainty include mutual information, expected pair-wise KL divergence, and reverse mutual information; measure of data uncertainty is the average of the entropy of each predicted distribution (expected entropy); while measures of total uncertainty include (negated) confidence and entropy of the average prediction (Gal, 2016; Malinin, 2019). We present results using the expected entropy as the uncertainty measure for abstaining to answer for both a measure of answer uncertainty in a negative marking scheme and a measure of unanswerability when a system does not encounter unanswerable examples at training time [2]. Formally, expected entropy, $\mathbb{E}[\mathcal{H}]$, for a given input is defined as:

$$\mathbb{E}[\mathcal{H}] = -\frac{1}{K}\sum_{k=1}^{K}\sum_{y} P_{\mathcal{M}_k}(y)\log P_{\mathcal{M}_k}(y) \tag{2}$$

where $P_{\mathcal{M}_k}$ denotes the discrete probability distribution using the the k^{th} model member of an ensemble of size K and $y \in \{A, B, C, D\}$.

4 Data and Experimental Set-Up

All experiments are based upon the ReClor and RACE datasets (Yu et al., 2020; Lai et al., 2017) or

---

[2] Knowledge uncertainty is theoretically better at out-of-distribution detection but empirical results showed the data uncertainty measure was better for unanswerability.

their variants. This section discusses how the default datasets are modified to perform experiments for answer uncertainty and unanswerability as well as performance criteria.

4.1 Training and evaluation data

	Examples	Ans	Unans
`TRN-def`	4,638	4,638	0
`TRN-mixed`	18,552	13,914	4,638
`TRN-ans`	13,914	13,914	0
`DEV-def`	500	500	0
`DEV-mixed`	2,000	1,500	500
`EVL-def`	1,000	1,000	0

Table 1: ReClor: statistics for data splits.

	Examples	Ans	Unans
`TRN-def`	87,866	87,866	0
`TRN-mixed`	351,464	263,598	87,866
`TRN-ans`	263,598	263,598	0
`DEV-def`	4,887	4,887	0
`DEV-mixed`	19,548	14,661	4,887
`EVL-def`	4,934	4,934	0

Table 2: RACE: statistics for data splits.

Table 12 summarises the statistics for ReClor. Yu et al. (2020) split the ReClor datset into a train, validation and test set that are respectively referred to here as the default (def) configurations: TRN-def, DEV-def and EVL-def. In this default configuration, each example consists of a unique question, contextual paragraph and four answer options with no overlap across the total 7,138 examples in the dataset. All questions have a correct answer amongst the four answer options such that all three default splits are 100% answerable.

Two further training splits are introduced in Table 12 beyond the default configurations: TRN-mixed and TRN-ans. TRN-mixed consists of a mixture of answerable and unanswerable examples, with exactly 25% unanswerability. In contrast, TRN-ans consists of only answerable examples that is 3 times TRN-def. Finally, DEV-mixed is the development set equivalent of TRN-mixed that consists of 25% unanswerable examples too.

Table 2 presents the equivalent statistics and modified datasets for RACE with the main distinction that RACE is a significantly larger dataset.

4.2 Data construction

This section describes the method by which the modified data splits, TRN-mixed, TRN-ans and DEV-mixed, are constructed from the default data splits of ReClor/RACE, TRN-def, DEV-def and EVL-def. As the default configuration only consists of answerable examples, the mixed datasets aim to achieve an equivalent dataset that also contain unanswerable examples. TRN-mixed is constructed from TRN-def as follows:

1. For each example, replicate it 4 times.
2. For each of the four versions of an example, replace one of the answer options with NOA. Ensure a different answer option is replaced for each version of the example.
3. Re-order each example such that NOA is the fourth (D) answer option.

Therefore, TRN-mixed is exactly 4 times the size of TRN-def with 75% answerable and 25% unanswerable examples. Similarly, DEV-mixed is constructed from DEV-def by following the above steps. TRN-ans is the answerable subset of TRN-mixed. Hence, TRN-ans can be considered to only have three answer options as the fourth NOA option is never the correct answer for this dataset.

Note that TRN-mixed and DEV-mixed consist of real unanswerable examples rather than synthetic equivalents. Moreover, the modified construction is not performed on the evaluation set because the unanswerability experiments have to be performed on the development sets as the default test set labels are not publicly available. See Appendix B for details of hyperparameter tuning of models.

4.3 Performance criteria

General performance on any development or evaluation set is reported in terms of accuracy. This is consistent with the performance metric used on the ReClor dataset and leaderboard (Yu et al., 2020).

In order to measure the effectiveness of uncertainty measures at measuring answer uncertainty for negative marking schemes, it is desirable for the uncertainty measure to be correlated with the error-rate. Therefore, the standard approach to assess robustness and uncertainty of error-retention curves (Gal, 2016; Lakshminarayanan et al., 2017; Malinin et al., 2021) is used here. An error retention curve plots a model's mean error over a dataset as measured by the classification error rate with respect to the fraction of the dataset for which the model's predictions are used. The classification error for a given example is 0 if the prediction matches the label and 1 otherwise. The fraction of the model's predictions to be used is dictated by thresholding the uncertainty measure where all examples are ordered from lowest to highest uncertainty. Ideally, the uncertainty measure should be perfectly correlated in terms of rank-ordering with the error-rate. Hence, it is expected that with an increasing retention fraction, the error rate will increase as increasingly uncertain examples will be retained. Therefore, the area under the retention curve (R-AUC) is used as an appropriate metric to assess the effectiveness of the uncertainty measure for a negative marking scheme where a lower value for R-AUC is indicative of better performance.

The ability to identify unanswerable examples in DEV-mixed is reported using the area under the precision-recall curve and the binary F1 where precision and recall are equally important. For performance on DEV-mixed, in decoding we use:

$$\hat{w} = \begin{cases} \underset{w \neq w_s}{\text{argmax}} \{P(w|x)\} & \text{if } P(w_s|x) > \beta \\ w_s & \text{otherwise} \end{cases} \tag{3}$$

where $\hat{w}$ denotes the predicted class; $P(w|x)$ denotes the discrete probability distribution output by the model over the classes conditioned on the input; w_s denotes the class corresponding to unanswerable (i.e. NOA) and β denotes the threshold that the probability mass assigned to the unanswerable class must exceed in order to be deemed unanswerable. The value of β is swept in order to find the overall performance at different operating points.

5 Results and Discussion

This section discusses the main findings of how the ELECTRA system fares against existing systems on the ReClor dataset and the role of uncertainty measures in using answer uncertainty for tackling negative marking schemes or detecting unanswerable examples for ReClor and RACE. Expected entropy is the chosen uncertainty measure. See the Appendix for other uncertainty measures' results.

5.1 Baseline results

Table 9 presents how the ELECTRA system compares against other PrLMs as well as the DAGN (Huang et al., 2021) and FocalReasoner (Ouyang et al., 2021) too on ReClor. Out of the presented systems, the ELECTRA systems achieve the best accuracy on DEV-def and EVL-def. Note that the best single ELECTRA system achieves an accuracy of 64.2% on EVL-def that out-performs the human performance of 63% achieved by graduate students (Yu et al., 2020). Ensembling boosts performance by 2.9% to 67.1%. Performance on the EVL-def is reported for the best member of the ensemble (on the development set) to avoid multiple submissions to the official leaderboard.

	Model	`DEV-def`	`EVL-def`
Paper	`Chance`	25.0	25.0
	`Students`	-	63.0
	`BERT`	53.8	49.8
	`XLNet`	62.0	56.0
	`RoBERTa`	62.6	55.6
Others	`ALBERT`	-	62.6
	`DAGN`	65.2	58.2
	`Focal`	66.8	58.9
Ours	`ELECTRA`	$67.8_{\pm 1.1}$	—
	-max	69.4	64.2
	-ensemble	70.2	67.1

Table 3: Accuracy on default ReClor from the paper Yu et al. (2020); others from the leaderboard and finally our implementations. Mean and standard deviation is quoted for single-seed results.

It is found that pre-training models on RACE (Lai et al., 2017) boosted performance of the best single model to an accuracy of 70.8% on DEV-def and 69.7% on EVL-def. We focus on the situation where only the ReClor data is available for training for fair comparison with other models. At the time of writing, the ELECTRA model ranked 4th on the ReClor leaderboard [3], and only limited details are available for the top three performing systems. However, the focus here is investigating negative marking schemes and unanswerability rather than developing the best system for the ReClor task for which the current system's performance is considered reasonable. See Appendix A.2.1 for the baseline results on RACE. Note, ReClor is considered a significantly more challenging dataset than RACE as human performance on ReClor by graduate students is 63% while human performance on RACE is 94.5%. As the ensembled system achieves superior performance to single systems, the experimental results in the following sections will report results for the ensembled ELECTRA system only.

Figure 2: Error retention curves for answer uncertainty.

5.2 Answer uncertainty

This section explores the effectiveness of using uncertainty measures for identifying answer uncertainty in the model's predictions to abstain from answering for negative marking schemes.

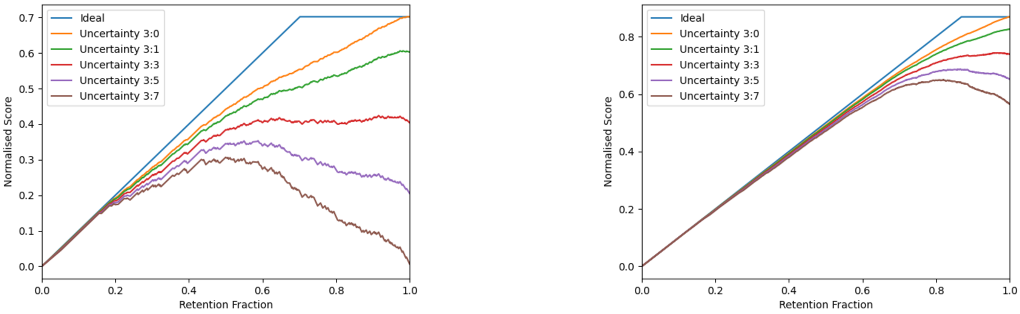
Figure 2 presents the error retention curves for a random measure, an ideal measure and expected entropy as an uncertainty measure for the ELECTRA system trained on TRN-def and evaluated on DEV-def. For ReClor, all curves, as expected, end at a classification error rate of 29.8% when all the data is retained which is consistent with an accuracy of 70.2% from Table 9. The ideal system is where the classification error of each point itself is used as the measure of uncertainty such that all misclassifed points are retained at the end. From Figure 2a, the random system has the largest R-AUC of 0.147 while the ideal system bounds the lowest area at 0.045. The uncertainty measure is able to achieve an R-AUC as low as 0.096 demonstrating that predictive uncertainty measures such as expected entropy are effective at identifying examples that are likely to be misclassified. Similar patterns are observed on RACE from Figure 2b with the main difference that the R-AUC values are lower for all systems as the baseline ELECTRA system on RACE achieves an accuracy of 86.3%. See Appendices A.1.2 and A.2.2 for the R-AUC values for other popular uncertainty measures.

In order to see the impact of using an uncertainty measure for abstaining to answer some questions, Figure 3 illustrates the normalised score using various negative marking schemes while sweeping through the number of examples retained ordered from lowest to highest uncertainty. Each negative marking scheme is expressed as $r : p$ (Equation 1), indicating the reward for a correct answer vs the penalty for an incorrect answer. The normalised score is the total number of points, S, divided by the maximum score achieved by correctly answering all questions. When a harsh negative marking scheme, such as 3:5, is applied it is beneficial to use an uncertainty measure like expected entropy in deployment to filter out the top 40% uncertain examples on ReClor and the top 10% on RACE to achieve the greatest score. Therefore, predictive uncertainty measures help identify examples for which the system should abstain from answering to achieve a higher overall score with aggressive negative marking schemes. However, further work is required to investigate how uncertainty measures may be useful in boosting vanilla performance of answering all questions when using a mild negative marking scheme like 3:1.

5.3 Unanswerability

Here, we assess the ability of uncertainty measures to identify unanswerable examples in DEV-mixed when using the ensembled ELECTRA-based system. The *Explicit* system trains a four-option system on TRN-mixed (with the fourth option indicative of the question being unanswerable as it corresponds to NOA) while the *Implicit* system trains a three-option system on TRN-ans that contains only answerable examples. This *Implicit* system uses the uncertainty over the three answer options to indicate whether the question is unanswerable. The *Explicit* system takes the maximal probability over the first 3 options and then uses the fourth option probability mass for unanswerability detection by sweeping its value β (Equation 3).

Table 13 presents the best F1 score for each approach at the corresponding precision and recall operating point from the precision-recall curves



(a) ReClor

(b) RACE

Figure 3: Aggressive negative marking schemes.

	Approach	P	R	F1 ↑	AUPR ↑
	Random	25.0	100.0	40.0	25.0
ReClor	Implicit	40.5	63.4	49.5	48.2
	Explicit	50.4	63.0	56.0	55.5
RACE	Implicit	46.1	73.6	56.7	47.9
	Explicit	70.1	70.6	70.3	78.3

Table 4: Detecting unanswerable examples.

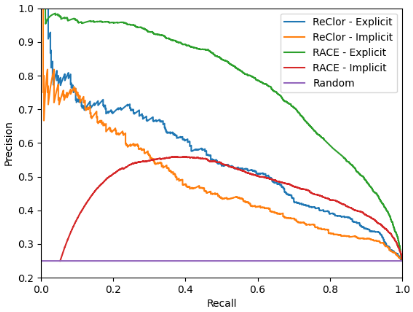


Figure 4: Unanswerabilty detection on DEV-mixed.

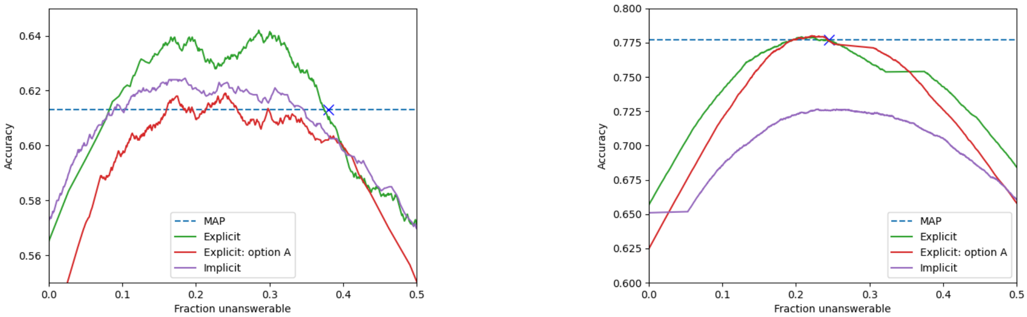
in Figure 4 for both ReClor and RACE. The area under the precision-recall curve (AUPR) is also reported. As expected, the *Explicit* system is the best performing - with an F1 score and AUPR of 56.0% and 55.5% respectively on ReClor, and 70.3% and 78.3% respectively on RACE - as the system encountered unanswerable examples at training time and hence unanswerable examples at test time are in-domain. In contrast, the *Implicit* system did not train with any unanswerable examples. Despite this, the predictive uncertainty, expected entropy in this case, is able to substantially surpass the random system in its ability to detect unanswerable examples at test time to achieve a binary F1 score and AUPR of 49.5% and 48.2% respectively on ReClor, and 56.7% and 47.9% respectively on RACE. Moreover, from the precision-recall curves, the *Implicit* system's ability to identify unanswerable examples surpasses the random curve across all recall rates with the trace lagging behind the *Explicit* system's curve. See Appendix A.1.3 and A.2.3 for the F1 and AUPR scores for other uncertainty measures at detecting unanswerability.

Table 5 compares the *Implicit* and *MAP* system for overall accuracy on DEV-mixed. The maximum-a-posteriori, *MAP*, system is where the ELECTRA system trained on TRN-mixed is directly evaluated on DEV-mixed such that the predicted answer option (out of the four including NOA) is the one with the greatest probability assigned to it. It is interesting to observe that the overall performance of the *Implicit* system at an unanswerability rate of 18.6% is able to outperform the *MAP* system on ReClor. Hence, predictive uncertainty measures are very powerful in this case at identifying unanswerable examples in order to boost overall performance as a system trained on only answerable examples from TRN-ans is capable of out-competing a *MAP* system trained on answerable and unanswerable examples from TRN-mixed. However, the uncertainty measure appears to be weaker on RACE.

	Approach	ACC ↑	%UNAS
ReClor	Implicit	62.5	18.6
	MAP	61.1	38.0
RACE	Implicit	72.6	23.0
	MAP	77.7	24.5

Table 5: Accuracy (ACC) and Percentage Unanswerable (%UNAS) on Dev-Mixed

Figure 5 shows the performance of the *Implicit* system over a range of thresholds, β, rather than



(a) ReClor

(b) RACE

Figure 5: Overall performance on DEV-mixed.

just the maximum performance shown in Table 5. On ReClor, from Figure 5a, it can be seen that it outperforms the MAP decoding over a range of thresholds. However, it is unfair to compare the *Implicit* system against the *MAP* system alone. Therefore, Figure 5 plots the overall accuracy on DEV-mixed for various systems with a sweep across the number of examples in the dataset predicted as unanswerable. Particularly, the plot for the *Explicit* system is given where the number of examples hypothesised as unanswerable is deduced by sweeping the threshold on the fourth answer option's probability mass (i.e. the probability assigned to NOA) as β. The inference process is as in Equation 3. On ReClor, the *Explicit* system is able to achieve a maximum accuracy of 64.2% at an unanswerability rate of 28.9%. This system outperforms the *MAP* system across a wide range of thresholds of about 10-40%.

As a contrast, the *Explicit: option A*'s performance is also shown. This is generated by sweeping over the threshold on option A rather than the fourth NOA option. If the probability mass assigned to option A is higher than the threshold, the predicted answer will be option A and otherwise the predicted answer is the option with the highest probability mass amongst the other three options. Note, *Explicit: option B* and *Explicit: option C* have similar profiles to *Explicit: option A*. Based on the difference in performance between *Explicit* and *Explicit: option A*, the NOA option operates in a different fashion to the other classes for the ReClor dataset. Intuitively, a possible reason is that the mathematical space for unanswerable questions is a lot larger than the space associated with answerable questions in relation to a specific contextual paragraph which is further evidenced given that the *MAP* system believes 38% of examples are unanswerable despite the unanswerability rate being only 25% at both training and test time.

However, for RACE, from Figure 5b, *MAP* is on par with *Explicit* which in turn peaks with *Explicit: option A*. The inability to out-perform the *MAP* system can be attributed to *MAP* operating at the expected unanswerability rate of about 25%. Therefore, the ability to out-compete a MAP system for ReClor is based on the *MAP* system over-predicting unanswerable examples at decoding time. This tendency to over-predict unanswerable examples may arise due to the complex nature of the questions in ReClor (Appendix C) while other multiple-choice datasets are simpler, leading to a more constrained space learned for NOA.

6 Conclusion

This paper addresses answer uncertainty and unanswerability in multiple-choice MRC. Measures of answer uncertainty are required to identify examples that the system may struggle to get correct and hence should abstain from answering such questions. Unanswerability detection is required for when the answer cannot be deduced using the information provided. An ELECTRA PrLM achieve competitive results on the default ReClor dataset, achieving up to 67.1% accuracy on the evaluation split. Ensemble-based predictive uncertainty measures are explored for both modes of operation: answer uncertainty for negative marking schemes and the presence of unanswerability. It is shown that uncertainty in the prediction such as expected entropy is correlated with the error rate of the MRC system allowing better than vanilla performance with an aggressive negative marking scheme for ReClor and RACE. Interestingly, it is found that expected entropy from the predictions of an implicitly trained system is competitive at unanswerability detection and is able to out-compete MAP decoding from an explicitly trained system that has been trained with unanswerable examples for ReClor.

Appendices

A Additional results

The Appendices detail additional results for answer uncertainty and unanswerability detection when using ensembled-based predictive uncertainty. The main paper uses expected entropy as the uncertainty measure of choice. The below sections explore other popular choices of uncertainty measures, including measures of knowledge uncertainty such as mutual information, expected pair-wise KL divergence (EPKL) and reverse mutual information, and also measures of total uncertainty including negative confidence and entropy of expected. The mathematical justifications for each uncertainty measure is motivated by Gal (2016); Malinin (2019).

A.1 ReClor

A.1.1 Baseline

Additional baseline results are provided here that contrasts and combines an ensemble of ALBERT systems with an ensemble of ELECTRA systems with ensembling. The ELECTRA and ALBERT systems involve the same hyperparameters (see Appendix B).

Model	`DEV-def` single	`DEV-def` ensemble	`EVL-def` ensemble
`ELECTRA`	$67.8_{\pm 1.1}$	70.2	67.1
`ALBERT`	$62.9_{\pm 2.4}$	71.6	68.6
`ELECTRA & ALBERT`	–	74.8	71.0

Table 6: Accuracy on development and test sets of ReClor. Mean and standard deviation is quoted for single-seed results.

A.1.2 Answer uncertainty

Uncertainty measure	R-AUC ↓
negative confidence	0.0939
entropy of expected	0.0942
expected entropy	0.0960
mutual information	0.1003
EPKL	0.1018
rev mutual information	0.1028
Ideal	0.0450
Random	0.1470

Table 7: Effectiveness of uncertainty measures for negative marking schemes measured by area under error-retention curves (R-AUC) on ReClor.

A.1.3 Unanswerability

`TRN`	Measure	F1 ↑	AUPR ↑
	Random	40.0	25.0
`mixed`	confidence	56.0	55.5
`ans`	negative confidence	48.3	45.6
	entropy of expected	48.8	47.5
	expected entropy	49.5	48.2
	mutual information	47.4	36.2
	EPKL	47.4	35.0
	rev mutual information	47.4	34.5

Table 8: Effectiveness of uncertainty measures for unanswerability detection for ReClor.

A.2 RACE

This section details additional results on RACE including the baseline results and comparisons with the other popular choices of uncertainty measures.

A.2.1 Baseline

	Model	`DEV-def`	`EVL-def`
Others	`Roberta`	—	83.2
	`ALBERT`	—	86.5
	-ensemble		89.4
	`ALBERT` + `DUMA`	—	88.0
	-ensemble		89.8
	`Megatron-BERT`	—	89.5
	-ensemble		90.9
Ours	`ELECTRA`	$86.5_{\pm 0.3}$	—
	-max	87.0	85.9
	-ensemble	86.9	86.3

Table 9: Accuracy on default RACE. Mean and standard deviation is quoted for single-seed results. Other systems include Roberta (Liu et al., 2019), ALBERT (Lan et al., 2020), ALBERT + DUMA (Zhu et al., 2020) and Megatron-BERT (Shoeybi et al., 2020).

A.2.2 Answer uncertainty

Uncertainty measure	R-AUC ↓
negative confidence	0.0238
entropy of expected	0.0244
expected entropy	0.0246
mutual information	0.0287
EPKL	0.0288
rev mutual information	0.0290
Ideal	0.0085
Random	0.0652

Table 10: Effectiveness of uncertainty measures for negative marking schemes measured by area under error-retention curves (R-AUC) on RACE.

A.2.3 Unanswerability

TRN	Measure	F1 ↑	AUPR ↑
	Random	40.0	25.0
`mixed`	confidence	70.3	78.3
`ans`	negative confidence	56.1	46.2
	entropy of expected	56.4	46.4
	expected entropy	56.7	47.9
	mutual information	52.3	41.0
	EPKL	52.2	40.6
	rev mutual information	52.0	40.4

Table 11: Effectiveness of uncertainty measures for unanswerability detection for RACE.

A.3 COSMOSQA

COSMOSQA (Huang et al., 2019) is a multiple-choice reading comprehension dataset that has naturally occurring unanswerable examples. Further results are investigated on this dataset for reference.

A.3.1 Data

	Examples	Ans	Unans
`TRN-def`	25,262	22,199	3,063
`TRN-ans`	22,199	22,199	0
`DEV-def`	2,985	2,541	444
`DEV-ans`	2,541	2,541	0

Table 12: Statistics for data splits for COSMOSQA.

These numbers disagree with those quoted in the paper in terms of number of samples and in terms of the unanswerability rate suggesting that some data has been modified or removed since the release of the original data. The following results are presented using an ensemble of 5 ELECTRA models, which is consistent with RACE. Expected entropy is used here as the main uncertainty measure.

A.3.2 Unanswerability

Approach	P	R	F1 ↑	AUPR ↑
Random	14.9	100	25.9	14.9
Implicit	50.2	47.1	48.6	52.4
Explicit	71.9	58.3	64.4	72.7

Table 13: Detecting unanswerable examples on default COSMOSQA (DEV-def).

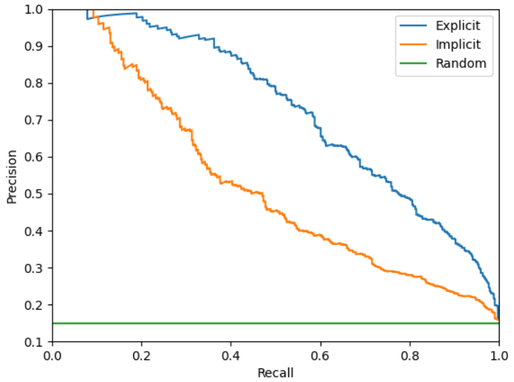

Figure 6: Unanswerabilty detection on DEV-def for COSMOSQA.

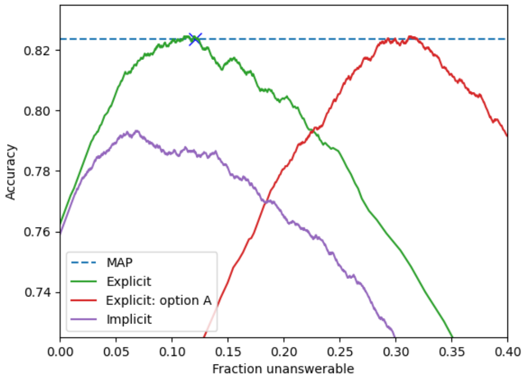

Figure 7: Overall performance on DEV-def for COSMOSQA.

B Hyperparameter tuning

An ensemble of 10/5/5 members for ReClor, RACE and COSMOSQA respectively are trained using the large [4] ELECTRA PrLM as a part of the multiple-choice MRC architecture depicted in Figure 1. Each model has 340M parameters. Grid search

---

[4] Configuration at: https://huggingface.co/google/electra-large-discriminator/blob/main/config.json.

was performed for hyperparameter tuning with the initial setting of the hyperparameter values dictated by the baseline systems from Yu et al. (2020). Apart from the default values used for various hyperparamters, the grid search was performed for the maximum number of epochs $\in \{2, 5, 10\}$; learning rate $\in \{2e-7, 2e-6, 2e-5\}$; batch size $\in \{2, 4\}$; truncated length of number of input tokens of the concatenated context, question and a given answer option $\in \{256, 512\}$. For systems trained on ReClor the final hyperparameter settings included training for 10 epochs at a learning rate of 2e-6 with a batch size of 4 and inputs truncated to 256 tokens. For RACE, training was performed for 2 epochs at a learning rate of 2e-6 with a batch size of 4 and inputs truncated to 512 tokens. For COSMOSQA, training was performed for 5 epochs at a learning rate of 2e-6 with a batch size of 4 and inputs truncated to 256 tokens. Cross-entropy loss was used at training time with models built using NVIDIA V100 graphical processing units with training time under 10 hours per model for ReClor, 12 hours for COSMOSQA and 20 hours for RACE. All hyperparameter tuning was performed by training on TRN-def and selecting values that achieved optimal performance on DEV-def. As there is no equivalent evaluation set available for the modified versions of ReClor, the final setting of hyperparameters of the system trained on TRN-def is also used for training on TRN-mixed and TRN-ans.

C Examples

This section takes a look at example questions from RACE, COSMOSQA and ReClor to compare the nature of the questions from each dataset.

ReClor

Context:
In a business whose owners and employees all belong to one family, the employees can be paid exceptionally low wages. Hence, general operating expenses are much lower than they would be for other business ventures, making profits higher. So a family business is a family's surest road to financial prosperity.

Question:
The reasoning in the argument is flawed because the argument

Options:

A ignores the fact that in a family business, paying family members low wages may itself reduce the family's prosperity

B presumes, without providing justification, that family members are willing to work for low wages in a family business because they believe that doing so promotes the family's prosperity

C ignores the fact that businesses that achieve high levels of customer satisfaction are often profitable even if they pay high wages

D presumes, without providing justification, that only businesses with low general operating expenses can succeed

Figure 8: Example question from ReClor.

RACE

Context:
This is Jim's room. It's not big, but it's very clean. There is a bed in the room. It's near the door. Under the bed, there are two balls. There is a desk and a chair near the window. There are two pictures in the room, too. They are on the wall.

Question:
Jim's bed is

Options:

A near the door

B near the window

C on the bookcase

D on the wall

Figure 9: Example question from RACE.

COSMOSQA

Context:
Do I need to go for a legal divorce? I wanted to marry a woman but she is not in the same religion, so I am not concern of the marriage inside church. I will do the marriage registered with the girl who I am going to get married. But legally will there be any complication, like if the other woman comes back one day, will the girl who I am going to get married now will be in trouble or is there any complication?

Question:
Why is this person asking about divorce?

Options:

A If he gets married in the church he won’t have to get a divorce

B He wants to get married to a different person

C He wants to know if he doesn’t like this girl can he divorce her

D None of the above choices

Figure 10: Example question from COSMOSQA.

Measuring the Language of Self-Disclosure across Corpora

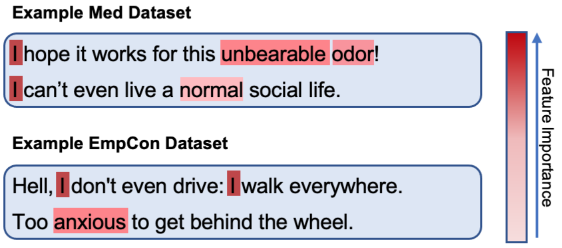
Abstract

Being able to reliably estimate self-disclosure – a key component of friendship and intimacy – from language is important for many psychology studies. We build single-task models on five self-disclosure corpora, but find that these models generalize poorly; the within-domain accuracy of predicted message-level self-disclosure of the best-performing single-task model (mean Pearson's r=0.69) is much higher than the respective across data set accuracy (mean Pearson's r=0.32), due to both variations in the corpora (e.g., medical vs. general topics) and labelling instructions (target variables: self-disclosure, emotional disclosure, intimacy). However, some lexical features, such as expression of negative emotions and use of first person personal pronouns such as 'I' reliably predict self-disclosure across corpora. We develop a multi-task model that improves results, with an average Pearson's r of 0.37 for out-of-corpora prediction.

1 Introduction

Interpersonal exchanges are a core component in human relationships. They are determined by intimacy, which in turn is characterized by the willingness of the involved parties to self-disclose (Rubin and Shenker, 1978). In general, self-disclosure can be defined as "revealing intimate information about one's self" (Derlega et al., 1993). Note that self-disclosure, which often involves revealing embarrassing facts about oneself that are considered violations of social norms ("I flunked my exam." or "I have a growth on my butt"), is different from revealing personally identifiable information (PII). Self-disclosure encompasses the sharing of thoughts, aspirations, feelings, likes and dislikes, while PII, such as date of birth or social security number, is used to unambiguously identify a person. Unlike self-disclosing, sharing PII does not necessarily suggest an intimate relationship between two people.



I hope it works for this unbearable odor!
I can't even live a normal social life.

Hell, I don't even drive: I walk everywhere.
Too anxious to get behind the wheel.

Figure 1: Two sentences from the Med and the EmpCon data set. In our work, we predict the associated self-disclosure and assess the most important features in both sentences, which are highlighted in the examples.

NLP researchers have labeled a variety of data sets with self-disclosure or some approximation of self-disclosure such as "intimacy", which is more accurately viewed as being a property of the relationship between two people than of an utterance. In this paper, we build models to predict self-disclosure from text, and assess how well these models generalize across five different corpora. We find that they mostly generalize poorly, but that there are some reliable linguistic markers of self-disclosure.

We draw on multiple corpora labeled for self-disclosure: conversations from an online breast cancer support community (Wang et al., 2015); annotated conversational turns (Omitaomu et al., 2022); medical posts from patient.info and Reddit (Valizadeh et al., 2021) and posts from the r/OffMyChest and the r/CasualConversations subreddits (Jaidka et al., 2020). The labels on these data sets vary both in terms of how self-disclosure is defined, and in their scaling (e.g., 0/1 or 1-5 Likert scales), complicating the analysis.

Research questions

1. Which linguistic features predict self-disclosure in messages?
2. How well do language models trained on one data set predict self-disclosure in different cor-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1035 - 1047
May 22-27, 2022

pora?

3. How to best build models that generalize self-disclosure across different corpora?

Better understanding the linguistic characteristics of self-disclosure is potentially useful in advising people on how to increase their self-disclosure, to increase intimacy and well-being (Sloan, 2010). Self-disclosure is a key component of both romantic and platonic intimacy (Laurenceau et al., 1998) and an indicator and influencing factor of self-esteem and well-being (Leung, 2002; Daley, 2010). Having more accurate models to identify self-disclosure in language will likely support further research into the role of self-disclosure in areas ranging from depression treatment to friendship formation.

Contributions

1. We identify the linguistic correlates of self-disclosure, for example the expression of negative emotions and the use of first-person personal pronouns like 'I'.
2. We find that self-disclosure models generalize poorly across corpora due to the differences in their domains and labels.
3. We build a multi-task RoBERTa-based model, which gives the current state-of-the-art for the measure of self-disclosure across multiple corpora.[1]

2 Background and Related Work

People reveal information about themselves to form and maintain personal relationships (Joinson and Paine, 2007). As an essential part of interpersonal communication, self-disclosure can have positive and negative effects on the person disclosing, which are reinforced in an online environment. Risks resulting from revealing private information can encompass a loss of privacy (Haimson et al., 2015; Vitak and Kim, 2014), a negative impact on identity and self-presentation (Morris and Millen, 2007), and negative consequences caused by context collapse, i.e. the disclosure to an unintended audience, that is especially prevalent on social media (Farnham and Churchill, 2011). On the other hand, disclosing private information can lead to increased social expression, social validation and perceived intrinsic rewards (Pennebaker, 1993; Goldfried et al., 2003).

Self-disclosure can be influenced by a variety of factors including anonymity, cultural norms, personality, loyalty and mutual trust (Postmes et al., 2001; Laursen, 1993). These have an impact on the risk/benefit dynamic in revealing personal information online. Bazarova and Choi (2014) have formulated a functional model of self-disclosure to capture these conflicting dynamics and allow for a more holistic understanding of self-disclosure by showing how people try to maximize their benefits when disclosing private information.

Self-disclosure is a determining factor in the level of intimacy between people. On an individual level, it has been shown that intimate relationships are an important resource for inter- and intrapersonal growth (Buhrmester, 1990). They strengthen a person's sense of belonging and self-worth (Rawlins, 2017) and provide a source of emotional support as well as a safe space for self-exploration (Buhrmester, 1990; Parker and Gottman, 1989). Through these mechanisms, self-disclosure can positively influence a person's mental health (Stiles, 1987), improving their feeling of connectedness to others, a primary human need (Ryan and Deci, 2000). For example, Buhrmester (1990) showed that intimate relationships, which are dependent on self-disclosure, lead to better competence, sociability and self-esteem as well as less self-reported depression and anxiousness, compared to reference groups with less intimate connections.

The steady rise of social media usage led to an increase in the availability of publicly disclosed 'private' information. This is especially interesting given that self-disclosure has been found to be higher online compared to face-to-face communication (Tidwell and Walther, 2002; Joinson and Paine, 2007), partially because sharing to larger audiences is facilitated in an online context (Bazarova, 2012). In the light of these developments, we use social networking sites (SNS) data to identify and subsequently predict self-disclosure in online posts. In previous works, self-disclosure was predicted in different contexts using unsupervised, semi-supervised and supervised models. Blose et al. (2020) used unsupervised learning to detect the voluntary disclosure of private information in Tweets. They investigated how self-disclosure was impacted due to the COVID-19 pandemic and found a significant shift towards support-seeking and supportiveness. In addition, Bak et al. (2014) developed a semi-supervised self-disclosure topic

---

[1] The code for the model is available on GitHub here: https://github.com/tea-shaped/self-disclosure-model.

model to automatically detect self-disclosure in tweets, with the aim of analyzing its effects on subsequent conversations. They find a significant positive correlation between self-disclosure and conversation length as well as frequency. Furthermore, Yang et al. (2017) investigated how publicness influences self-disclosure in health support groups by applying a supervised model based on the Linguistic Inquiry and Word Count (LIWC) as well as other linguistic features and word embeddings to assess the level of positive and negative self-disclosure. Considering the broader concept of intimacy, Pei and Jurgens (2020) designed a computational framework to study the expression of intimacy in questions. They predicted intimacy using a semi-supervised model, showing that it is an impactful dimension in language that is influenced by social settings.

Our study differs in that we aim to understand self-disclosure across different platforms and contexts. We contribute to previous efforts (e.g. Preoţiuc-Pietro et al. (2015)) by focusing on the specific prediction of self-disclosure in order to assess well-being and mental health from social data. As such, we are not limited to one SNS but rather aim to develop a supervised model that generalises across multiple platforms. We further compare the performance of RoBERTa-, LIWC-, LDA- and EmoLex-based models to show which linguistic features are predictive of self-disclosure. Finally, given that we find that single-task models are insufficient, we develop a multi-task model across all available data sets to assess self-disclosure. This is an innovative approach that has not yet been pursued in this realm to the best of our knowledge.

3 Data Sets

To develop a general model to detect the degree of self-disclosure in messages, we gathered five data sets, trained models on them, and tested the performance of these models across all data sets. The available data sets offer a challenge in that they all have different labels, including 'self-disclosure', 'intimacy', and 'emotional disclosure'. These labels differ both in the instructions provided to the annotators (there is no consistent definition of self-disclosure used in computational linguistics) and in their scales. The fact that some labels are binary and others are on 1-to-3, 0-to-5, or 1-to-7 Likert scales complicates the analysis. We thus evaluate the accuracy of models by looking at the correlation of the prediction with the true label, allowing us to see e.g. how accurately a prediction of a 1-to-5 label estimates a binary label.

Data Set	**Data Source**	**Size**
OnSup	online support forum (Wang et al., 2015)	1,000
OffChe	Reddit (Jaidka et al., 2020)	12,860
Int	Reddit (Pei and Jurgens, 2020)	2,387
EmpCon	conversations by MTurk workers (Omitaomu et al., 2022)	5,820
Med	patient.info (Valizadeh et al., 2021)	6,417

Table 1: Overview of the data sets considered.

Online Support data set (OnSup) The OnSup data set was collected by Wang et al. (2015) from discussion boards of an online breast cancer support community. The authors randomly selected 1,000 exchanges, of which the thread-starting messages were each manually labeled by ten Amazon Mechanical Turk (MTurk) workers for positive and negative self-disclosure. Self-disclosure in this context was defined as "the extent to which the writer has discussed her feelings and emotions with others, such as happiness, fears, sadness, and anger." (Wang et al., 2015) Given examples for positive self-disclosure included phrases like "Now that chemo is done, I find myself waking up in the morning feeling a huge burden has been lifted from my shoulders." and "I am freaked out after reading my mammogram report." for negative self-disclosure. The individual ratings, ranging from 1 (no self-disclosure) to 7 (a great deal of self-disclosure) were combined by taking the workers' average. We further introduced a general self-disclosure indicator for this data set by adding together the negative and positive self-disclosure scores that were introduced by Wang et al. (2015). This allows for the comparison across data sets, since the other considered data sets report their respective notions of self-disclosure as a combined value, rather than splitting it into positive and negative disclosure.

Empathic Conversations data set (EmpCon) The EmpCon data set by Omitaomu et al. (2022) contains 5,819 conversational turns, where each turn has been labeled by four MTurk workers for empathy, emotion, emotional polarity and self-disclosure. The instructions the annotators were given included the following Human Intelligence Task (HIT): "When judging self-disclosure, think: Did this make you know the writer of the statement better?". The workers labeled the degree to which they agreed with this notion on a scale from 1 ('Not at all') to 3 ('A Lot').

Medical data set (Med) The Med data set by Valizadeh et al. (2021) contains online conversations from randomly-selected forums on patient.info and other online platforms, filtered for medical keywords and hashtags. Each message was labeled for medical self-disclosure. The assigned labels ranged from 0 ('no self-disclosure') to 5 ('high self-disclosure'). The label '5' was given for instances were the post writer specifically mentioned that he/she was diagnosed with a specific illness, was taking specific medication, had undergone surgery or was about to have one, or other cases of disclosing specific medical indicators.

OffMyChest data set (OffChe) Jaidka et al. (2020) collected the OffMyChest conversations data by letting 12,860 Reddit top comments of the top posts from the r/OffMyChest and the r/CasualConversations subreddits be labeled for emotional disclosure on a binary scale. The latter was defined as comments mentioning the authors personal feelings e.g. "My only concern was for my son." and "My heart is breaking for you.".

Intimacy data set (Int) Compared to the previous four data sets, the fifth one we're taking into consideration contains 2,397 questions drawn from question-centered subreddits such as r/AskReddit. However, instead of being labeled for self-disclosure, the questions were evaluated for intimacy, which was defined by the authors Pei and Jurgens (2020) as "how an individual relates to their audience in their perceived interdependence, warmth, and willingness to personally share". They employed a best-worst-scaling for labeling by showing annotators a tuple of four questions, among which the least and most intimate question should be identified. That way, five pairwise comparisons were obtained per tuple that were used as part of a Luce Spectral Ranking (Maystre and Grossglauser, 2015) to infer a continuous latent intimacy score on a scale from -1 (least intimate) to 1 (most intimate).

4 Features

Each of the above-mentioned data sets have been used to train discriminative, supervised machine learning models to correlate linguistic characteristics with the perceived presence of self-disclosure. In this section, we present the features we took into consideration.

N-gram distributions We tokenized the texts using the Happier Fun Tokenizer (Schwartz et al., 2017) and extracted uni-, bi- and trigrams.

LIWC The theory-based LIWC lexicon (Pennebaker et al., 2007) is widely used to analyze the usage of word semantic categories within text. It contains 73 categories ranging from parts of speech to emotions and cognitive styles, including personal pronouns such as 'I', which have been shown to be related to self-disclosure, and collections of words for positive and negative emotions (called POSEMO and NEGEMO respectively). LIWC word frequencies capture emotions well (Kahn et al., 2007), and thus are expected to correlate with self-disclosure, since emotions are more associated with self-disclosure than facts.

LDA topics Given that data-driven topics tend to be more representative of online posts, we also used Latent Dirichlet Allocation (LDA) Facebook topics. This is a normalized frequency distribution of 2,000 topics based on a Facebook corpus with approximately 18 million posts obtained from the Differential Language Analysis ToolKit (DLATK) repository (Schwartz et al., 2013). We used these topics to uncover hidden topics as well as words that represent these topics in the data sets.

Emotion lexica High self-disclosure statements tend to be more emotional. In addition to the emotion-related categories in LIWC, we used the NRC EmoLex lexicon which has 14,182 manually labeled entries for the emotions 'anger', 'anticipation', 'disgust', 'fear', 'happiness', 'sadness', 'surprise' and 'trust' as well as 'positive' and 'negative prevalence'.

RoBERTa embeddings Finally, we considered word embeddings, i.e. real-numbered vectors mapped from words or phrases representing their distributional semantic meaning, to obtain a conceptualized token embedding. In this context, RoBERTa, a bi-directional transformer (Liu et al., 2019), was used for classification using sentence representations obtained from the model. Specifically, we used RoBERTa embeddings as features in our proposed models.

5 Models

5.1 Single-Task Models

A five-fold cross-validated Ridge regression with the data set specific target variables was trained separately on 1-to-3 grams, LIWC, LDA and EmoLex topics, as well as RoBERTa embeddings for each of the target data sets. The alpha values used can be found in Table 8 in the appendix. We subsequently used the best-performing model for each data set to predict self-disclosure on the other data sets to assess the across-data set accuracy of the single-task models.

5.2 Multi-Task Models

In addition to the described single-task models, we developed models based on LIWC and RoBERTa features in which multiple tasks, i.e. the prediction of the different notions of self-disclosure across the available data sets, were learned simultaneously. We expected that multi-task learning would improve the results obtained by the single-task model. However, compared to standard multi-task learning, we faced the issue that each of the data sets had different outcomes on different scales. Thus, in contrast to standard multi-task learning, where outcomes for all tasks are available for each instance, we were missing 4/5th of the labels for each observation.

Estimating a model across the multiple data sets thus required handling the fact that the labels on each data set are different – and are on different scales. One option to handle this would be to translate all the labels to lie on the same range. This, however, assumes that a linear transformation would suffice, and that the correct transformation could be found. Instead, we build a single neural net that takes in an embedding of the post, and outputs predictions for all of the labels. Given the relatively small training sets, we used a neural network with one single-dimensional hidden layer. The output of that hidden layer can be viewed as a latent variable capturing self-disclosure, which is then transformed to yield each of the actual self-disclosure labels. For any given observation, only one label is observed, so that training loss is estimated as the sum over the training data (e.g., all observations in three of the four data sets) of the loss on the label that is present for that observation. Note that the loss is the squared error for continuous labels and the cross entropy for discrete labels. The labels for each continuous data set were normalized to zero mean and unit variance to put all losses on a similar scale.

Since we are interested in the statistical similarity between the labels of the different data sets, Pearson's r values between the single-dimensional latent variable and the holdout data set labels are reported. Networks with and without a sigmoid activation after the hidden dimension were explored with the latter found to be more effective. Hyperparameters and optimization details can be found in Tables 9, 10, and 11 in the appendix.

6 Results

We now discuss the quantitative results and their implications. Since we found in the analysis that the Int data set does not generalize well due to the fact that it only consists of questions, we focus on the four remaining data sets in our analysis and only report the Int results in the appendix.

6.1 General Model to Predict Self-Disclosure

We computed both the single-task and multi-task models for the different data sets. Starting with the former, we calculated the within-data set Pearson's r based on a Ridge regression for different feature sets for all considered data sets:

Model	**Emp-Con**	**OnSup**	**Med**	**Off-Che**
Ngrams	0.64	0.53	0.61	0.17
LIWC	0.64	0.66	0.64	0.29
LDA	0.57	0.22	0.62	0.41
Emo	0.32	0.25	0.19	0.10
RoBERTa	**0.73**	**0.72**	**0.85**	**0.47**

Table 2: Prediction performance for self-disclosure models (captured by Pearson's r) within data sets, averaged over a five-fold cross-validation.

Table 2 shows that the in-domain prediction of self-disclosure was generally most accurate with RoBERTa embeddings. We therefore used these RoBERTa embedding-based models to calculate the cross-data set performance, shown in Table 3.

The across-data set Pearson's r ranges from 0.16 to 0.48, with an average of 0.32, a significant drop compared to the best-performing (i.e. RoBERTa)

	Emp-Con	**OnSup**	**Med**	**Off-Che**
EmpCon	(0.73)	**0.42**	**0.48**	**0.21**
OnSup	**0.44**	(0.72)	0.35	0.16
Med	0.19	0.28	(0.85)	0.17
OffChe	0.34	0.41	0.44	(0.47)
Avg	0.32	0.37	0.42	0.18

Table 3: Across-data-set prediction results (Pearson's r) for self-disclosure, using RoBERTa embeddings. The first column shows the data set the model has been trained on, the first row the data set it has been tested on. The diagonals are within data set cross-validation accuracies. The last row shows the average of the Pearson's r values for the respective column, excluding the within-data-set accuracy reported in brackets.

within-data-set average r of 0.69.[2] Looking at the individual across-data set Pearson's r values, we find that the EmpCon data set, consisting of labeled conversation turns, performs reasonably well on the OnSup samples, most likely because both data sets resemble more structured conversations instead of single independent posts.

Predictive accuracies for the linear multi-task model are presented in Table 4. As expected, single-task models performed best on the same corpus that they were trained on. On average, the out-of-task multi-task models outperformed the across-data set single task models (single-task across data set average: r=0.32, linear multi-task average: r=0.37). We found that a multi-task model trained on the EmpCon, OnSup, and OffChe data sets performed best. This is in line with our expectations, since these three data sets are less domain-specific than the Med data set and hence, generalize better. We further investigated whether the multi-task model did better because it was trained on more data or because it captured the notion of self-disclosure more effectively. To do so, we trained a multi-task model on 6,525 data points across the different data sets, i.e. as much as on average a single-task model had available, and achieved a Pearson's r of 0.36, which still on average outperforms out-of-distribution single-task models.

Target Data Set	**Linear**
EmpCon	0.37
OnSup	0.42
Med	0.46
OffChe	0.24
Avg	0.37

Table 4: Prediction results (Pearson's r) for linear multi-task models based on RoBERTa embeddings. The first column is the target data set for the respective model that was trained on the remaining three data sets. The nonlinear results are similar and reported in the appendix.

Both the linear and the nonlinear multi-task models based on LIWC features performed worse than the multi-task models based on RoBERTa embeddings, which is why we only report the former in the appendix. Given these results, we recommend a linear multi-task model based on all data sets we considered to predict self-disclosure on a message level. The corresponding model will be made available upon publication.

6.2 Linguistic Features Predictive of Self-Disclosure

We found a strong positive correlation between the use of the personal pronoun 'I' (as captured by the LIWC category 'I') and self-disclosure across all data sets, and a similarly strong negative correlation between the use of 'you' and self-disclosure. This is to be expected; there should be more self-disclosure when talking about oneself than when talking about the person you are talking to. Furthermore, interrogatives, i.e. question words, are negatively correlated with self-disclosure across all considered data sets. Asking questions is low self-disclosure, since the person asking doesn't reveal as much information about themselves. It is worth noting that the signal for predicting self-disclosure is spread over many more categories of words; simply using 'I', 'you' and questions is insufficient to build an accurate model.

Positive emotions correlate much more weakly with self-disclosure than negative emotions, as shown by both LIWC emotion (Table 6) and EmoLex topics (Table 12 in the appendix). This is consistent with the norm violation notion of self-disclosure mentioned in the introduction. A sample set of words from the EmpCon data set that are strongly correlated with self-disclosure within the

---

[2] While the Pearson's r scores for the considered models are low compared to many results in computational linguistics, which are between 0.8 and 0.95 for problems like POS tagging, they are in line with most predictions of psychological constructs, where r values of about 0.3 to 0.4 are the norm due to the wider range of unobserved factors influencing them. In this context, average Pearson's r scores, especially across data sets, of 0.3 on average indicate a significant predictive signal.

Topic	Emp-Con	OnSup	Med	Off-Che
I	**0.35**	**0.36**	**0.44**	**0.16**
THEY	0.07	-	-	-0.03
SHEHE	0.07	0.12	-0.06	-
WE	0.06	-	-0.09	-
YOU	-0.29	-0.13	-0.40	-0.05

Table 5: LIWC-based classifier accuracy: Pearson's r of the linguistic topics for all data sets at the $p < 0.01$ level. A hyphen indicates that the respective category was not significant.

Topic	Emp-Con	OnSup	Med	Off-Che
NEGEMO	**0.24**	**0.45**	0.07	**0.12**
SAD	0.13	0.18	-	0.08
ANX	0.11	0.38	**0.08**	0.04
ANGER	0.11	0.22	-	0.09
POSEMO	-0.05	-0.14	-0.21	0.12

Table 6: LIWC-based classifier accuracy: Pearson's r of the emotion topics for all data sets at the $p < 0.001$ level. A hyphen indicates that the respective category wasn't significant.

Figure 2: Sample correlation of LIWC NEGEMO words with self-disclosure based on the *EmpCon data set*, depicted as LIWC topic cloud. The size of each category is proportional to its correlation with the considered target label. Correlations are significant at $p < 0.01$.

LIWC NEGEMO category is pictured in Figure 2. Due to socio-cultural norms, interpersonal interactions are constrained with regards to acceptable or desired behavior (Allan, 1993). Disclosure of personal, negative emotions poses a higher risk in that it is a violation of norms (Caltabiano and Smithson, 1983), while the disclosure of positive information such as accomplishments is more normative. Thus POSEMO correlates predominantly negatively with self-disclosure across the data sets.

6.3 Generalization across Different Corpora

In this section, we discuss differences in the predictive linguistic markers found across the considered data sets, and in the ability of our models to predict self-disclosure.

We found that self-disclosure models based on the Int data set generalized extremely poorly (average Pearson's r=0.14, see Table 16 in the appendix). The Int collection is not representative of self-disclosure because it only includes questions, which only obliquely reveal information about the person asking them. As mentioned above, we thus only reported the results from the Int data set in the appendix, and focused on the remaining data sets in our analysis.

The Med data set is also qualitatively different from the other data sets in that it is domain-specific. Revealing medical information is often particularly self-disclosing. Many medical conditions can be embarrassing to disclose to strangers because information related to illness tend to be negative and potentially embarrassing, hence disclosing medical information is norm-violating. Interestingly, negative emotions in a medical context are not as predictive of self-disclosure as in more general data sets like the other three considered in this paper (Figure 3b). A possible explanation for these deviations in posts related to the medical domain is that norms in this context differ from general norms: Strong emotions like anger or disgust are less prevalent when talking about medical diagnoses and indicators, while the medical information itself is already considered a highly personal information, leading to a higher self-disclosure scores without the presence of negative emotions. This is supported by the results in Table 7. Compared to the other data sets, we find that the BIO and HEALTH categories show a stronger positive correlation to self-disclosure in the Med data set than in the other corpora. Interestingly, strong emotions like anger or anxiety tend to be less prevalent in this domain-specific data set, too, presumably for the above-mentioned reasons.

We further observe that the OffChe data set has less overall explanatory power within-data-set than the other data sets, but shows a relatively stable across-data-set performance. This is possibly because the OffChe data set has more than 12,000 data points, allowing for a better generalization, but at the same time it has lower internal predictive accuracy because self-disclosure was only measured on a binary scale. The per-message signal is thus

(a) The *OffChe data set*

(b) The *Med data set*

Figure 3: Correlation of LIWC categories with self-disclosure in (a) the *OffChe data set* and (b) the *Med data set*. The size of each category name is proportional to its correlation with the self-disclosure label. Correlations are significant at $p < 0.01$.

Topic	**Emp-Con**	**OnSup**	**Med**	**Off-Che**
FUNCTION	0.36	0.30	0.09	0.05
I	0.35	0.36	0.44	0.18
NEGEMO	0.24	0.45	0.07	0.12
PPRON	0.17	0.37	0.08	0.07
BIO	0.14	-	0.20	0.02
HEALTH	0.12	-	0.19	-
ANX	0.11	0.38	0.08	0.04
ANGER	0.11	0.22	-	0.09
FOCPAST	0.03	0.12	0.31	-
POSEMO	-0.05	0.08	-0.21	0.12
AFFECT	0.12	0.13	-0.14	0.18

Table 7: Top 3 significant, positively correlated LIWC categories per data set and corresponding Pearson r's for all data sets, sorted by decreasing values in the EmpCon data set.

weaker for OffChe data points than for the other data sets for which the target variable was measured on a continuous scale. This is confirmed by the results in Table 7, where all LIWC categories are significantly less predictive of the OffChe data than for the other data sets. However, the LIWC categories that are most strongly correlated with self-disclosure in the OffChe data set are very intuitive and in line with our previous results, since for example categories like NEGEMO, ANGER and AFFECT are among the highest correlates (Figure 3a).

7 Limitations & Ethical Considerations

Several limitations of our study should be taken into account when considering results in a wider context. A key issue in building a general self-disclosure models was the differing labels based on differing definitions of self-disclosure across the data sets considered. (This is a common problem in computational social science, where constructs such as "happy" or "liberal" are often measured using widely different measures, see Casper et al. (2018) for more information). It needs to be taken into account that we assume in our paper that the different notions of self-disclosure across the considered data sets approximate the definition of self-disclosure validated in psychological literature. However, the data sets we took into account were not annotated based on such validated definitions but rather had differing labeling instructions, which might lead to inaccuracies when predicting 'true' self-disclosure. In future work, data that is labelled for a validated self-disclosure definition should be collected and analyzed. We further only tested a limited number of multi-task models. In future work, we'd suggest investigating these in more detail, which would further contribute to explaining why our multi-task model outperformed the single-task model.

In addition, we have not studied how self-disclosure prediction differs among different cultures, genders and races. Specifically, it is unclear how well our recommended general self-disclosure model applies to specific subgroups. For example, women tend to self-disclose more and express more emotional content than men (Sheldon, 2013). Whether this suggests that different models of self-disclosure would be helpful for men and women is less clear. Similarly, the amount of self-disclosure varies widely across settings and cultures. How this affects models is similarly unclear. These variations should be studied in a subsequent research project. Secondly, our training corpora included mostly native English speakers and hence might not generalize well to non-native speakers. Finally, self-disclosure detection could be used for unethical targeting, e.g. in the context of insurance companies who want to discriminate on prices for people who don't self-disclose much, given that self-disclosure can influence relationships and subsequently the mental health of a person. The application of our model for such usages is strongly advised against.

8 Conclusion

Self-disclosure is a determining factor of the quality of interpersonal relationships, where closer friendships include more self-disclosure (Rubin and Shenker, 1978). Furthermore, the amount of self-disclosure on a platform should also strongly affect how much information can be extracted about personality and emotion from language written on that platform; Linkedin, for example, should show less self-disclosure than Facebook. Motivated by these observations, we studied to what extent self-disclosure can be predicted by looking at lexical features. Many aspects of language indicate self-disclosure. The expression of negative emotions and the use of first person pronouns are particularly predictive. Models trained on different data sets with different annotations of self-disclosure generalize poorly across corpora. Our best performing model, a RoBERTa-based linear multi-task model trained on on all our data sets, is available at https://github.com/tea-shaped/self-disclosure-model.

A Appendix

A.1 Model Architectures

This section includes additional information about our single- and multi-task model architectures.

A.1.1 Single-task Model

In Table 11, we report the alpha values used in the single-task within-data set models. They were determined by a grid search over [0.0001, 0.001, 0.01, 1, 10, 100, 1000].

Topic	Emp-Con	On-Sup	Med	Off-Che
Ngrams	0.01	0.01	0.01	1
LIWC	0.01	0.01	1	1
LDA	0.01	0.01	0.01	0.01
Emo	0.01	0.01	0.01	1
ROB	100	100	10	100

Table 8: Alpha values for within-data set, single-task self-disclosure models.

A.1.2 Multi-task Model

For the multi-task models, we computed the optimal number of epochs for each considered learning rate ([1e-3, 1e-4, 1e-5]), where the learning rate was decreased by a factor of 10 when validation loss was static for 25 epochs. Afterwards, we performed for each target data set a five-fold cross-validation on the combined task of the three remaining data sets. Our batch size was 512 and we applied Adam optimization. If a batch was missing one of the data sets, it was skipped, so each batch contained all tasks. Heterogeneous batches were normalized by the number of examples in a batch and labels were normalized to the 0-1 range if they were continuous. As loss functions, we used the Mean Squared Error for continuous labels and the Binary Cross Entropy loss for discrete labels. The training was stopped when the learning rate reached 1e-6. The weighting was done equally by task. Note that in our multi-task training, almost all outputs were missing, since we didn't have all the different self-disclosure labels across all data sets but rather one specific one per data set.

For the initial **linear multi-task model**, we used a weight decay of 1.0 and a maximum learning rate of 1e-1. We let the model with the architecture shown in Table 9 train for 500 epochs.

Architecture Linear Model
Linear Layer from feature space to single dimension
Linear Layer from single dimension to output dimension (= number of tasks)

Table 9: Linear multi-task model architecture.

In addition, we found that the **nonlinear multi-task models** described in Table 10 turned out to be optimal for the **RoBERTa features**. This model trained for 300 epochs with a maximum learning rate of 2e-1 and a weight decay of 0.001.

Architecture Nonlinear RoBERTa Model
Dropout Layer with p=0.2
Linear Layer from feature space to 10 dimensions
Dropout Layer with p = 0.2
Batch Normalization Layer
Sigmoidal Activation
Linear Layer from 10 dimensions to single dimension
Batch Normalization Layer
Sigmoidal Activation
Linear Layer from single dimension to output dimension = number of tasks

Table 10: Nonlinear RoBERTa multi-task model architecture.

Finally, the **nonlinear multi-task model** reported in Table 11 was optimal for the **LIWC features**. It was trained over 300 epochs with a maximum learning rate of 5e-1 and a weight decay of 0.05.

Architecture Nonlinear LIWC Model
Dropout Layer with p=0.2
Batch Normalization Layer
Linear Layer from feature space to single dimension
Sigmoidal Activation
Batch Normalization Layer
Linear Layer from single dimension to output dimension = number of tasks

Table 11: Nonlinear LIWC multi-task model architecture.

A.2 Additional Results

In this section, we show additional results from our analysis, including the EmoLex classifier, the single-task results for the Int data set (both within- and across data set), the linear and nonlinear multi-task models based on LIWC as well as the nonlinear multi-task model based on RoBERTa embeddings.

A.2.1 EmoLex-based Classifier

Table 12 shows the results for the EmoLex-based classifier. Since they were in line with the emotion-related LIWC categories, we only reported the latter in the main text.

Topic	Emp-Con	On-Sup	Med	Off-Che
Anger	0.18	0.21	0.05	0.07
Anticip	-0.23	-	-0.08	0.04
Disgust	0.16	0.12	0.09	0.07
Fear	0.15	0.20	0.10	0.03
Joy	0.03	-0.09	-0.13	0.07
Sadness	0.17	0.26	0.10	0.05
Surprise	-	-	-0.08	0.04
Trust	0.04	-	-0.09	0.04
Positive	0.07	-0.10	-0.16	0.05
Negative	0.21	0.31	0.11	0.07

Table 12: Summary of the EmoLex-based classifier showing Pearson's r of the emotion topics for all data sets at $p < 0.001$. A hyphen indicates that the respective category wasn't significant.

A.2.2 Int Data Set

As discussed in the main text, we omitted the predictions from the Int data set since the corpus wasn't representative for our purposes as it only contained questions. In Tables 13 and 14, the key linguistic characteristics of the Int data set are shown.

Topic	Pearson's r
I	-
THEY	-
SHEHE	0.07
WE	-0.07
YOU	0.46

Table 13: LIWC-based classifier accuracy: Pearson's r of the pronoun topics for the Int data set at the $p < 0.01$ level. A hyphen indicates that the respective category wasn't significant.

Topic	Pearson's r
SAD	0.06
ANX	0.14
ANGER	0.07
POSEMO	0.05
NEGEMO	0.18

Table 14: LIWC-based classifier, reported as Pearson's r of the emotion topics for the Int data set at the $p < 0.01$ level. A hyphen indicates that the respective category wasn't significant.

In Table 15, we present the within-data set results for models based on the Int data set, averaged over a five-fold cross validation.

Model	Pearson's r
Ngrams	0.66
LIWC	0.64
LDA	0.55
EmoLex	0.08
RoBERTa	0.80
Avg	0.55

Table 15: Prediction performance for self-disclosure models based on the Int data set (captured by Pearson's r) within-data set, averaged over a five-fold cross-validation.

Table 16, on the other hand, shows the across-data set results for the best-performing within-data set Int model, i.e. the RoBERTa model, applied to all other considered data sets.

Data Set	Pearson's r
EmpCon	0.07
OnSup	0.29
Med	0.04
OffChe	0.16
Avg	0.14

Table 16: Prediction performance for Int self-disclosure RoBERTa model (captured by Pearson's r) across-data set averaged over a five-fold cross-validation.

A.2.3 Multi-task Models

In this section, we report additional multi-task models. Table 17 shows the results for the **RoBERTa-based nonlinear multi-task model**.

Target Data Set	**Pearson's r**
EmpCon	0.45
OnSup	0.29
Med	0.34
OffChe	0.22
Avg	0.33

Table 17: Prediction results (Pearson's r) for nonlinear multi-task models based on RoBERTa embeddings. The first column is the target data set for the respective model that was trained on the remaining three data sets.

Table 18 shows the results for the **LIWC-based nonlinear multi-task model**.

Target Data Set	**Pearson's r**
EmpCon	0.48
OnSup	0.29
Med	0.28
OffChe	0.14
Avg	0.30

Table 18: Prediction results (Pearson's r) for nonlinear multi-task models based on LIWC embeddings. The first column is the target data set for the respective model that was trained on the remaining three data sets.

Finally, we included the results for the **LIWC-based linear multi-task model** in Table 19.

Target Data Set	**Pearson's r**
EmpCon	0.31
OnSup	0.45
Med	0.26
OffChe	0.06
Avg	0.27

Table 19: Prediction results (Pearson's r) for linear multi-task models based on LIWC embeddings. The first column is the target data set for the respective model that was trained on the remaining three data sets.

When Chosen Wisely, More Data Is What You Need: A Universal Sample-Efficient Strategy For Data Augmentation

Abstract

Data Augmentation (DA) is known to improve the generalizability of deep neural networks. Most existing DA techniques naively add a certain number of augmented samples without considering the quality and the added computational cost of these samples. To tackle this problem, a common strategy, adopted by several state-of-the-art DA methods, is to adaptively generate or re-weight augmented samples with respect to the task objective during training. However, these adaptive DA methods: (1) are computationally expensive and not sample-efficient, and (2) are designed merely for a specific setting. In this work, we present a universal DA technique, called *Glitter*, to overcome both issues. Glitter can be plugged into any DA method, making training sample-efficient without sacrificing performance. From a pre-generated pool of augmented samples, Glitter adaptively selects a subset of worst-case samples with maximal loss, analogous to adversarial DA. Without altering the training strategy, the task objective can be optimized on the selected subset. Our thorough experiments on the GLUE benchmark, SQuAD, and HellaSwag in three widely used training setups including consistency training, self-distillation and knowledge distillation reveal that Glitter is substantially faster to train and achieves a competitive performance, compared to strong baselines.[1]

1 Introduction

The undeniable importance of data in deep learning (Sambasivan et al., 2021; Rogers, 2021) and the costly process of data annotation has propelled researchers into leveraging Data Augmentation (DA) in a broad range of applications from computer vision (Cubuk et al., 2019; Wang et al., 2020) to natural language processing (NLP) including machine translation (Sennrich et al., 2016; Shen et al., 2020), language understanding (Shen et al., 2020; Qu et al., 2021; Du et al., 2021; Kamalloo et al., 2021), and question answering (Alberti et al., 2019; Longpre et al., 2019; Shakeri et al., 2020). DA is shown to be effective in improving generalization of deep neural networks (DeVries and Taylor, 2017; Xie et al., 2020) and in increasing the number of training samples especially in low resource data regimes (Sennrich et al., 2016; Zhang et al., 2018). Nonetheless, in NLP, the discrete nature of text poses additional complexity to DA as generating semantically viable text from another text is challenging (Feng et al., 2021).

DA methods can be broadly categorized into *task-aware* and *task-agnostic* methods. Task-agnostic DA methods essentially generate augmented text regardless of the task at hand and often do not warrant additional training or fine-tuning. They can be based on some hand-crafted heuristics (Zhang et al., 2015; Wei and Zou, 2019), back-translation (Sennrich et al., 2016; Edunov et al., 2018), or token replacement from a pre-trained language model (Kobayashi, 2018; Wu et al., 2019; Ng et al., 2020). Even though deploying task-agnostic methods is straightforward, these methods do not take into account any task-specific information, and thus, their performance is usually limited. On the other hand, task-aware DA methods are capable of generating augmented samples, conditioned on the downstream task objective (Hu et al., 2019; Xie et al., 2020; Rashid et al., 2021). These methods adapt augmented examples specifically for a task in that they construct augmented examples, sometimes partly, during training. Despite their advantages, they often incur additional training costs, resulting in a prohibitively slow and a computationally expensive training.

In general, the central problems surrounding DA techniques in NLP can be summarized as follows:

---

[*] Equal Contribution.

Findings of the Association for Computational Linguistics: ACL 2022, pages 1048 - 1062
May 22-27, 2022

First, DA methods are mostly not sample-efficient in that they add arbitrary number of augmented samples to the training data and naively incorporate all of them into training without investigating how many of augmented samples are actually needed. Second, although more effective, task-aware methods are notoriously time-consuming to train. This is especially problematic in large-scale datasets such as SQuAD (Rajpurkar et al., 2016) and MNLI (Williams et al., 2018). Third, most DA methods are not universal as they work solely with a particular setup—e.g., training a single-network (Xie et al., 2020), or training in teacher-student settings (Rashid et al., 2021). Overall, the importance of both sample efficiency and training efficiency for DA has been often overlooked.

Motivated by the above problems, in this work, we introduce a universal DA method, Glitter ✨[2], which can be plugged into any DA method to make them sample-efficient, and task-aware without sacrificing performance. Specifically, given a pool of augmented samples that are generated offline, our proposed method follows a minimax approach (Farnia and Tse, 2016) to select a small subset with maximal expected loss (*maximization step*) during training. Without any further adjustments to the training algorithm, the task objective can be optimized for this selected subset (*minimization step*).

Our key contributions in this paper can be summarized as follows:

1. Glitter is a universal method which can be effortlessly applied to any DA method to enforce sample efficiency while maintaining (or even boosting) their performance.
2. We devise strategies to adapt Glitter for a variety of widely used training setups including single-network, consistency training, self-distillation and knowledge distillation.
3. Through our empirical evaluations, we show that Glitter achieves superior performance over state-of-the-art DA methods on GLUE, SQuAD, and HellaSwag, while significantly speeding up the training.

2 Related Work

2.1 Task-agnostic DA in NLP

Contextual augmentation techniques (Kobayashi, 2018; Wu et al., 2019) use pre-trained language models for DA. Kobayashi (2018) propose bidirectional LSTM language models for word substitution conditioned on the label of their input text. SSMBA (Ng et al., 2020) and TinyBERT (Jiao et al., 2020) perturb the input by masking some of the tokens, and then, sample tokens from a BERT model to replace the masked tokens and generate augmented samples. Back-Translation (Sennrich et al., 2016) augments data using two consecutive translation models: the first model to translate the input into an arbitrary target language; then, a second model to translate the result back into its original language. Mixed-up (Guo et al., 2019) generates augmented samples based on interpolating word embedding and sentence embedding vectors. Shen et al. (2020) introduce a set of cut-off techniques that zero out contiguous spans of the embedding matrix at token level, feature level and span level. EDA (Wei and Zou, 2019) consists of simple word-level operations including synonym replacement, random deleting, random insertion and random swapping.

2.2 Task-aware DA in NLP

One approach to leverage task-specific information is to assign different weights to augmented samples based on their individual impacts on the model (Yi et al., 2021). Although effective, the re-weighting mechanism largely ignores sample efficiency. Wu et al. (2019) introduce a mask-and-reconstruct approach, namely c-BERT, that fine-tune a pre-trained BERT model to predict label-compatible tokens. CoDA (Qu et al., 2021) combines various label-preserving transformations with adversarial training jointly with a contrastive regularization objective. Unsupervised DA (UDA; Xie et al. 2020) uses off-the-shelf DA methods and adds an auxiliary *consistency loss* to the training objective. However, UDA is not sample-efficient and it is designed only for a single-network setup; how to deploy it in other training scenarios such as knowledge distillation is not clear. Hu et al. (2019) propose a reinforcement learning-based technique where the reward function is defined based on whether generated augmented samples are label-preserving or not.

2.3 DA for KD

KD (Buciluă et al., 2006; Hinton et al., 2015), initially proposed as a model compression technique, aims at transferring the knowledge of an already trained model, called *teacher*, to a smaller or a

---

[2] Inspired by "*All that is gold does not glitter*" —J.R.R. Tolkien, The Fellowship of the Ring.

same-size *student* model. Several studies found that DA can significantly boost KD's performance in NLP. TinyBERT (Jiao et al., 2020) uses a task-agnostic DA technique for its task-specific fine-tuning. Kamalloo et al. (2021) and Rashid et al. (2021) showed that DA can also be tailored for KD. In particular, MATE-KD (Rashid et al., 2021) tunes a separate masked language model in order to generate augmented samples with maximum divergence. Kamalloo et al. (2021) and Du et al. (2021) employ kNN retrieval to fetch augmented samples from a massive sentence bank.

Glitter differs from previous work in that it simultaneously focuses on sample efficiency, and universality such that it can be freely used in any training setting.

3 Methodology

In this section, we introduce our task-aware DA method, Glitter ✨, that aims at using an efficient number of augmented samples without sacrificing performance. Our proposed strategy is agnostic to DA methods; it can be seamlessly plugged into any DA method with any training setting to enforce sample efficiency.

Existing learning-based DA methods train a separate DA model and adapt its output for a particular objective function that is entirely task-dependent:

$$\begin{aligned} \phi^* &\leftarrow \min_{\phi} \ell_{DA}(M(\Omega(x;\phi);\theta)) \\ x'^* &= \Omega(x;\phi^*) \end{aligned} \tag{1}$$

where $\ell_{DA}()$ is a loss function, geared towards the objective of the task, $\Omega(;\phi)$ is the DA model with trainable parameters ϕ, and $M(;\theta)$ refers to the original model, parameterized by θ.

In contrast to learning-based DA, we propose to generate many augmented candidates using any arbitrary DA method prior training, and adaptively select most suitable candidates during training. This procedure does not introduce additional trainable parameters into training, and more importantly, is capable of automatically ignoring unnecessary augmented examples. Let $(x_i, y_i)_{i=1}^{N} \in \{(\mathcal{X}, \mathcal{Y})\}$ represent training data such that a pair $x_i \in \mathcal{X}$ and $y_i \in \mathcal{Y}$ are an input example and its corresponding label. Suppose a pool of K augmented examples, $X'(i) = \{x'_k(i)\}_{k=1}^{K}$, are sampled from some DA model for each training example $(x_i, y_i) \in (\mathcal{X}, \mathcal{Y})$. Note that Glitter imposes no restrictions on how to augment training data; augmented samples can be generated via a single or even multiple DA models.

Sample Selection. Given a pool of augmented samples, our approach is to adaptively select the best candidates according to particular defined criteria. Inspired by the minimax approach (Farnia and Tse, 2016; Volpi et al., 2018), our selection mechanism is based on finding top-k_1 (out of K) worst-case augmented samples from the X' set. Minimizing the main model loss function on these worst-case augmented samples will help improving generalization of the model (Volpi et al., 2018). In order to rank augmented samples, we evaluate $X'(i)$ based on a distance function with respect to the corresponding original training sample, x_i, within the model's latent space:

$$\begin{aligned} X'^*(i) &\leftarrow \text{top}_{k_1}\Big(\ell_{\text{eval}}\big(M(x_i;\theta), M(X'(i);\theta)\big)\Big) \\ X'^*(i) &= \{x'^*_j(i)\}_{j=1}^{k_1} \subset X'(i) \end{aligned} \tag{2}$$

where $\text{top}_{k_1}()$ denotes returns top-k_1 indices based on the scores returned by ℓ_{eval}, $X'^*(i)$ is the set of k_1 selected augmented samples for x_i; $\ell_{eval}()$ is the evaluation loss which is determined via the task objective.

Updating the Model Parameters. After obtaining the top-k_1 augmented samples, we group them with the original training samples, $\{x_i\} \cup X'^*(i)$, and subsequently, update the model parameters only based on this selected set of augmented samples on the original loss:

$$\begin{aligned} \mathcal{L}(\theta) &= \sum_{i=1}^{N} \ell_{\text{task}}\Big(M(x_i;\theta), M(X'^*(i);\theta), y_i\Big) \\ \theta_t &\leftarrow \theta_{t-1} - \lambda \nabla_\theta(\mathcal{L}(\theta))|_{\theta_{t-1}} \end{aligned} \tag{3}$$

where N is the number of training samples, λ is the learning rate, and $\ell_{\text{task}}()$ is the final task loss—e.g., cross entropy (ce) for classification—that is computed over both original data and selected augmented data. In the remainder of this section, we discuss how Glitter can be applied to popular training settings including general DA for single networks, and DA for teacher-student (KD) setups. Note that Glitter is not restricted to these settings and may be adapted for other settings such as DAIR (Huang et al., 2022).

3.1 General DA for Single Networks

We consider three potential setups for the single network scenario: (1) General single network, (2)

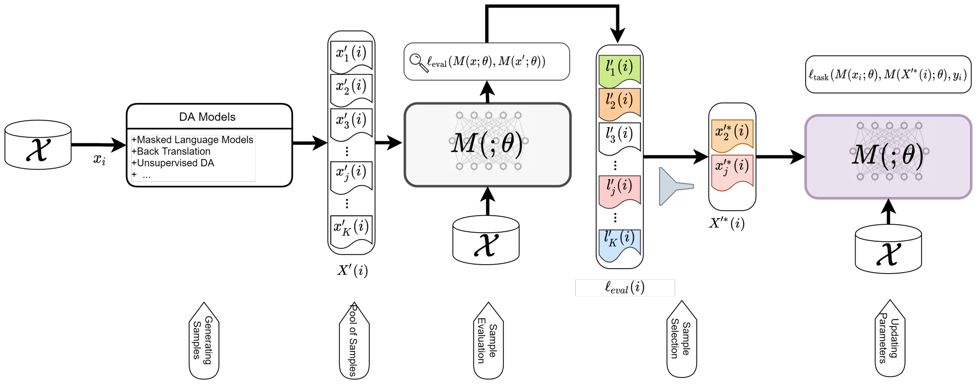

Figure 1: Illustration of Glitter ✨ (from left to right): first, generating augmented samples from different DA techniques; second, forming a pool of samples $X'(i)$; third, evaluating the augmented samples using the $\ell_{eval}()$ loss; fourth, filtering the top-k_1 samples based on their corresponding $\ell_{eval}()$; fifth, updating the parameters of the model by minimizing the task loss $\ell_{\text{task}}(:\theta)$.

Self-distillation, and (3) Consistency training.

General Single Network. In this setup, augmented samples are exploited in a semi-supervised manner where we can evaluate them based on the divergence of their predicted output $M(x'_k(i);\theta) = p(y|x'_k(i);\theta)$ from the ground-truth label or the prediction of the original corresponding training sample $M(x_i;\theta) = p(y|x_i;\theta)$ using the cross entropy loss, ℓ_{ce}:

$$\begin{aligned} &\ell_{\text{eval}} = \ell_{ce}\big(y_i, M(x'_k(i);\theta)\big) \\ &\text{or} \\ &\ell_{\text{eval}} = \ell_{ce}\big(M(x_i;\theta), M(x'_k(i);\theta)\big). \end{aligned} \tag{4}$$

The cross entropy criterion is not the only option here. Other choices for ℓ_{eval} include (but not limited to) focal loss (Lin et al., 2017), and tilted loss (Li et al., 2021).

For the final task loss, ℓ_{task} we can deploy a standard cross entropy loss over both training samples and their corresponding selected augmented samples:

$$\begin{aligned} &\ell_{\text{task}} = \ell_{ce}\big(y_i, M(x_i;\theta)\big) + \\ &\frac{1}{k_1} \sum_{x \in X'^*(i)} \ell_{ce}\big(y_i, M(x;\theta)\big). \end{aligned} \tag{5}$$

Consistency Training (CT; Xie et al. 2020). In this configuration, we can employ the same ℓ_{eval} introduced in Eq. (4). As a result, our method naturally selects top-k_1 most inconsistent augmented samples for each training sample. Then, the network is optimized to make predictions for input augmented samples that are consistent with predictions of their corresponding original training samples:

$$\begin{aligned} &\ell^{\text{CT}}_{\text{task}} = \ell_{ce}\big(y_i, M(x_i;\theta_t)\big) + \\ &\frac{1}{k_1} \sum_{x \in X'^*(i)} \ell_{ce}\big(M(x_i;\theta_{t-1}), M(x;\theta_t)\big). \end{aligned} \tag{6}$$

As stated by Xie et al. (2020), the second term in Eq. (6) leverages the previous prediction of the network for each training example.

Self-Distillation (Self-KD). In Self-KD, we first train a model, and then, use it ($M(;\theta^*)$) as a teacher to train an identical model but initialized from scratch using KD (Furlanello et al., 2018). How to adjust ℓ_{eval} and ℓ_{task} is detailed in §3.2.

3.2 DA for Teacher-Student (KD)

In this setup, we have a teacher model, $T(;\psi^*)$ with parameters ψ that is already trained on the training data, along with a student model, $M(;\theta)$, which we aim to train. The selection criterion for augmented samples is to maximize divergence between the teacher and the student:

$$\ell^{\text{KD}}_{\text{eval}} = \ell_{KL}\Big(T\big(x'_k(i);\psi^*\big), M\big(x'_k(i);\theta\big)\Big) \tag{7}$$

where ℓ_{KL} refers to the KL divergence. After selecting the maximum divergence augmented samples, then we calculate the KD loss as following:

$$\begin{aligned} &\ell^{\text{KD}}_{\text{task}} = \alpha\, \ell_{ce}\big(y_i, M(x_i;\theta)\big) + (1-\alpha)\times \\ &\frac{1}{k_1+1} \sum_{x \in \{x_i\} \cup X'^*(i)} \ell_{KL}\big(T(x;\psi^*), M(x;\theta)\big) \end{aligned} \tag{8}$$

where α is a hyperparameter.

4 Experiments

4.1 Setup

To incorporate unlabelled augmented data into training, we adopt CT (Xie et al., 2020) and KD (Hinton et al., 2015). To this end, we conduct experiments under two settings:

Standalone where we train a single model on the augmented data. In this setting, we seek to answer two questions: (1) How much is DA capable of improving the model generalization? (2) Does sample efficiency of Glitter hurt performance? For this purpose, we fine-tune RoBERTa$_{\text{base}}$ (Liu et al., 2019) using CT and Self-KD on augmented data.

Distilled where we distill DistilRoBERTa (Sanh et al., 2019) (student) from RoBERTa$_{\text{Large}}$ (Liu et al., 2019) (teacher) using the augmented data. Note that the teacher is already trained on the original data and DA comes into play only during distilling the student model. Our goal here is to investigate whether DA is an effective means in knowledge transfer to curb the capacity gap (Cho and Hariharan, 2019) between a large model and a small one.

In both settings, we take the best performing model on the development set and evaluate it on the test set (depicted by *Test*). Additionally, for the standalone model setting, we also report results on the development set when models are trained only for 5 epochs (depicted by *Dev*), similar to CoDA (Qu et al., 2021), to make a comparison with baselines. Our *Dev* results are an average of 10 runs with different seeds. The implementation details and hyperparameters are provided in §A.

4.1.1 DA Methods

We leverage three widely used textual augmentation methods:

1. **EDA** (Wei and Zou, 2019)[3]: We randomly replace 5% of the tokens with their synonyms and randomly delete up to 10%.

2. **Back-Translation (BT; Sennrich et al. 2016)**: We use fairseq (Ott et al., 2019) to translate sentences into German and then back into English. We do nucleus sampling (Holtzman et al., 2020) with $p = 0.9$ for both translations. We find that $p = 0.6$ works better on sentiment classification.

3. **Mask-and-Reconstruct (MR; Ng et al. 2020)**: We randomly mask 15% of the tokens and construct a new sentence by sampling from a pre-trained BERT$_{\text{Large}}$ for masked tokens. We adopt top-k sampling with $k = 20$ to select new tokens. For MNLI, we obtain better results with top-10 sampling.

For each augmentation method, we generate 12 augmented examples per training instance for all datasets, except for large datasets—i.e., MNLI, QQP, and SQuAD—where the number of augmented examples are 8 per train example.

4.1.2 Baselines

Because the two environments—i.e., standalone and distilled—are different in nature, we compare Glitter with different baselines for each environment. For both, Vanilla-DA that takes all augmented data into account without reservation is the first baseline.

The baselines for the standalone setting are: CoDA (Qu et al., 2021), MMEL (Yi et al., 2021), and HiddenCut (Chen et al., 2021). And for distilled, we consider MATE-KD (Rashid et al., 2021).

4.2 GLUE

The GLUE benchmark (Wang et al., 2019) is a well-known suite of nine[4] tasks that aim at evaluating natural language understanding models. We present test results in the distilled mode in Table 1. Glitter consistently outperforms Vanilla-DA, while it is faster to train. Specifically, Glitter achieves parity with Vanilla-DA for EDA in terms of the overall average score, while scoring +0.2% and +0.4% higher for BT and MR, respectively. We observe that only in few cases Vanilla-DA negligibly outperforms Glitter—e.g., on MRPC, and STS-B for BT. Nonetheless, Glitter *8x/1x* trains 50% faster than Vanilla-DA *8x* on average, and 30% faster for *8x/2x*. Also, Glitter surpasses MATE-KD by +0.2% in the overall score. Unlike Glitter, MATE-KD introduces additional parameters to the model during training and it trains drastically slower because it generates augmented examples on-the-fly. Moreover, Table 1 illustrates that MR yields the best test results across the three DA methods except for SST where BT leads to better results. Based on this observation, we report results on MR augmented

Table 2: Test result of the standalone experiments on GLUE using RoBERTa$_{\text{base}}$.

data for all GLUE datasets except for SST in the remainder of our experiments.

For the standalone mode, Tables 2 and 3 present the results on test and dev, respectively. Similar to distilled, Glitter outperforms Vanilla-DA by +0.5% for both self-KD and CT. Self-KD yields better results than CT on all GLUE tasks except CoLA. CT falls short on most GLUE tasks, compared to no DA results—i.e., top-2 rows in Table 2. This is why, we only evaluated Glitter with self-KD on the dev data. Glitter achieves superior performance gains, compared to all three baselines on all datasets except QNLI. The key advantage of Glitter is that the training procedure remains intact.

4.2.1 Out-of-Domain Generalization

We also evaluate Glitter on OOD datasets. To this end, we test our models, already trained on GLUE tasks, on OOD datasets whose data distribution differs from the original data. In particular, here are our selected OOD datasets:

- SST: IMDb (Maas et al., 2011), IMDb-Cont. (Gardner et al., 2020), and IMDb-CAD (Kaushik et al., 2020), as done in Chen et al. (2021). Although both SST and IMDb datasets are collected on movie reviews, IMDb reviews tend to be substantially longer than SST sentences.
- STS-B: SICK (Marelli et al., 2014), a semantic relatedness dataset, created from image and video captions. SICK and STS-B are collected on roughly identical domains, but from different sources.
- QQP: PAWS$_{\text{QQP}}$ (Zhang et al., 2019), analogous to Chen et al. (2021), and MQP (McCreery et al., 2020), a medical question similarity dataset.

Table 3: Dev results of the standalone experiment on GLUE using RoBERTa$_{\text{base}}$. ($^\spadesuit$) denotes results are taken verbatim from: RoB and CoDA (Qu et al., 2021), and HiddenCut (Chen et al., 2021). (†) indicates the results are obtained from our implementation of MMEL (Yi et al., 2021).

- MNLI: SciTail (Khot et al., 2018), collected from school-level science questions, and similar to Chen et al. (2021), A-NLI (Nie et al., 2020), and HANS (McCoy et al., 2019).
- RTE: HANS (McCoy et al., 2019).

Table 10 in §B.1 showcases the OOD results for the distilled mode. Glitter outperforms Vanilla-DA in most cases, and is on par with it for nearly the rest. The only exceptions are IMDb-Cont., MQP, and PAWS$_{\text{QQP}}$ where Vanilla-DA outperforms Glitter by almost 1% on average. Also, all models do not generalize well to PAWS$_{\text{QQP}}$ and A-NLI because their performance is below a majority-class performance. Moreover, a fine-tuned DistilRoBERTa achieves the best OOD performance on HANS, highlighting that DA is not actually helpful for OOD accuracy on HANS.

Table 3 (the right side) reports the OOD results for standalone models. The complete results are presented in §B.2—i.e., Table 11 on test and Table 12 on dev. Glitter overwhelmingly outperforms all the baselines with a few exceptions. In the dev results, the fine-tuned model with no DA achieves the best OOD generalization on IMDb, and SciTail, while HiddenCut scores the highest on A-NLI with a 1% margin. Similarly, in the test results, Glitter trails Self-KD with no DA on IMDb, IMDb-CAD, and SciTail.

4.3 HellaSwag

HellaSwag (Zellers et al., 2019) is a dataset for situated commonsense reasoning that involves picking the best ending given a context. We augment contexts in HellaSwag using only BT to ensure that the choices remain meaningful for the augmented contexts. Because our standalone results have been consistent with the distilled results, we report our results only in the distilled mode. According to our results demonstrated in Table 4, Glitter comfortably surpasses Vanilla-DA by a +2.3% margin.

Method	**SQuAD** EM/F_1	**HellaSwag** Acc
RoB$_{\text{Large}}$	88.9/94.6	85.2
DistilRoB	80.9/87.9	42.9
KD	81.1/88.2	42.5
+ Vanilla-DA *(8x)*	81.8/89.1	41.8
+ Glitter ✨ *(8x/2x)*	**83.6/90.3**	**44.1**

Table 4: Dev results of the distilled experiment on two downstream tasks.

4.4 SQuAD

SQuAD (Rajpurkar et al., 2016) is a crowd-sourced reading comprehension benchmark that consists of more than 100K questions, derived from Wikipedia passages. The task objective is to extract an answer span from a given question/passage pair. We augment questions in SQuAD v1.1 using only BT to ensure that the answer can still be found in the given passage for the augmented questions. Analogous to HellaSwag, we report our results only in the distilled mode. As shown in Table 4, Glitter outperformas Vanilla-DA by +1.8% in exact-match accuracy on the development set.

We also evaluate our trained models under distribution shift by testing them on QA datasets from four different domains: Wikipedia, New York Times, Reddit, and Amazon product reviews (Miller et al., 2020). The OOD results are presented in Table 5. Glitter is consistently superior to Vanilla-DA in all four domains.

5 Ablation Study and Discussion

In this section, we aim to answer the following questions:

Method	Wiki	NYT	Reddit	Amzn
	EM	EM	EM	EM
RoB$_{\text{Large}}$	84.4	85.9	76.6	74.4
DistilRoB	76.6	78.1	66.2	62.9
KD	76.5	78.7	65.7	63.0
+ Vanilla-DA	77.3	79.0	65.9	63.3
+ Glitter ✨	**79.3**	**80.7**	**68.1**	**64.7**

Table 5: OOD results for models trained on SQuAD and tested on QA datasets from four different domains (Miller et al., 2020).

Method	SST	MRPC	QNLI	RTE
	Acc	F$_1$	Acc	Acc
Vanilla-DA	95.1	92.2	93.3	84.8
$\beta = 0.7$	95.1	92.5	93.4	84.8
$\beta = 0.9$	95.0	92.2	93.3	83.8
LP	94.8	92.4	93.3	84.8
Glitter ✨	95.8	92.8	93.4	85.9
$\beta = 0.7$	95.0	91.5	93.5	85.2
$\beta = 0.9$	95.0	92.5	93.3	84.1
LP	95.1	92.2	93.5	85.9

Table 6: Dev results of self-KD exhibiting the effectiveness of different pre-processing techniques to filter augmented examples on 4 GLUE tasks. β and LP depict a minimum confidence threshold, and label preserving, respectively.

- How does training time of Glitter compare against Vanilla-DA?
- Instead of adaptively selecting augmented data during training, can we pre-process them to dispense with unnecessary examples prior to training?
- How many augmented examples are required for Glitter to work?
- Is our selection strategy based on sorting of ℓ_{eval} in Glitter important?

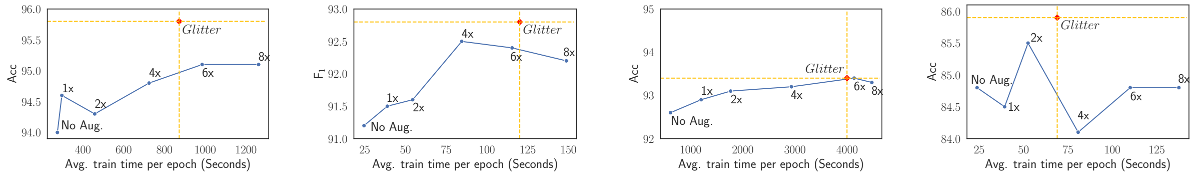
For this purpose, we conduct a detailed analysis on 4 GLUE tasks—i.e., SST, MRPC, QNLI, and RTE. We trained models based on Vanilla-DA and Glitter using Self-KD and tested them on the development set (the dev setting).

Runtime Analysis. Throughout our experiments in §4, we compare Glitter with Vanilla-DA when number of augmentations are similar for both methods—i.e., *8x*. A natural question is: how would both DA methods behave with fewer augmented data? To this end, we vary augmentation size from $1x$ to $8x$ and train different Vanilla-DA models on each augmented dataset. We measure average the training time per epoch for all models. Figure 2 illustrates the dev accuracy as the training time increases. The training speed of Glitter *8x/2x* is slightly faster than Vanilla-DA *6x* on SST, MRPC, and QNLI and for Glitter *8x/1x*, is faster than Vanilla-DA *4x* on RTE. Glitter is superior of the two on all datasets.

Effect of Pre-processing Augmented Data. We conjecture that Glitter does not need any data engineering on augmented examples to obtain preferable performance gains. However, Vanilla-DA may require some pre-processing by weeding out potentially noisy data to become more effective. To investigate this, we exploit two pre-processing techniques: **(1) Confidence-based filtering:** Augmented examples for which the model's confidence is below a minimum threshold β are discarded, **(2) Label-preserving augmentation (LP):** Augmented examples for which the model predicts a different label than the original example are discarded. The results, reported in Table 6, show no meaningful performance gains by these pre-processing techniques. For Vanilla-DA, minimum confidence threshold of 0.7 performs slightly better as it brings minor improvements on MRPC (+0.3%) and QNLI (+0.1%), but is still lower than Glitter. On the other hand, applying these techniques slightly deteriorates the performance of Glitter in almost all cases. The only improvements are +0.1% on QNLI for LP and β=0.7.

Effect of Augmentation Size in Glitter. We explore how augmentation size affects the performance of Glitter. Throughout our experiments, we fix the augmentation size to *8x*, but now, we reduce augmentation size K to $6x$ and $4x$, while retaining selection size k_1 as before—i.e., 1 for RTE, and 2 for the rest. Our results, shown in Table 7, reveal that when K becomes close to k_1, Glitter's performance declines. Nonetheless, for a sufficiently large augmentation, Glitter starts to shine. For SST, and MRPC, the magic number is $8x$, whereas for QNLI, and RTE, Glitter performs best on $6x$. Another parameter in Glitter is the selection size k_1. We find that for all tasks, the best value can be chosen from $\{1, 2\}$ (2 by default). Using this method, tuning k_1 is straightforward and does not impose additional complexity to our method.

Effect of Selection Strategy in Glitter. In this section, our objective is to assess whether our proposed selection algorithm is crucial in Glitter. To



(a) SST (b) MRPC (c) QNLI (d) RTE

Figure 2: Runtime Analysis of DA when training RoBERTa$_{\text{base}}$ using self-KD. The red point signifies Glitter.

Method	SST	MRPC	QNLI	RTE
	Acc	F_1	Acc	Acc
Glitter ✨ (8x)	95.8	92.8	93.4	85.9
Glitter ✨ (6x)	94.7	92.7	93.7	86.3
Glitter ✨ (4x)	95.0	92.1	93.3	85.7
Glitter-Rnd (8x/2x)	94.3	91.4	93.2	85.2
Glitter-Rnd (8x/1x)	94.3	91.8	93.2	84.5

Table 7: Dev results of self-KD for studying the effect of augmentation size and the selection algorithm for 4 GLUE tasks.

this end, we sample random augmented examples at each iteration, namely *Glitter-Rnd*, instead of selecting worst-case examples. As illustrated in Table 7 (the bottom two rows), the performance drops on all datasets—i.e., 0.2% on QNLI, and more than 1% on the rest, confirming the effectiveness of our selection algorithm.

6 Conclusion

In this work, we proposed a universal DA technique, namely *Glitter*, that can be freely applied to any DA technique to enforce sample efficiency without introducing additional parameters or changing the training procedure. We extensively evaluated Glitter on a broad range of NLU tasks and in various widely used settings including consistency training, self-distillation and knowledge distillation and demonstrated substantial efficiency gains without compromising effectiveness. Extending Glitter to auto-regressive models for machine translation and abstractive summarization is an interesting direction for future work.

A Implementation Details

A.1 Fine-tuning details

We adopted the publicly available pre-trained RoBERTa (Liu et al., 2019) and DistilRoBERTa (Sanh et al., 2019)—using the Huggingface Transformers library (Wolf et al., 2020) and the Pytorch Lightning library[5].

For the *test* settings, the model is evaluated on the development data once per epoch for small datasets and twice per epoch for large ones—i.e., SST-2, MNLI, QNLI, SQuAD, and HellaSwag. The best performing model is chosen for testing. Our learning rate schedule follows a linear decay scheduler with a warm-up, specified as a ratio of the total number of training steps. Maximum number of epochs is set to 20 for all tasks except SQuAD, following (Mosbach et al., 2021). For large datasets, we early stop with a patience of 10. The learning rate, and the batch size are tuned for each task separately. The details of hyperparameters are summarized in Table 9. We ran RoBERTa$_{\text{base}}$ experiments with the similar hyperparameters, but with these exceptions: On QNLI, learning rate, batch size, and weight decay are set to 3e-5, 64, and 0.1; warmup ratio is set to 0.06 on QQP.

For *dev* experiments, we follow CoDA (Qu et al., 2021) on the GLUE tasks. Specifically, we train the model for 5 epochs with a batch size of 32, learning rate 1e-5, warmup ratio 0.06, weight decay 0.1, and linear learning rate decay. For SQuAD, and HellaSwag, the hyperparameters are detailed in Table 8.

All experiments were conducted on two Nvidia Tesla V100 GPUs.

Hyperparam.	**SQuAD**	**HellaSwag**
Learning rate	1.5e-5	1.5e-5
Batch size	16	32
Max length	512	512
Max epochs	3	20
Warmup ratio	0.06	0.06
Grad. acc. steps	4	1
Weight Decay	0.01	0.01
temp. τ (for KD)	5.0	10.0

Table 8: Hyperparameters of DistilRoBERTa on two downstream tasks.

A.2 Knowledge distillation details

We implemented knowledge distillation by caching the teacher's logits prior to training. We performed grid search to find the best softmax temperature τ from $\{5.0, 10.0, 12.0, 20.0, 30.0\}$. The value of τ used in our experiments are reported in Tables 8 and 9 for DistilRoBERTa and RoBERTa$_{\text{base}}$; with the exception $\tau = 20.0$ on MRPC for RoBERTa$_{\text{base}}$. Loss weight α, in Eq. (8), is set to 0.5 for all tasks except CoLA in which $\alpha = 0.75$.

B OOD results

B.1 Distilled Mode

OOD results for models trained in the distilled mode are presented in Table 10.

B.2 Standalone Mode

Table 11 presents OOD results for models trained using *test* settings, and Table 12 (complementary to Table 3 in §4.2.1) presents OOD results for dev experiments.

Explaining Classes through Stable Word Attributions

Abstract

Input saliency methods have recently become a popular tool for explaining predictions of deep learning models in NLP. Nevertheless, there has been little work investigating methods for aggregating prediction-level explanations to the class level, nor has a framework for evaluating such class explanations been established. We explore explanations based on XLM-R and the Integrated Gradients input attribution method, and propose 1) the Stable Attribution Class Explanation method (SACX) to extract keyword lists of classes in text classification tasks, and 2) a framework for the systematic evaluation of the keyword lists. We find that explanations of individual predictions are prone to noise, but that stable explanations can be effectively identified through repeated training and explanation. We evaluate on web register data and show that the class explanations are linguistically meaningful and distinguishing of the classes.

1 Introduction

In recent years, various approaches to explaining predictions of deep neural networks have been attracting interest in the fields of NLP and computer vision (see, Montavon et al. (2018)). Several techniques have been suggested in this vein, including model attention visualization (see, e.g., Vig and Belinkov (2019)), and input attribution (or saliency) methods (see Bastings and Filippova, 2020; Ding and Koehn, 2021; Simonyan et al., 2014), which focus on explaining individual predictions. However, showing how a model perceives larger units such as entire classes in a text classification task would be crucial for gaining a global understanding of deep classifiers and salient word features.

Moreover, text classification models often struggle to truly generalize (Laippala et al., 2021; Petrenz and Webber, 2011). For instance, McCoy et al. (2020) show in repeated experiments with BERT on a text inference task that, while consistent test set performance was achieved, the degree of generalization as measured on a related task varied significantly, due to randomized initializations of the decision layer and order of training examples. Similarly, Laippala et al. (2021) demonstrate that resampling of the data had a positive impact on feature stability of linear support vector machines. Thus, various random aspects of the training process may affect the reliability of modeling results, beyond predictive performance on a test set, especially in deep language models.

In this paper, we propose a method for explaining classes in a text classification task using deep language models based on input attributions estimated with the Integrated Gradients (IG) method (Sundararajan et al., 2017). We focus specifically on IG as it provides a general framework for estimating feature importance in deep neural networks and has been shown to provide reliable saliency maps in text classification among other tasks. For a discussion on the merits of IG, cf. Prasad et al. (2021), and Bastings and Filippova (2020) on saliency vs. attention methods in general.

Our class explanation method works by aggregating attributions in two ways: across documents and across models. On the one hand, we classify documents and aggregate word attribution scores from them, in order to extract the overall most predictive word features of a particular class. On the other hand, we aggregate these attributions over multiple random train/validation data splits and instances of a classifier, in order to identify stable attributions that are consistently assigned across rounds. Thus, we consider the level of a particular classifier configuration—i.e., the combination of language model, decision layer, hyperparameters, loss function, etc.—and strive to capture its perception of a corpus.

Our method explains a class in the form of a list of words ranked by the aggregated attribution

Findings of the Association for Computational Linguistics: ACL 2022, pages 1063 - 1074
May 22-27, 2022

scores, and filtered based on their stability across experiments. Following corpus linguistics' long tradition of analyzing style and content of text classes, we refer to these attributions as keywords (see Scott and Tribble, 2006; Stubbs, 2010, for discussion). This type of analysis is concerned with identifying the words that are most informative about the characteristics conveyed by a given text class.

While keyword analysis is widely employed in corpus linguistics, quantitative measures have been used only for extraction and not as a framework for evaluation, which is rather done qualitatively (cf. Egbert and Biber, 2019). Thus, as a contribution of this paper, we propose three lexical measures of keyword quality, which help us optimize and evaluate our method. We also study syntactic and semantic properties to nuance our understanding of keywords obtained with a deep classifier and IG.

We test our method by training a set of classifiers on the Corpus of Online Registers of English (CORE) (Egbert et al., 2015). CORE is sampled from the searchable English-language web and aims to be representative of the distribution of registers (or genres) found online. Recent work in both linguistics and NLP has, however, demonstrated challenges of categorizing language use on the web pertaining to its extreme variation within and across classes (Titak and Robertson, 2013; Dayter and Messerli, 2021; Madjarov et al., 2019; Biber and Egbert, 2019). Therefore, explanation methods are especially needed in web register classification, in order to explore the robustness and linguistic motivation of blackbox models.

We put forward our *Stable Attribution Class Explanation* method (SACX)[1] as a support in understanding classes and their modeling by deep language model classifiers, in text classification tasks where keywords provide a suitable means of explanation. It can assist model development and debugging by highlighting salient word features, at a more general level compared to attributions at the document and classifier instance level.

2 Data

CORE (Egbert et al., 2015) is a large-scale collection of web texts annotated for their genre, or register (Biber, 1988). In total, the dataset consists of nearly 50,000 texts. In our experiments, we combine the train and development sets, totaling 38,760 texts. The CORE register classes are coded using a two-level taxonomy developed in a data-driven manner to cover the full range of web language use. We focus on the upper level which consists of eight register classes: Narrative (NA), Opinion (OP), How-to (HI), Interactive discussion (ID), Informational description (IN), Lyrical (LY), Spoken (SP) and Informational persuasion (IP). Additionally, the dataset includes hybrid documents featuring characteristics of several registers and thus coded with several register labels (see Table 5 in Appendix).

3 Methods

3.1 Classifier and attribution method

As a classifier, we use the XLM-R deep language model (Conneau et al., 2020) because of its strong ability to model multiple languages, both in monolingual and cross-lingual settings. We opt for the base size rather than the large, due to its relatively frugal use of resource and comparable predictive performance on CORE (Repo et al., 2021). The task is modeled as a multilabel classification task using a sequence classification head, binary cross-entry with sigmoid loss and a fixed prediction threshold. We optimize the classifier hyperparameters against the development set, in order to reuse the settings in the explanation process described below.

We use the IG method to obtain explanations from the XLM-R predictions[2] (Sundararajan et al., 2017). IG takes the network input in the form of token embeddings and a corresponding blank reference input (same-length sequence of embeddings for a fixed placeholder token), and calculates a linear interpolation between them over a number of steps (e.g., 50). It then calculates gradients to measure the relationship between changes in an embedding and changes in the model predictions. This produces attribution scores for each dimension of the input token embeddings. Our explanation method then aggregates these in several steps into class representations.

3.2 The Stable Attribution Class Explanation method (SACX)

The class descriptions are extracted through the steps detailed below and illustrated in Figure 1.

---

[1] The code is available at: `https://github.com/TurkuNLP/class-explainer/`

[2] We use the Huggingface transformers library for modeling and the Captum implementation of IG (Kokhlikyan et al., 2020).

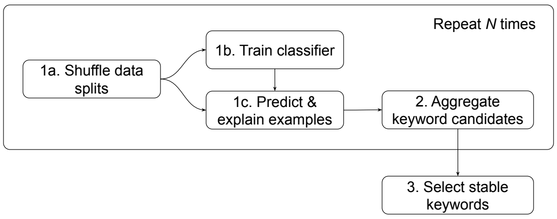

Figure 1: Overview of the SACX method.

Step 1: Train and explain. We combine the training and development sets of the corpus and randomly split them into a new training and validation set according to a set ratio r, using stratification to keep class distributions stable (cf. Laippala et al., 2021). The pre-trained language model is loaded and the decision layer is randomly initialized. Both are fine-tuned on the new training set. Documents in the validation set are classified by a threshold τ on the posterior probabilities, and the IG method is applied in order to obtain attribution scores for the network inputs, i.e., each dimension of each input token embedding, w.r.t. each predicted class c.

Step 2: Aggregate attributions from documents. The attribution scores for each embedding dimension are summed up per token to provide a token-level score, while all tokens in a document d are normalized by the L_2 norm. This provides a word attribution score $s_{w,d,c}$ directly if the word w consists of a single token, otherwise it is calculated as the maximum of all sub-word token scores. We calculate the average attribution scores $\bar{s}_{w,c}$, for each (w, c), as a means for ranking the keywords for each class. In order to reduce noise, we only select the n top-scoring words per document d, and we only consider true positive predictions. We note that the method could alternatively be used for error analysis by targeting false predictions.

Step 3: Select stable keywords. The above process is repeated N times, each time randomly shuffling and splitting the data and reinitializing the classification head according to Step 1, in order to quantify the stability of the keywords. The keyword candidates ranked by $\bar{s}_{w,c}$ are filtered based on selection frequency: a word is considered stable if the ratio by which it is selected (in Step 2) across the experiments is larger than a threshold value t.

Finally, we perform a light cleaning by ignoring words that occur in less than k documents and do not contain any alphabetic characters. We optimize the parameters t, n and τ in the experiments.

3.3 Baseline methods

We use the two following methods for extraction of class keywords, as baselines in comparison:

TF-IDF. As a naïve approach, we create a TF-IDF model with logarithmic scaling, a minimum document frequency of 10 and a maximum document frequency at 50% of the number of documents in the largest class. To extract the keywords, a class vector is formed by first averaging the document vectors for a given class from the weight matrix and then taking the 100 highest scoring terms as keywords for each class.

SVMs. As a strong baseline, we follow Sharoff et al. (2010); Laippala et al. (2021). We use a linear Support Vector Machine (SVM) with L2 penalty and TF-IDF vectorizer with a minimum document frequency of 0.05%, in Scikit-learn (LinearSVC). SVMs were adapted to the multilabel setting using a one-versus-rest strategy, and the C value optimized with grid search (0.5 providing the best scores). We train the SVMs on the same random splits as XML-R. During each round, the 1000 best positive features for each class are extracted. For the selection of the stable keywords, a selection frequency threshold of 0.6 was chosen.

4 Evaluation setting

We evaluate the keyword quality based on usefulness and relevance, which are established concepts in feature selection and evaluation in machine learning (e.g., Blum and Langley, 1997; Kohavi and John, 1997; Guyon and Elisseeff, 2003). Usefulness refers to the discriminative power of the features used in a task, e.g., as measured by how well they allow to discriminate the classes in a test set. Relevance refers to the association of the features with the actual object of study, i.e., their generalizability beyond a test set. Not all useful features are relevant—for instance, some useful features may inherit their usefulness from data idiosyncrasies, unrepresentative train/test splits and spurious statistics (see Ribeiro et al., 2016). In the case of keywords, useful keywords allow to discriminate the classes in the data, while relevant keywords reflect meaningful and linguistically motivated characteristics associated with the classes.

We propose three measures for assessing usefulness of keywords based on lexical overlap, presented in Section 4.1, which we use to optimize parameters of our explanation method and to compare against the baseline methods. In Section 4.2, we present further analyses conducted to assess the relevance of keywords and to form a qualitative understanding of the differences in output of the methods. The results are presented in Section 5.

4.1 Lexical measures of usefulness

Our measures related to usefulness focus on 1) distinctiveness—how distinct or overlapping keywords are between classes, 2) coverage—how well the keywords cover the documents of the corpus, and 3) a combination of the two that measures distinctiveness based on coverage. Similar to previous studies, we only consider the top-100 keywords (see Pojanapunya and Todd, 2018).

4.1.1 Distinctiveness (intrinsic)

We first propose a simple intrinsic measure, which assesses the distinctiveness of keywords, by looking at keyword overlap. Specifically, it measures the fraction of keywords unique to a class, averaged across classes:

$$Dist_{int} = \frac{1}{|C|} \sum_{c \in C} \frac{|\{k | k \in K_c \setminus K_{\neg c}\}|}{|K_c|}$$

for the set of classes C and keywords K for class c or all other classes $\neg c$. Whereas keyword analysis tends to focus on binary categories and methods that separate keyword by design, our measure fits more general uses, e.g., in settings with multiple classes.

4.1.2 Coverage

In the next step, we look at lexical coverage of the keywords in associated documents in the corpus as an indicator of usefulness. We define coverage of a class as the average proportion of keywords that occur across all its documents, and the global coverage measure as the macro average across all classes:

$$Cov = \frac{1}{|C|} \sum_{c \in C} \frac{1}{|T_c|} \sum_{t \in T_c} \frac{|\{k | k \in K_c \cap t\}|}{|K_c|}$$

where T_c is the set of texts of class c, either based on true class membership or true positive predictions. We again focus on true positives as we are interested in evaluating the quality of the keywords relative to the learned representation, not factoring in the model's predictive performance.

4.1.3 Distinctiveness (extrinsic)

Having defined a measure of coverage, we derive an extrinsic measure of distinctiveness as the coverage of keywords within a class relative to the coverage across the class boundary, of unrelated documents. We define a cross-coverage measure:

$$XCov = \frac{1}{|C|} \sum_{c \in C} \frac{1}{|T_{\neg c}|} \sum_{t \in T_{\neg c}} \frac{|\{k | k \in K_c \cap t\}|}{|K_c|}$$

of keywords K and texts $T_{\neg c}$, which is the set of texts not labeled with class c.

The extrinsic distinctiveness is then defined as:

$$Dist_{ext} = \frac{Cov - XCov}{Cov}$$

which provides an easy-to-interpret metric in the range $[0, 1]$, where a distinctiveness score of 0 means that there is no difference in keyword coverage within and across classes, and a score of 1 indicates a perfect separation between classes.

Egbert and Biber (2019) propose a similar notion of "content-distinctiveness" based on text dispersion keyness (incorporating document frequency) as a desirable quality of keywords.

4.2 Syntactic and semantic analysis of relevance

Our analysis of relevance focuses on syntactic and semantic properties associated with the keywords. While traditionally the relevance of keywords is assessed qualitatively and based on intuition (e.g., Scott and Tribble, 2006; Bondi and Scott, 2010; Gabrielatos and Marchi, 2011; Phillips, 1989; Williams, 1976), the goal of the proposed analysis is to provide inference for contrasting the three methods. This also allows us to deepen our understanding of the keywords.

First, we assess the proportion of content and function words among the keywords. This is an important qualitative distinction in keyword analysis, and generally methods extracting keywords with a stronger affinity to topicality/content rather than grammatical/functional elements are considered to be superior (cf. Egbert and Biber, 2019).

We parse the corpus with Turku Neural Parser (Kanerva et al., 2018), identify the most frequent part-of-speech (POS) per keyword, and group their distribution into two lexical categories: function and content words. Function words consist of adpositions, conjunctions, pronouns, auxiliaries, adverbs, interjections and determiners, and content words of adjectives, nouns, proper nouns and verbs. Other POS classes (numbers, symbols, punctuation, particles) are excluded from the analysis.

Class	F1 (*M*)	*SD*	Sup. (*M*)
Lyrical (LY)	82.28	8.78	180.58
Narrative (NA)	77.83	1.79	5779.71
Inter. discussion (ID)	75.67	3.06	915.35
Inform. description (IN)	65.73	1.42	3352.49
Opinion (OP)	55.41	5.08	2803.13
How-to (HI)	54.23	5.85	538.51
Inform. persuasion (IP)	43.83	6.14	527.80
Spoken (SP)	25.93	23.10	195.49
Micro AVG	68.37	1.84	–

Table 1: Predictive performance of XML-R classifier as mean F1-score (%), with standard deviation and mean support across the resampling rounds ($N = 100$).

Second, we examine the keywords from the perspective of semantic coherence. We analyze keyword similarities relative to the semantic structure of the corpus as a whole using word embeddings and clustering. We turn the dataset vocabulary into word vectors, using FastText vectors pre-trained on Common Crawl, 600B tokens in 300 dimensions (Mikolov et al., 2018). This ensures that the semantic vectors are independent from the explanation methods, while being trained on data similar to CORE, namely unrestricted web text. The analysis is further described in Section 5.5.

5 Results

After completing $N = 100$ rounds of experiments, we first inspect the predictive performances of the trained classifiers and study the degree of stability of the attributions. Then, we report the results of the optimization of our method against the usefulness-focused lexical measures, and qualitatively inspect the extracted top keywords. Finally, we present the syntactic and semantic analyses focusing on keyword relevance.

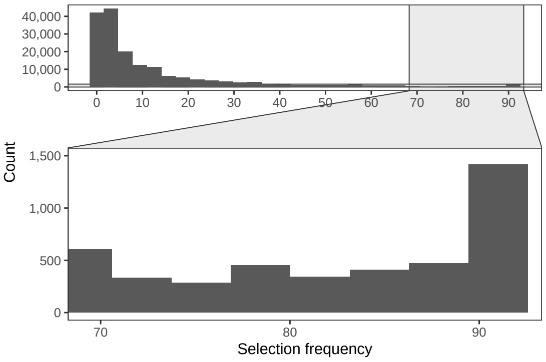

Figure 2: Distribution of selection frequency of keyword candidates for all classes, based on $N = 100$ rounds. The upper panel shows the full range and the lower the subrange of stable keywords.

5.1 Predictive performance

Table 1 summarizes the predictive performance of the 100 XLM-R classifiers that we have trained.[3] The micro average F1-score was a good 68% on average. Similar to previous studies (Repo et al., 2021; Rönnqvist et al., 2021; Biber and Egbert, 2016), we observed a large variation among classes, ranging from an F1-score of 44% (Informational persuasion) to 81% (Lyrical). Our method was able to extract stable keywords for all the classes expect for Spoken, where no keyword candidate passed the selection frequency threshold. This was mirrored both in its significantly lower class-specific F1-score of 26% and the exceptionally high standard deviation of 23%, likely related to the small sample size. For comparison, the SVMs baseline achieved a micro F1-score of 65.00% (*SD* = 0.33%).

5.2 Stability of keywords

We investigated the (in)stability of keywords across the 100 runs, and the utility of the selection frequency threshold t, by studying the selection frequency of the keyword candidates. The distribution of selection frequency is visualized in Figure 2. We see that the vast majority of keyword candidates appear only in a low number of runs.

For instance, for Informational Description exhibiting the lowest standard deviation in F1-score (1.42%), the top-10 unfiltered words were: *lollies, verdant, especially, endorsing, forebears, equations, gerald, colin, indy* and *exaggerating*. These keyword candidates scored in the range 0.79–0.93, but had selection frequencies of only 1 and 3 (for colin). By comparison, the first word with a selection frequency above $t = 0.7$ is *abstract* (selection frequency 98%), with a score of 0.56 which ranks it 45th before filtering (cf. Table 3). In fact, in order to extract the top-100 stable keywords we consider in evaluation, we need to traverse the unfiltered lists of keyword candidates, on average, down to rank 22,940 (range 1,775–67,859 for all classes). This illustrates the extent of instability among the attributions.

Finally, comparing the keywords extracted from the XLM-R and SVMs, we observed that the SVMs produced more consistent results with a mean selection frequency of 92.16% among the top-100 filtered keywords vs. 74.01% for the aggregations based on XLM-R and IG. This further highlights

---

[3] The optimal setting used was learning rate 7.5e-5 and batch size 30 for 12 epochs with early stopping (patience 1).

Method	Dist., intrinsic	Dist., extrinsic	Coverage
SACX	82.57	44.27	10.08
SVMs	91.43	39.94	10.53
TF-IDF	29.86	43.92	10.37

Table 2: Method comparison based on distinctiveness (dist.) and coverage (in %).

how inconsistent the attributions obtained by the IG method are across different runs, and thereby confirms the necessity of selection frequency filtering in obtaining stable and likely meaningful keywords.

5.3 Comparison on lexical usefulness measures

We apply the three lexical measures introduced in Section 4.1 to evaluate the keywords of our proposed method and the baselines. We set the parameters $r = 0.67$ (split), $N = 100$ (runs) and $k = 5$ (minimum document frequency), while optimizing the rest with grid search against the lexical measures. Weighting the three measures against each other is not entirely trivial, as they capture different qualities and we do not have a clear preference a priori. With different settings we are able to maximize different measures: intrinsic distinctivenss to 85.43%, extrinsic distinctiveness to 58.98%, and coverage to 11.33%.[4] However, maximizing either form of distinctiveness severely hurts coverage. We found a good balance with the settings $t = 0.7$ (selection frequency threshold), $n = 20$ (words per document) and $\tau = 0.7$ (prediction threshold), which achieves comparable coverage to the other methods and competitive numbers for the distinctiveness measures. The results for this setting and the baselines are listed in Table 2.

Based on intrinsic distinctiveness both our SACX method (83.6%) and SVMs (91.4%) displayed strong discriminative power, contrasting TF-IDF (29.9%). In terms of lexical coverage across the documents, all methods performed at the same level (10.08–10.53%). Similarly, the methods displayed a modest difference in performance based on extrinsic distinctiveness: SACX (44.3%) followed by TF-IDF (43.9%) and SVMs (39.9%). Taken together, the results demonstrate that the keywords extracted by our method were useful in discriminating between the classes, performing similarly to SVMs, while TF-IDF stood out with its weak separation of keywords across the classes.

5.4 Extracted keywords

The top-15 keywords of each class are presented in Table 3 and the keywords extracted with the baseline methods in Table 6 in Appendix.[5]

Our method was able to extract relevant keywords that clearly reflect our understanding of these seven classes and also share similarities with keywords discovered for these data in previous studies (e.g., Biber and Egbert, 2019; Laippala et al., 2021). The keywords are predominantly content words reflecting the class characteristics, such as *faq, question, answer, forum* extracted for Interactive discussion (ID). Similarly, linguistically-motivated patterns emerged from other classes, such as keywords associated with research papers and reports from Informational description (IN) (*abstract, introduction, summary, bio*) and keywords, in particular proper nouns, reflecting news and sports from Narrative (NA) (*afp, reuters* and *bundesliga, nba, ufc, playoffs, nfl, uefa, psg*).

The keywords extracted with the baseline methods are linguistically motivated as well. However, instead of extracting mainly content words, they identified also function words as keywords, such as *or, it, we, doesn* and *dont* (cf. Section 4.2). Many of these function words identified as keywords are linguistically motivated and reflect descriptions established in previous studies on register analysis (Biber, 1988; Biber and Egbert, 2016, 2019).

5.5 Analysis of relevance of the keywords

In our syntactic analysis, we evaluate relevance based on the relative frequencies of content and function words, as listed in Table 4. Relative to the baselines, SACX shows a tendency to extract less function and more content words, in particular more nouns (including proper nouns). This suggests that it is more likely to focus on topical keywords. The distributional differences were statistically significant ($X^2(8, N = 2,100) = 111.33, p < 0.001$) and a residual analysis confirmed the negative association with function words and the positive one with proper nouns.

In our semantic analysis, we visualize the full lexical space by reducing the 300 dimensions to two using Uniform Manifold Approximation and Projection (McInnes et al., 2018). The SACX key-

---

[4] The settings being in the same order: $t = (0.7, 0.4, 0.8)$, $n = (50, 40, 30)$, $\tau = (0.7, 0.5, 0.7)$. Tested ranges were $t = [0.3, 0.8]$, $n = [10, 50]$, $\tau = [0.5, 0.9]$.

[5] Full lists of keywords from all methods are available during review as supplementary material, online upon publication.

Table 3: Top-15 extracted keywords for each class ranked by mean aggregated attribution score (Score). The lists are filtered by threshold on selection frequency (SF in %).

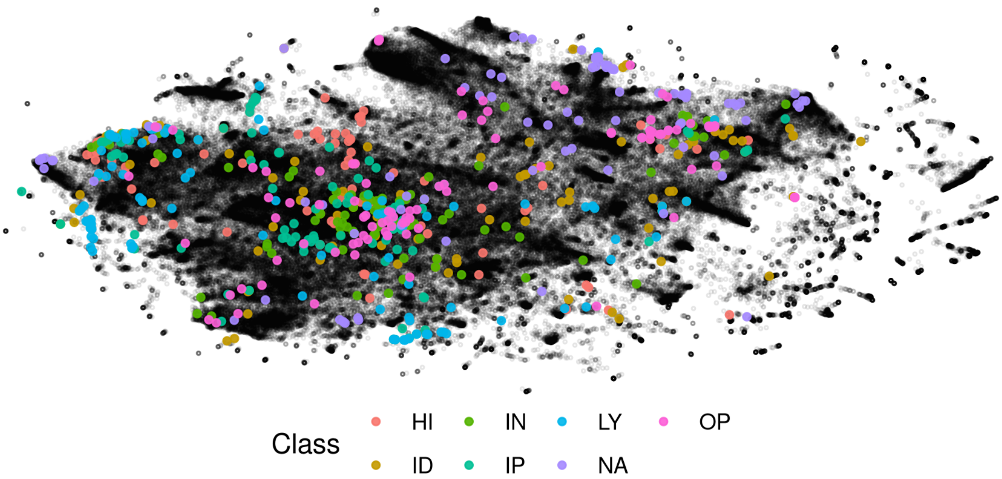

Figure 3: The lexical space of CORE, with keywords extracted from XLM-R colored based on class.

words are highlighted and colored by class, in Figure 3, and the baseline keywords in Figure 6 in Appendix. We observe that the SACX keywords cluster densely to a higher degree, suggesting semantically more coherent keywords.

To formally test this, we clustered the semantic vectors of the whole vocabulary using model-based clustering with mixtures from von Mises-Fisher distributions (Banerjee et al., 2005; Hornik and Grün, 2014) as the data were unit vectors. We

Method	Content word				Function
	Adj.	Noun	Prop.n.	Verb	
SACX	8.61	48.49	13.77	16.79	12.34
SVMs	12.10	49.86	6.34	15.99	15.71
TF-IDF	13.09	39.86	1.29	30.07	15.68

Table 4: Distribution of lexical classes of the keywords for each method (in %).

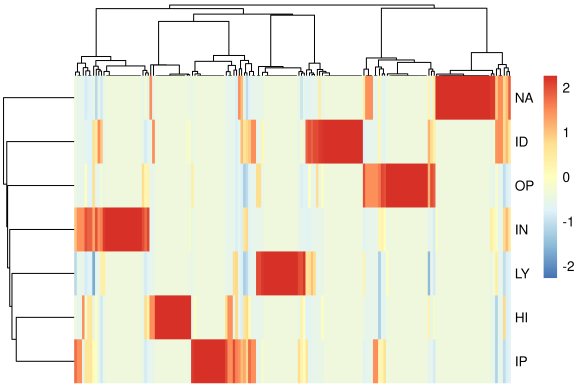

Figure 4: Cluster solution with clusters mapped to SACX keywords (columns) relative to the classes (rows). The color indicates the strength of association.

found 500 clusters to be optimal, based on BIC (Schwarz, 1978) and visual inspection indicating no substantive difference with fewer clusters.

Density was parametrized by the mean direction μ and the concentration parameter κ characterizing the strength of concentration of the data about the mean direction. This analysis showed that SACX was 1.25 times (OR 95% CIs = 1.03, 1.5) more likely to extract the keywords from dense clusters (above average k) than the other two methods together. Considering the previously noted propensity of SACX to extract proper nouns, we also studied their frequencies in dense vs. sparse clusters. We found that SACX was 5.85 times (OR 95% CIs = 3.07, 11.1) more likely to extract proper nouns from dense clusters than the other two methods together. This suggests that its keywords are both more specific and coherent in terms of vector space similarity.

Figure 4 visualizes the SACX keywords by the clusters they were assigned (columns) relative to the classes (rows), with a hierarchical biclustering on the axes. It further demonstrates the semantic coherence of the keywords as indicated clearly by the horizontal tightness and the strength of association (increase in redness). By comparison, in Figure 5 in Appendix, we see somewhat less coherence with SVMs, and clearly less with TF-IDF.

6 Conclusion

We have presented the Stable Attribution Class Explanation method (SACX) for explaining classes in text classification, based on IG input attributions from deep language model classifiers. SACX produces lists of keywords reflecting a classifier's perception of classes. However, input attributions are prone to noise, which we have shown can be effectively filtered, as we performed 100 rounds of training an XLM-R classifier and applying IG.

We have demonstrated that these *stable* keywords are of good quality—both useful as features and meaningfully relevant of the text classes studied. We have proposed lexical measures for evaluating distinctiveness and corpus coverage of keywords, and we have compared our method against two baseline class explanation methods. We compared the methods based on syntactic and semantic properties of the keywords, and found SACX to distinguish itself in that it extracts more content and less function words—a property which is generally considered to be a hallmark of a superior keyword analysis method in corpus linguistics. In particular, SACX has the ability to focus on more specific, topical words in the form of proper nouns, when relevant for depicting the class (such as for Narrative).

We have shown that SACX produces keywords that are highly coherent and tend to cluster densely throughout semantic vector space, rather than being evenly dispersed such as the word features extracted from SVMs. We also demonstrated that proper nouns are a distinguishing feature of these dense clusters, further illustrating the coherence of SACX keywords. We speculate that the use of token embeddings, and the XLM-R model's ability to learn local and highly non-linear functional forms afforded by the significant number of parameters, may give rise to these keyword characteristics.

In the future, we seek to explore the utility of the method in various settings, and further investigate the quality and nature of its class explanations. We will test it on further text classification tasks and types of models, as well as apply the approach to other languages and cross-lingual settings. In particular, understanding model behavior in zero-shot classification through stable explanations at the class level may provide a useful tool in detecting systematic biases. In the context of register identification, recent pursuits in this direction of multi- and cross-lingual modeling (Repo et al., 2021; Rönnqvist et al., 2021; Laippala et al., 2019) have been making good progress in terms of predictive performance, but interpretability tools such as ours could offer linguistic insight, e.g., into language-independent markers of the classes.

Moreover, as we have demonstrated that input attributions are highly prone to noise at the level of individual classifier instances, the type of filtering we have proposed can be used, not only to stabilize class-level explanations, but, more generally to generate stable saliency maps for particular text inputs based on multiple classifier instances. Future work should explore this direction further, as the contextualized interpretation of individual text inputs can provide a useful complement to the keyword-based class explanations for understanding model behavior.

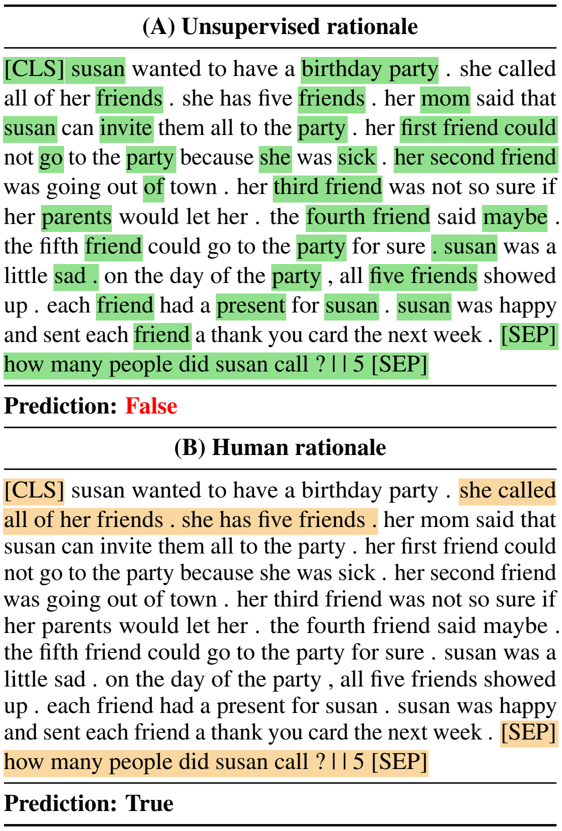
Abstract

Learning from rationales seeks to augment model prediction accuracy using human-annotated rationales (i.e. subsets of input tokens) that justify their chosen labels, often in the form of intermediate or multitask supervision. While intuitive, this idea has proven elusive in practice. We make two observations about human rationales via empirical analyses: 1) maximizing rationale supervision accuracy is not necessarily the optimal objective for improving model accuracy; 2) human rationales vary in whether they provide sufficient information for the model to exploit for prediction. Building on these insights, we propose several novel loss functions and learning strategies, and evaluate their effectiveness on three datasets with human rationales. Our results demonstrate consistent improvements over baselines in both label and rationale accuracy, including a 3% accuracy improvement on MultiRC. Our work highlights the importance of understanding properties of human explanations and exploiting them accordingly in model training.

1 Introduction

In the past several years, explainability has become a prominent issue in machine learning, addressing concerns about the safety and ethics of using large, opaque models for decision-making. As interest has grown in explanations for understanding model behavior, so has interest grown in soliciting gold-standard explanations from human annotators and using them to inject useful inductive biases into models (Hase and Bansal, 2021). Many such explanation datasets have become available recently (Wiegreffe and Marasović, 2021).

A common format for explanations in NLP is the *rationale*, a subset of input tokens that are relevant to the decision. A popular architecture for generating such explanations is the *rationale model*, an explain-then-predict architecture which first extracts a rationale from the input and then makes a prediction from the rationale-masked text (that is, only the tokens included in rationale) (Lei et al., 2016; DeYoung et al., 2019). Without external supervision on this rationale, we typically pursue parsimony via a sparsity objective. Table 1A shows an example unsupervised rationale.



(A) Unsupervised rationale

[CLS] susan wanted to have a birthday party . she called all of her friends . she has five friends . her mom said that susan can invite them all to the party . her first friend could not go to the party because she was sick . her second friend was going out of town . her third friend was not so sure if her parents would let her . the fourth friend said maybe . the fifth friend could go to the party for sure . susan was a little sad . on the day of the party , all five friends showed up . each friend had a present for susan . susan was happy and sent each friend a thank you card the next week . [SEP] how many people did susan call ? | | 5 [SEP]

Prediction: False

(B) Human rationale

[CLS] susan wanted to have a birthday party . she called all of her friends . she has five friends . her mom said that susan can invite them all to the party . her first friend could not go to the party because she was sick . her second friend was going out of town . her third friend was not so sure if her parents would let her . the fourth friend said maybe . the fifth friend could go to the party for sure . susan was a little sad . on the day of the party , all five friends showed up . each friend had a present for susan . susan was happy and sent each friend a thank you card the next week . [SEP] how many people did susan call ? | | 5 [SEP]

Prediction: True

Table 1: An example of unsupervised versus human-provided rationale in MultiRC. The unsupervised model struggles to localize its attention and makes an incorrect prediction. The same model makes a correct prediction by only looking at the human rationale.

With the benefit of a human-annotated rationale for the true label, we can begin to understand model mistakes in terms of reliance on inappropriate features (and correct them). In the example above, the unsupervised rationale suggests that the model's

Findings of the Association for Computational Linguistics: ACL 2022, pages 1075 - 1088
May 22-27, 2022 ©2022 Association for Computational Linguistics

mistake is due to missing key information about how many friends Susan has (i.e., "five"). Forcing the model to see these key tokens by only using the human rationale as the input fixes this mistake (Table 1B). Prior work has shown that this is not a fluke. For some datasets, human rationales consistently improve model accuracy over baseline when used as an input mask, by orienting model attention toward informative tokens and away from confounding ones (Carton et al., 2020).

Knowing that human rationales contain useful predictive signal, the key question becomes: **can we improve model prediction accuracy by incorporating human rationales into training?**

Numerous approaches to using human rationales in training have been tried, including: regularizing the parameters of a (linear) model (Zaidan et al., 2007); regularizing model output gradients (Ross et al., 2017); regularizing internal transformer attention weights (Jayaram and Allaway, 2021); and direct supervision on a rationale model (DeYoung et al., 2019), which serves as our baseline approach in this paper. These approaches have generally failed to significantly improve model prediction accuracy (Hase and Bansal, 2021).

A quality these prior approaches have in common is treating human rationales as *internally and collectively uniform* in predictive utility. That is, any token included in the human rationale is treated as equally important to include in the input representation; vice versa for tokens excluded. Furthermore, all human rationales are weighted equally.

The reality, we demonstrate empirically via ablation studies in §4, is that the predictive utility of human rationales is distributed unevenly between tokens in a rationale, and unevenly between rationales in a dataset. Based on this analysis, we suggest that learning objectives which weight every token equally (accuracy in the case of direct supervision), and every rationale equally, are not optimal for improving downstream model accuracy.

We operationalize these hypotheses in four distinct modifications to the baseline rationale model architecture. Three of these modify the naive tokenwise accuracy supervision objective, and the fourth implements "selective supervision", ignoring unhelpful human rationales in training.

Evaluating on three datasets, our proposed methods produce varying levels of improvement over both a baseline BERT model and a baseline BERT-to-BERT supervised rationale model, ranging from substantial for MultiRC (3%) to marginal for E-SNLI (0.4%). Additionally, our methods also improve rationale prediction performance.

Taken together, our results demonstrate the importance of considering the variance of predictive utility both between and within human rationales as a source of additional training signal. Our proposed modifications help pave the way toward truly effective and general learning from rationales.

2 Related Work

2.1 Rationalization

The extractor-predictor rationale model proposed by Lei et al. (2016) and described in more detail in §5, is an approach to feature attribution, which is one among many families of explanation methods (see Vilone and Longo (2020) for a recent survey).

Recent work has extended the original architecture in various ways, including replacing the use of reinforcement learning with differentiable binary variables (Bastings et al., 2020; DeYoung et al., 2019), alternatives to the original sparsity objective (Paranjape et al., 2020; Antognini and Faltings, 2021), and additional modules which change the interaction dynamics between the extractor and predictor (Carton et al., 2018; Yu et al., 2019; Chang et al., 2020). Pipeline models (Lehman et al., 2019) are similar, but train the two modules separately rather than end-to-end.

Rationale models are a powerful approach to NLP explanations because of how specific objectives can be put on the properties of the rationale, but they have some downsides. First, they are unstable, the extractor often collapsing to all-0 or all-1 output (DeYoung et al., 2019; Yu et al., 2019). We introduce an engineering trick in §5 that appears to lessen this risk. Also, with end-to-end training comes the risk of information leakage between the extractor and predictor (Jethani et al., 2021; Hase et al., 2020; Yu et al., 2021). This idea of leakage plays a part in how we estimate explanation predictive utility in section §4.

2.2 Learning from Explanations

Wiegreffe and Marasović (2021) present a review of explainable NLP datasets, a number of which have been incorporated into the ERASER collection and benchmark (DeYoung et al., 2019).

Early work in learning from human explanations include Zaidan et al. (2007) and Druck et al. (2009), and a line of work termed "explanatory debugging"

(Kulesza et al., 2015; Lertvittayakumjorn and Toni, 2021). More recent work spans a variety of approaches, categorized by Hase and Bansal (2021) into regularization (e.g., Ross et al. (2017)), data augmentation (e.g., Hancock et al. (2018)), and supervision over intermediate outputs (e.g., DeYoung et al. (2019); Jayaram and Allaway (2021)).

Significant improvements to model accuracy as a result of explanation learning have proven elusive. Studies occasionally claim such improvement, such as Rieger et al. (2020), which observes general improvements on a medical vision task. More commonly their claims pertain to secondary objective such as explanation quality (e.g., Plumb et al. (2020)), robustness (e.g., Ross et al. (2017), Srivastava et al. (2020)), or few-shot learning (e.g., Yao et al. (2021)). Hase and Bansal (2021) gives an overview of the problem and discusses circumstances under which learning from explanations is liable to work. Our paper contributes to this discussion by considering the variance of training signal quality both within and between human rationales, and how to exploit these variances.

3 Data

We consider three datasets in this work. All three are document-query text comprehension tasks, where the task is to determine whether the query is true or false given the document. We use the train, development, test splits offered by DeYoung et al. (2019). Table 2 shows the basic statistics of each dataset based on the training set.

- **MultiRC** (Khashabi et al., 2018). A reading comprehension dataset of 32,091 document-question-answer triplets that are true or false. Rationales consist of 2-4 sentences from a document that are required to answer the given question.
- **FEVER** (Thorne et al., 2018). A fact verification dataset of 76,051 snippets of Wikipedia articles paired with claims that they support or refute. Rationales consist of a single contiguous sub-snippet, so the basic unit of rationale is sentence.
- **E-SNLI** (Camburu et al., 2018). A textual entailment dataset of 568,939 short snippets and claims for which each snippet either refutes, supports, or is neutral toward. Input texts are much shorter than MultiRC and FEVER, and rationales are at the token level.

Dataset	Text length	Rationale length	Rationale granularity
MultiRC	336.0	52.0	sentence
FEVER	355.9	47.0	sentence
E-SNLI	23.5	6.1	token

Table 2: Basic statistics of the datasets.

4 Analysis

To understand properties of human rationales for the purpose of learning from rationales, we analyze the effect of human rationales when they are used as inputs to a trained model.

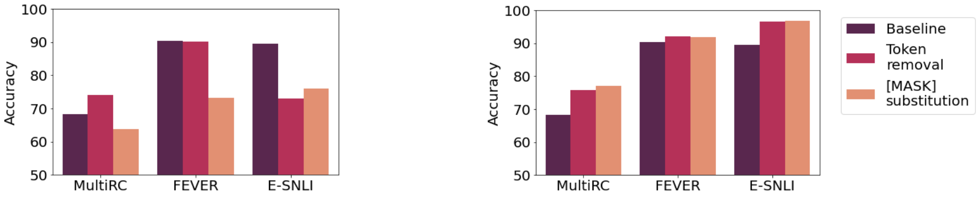
4.1 Human Rationales have Predictive Utility

A basic question about the viability of learning from rationales is whether human rationales bear the potential for improving model performance. That is, do human explanations successfully reveal useful tokens while occluding confounding tokens, such that a model evaluated only on the revealed tokens is able to get improved performance relative to the full input? We refer to such rationale-redacted inputs as *rationalized inputs*.

We define *sufficiency-accuracy* (**SA**) as how accurate the model is across a corpus of rationalized input. This is an aggregate measure, similar to *sufficiency* as defined in DeYoung et al. (2019) but focused on absolute performance rather than similarity to baseline model output. We refer to the sufficiency-accuracy of the human rationales as *human sufficiency-accuracy* (**HSA**).

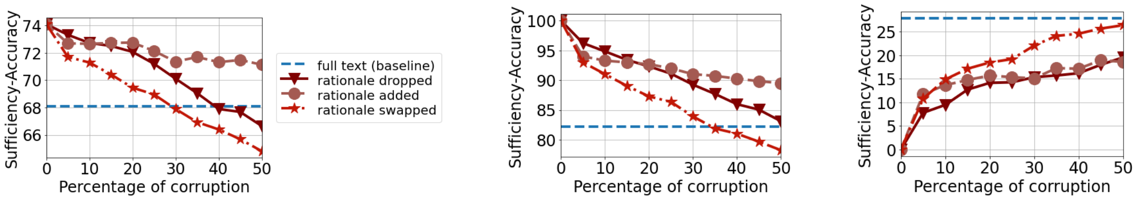
Estimating sufficiency-accuracy is problematic. The natural way to probe whether the tokens in a rationale are sufficient for an accurate prediction is to remove the non-included tokens from the input, run the model on just the included tokens, and assess its accuracy. But a version of the input where a majority of tokens are removed or masked (by a [MASK] special token in the case of BERT), is out-of-distribution relative to the training data, which has no removal or masking. This difference may lead to unpredictable output from the model when tested on masked input. This **masking-is-OOD** problem has not received much discussion in the literature, though Jacovi and Goldberg (2021) propose to mitigate it with random masking during model training. The effect of this problem will be to underestimate the sufficiency-accuracy of rationales tested against an un-adapted model.

The opposite problem stems from overfitting rather than OOD issues: **label leakage**. A human rationale may contain signal about the true label



(a) Fine-tuned on full input (unadapted). (b) Fine-tuned on both full and human-rationalized input (adapted).

Figure 1: Baseline performance vs. human sufficiency-accuracy for rationalized inputs with token removal and [MASK] token substitution. As rationalized inputs are different from the full text inputs that the original training set includes, we build a calibrated model where the model is trained on both full text inputs and rationalized inputs.



(a) All samples (b) Human sufficiency-accuracy = 1 (c) Human sufficiency-accuracy = 0

Figure 2: Sufficiency-accuracy of human rationales on baseline BERT model with increasing levels of corruption via swaps, drops and additions. Model performance decreases quickly when we drop rationale tokens , but stays high as we add non-rationale tokens. These effects are moderated by HSA.

that goes beyond the semantics of the tokens included in the rationale, and a model trained on human-rationalized input may learn to pick up on these spurious signals. A known example is in E-SNLI, where annotators had different explanation instructions based on their chosen label. This issue is discussed in several recent papers (Yu et al., 2021; Jethani et al., 2021; Hase et al., 2020), albeit mostly concerning model-generated rather than human explanations. The effect of this problem will be to overestimate the sufficiency-accuracy of rationales tested against an adapted model.

Fig. 1 shows sufficiency-accuracy results for human rationales on both unadapted and adapted models. We expand on the analysis presented by Carton et al. (2020) by showing results for both masking-via-removal and masking-via-[MASK]-token-substitution.

Fig. 1a shows that token removal suffers less from the masking-is-OOD problem on an unadapted model than [MASK] token substitution. [MASK] token substitution results in lower accuracy across the board, while removal improves baseline accuracy for MultiRC, matches it for FEVER, and lowers it for E-SNLI.

With adaptation (Fig. 1b), token removal and [MASK] token substitution have near-identical effects, improving accuracy by a large margin for MultiRC and E-SNLI, and a small margin for FEVER. The near-100% sufficiency-accuracy for E-SNLI is probably due to label leakage.

If an unadapted model is liable to underestimate sufficiency model, and an adapted model to overestimate, then we suggest that the potential benefit of learning from rationales lies somewhere between the two. On this hypothesis, this figure suggests that MultiRC has a large potential benefit, FEVER a small one, and E-SNLI an unclear benefit depending on how much of the predictive utility of E-SNLI rationales is due to label leakage. The results in §6 ultimately bear out these expectations.

4.2 Importance of Rationale Accuracy

We focus on MultiRC, where evaluating a non-rationale-adapted fine-tuned BERT model on human-rationalized data results in a sufficiency-accuracy of 74%, a significant improvement over the normal test accuracy of 68%. But how robust is this improvement to rationale prediction error? We examine how the sufficiency-accuracy of human rationales changes as they are corrupted by random addition, dropping, and swapping of tokens.

In this analysis, an $N\%$ drop removes $N\%$ of tokens from each rationale in the dataset, reducing recall to $100 - N$. An $N\%$ addition adds tokens numbering $N\%$ the size of each rationale, from the set of non-rationale tokens, reducing precision to $\frac{100}{100+N}$. An $N\%$ swap performs both operations, swapping $N\%$ of rationale tokens for the same number of non-rationale tokens.

The "dropped" curve in Fig. 2a shows that human rationales afford improved accuracy over the baseline until roughly 40% of tokens have been dropped from them, suggesting that a minimum of 60% recall is needed to derive an advantage from human rationales over the full input. Per the "added" curve, adding the same number of irrelevant tokens to the rationale has a much less severe impact on accuracy, suggesting that errors of omission are significantly worse than errors of inclusion for learning from rationales.

Fig. 2b and 2c respectively show the effect of this perturbation on high- and low-sufficiency-accuracy human rationales, which constitute 74% and 26% of rationales respectively for this model. High-SA rationales follow a similar trend to the whole population, but the recall requirement is lower than Fig. 2a to exceed model accuracy with the full input (the "dropped" curve meets the blue line at 50%). In comparison, low-SA rationales demonstrate interesting properties. These rationales actually have a sabotaging effect in a quarter of cases: the model would have an accuracy of 27% with the full input, which is lowered to 0% by the presence of these rationales. Also, addition and dropping have a similar effect in mitigating this sabotage. Similar results hold on FEVER and E-SNLI except the apparent required recall is much higher (>90%) for both methods (see the appendix), indicating challenges for learning from rationales on these datasets.

In summary, our analyses inspire two general observations about learning from rationales: 1) moving away from naive accuracy (toward recall, for example) as a rationale supervision objective, and 2) focusing on useful rationales over harmful ones.

5 Methods

We propose architecture changes based on these insights. Our code is available at `https://github.com/ChicagoHAI/learning-from-rationales`.

5.1 Background and Baseline Models

Our training data include input tokens, their corresponding rationales, and labels. Formally, an instance is denoted as $(\boldsymbol{x}, \boldsymbol{\alpha}, y)$, where $\boldsymbol{x} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_L)$ is a text sequence of length L and human rationale $\boldsymbol{\alpha}$ of the same length. $\boldsymbol{\alpha}_i = 1$ indicates that token $\boldsymbol{x}_i$ is part of the rationale (and relevant for the prediction), $\boldsymbol{\alpha}_i = 0$ otherwise.

We use HuggingFace's BERT-base-uncased (Devlin et al., 2018; Wolf et al., 2020) as the basis for our experiments and analysis. Used in the standard way, BERT ignores $\boldsymbol{\alpha}$ and is fine-tuned on tuples of $(\boldsymbol{x}, y)$. This is our simplest baseline.

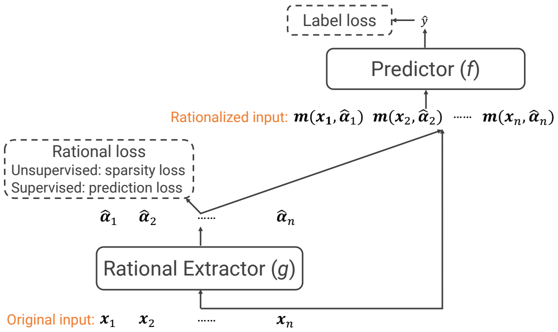


Figure 3: Illustration of our multi-task framework. Our main innovation lies in how we define rationale loss for the supervised case and the masking function m.

Rationale model. We use the rationale model of Lei et al. (2016) for both supervised and unsupervised rationale generation, in its updated BERT-to-BERT form (DeYoung et al., 2019). This model consists of two BERT modules: a rationale extractor g that generates a binary attention mask $\hat{\boldsymbol{\alpha}}$ as the rationale, and a predictor f which makes a prediction using the rationalized input via a masking function m on $\boldsymbol{x}$ and $\hat{\boldsymbol{\alpha}}$ (Fig. 3):

$$g(\boldsymbol{x}) \to \hat{\boldsymbol{\alpha}},$$
$$f(m(\boldsymbol{x}, \hat{\boldsymbol{\alpha}})) \to \hat{y}.$$

The two components are trained in tandem. In the unsupervised scenario, the joint objective function consists of a prediction loss term and a rationale sparsity term, encouraging the model to retain only those tokens in $\boldsymbol{x}$ that are necessary for accurate prediction:

$$\mathcal{L}_u = \mathcal{L}_p(y, \hat{y}) + \lambda_{sp}||\hat{\boldsymbol{\alpha}}||,$$

where $\mathcal{L}_p$ is typically cross entropy.

In the supervised scenario, given a human rationale $\boldsymbol{\alpha}$, we replace the sparsity objective with a rationale supervision objective:

$$\mathcal{L}_{su} = \mathcal{L}_p(y, \hat{y}) + \frac{\lambda_{su}}{L}\sum_{i=1}^{L}\mathcal{L}_p(\boldsymbol{\alpha}_i, \hat{\boldsymbol{\alpha}}_i),$$

where λ_{su} is a hyperparameter that controls the weight of rationale loss compared to label loss.

Each of these scenarios represents a baseline for our experiment. We refer to the unsupervised version as *unsupervised rationale model*, and the supervised version as *supervised rationale model.*

Implementation details. The original Lei et al. (2016) model generates binary rationales by Bernoulli sampling from continuous probability values produced by the generator, and uses the REINFORCE algorithm (Williams, 1992) to propagate approximate gradients through this non-differentiable operation.

We instead use Gumbel Softmax (Jang et al., 2017) to generate differentiable approximate binary rationale masks. In this framework, the generator produces logits $\boldsymbol{z_i}$ to which are added random noise $G \sim \mathit{Gumbel}(0, 1)$, before applying a softmax to produce class probabilities $\boldsymbol{c_i}$. This approximates a discrete distribution parameterized by $e^{\boldsymbol{z_i}}$. We then use the positive class probability $\boldsymbol{c}_i^1$ as the rationale value $\hat{\boldsymbol{\alpha}}_i$.

$$\boldsymbol{c}_i = \mathrm{softmax}(\boldsymbol{z_i} + \boldsymbol{G} \sim \mathit{Gumbel}(0, 1)); \hat{\boldsymbol{\alpha}}_i = \boldsymbol{c}_i^1$$

Generating stable rationales. We find it helpful as an engineering trick to pre-train the predictor layer of this model on the full input before co-training the predictor and extractor on the joint objective. This step appears to mitigate some of the issues this model has with rationale collapse, noted for example by DeYoung et al. (2019).

Given $\hat{\boldsymbol{\alpha}}_i$, we mask non-rationale tokens by multiplicatively substituting the [MASK] token vector across their vector representations, analogously to what is done during the MASK-LM pretraining of the BERT model:

$$m_s(\boldsymbol{x}_i, \hat{\boldsymbol{\alpha}}_i) = \hat{\boldsymbol{\alpha}}_i \cdot \boldsymbol{e}_i + (1 - \hat{\boldsymbol{\alpha}}_i) \cdot \boldsymbol{e}_{\text{[MASK]}},$$

where $\boldsymbol{e}_i$ represents the embedding associated with $\boldsymbol{x}_i$ and $\boldsymbol{e}_{\text{[MASK]}}$ is the embedding for the [MASK] token. We never mask special tokens [CLS] or [SEP], and we set $\hat{\boldsymbol{\alpha}}_i = 1$ for the query in MultiRC and FEVER as well because the query is always part of human rationales in these two datasets.

5.2 Learning from Human Rationales

Inspired by the analysis in §4, we propose four strategies for improving the efficacy of learning from rationales: 1) tuning class weights for rationale supervision; 2) enforcing sentence-level rationalization; 3) using non-occluding "importance embeddings"; and 4) selectively supervising only rationales with high sufficiency-accuracy. The first three are designed to loosen the supervision's dependence on flat tokenwise accuracy, while the last tries to operationalize our observations about helpful versus non-helpful rationales.

Class weights. Rationales may become more effective enablers of model prediction accuracy at different balances of precision and recall. We can adjust this balance simply by using differing weights to positive and negative classes in rationale supervision:

$$\mathcal{L}_w = \mathcal{L}_p(y, \hat{y}) + \frac{1}{L} \sum_{i=1}^{L} (1 + \lambda_{su}^1 \alpha_i) \mathcal{L}_p(\alpha_i, \hat{\alpha}_i),$$

where λ_{su}^1 controls the relative weight of rationale vs. non-rationale tokens. In particular, as we will discuss in §4, we find that increased recall is associated with increased model accuracy. Thus, we explore several values for λ_{su}^1 in our experiment to encourage higher recall.

Sentence-level rationalization. Another divergence from strict token-wise accuracy is to rationalize at the sentence rather than the token level. Given a function sent mapping a token x_i to its corresponding sentence s consisting of tokens $\{..., x_i, ...\}$, we average token-level logits $\boldsymbol{z_i}$ across each sentence to produce a binary mask at the sentence level and then propagate that mask value to all sentence tokens:

$$\hat{\boldsymbol{\alpha}}_i = \hat{\boldsymbol{\alpha}}^s_{\mathit{sent}(i)},$$

where $\boldsymbol{z}^s = \frac{1}{|\{i|\mathit{sent}(i)=s\}|} \sum_{\{i|\mathit{sent}(i)=s\}} \boldsymbol{z_i}$ is used to generate $\hat{\boldsymbol{\alpha}}^s_{\mathit{sent}(i)}$.

Importance embeddings. Another way to mitigate the impact of false negatives in predicted rationales is for these negatives to still remain visible to the predictor. This variant uses additive embeddings for rationalization rather than occluding masks, using a two-element embedding layer $\boldsymbol{e}$ constituting one embedding for rationale tokens and one for nonrationale tokens, added to the input vectors according to the predicted rationale. This way, input tokens are tagged as important or unimportant, but the predictor f has the freedom to learn how to engage with these tags for maximum label accuracy, rather than being fully blinded to "unimportant" tokens.

$$m_e(\boldsymbol{x}_i, \hat{\boldsymbol{\alpha}}_i) = \boldsymbol{e}_i + (1 - \hat{\boldsymbol{\alpha}}_i) \cdot \boldsymbol{e}_{\text{non-rationale}} + \hat{\boldsymbol{\alpha}}_i \cdot \boldsymbol{e}_{\text{rationale}}.$$

An important drawback of this approach is that the predictor now has access to the full input instead of only the rationalized input, so these rationales provide a weak guarantee that important tokens are actually used to make predictions. This method also represents a large distribution shift from full text, so we find it necessary to calibrate the predictor using human rationales, as described in Fig. 1b.

Selective supervision. Our fourth modification attempts to improve rationale prediction performance on high-sufficiency-accuracy rationales by selectively supervising only on human rationales with this property, ignoring those where human ratio-

Dataset	Model	Acc.	Rationale prediction			Human Suff. Acc.	Methods

Table 3: Best-performing model variant compared to baseline models.

nales do not allow a correct prediction.

Specifically, for every training batch, we use the true human rationales $\boldsymbol{\alpha}$ as an input mask for the BERT predictor to get the HSA for each document. HSA then serves as a weight on the human rationale supervision during the main training batch:

$$\mathcal{L}_{ss}=\mathcal{L}_p(y,\hat{y})+I(y=f(m(\boldsymbol{x},\boldsymbol{\alpha})))\frac{\lambda_{su}}{L}\sum_{i=1}^{L}\mathcal{L}_p(\boldsymbol{\alpha}_i,\hat{\boldsymbol{\alpha}}_i).$$

By weighting supervision this way, we hope to ignore low-quality human rationales during training and focus instead on those that enable good accuracy.

6 Results

6.1 Experiment Setup

Our goal in this experiment is to understand the impact of our four proposed model/training modifications. We do this with a comprehensive scan: We try three positive rationale supervision class weights λ_{su}^1 ($\{0, 2, 4\}$), and toggle sentence-level rationalization, importance embedding, selective supervision on and off. In addition, we vary rationale supervision loss weight λ_{su} in $\{0.5, 1, 2\}$. This resulted in 72 models for MultiRC and FEVER, and 36 models for E-SNLI (for which sentence-level rationalization is not applicable).

The best resultant model is our *best overall model*. The best model with $\lambda_{su^1} = 1$ (i.e., identical class weights for human rationales) and no other learning strategy enabled is our baseline *supervised rationale model*. We additionally train three *unsupervised rationale models* with sparsity weights 0.15, 0.25, and 0.35, selecting as representative the one which produced the sparsest rationales while maintaining a reasonable level of accuracy (because in this architecture, there is invariably a trade-off between accuracy and sparsity).

To evaluate the performance of our models, we consider both accuracy of the predicted labels ($\hat{y}$) and performance of rationale prediction in terms of F1, precision, and recall. We use Pytorch Lightning (Falcon et al., 2019) for training with a learning rate of 2e-5 and gradient accumulation over 10 batches for all models. Early stopping was based on validation set loss with a patience of 3, evaluated every fifth of an epoch. Training was performed on two 24G NVidia TITAN RTX GPUs.

6.2 Model Performance

Table 3 compares our best overall model against the baselines, and presents the learning strategies used in the models.

Prediction accuracy. For MultiRC, this best model includes every proposed modification (sentence-level rationalization, importance embeddings, class weights) except for selective supervision, and yields a 3-point improvement from the baseline accuracy of 68.1% to 71.2%. We observe a more modest improvement on FEVER, with the best model using sentence-level rationalization and importance embeddings, and scoring a 1-point improvement from 90.2% to 91.5%. We note, however, that this approaches the accuracy of the model with access to a human rationale oracle (91.6%). Finally, we observe a tiny improvement of 0.4% on E-SNLI, though our proposed methods do improve upon the baselines of unsupervised and supervised rationale model, which causes a performance drop.

A McNemar's significance test with Bonferroni correction between the best and baseline model finds that the accuracy improvement is significant for MultiRC and FEVER (p =2e-7 and 3e-6 respectively) and not significant for E-SNLI ($p = 0.1$). The limited improvement in E-SNLI echos the performance drop in Fig. 1a without adaptation, suggesting that human rationales in this dataset are too idiosyncratic to improve model performance.

Factor analysis. We use regression analysis to

Method	Coefficients		
	MultiRC	FEVER	E-SNLI
Sentences	.015***	.001	-
Class weights	.017***	.007***	.005
Importance embeddings	.012***	.006***	-.010**
Selective supervision	0.004	-.006***	-.032***

Table 4: Regression coefficients for effect each proposed method on overall prediction accuracy

Dataset	Sel. Sup.	Acc.	F1.	
			High-HSA	Low-HSA
MultiRC	**No**	**71.2**	**59.3**	**57.2**
	Yes	71.0	56.2	54.1
FEVER	**No**	**91.5**	**79.0**	**72.5**
	Yes	90.6	61.2	57.0
E-SNLI	**No**	**90.1**	**61.2**	**48.0**
	Yes	88.8	49.0	44.9

Table 5: Label accuracy and predicted rationale F1 for high- versus low-HSA examples.

understand the impact of the different modifications on model accuracy. Table 4 suggests that rationale class weighting has the highest positive effect on accuracy across datasets. Importance embeddings have a positive effect for MultiRC and FEVER and a negative effect for E-SNLI, while sentence-level rationalization improves only MultiRC.

Selective supervision is found to have a nonexistant or negative effect across all three datasets. Table 5 details this result, showing model accuracy and rationale performance for the best model with (yes) vs. without (no) selective supervision. If our method succeeded, F1 for high-HSA examples would increase from the "No" to the "Yes" models and remain flat or decrease for low-HSA examples. Indeed, we observe lower rationale F1 for low-HSA examples, but the rationale F1 also drops substantially for high-HSA examples, possibly because of the reduced available training data.

Rationale performance. Although our modifications are designed to improve label prediction performance, they also improve rationale prediction performance in most cases. The only exception is the reduced precision in E-SNLI compared to the supervised rationale model.

6.3 Qualitative Analysis

Table 6 shows three examples, each drawn from a different dataset, to illustrate different outcomes. For each example, we show the human rationale and predicted rationales for both the baseline supervised rationale model and our best overall model. Incorrect predictions are colored red.

Example 6a shows an instance sampled from MultiRC where our best model, with higher recall and sentence-level rationalization, more successfully captures the (sufficient) information present in the human rationale, allowing for a correct prediction where the supervised rationale model fails.

Example 6b presents a contrasting example from the FEVER dataset. The human rationale omits important context, that Legendary Entertainment is a subsidiary of Wanda Group, making it harder to infer that it is *not* a subsidiary of Warner Bros. Our best model succeeds at capturing this snippet in its rationale, but still predicts the incorrect label, illustrating that a sufficient (for humans) rationale does not always produce a correct label.

Finally, example 6c shows a case where the baseline supervised rationale model succeeds while our best model fails. This is a hard-to-interpret example, mainly a demonstration of the limitations of rationales as an explanatory device for certain kinds of task. This begs a question: how relevant are rationales as an explanation or learning mechanism when models like GPT-3 (Brown et al., 2020) are increasingly capable of human-level *natural language* explanations (Table 7)?

Our position is that however an explanation is presented, meaning is still localized within text, so rationales can still serve as a useful interface for scrutinizing or controlling model logic, even if they require additional translation to be comprehensible to humans. Works that hybridize the two ideas such as Zhao and Vydiswaran (2020) may represent a good way of resolving this issue.

7 Discussion

The analysis in section §4 explores the limits of potential improvement from learning from rationales. It suggests two insights toward improved learning from rationales: 1) that insofar as they boost model accuracy, not all human rationale tokens are equally valuable, e.g., with false positives causing less degradation than false negatives; and 2) we could in principle boost label accuracy with good rationale accuracy on useful (high-SA) rationales and low accuracy on useless (low-SA) ones.

We exploit these two insights with four modifications to the baseline architecture. Three of these diverge from flat rationale supervision accuracy: rationale supervision class weighting, sentence-level rationalization, and importance embeddings. The last, selective supervision, pursues utility-discriminative weighting during model training.

Source	**Natural language explanation**
Human	There is no indication that the dog is sitting down while playing catch on his nose.
Human	A dog can catch a ball by not to sitting down.
GPT-3	The entailment of this sentence is that the dog is sitting down, and the contradiction would be if the dog was standing up. This sentence is neutral, meaning it doesn't entail or contradict anything.

Table 7: Examples of natural language explanations for the "neutral" prediction on E-SNLI example from Table 6c. See Appendix §D for GPT-3 prompt details.

Taken together, our proposed methods yield a substantial 3% improvement over baseline performance for MultiRC, a 1% improvement on FEVER, and a tiny .4% improvement on E-SNLI, mirroring the potential improvements observed in the analysis. We find that all three token supervision methods are useful in achieving this, while selective supervision has a marginal or negative effect.

In summary, our results support the potential for learning from rationales in certain datasets, and demonstrate the importance of understanding the properties of human rationales to properly exploit them for this purpose. We believe that these two insights are useful steps towards effective learning from rationales, and could yield even greater improvements if operationalized optimally.

Limitation. A limitation of our analysis is that all three datasets are document-query style reading comprehension tasks, as opposed to, e.g., sentiment analysis. Because of the popularity of this type of task in NLP benchmarks, this type of dataset represents a majority of what is available in the ERASER collection (DeYoung et al., 2019). By contrast, sentiment is often scattered throughout a text, so human rationales for sentiment are likely to contain redundant signal, which could impact their predictive utility. We leave a more comprehensive survey of NLP tasks for future work.

Table 8: Comparison of best model with each proposed factor against best model without that factor.

A Detailed Factor Analysis

Table 8 compares, for each proposed method, the performance of the best model using that method and the best model not using it. The story shown here is similar to the regression analysis in Table 4, but one new insight is that the improvement in model prediction performance appears to be driven by the sentence-level rationalization method, as it cuts down on stray tokens dropped from or added to the predicted rationales.

B Rationale Perturbation on FEVER and E-SNLI

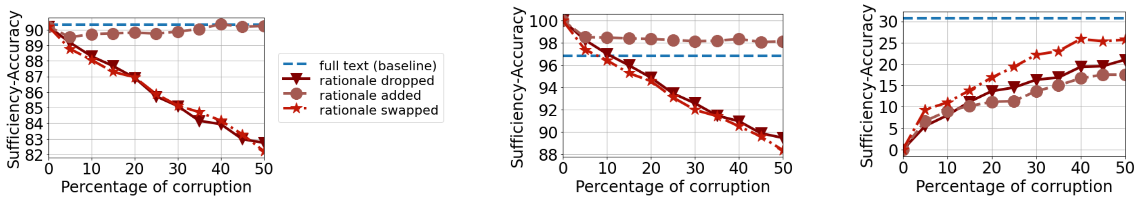
Furthering the analysis in §4.2, we extend the human rationale perturbation experiment to FEVER and E-SNLI.

Fig. 4 show the result for FEVER. Fig. 4a shows that the baseline accuracy is so high for this dataset that to match just the baseline accuracy for FEVER, we require near perfect prediction of human rationales.

Moreover, even for documents with HSA $= 1$, the model performance drops below baseline on dropping just $\sim$ 10% tokens (synonymous with rationale recall = $\sim$0.9) in Fig. 4b. Interestingly, the model performance remains consistently above the baseline when adding non-rationale tokens (synonymous with decreasing rationale precision). In comparison, the model performance for MultiRC in Fig. 2b drops below baseline after dropping $\sim$50% of the tokens.

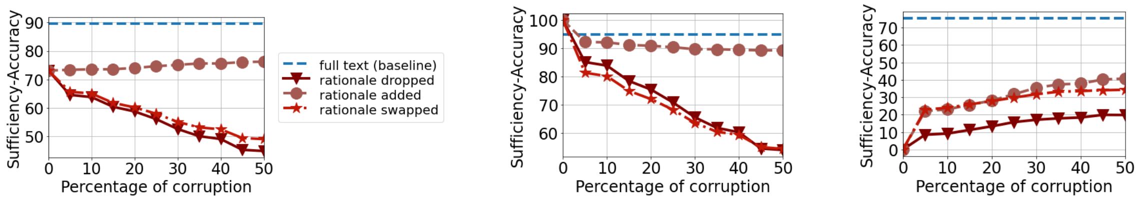
For FEVER examples with HSA $= 0$ (Fig. 4c), the model performance remains below the baseline accuracy consistently, supporting the second hypothesis in §4.2. The near-perfect need to predict rationales in FEVER may explain behind the difference in improvements of model performance between MultiRC and FEVER.

Fig. 5 covers E-SNLI. We see that the model performance decreases after dropping rationale tokens (signifying decreasing recall) and it consistently remains below the baseline. In contrast, the model performance shows a slight improvement after adding non-rationale tokens (signifying decrease in rationale precision). Moreover, for documents with HSA $= 1$, the model performance drops below baseline at $\sim$3% for dropping and swapping rationale tokens, where as the model performance plateaus with addition of non-rationale tokens. These insights highlights the substantial challenges in learning from explanations for E-SNLI.



(a) All samples (b) Human sufficiency-accuracy = 1 (c) Human sufficiency-accuracy = 0

Figure 4: Performance of corrupted rationale for FEVER. Model performance drops below baseline accuracy immediately on both dropping human rationales (i.e., recall ↓) and adding non-rationale tokens (i.e., precision ↓). For HSA = 1, model performance remains consistently above baseline on adding non-rationale tokens (i.e. precision ↓)



(a) All samples (b) Human sufficiency-accuracy = 1 (c) Human sufficiency-accuracy = 0

Figure 5: Performance of corrupted rationales for E-SNLI. Model performance for human rationale remains below baseline accuracy and slightly increases with addition of non-rationale tokens (i.e. precision ↓). Even for HSA = 1, model performance drops below baseline accuracy at just ∼4% corruption.

C Rationale Perturbation for Adapted Models

We perform the same perturbation analysis on calibrated model trained on both full and rationalized input, for which distribution shift from masking are less of a concern.

In Fig. 6, for MultiRC, we find that model performance plateaus with addition of non-rationale tokens and drops quickly with rationale tokens even for a calibrated model. This observation is consistent for FEVER (Fig. 7).

For E-SNLI, we find different properties using a calibrated BERT model compared to the standard BERT model show in Fig. 5a.

In contrast to MultiRC and FEVER, we find that the model performance drops more rapidly with the addition of non-rationale tokens compared to removal of rationale tokens. This is consistent for documents with HSA = 1, suggesting that for E-SNLI, rationale precision maybe more important when using a calibrated model. Similar to FEVER, we see the model performance drop below the baseline with very little corruption of rationales, echoing the need to perfectly mimic human rationalization for effective learning from rationales for this dataset.

D GPT-3 Prompt

We generate a zero-shot GPT-3 (Brown et al., 2020) explanation using the Davinci model variant on the OpenAI playground[1], and a modified version of the prompt proposed by Wiegreffe et al. (2021):

> Let's explain classification decisions.
>
> A big dog catches a ball on his nose.
>
> question: A big dog is sitting down while trying to catch a ball.
>
> entailment, contradiction, or neutral?

A second step prompting for an explanation is not needed, as GPT-3 gives its prediction in the form of a natural language explanation.

---

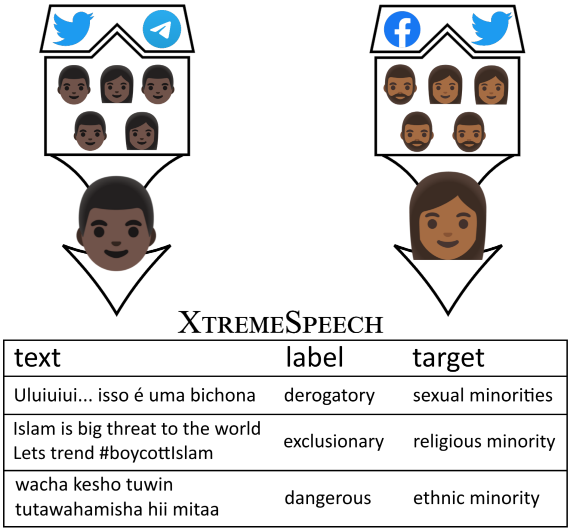
Abstract

Building on current work on multilingual hate speech (e.g., Ousidhoum et al. (2019)) and hate speech reduction (e.g., Sap et al. (2020)), we present XtremeSpeech,[1] a new hate speech dataset containing 20,297 social media passages from Brazil, Germany, India and Kenya. The key novelty is that we directly involve the affected communities in collecting and annotating the data – as opposed to giving companies and governments control over defining and combatting hate speech. This inclusive approach results in datasets more representative of actually occurring online speech and is likely to facilitate the removal of the social media content that marginalized communities view as causing the most harm. Based on XtremeSpeech, we establish novel tasks with accompanying baselines, provide evidence that cross-country training is generally not feasible due to cultural differences between countries and perform an interpretability analysis of BERT's predictions.



XtremeSpeech

text	label	target
Uluiuiui... isso é uma bichona	derogatory	sexual minorities
Islam is big threat to the world Lets trend #boycottIslam	exclusionary	religious minority
wacha kesho tuwin tutawahamisha hii mitaa	dangerous	ethnic minority

Figure 1: Overview of hate speech data collection. Instead of querying for data on our own, we work with fact-checkers advocating for targeted communities who collect and label data as they organically come across it. This inclusive approach results in datasets more representative of online speech the communities are exposed to. See §3.2 for definition of XtremeSpeech labels.

1 Introduction

Much effort has been devoted to curating data in the area of hate speech, from foundational work (Waseem and Hovy, 2016; Davidson et al., 2017) to more recent, broader (Sap et al., 2020) as well as multilingual (Ousidhoum et al., 2019) approaches. However, the demographics of those targeted by hate speech and those creating datasets are often quite different. For example, in Founta et al. (2018), 66% of annotators are male and in Sap et al. (2020), 82% are white. This may lead to unwanted bias (e.g., disproportionately labeling African American English as hateful (Sap et al., 2019; Davidson et al., 2019a)) and to collection of data that is not representative of the comments directed at target groups; e.g., a white person may not see and not have access to hate speech targeting a particular racial group.

An example from our dataset is the Kenyan social media post "… We were taught that such horrible things can only be found in Luo Nyanza." The Luo are an ethnic group in Kenya; Nyanza is a Kenyan province. The post is incendiary because it suggests that the Luo are responsible for horrible things, insinuating that retaliation against them may be justified. Only a group of people deeply rooted in Kenya can collect such examples and understand their significance.

XtremeSpeech. In this paper, we present XtremeSpeech, a new hate speech dataset containing 20,297 social media passages from Brazil, Germany, India and Kenya. The key novelty is that we empower the local affected communities (as opposed to companies and governments) to collect

Findings of the Association for Computational Linguistics: ACL 2022, pages 1089 - 1104
May 22-27, 2022 ©2022 Association for Computational Linguistics

and annotate the data, thus avoiding the problems inherent in approaches that hire outside groups for hate speech dataset creation. In more detail, we built a team of annotators from fact-checking groups from the four different countries. These annotators both collected and annotated data from channels most appropriate for their respective communities. They were also involved in all phases of the creation of XtremeSpeech, from designing the annotation scheme to labeling. Our inclusive approach results in a dataset that better represents content targeting these communities and that minimizes bias against them because fact-checkers are trained to be objective and know the local context. Figure 1 gives a high-level overview of data collection and annotation for XtremeSpeech.

XtremeSpeech also is a valuable resource because existing hate speech resources are not representative for problematic speech on a worldwide scale: they mainly cover Western democracies. In contrast, our selection is more balanced, containing three countries from the Global South and one Western democracy.

We present a data statement (see Bender and Friedman (2018)) in Appendix A.

Anthropological perspective. It has been argued that the NLP community does not sufficiently engage in interdisciplinary work with other fields that address important aspects of hate speech (Jo and Gebru, 2020). In this work, we take an anthropological perspective: the research we present is a collaboration of anthropologists and computational linguists. As a discipline that engages in the study of society and culture by exploring the lived worlds of people, and with a commitment to the application of knowledge to address human problems, sociocultural anthropology can provide a highlevel framework for investigating and theorizing about the phenomenon of hate speech and its cultural variations.

We also take an anthropological perspective for defining the terminology in this paper. Potentially harmful online speech is most often referred to by NLP researchers and general media[2] as **hate speech**. From its original, culturally-grounded meaning, *hate speech* has evolved into a primarily legal and political term with different definitions, depending on who uses it (Bleich, 2014; Saltman and Russell, 2014; Bakalis, 2018). We therefore use the concept of **extreme speech** from anthropology and adopt its definition as *speech that pushes the boundaries of civil language* (Udupa and Pohjonen, 2019; Udupa et al., 2021). In investigating extreme speech, anthropologists focus on cultural variation and historical conditions that shape harmful speech.

Extreme speech categories. We differentiate between extreme speech that requires removal (**denoted R**) and speech for which moderation (**denoted M**) is sufficient. Extreme speech of the M category consists of **derogatory** speech – roughly, disrespectful and negative comments about a group that are unlikely to directly translate into specific harm. We further subdivide R extreme speech into **exclusionary** extreme speech (roughly: speech inciting discrimination) and **dangerous** extreme speech (roughly: speech inciting violence); definitions are given in §3.2. This distinction is important when considering removal of extreme speech; e.g., dangerous speech may warrant more immediate and drastic action than exclusionary speech.

XtremeSpeech does not contain neutral text, focusing solely on M and R extreme speech. Neutral text has been shown to be easier to label both for humans and models while identifying and subclassifying non-neutral text (i.e., extreme speech) remains the Achilles' heel of NLP models (Davidson et al., 2017; Ranasinghe and Zampieri, 2020).

Finally, we also annotate the targets of extreme speech; examples are "religious minorities" and "immigrants" (frequent targets in India and Germany, respectively).

Classification tasks. We define three classification tasks. (i) **REMOVAL.** The two-way classification M vs. R. (ii) **EXTREMITY.** The three-way classification according to degree of extremity: derogatory vs. exclusionary vs. dangerous. (iii) **TARGET.** Target group classification.

We propose a series of baselines and show that model performance is mediocre for REMOVAL, poor for EXTREMITY and good for TARGET. Further, we show that `BERT`-based models are unable to generalize in cross-country and cross-lingual settings, confirming the intuition that cultural and world knowledge is needed for this task. We also perform a model interpretability analysis with LIME (Ribeiro et al., 2016) to uncover potential model biases and deficiencies.

Contributions. In summary, we **(i)** establish

---

[2] https://items.ssrc.org/disinformation-democracy-and-conflict-prevention/classifying-and-identifying-the-intensity-of-hate-speech/

a community-first framework of data curation, **(ii)** present XtremeSpeech, a dataset of 20,297 *extreme speech* passages from Brazil, Germany, India and Kenya, capturing target groups and multiple levels of extremity, **(iii)** propose a series of tasks and baselines, as the basis for meaningful comparison with future work, **(iv)** show performance both for models and humans is low across tasks except in target group classification, **(v)** confirm the intuition that extreme speech is dependent on social and cultural knowledge, with low cross-lingual and cross-country performance.

2 Related Work

Earlier work in hate speech detection focused on data collection, curation and annotation frameworks (Waseem and Hovy, 2016; Davidson et al., 2017; Founta et al., 2018). Recent work has expanded the set of captured labels to include more pertinent information such as targets and other forms of abuse (Sap et al., 2020; Hede et al., 2021; Guest et al., 2021; Grimminger and Klinger, 2021; Ross et al., 2017) as well as benchmarking (Röttger et al., 2021; Mathew et al., 2021). Analysis of datasets has been performed too (Madukwe et al., 2020; Kim et al., 2020; Wiegand et al., 2019; Swamy et al., 2019; Davidson et al., 2019a).

Work has also been conducted to expand research to multiple languages (Ousidhoum et al., 2019; Ranasinghe and Zampieri, 2020; Ross et al., 2017; Nozza, 2021; Zoph et al., 2016; Marivate et al., 2020; Nekoto et al., 2020). XtremeSpeech contributes to this goal by providing Brazilian Portuguese, German, Hindi and Swahili data.

Research has also been conducted to investigate annotation bias and annotator pools (Al Kuwatly et al., 2020; Waseem, 2016; Ross et al., 2017; Shmueli et al., 2021; Posch et al., 2018), as well as bias (especially racial) in existing datasets (Davidson et al., 2019b; Laugier et al., 2021). It was found that data can reflect and propagate annotator bias. To address this, we diversify the annotator pool in our work.

In another line of work, theoretical foundations are being established, in the form of taxonomies (Banko et al., 2020), definitions (Wiegand et al., 2021; Waseem et al., 2017) and theory (Price et al., 2020; Laaksonen et al., 2020). We are adding to this with definitions based on fieldwork and grounded research, inspired by anthropological and ethnographic work that investigates the societal impact of online hate and extreme speech (Boromisza-Habashi, 2013; Donovan and danah boyd, 2021; Haynes, 2019; Udupa and Pohjonen, 2019; Hervik, 2019).

Further, strides have been made in the ethics of AI. Who should collect data and who is responsible for model deployment decisions? Calls have been made for more inclusive pools of annotators and domain experts overseeing NLP projects, as well as exploration of other ethical dilemmas (Leins et al. (2020); Jo and Gebru (2020); Mitchell et al. (2020); Vidgen et al. (2019); Gebru (2019); Mohamed et al. (2020), *inter alia*). With our focus on community-embedded fact-checkers our framework is more inclusive than previous work.

3 Dataset

3.1 Dataset Description

XtremeSpeech consists of 20,297 passages, each targeted at one or more groups (e.g., immigrants). Data is collected from Brazil, Germany, India and Kenya. Passages are written in Brazilian Portuguese, German, Hindi and Swahili, as well as in English. English can either be used on its own, or in conjunction with the local language in the form of code switching. We capture this in the annotation: passages that contain English – even if it is only a hashtag in a tweet – are marked as containing both languages. Table 1 shows the distribution of languages.

Further, XtremeSpeech is platform-agnostic, with text collected from multiple online platforms, as well as direct messaging (anonymized) from the third quarter of 2020 until the end of 2021. In more detail, Brazilian annotators sourced WhatsApp groups, the German team collected data from Facebook, Instagram, Telegram, Twitter and YouTube, Indian annotators sourced Facebook and Twitter and the Kenyan annotators collected data from Facebook, Twitter and WhatsApp. While forms of extreme speech may originate from one place, dissemination to other platforms is swift (Rogers, 2020). Proprietary efforts have also taken a platform-agnostic approach.[3]

Passages were labeled both on content and target levels. On their content they are labeled as derogatory, exclusionary or dangerous. On the target level, we make a distinction between text targeted at protected groups and at institutions of

---

[3] `https://www.perspectiveapi.com/`

power. We take into account the following protected groups: ethnic minorities, immigrants, religious minorities, sexual minorities, women, racialized groups, historically oppressed caste groups, indigenous groups and large ethnic groups. We also give the annotators the option to input any other group. For institutions of power, possible targets are politicians, legacy media and the state. To allow for political discourse, extreme speech against institutions of power should not be filtered out, so such speech was marked as derogatory.

3.2 Extreme Speech Definitions

Building on Benesch (2018) and Udupa (2021), we define extreme speech labels as follows:[4]

Derogatory Extreme Speech: Text that crosses the boundaries of civility within specific contexts and targets either individuals/groups based on protected characteristics (e.g., ethnicity and religious affiliation) or institutions of power (state, media, politicians). Includes derogatory expressions about abstract categories/concepts.

Exclusionary Extreme Speech: Text that calls for or implies exclusion of vulnerable groups based on protected attributes (for example, ethnicity, religion and gender). Exclusionary text marginalizes, delegitimizes and discriminates against target groups. Text targeting abstract concepts or institutions is not exclusionary, except when there is reason to believe that such attacks call for or imply the exclusion of vulnerable groups associated with these abstract concepts or institutions.

Dangerous Extreme Speech: Text that has a reasonable chance to trigger harm against target groups (e.g., ostracism and deportation). All the following criteria should be met for a passage to be classified as dangerous: (i) content calls for harm, (ii) speaker has high degree of influence over audience, (iii) audience has grievances and fears that the speaker can cultivate, (iv) target groups are historically disadvantaged and vulnerable to harm, (v) influential means to disseminate speech.

Whereas derogatory extreme speech is a form of speech that *requires moderation but, generally, not removal* (denoted with M), exclusionary and dangerous speech are forms of speech that do *require removal* (denoted with R) in most cases to protect users from potential harm. We make a distinction between exclusionary and dangerous speech in order to introduce a more fine-grained scale of extremity that can dictate more focused policy (e.g., more severe punishment may be appropriate for dangerous speech). It has been shown in previous work that while neutral text is easier to detect (Davidson et al., 2017; Ranasinghe and Zampieri, 2020; Risch and Krestel, 2020), models find it hard to differentiate between different types of extreme speech (e.g., between our definitions of M or R, or between merely offensive versus hateful speech), a task challenging even for humans. By focusing on the difficult distinctions within non-neutral text, we hope to contribute to research that will be able to classify types of potentially harmful speech correctly in the future, which is both the critical point of extreme speech research and the main obstacle towards effective filtering.

Exemplary cases for the three labels (derogatory, exclusionary, dangerous) were discussed in detail with the annotators. We believe our interdisciplinary approach will lead to data more aligned with the real world and will benefit the target groups and communities to greater effect.

3.3 Data Collection

3.3.1 Annotator Profiles

We selected Brazil, Germany, India and Kenya to cover a range of cultures and communities. Each annotator is a fact-checker who i) is local, ii) is independent (i.e., not employed by social media companies or large media corporations) and iii) investigates the veracity of news articles, including articles directed at or related to local communities. There are 8 female and 5 male annotators (per country, female/male counts are 2/1 in Brazil, 4/0 in Germany, 2/2 in India and 0/2 in Kenya).

Fact-checking companies were scouted and individual fact-checkers interviewed by our anthropology team to verify their familiarity with extreme speech, their expertise in local community affairs and their ability to act as annotators in our project.

We see independent fact-checkers as a key stakeholder community that provides a feasible and meaningful gateway into cultural variation in online extreme speech. Through their job as fact-checkers, they regularly come in contact with extreme speech, with communities that peddle extreme speech as well as with communities targeted by extreme speech (further details in Appendix C).

3.3.2 Annotation Scheme

Through an online interface, data is entered as found in online media. This interface (in the form

---

[4] Definitions were shared as annotation instructions.

of a web page, see Appendix C.4) serves both as the data entry point and the annotation form. After finding a passage of extreme speech, annotators enter it in our form and are prompted to label it (see categories in §3.1).

3.4 Inter-annotator Agreement

To verify the quality of XtremeSpeech, we calculate inter-annotator agreement. The data collected from one annotator is shown to another for verification (details in Appendix C.2). Only the text passage is shown to annotators, without prior category assignments. The agreement scores we measure are: Cohen's kappa (κ, McHugh (2012)), Krippendorff's alpha (α, Krippendorff (2011)), intraclass correlation coefficient (two-way mixed, average score ICC$(3, k)$ for $k = 2$, Cicchetti (1994)) and accuracy (defined as the percentage of passages where both annotators agreed).

For the three extreme speech labels, $\kappa = 0.23$, $\alpha = 0.24$ and ICC$(3, k) = 0.41$ (considered "fair" (Cicchetti, 1994)). Accuracy is 63% overall, 78% for derogatory, 40% for exclusionary and 19% for dangerous. For the M vs. R task, accuracy is 78.4% for M and 46.3% for R. For the classification of the target of extreme speech, $\kappa = 0.69$.

Scores are low compared to other NLP tasks, which is unfortunately a widespread phenomenon in hate speech research. In Founta et al. (2018), only in 55.9% of passages did at least 4 out of 5 annotators agree. In Sap et al. (2020), the α score was 0.45, with a 76% agreement on "offensiveness" and 74% on "targeted group". In Davidson et al. (2017), there was a 90% agreement on whether text was neutral, offensive, or hateful. In Ross et al. (2017), a German dataset, α was between 0.18 and 0.29, while in Ousidhoum et al. (2019), a multilingual dataset, α was between 0.15 and 0.24.

We argue that in our work, not only are we dealing with a heavily imbalanced dataset, but also that the task is even more challenging than prior work, which collects both neutral passages and hate speech (e.g., in Davidson et al. (2017)). We only collect extreme speech, so whereas in prior work the annotators need to differentiate between neutral and extreme speech (a relatively easier task (Ranasinghe and Zampieri, 2020; Risch and Krestel, 2020)), our annotators only make decisions on the hard task of determining different degrees of extremity.

	Brazil	Germany	India	Kenya

Both	0	71	1174	2081

Table 1: XtremeSpeech passages per country and language combination

3.5 Reannotation

After discussing inconsistently labeled passages with the annotators, we found that there was disagreement about groups currently in power, specifically, the Kikuyu and Kalenjin ethnic groups (more information in Appendix D). One annotator considered them ethnic minorities because most other ethnic groups are pitted against them. The other annotator did not view them as minorities because they are (i) the two most populous ethnic groups and (ii) are not in the minority when it comes to representation in positions of power. A consensus was reached to add a new target label, "large ethnic group", to correctly represent this state of affairs in the annotation.

As is common practice, instead of limiting the reannotation to passages the annotators disagreed on, we provided all potentially affected passages for reannotation, i.e., all "indigenous group" and "ethnic minority" passages.

3.6 Dataset Analysis

3.6.1 Extreme Speech Analysis

XtremeSpeech contains 20,297 passages from the four countries. From each country, we chose to only collect data on one local language plus English. The distribution of languages is shown in Table 1. While for Germany and Brazil, English is rarely used, in India and Kenya it is more prominent, both on its own and in code switching.

The distribution of labels, shown in Table 2, varies a lot from country to country. For example, in Germany annotators labeled far fewer passages as dangerous speech, reflecting stricter regulatory controls over speech compared to the other countries. Data is also heavily imbalanced in Brazil, with the majority of passages being derogatory.

The distribution of targets per country (shown in Table 4) again shows large divergences between countries. In Germany, immigrants are the main target group because of right-wing opposition to recent immigration. In India, religious minorities dominate the target group statistics because of the conflict between Hindus and Muslims. Thus

	Brazil	Germany	India	Kenya	*Total*
Der.	4774	2643	2225	3389	*13031*
Exc.	115	2340	1422	1024	*4901*
Dan.	220	16	1361	768	*2365*

Table 2: Distribution of extreme speech labels in XtremeSpeech (Der = Derogatory, Exc = Exclusionary, Dan = Dangerous)

XtremeSpeech reflects a country's social and political situation to a reasonable extent.

3.6.2 Word Frequency

Table 3 shows the most frequent words for the three extreme speech labels for the four countries. We see that words indicative of sociopolitical conflict appear frequently: "comunista" and "feminista" in Brazil; "merkel" (a German politician) and "deutsche" (meaning: "German"), as well as the word for Jew, "jude" in Germany; words referring to religion (e.g., "muslims", "hindus") in India. In Kenya, political entities ("Ruto" and "Raila", names of two Kenyan politicians) as well as ethnic groups (e.g., "Kikuyus", "Kalenjins", two powerful groups in Kenya) are among the most frequent words, with ethnic groups appearing particularly prominently in the two forms of extreme speech that should be removed (R).

4 Experiments

We establish XtremeSpeech baselines for large pretrained models and traditional machine learning models (details in Appendix E). As introduced in §1, we address three novel tasks: predicting the extremity of speech (EXTREMITY), whether a passage should be removed or not (REMOVAL) and the target of extreme speech (TARGET).

Unless noted otherwise, our measure is micro-averaged F1. We split each country set 80:10:10 into train:dev:test, sampling equally for all labels.[5] In Tables 5, 6, 7, 8, 9 we show results on the development set (test set results in Appendix G).

We evaluate both multilingual (`mBERT`, `XLM-R` (Conneau et al., 2020)) and monolingual (`langBERT`) models. Each monolingual model was pretrained on the local language we are using for each corresponding country; e.g., the Indian model was pretrained on Hindi. For finetuning and classification with `BERT`-based models, a task-specific head is added that takes as input the [CLS] token representation.

4.1 EXTREMITY Task

Table 5 shows that baseline performance is rather low in three-way classification (EXTREMITY). In India and Kenya, performance is acceptable; in Germany as well if we exclude the dangerous label, which only has 16 passages. In Brazil, however, where the predominant class is derogatory speech (with more than 90% of all passages labeled as derogatory), performance is low, with no model managing to detect exclusionary speech.

`XLM-R` performs relatively poorly, only scoring competitively in the low-resource Kenyan set. `langBERT` is competitive for Brazil and Germany, less so for Kenya and performs badly for India. This can be explained by the divergence of pretraining and XtremeSpeech text: all `langBERT` models are pretrained on a single language (Brazilian Portuguese, German, Hindi and Swahili, respectively). In the Brazilian and German sets there is primarily only one language used so `langBERT` performs better in those sets, while it performs worse in countries where English is more predominant both as a standalone language and in code switching, which is the case for India and Kenya.

4.2 REMOVAL Task

Table 6 shows that results are overall better for the binary task M (moderation) vs. R (removal) than for the fine-grained EXTREMITY task. `BERT`-based models perform particularly well. `mBERT` performs especially well for India and the monolingual `langBERT` models again perform well for Brazil and Germany; this time we see improvements for Kenya too. LSTMs perform well, in some instances competitively with transformers. `XLM-R` does not seem to compute good representations and performs poorly for all languages except for the low-resource Kenyan dataset.

4.3 TARGET Task

Table 7 shows that transformers are effective for the 8-way multilabel classification of target. In Table 3 and Table 10, we show top words according to frequency in the dataset and contribution to `mBERT` predictions in the EXTREMITY task, respectively. Words denoting ethnicity ("kikuyu"), religion ("hindu", "Muslim") and gender ("puta", "girls") appear often and, not surprisingly, are reliable indicators of targeted groups, making this task easier than the other two.

---

[5] The German subset only contains 16 dangerous passages, so results for dangerous speech are of limited utility.

Table 9: F1 on dev for EXTREMITY for cross-country transfer in English (IN/KE = India/Kenya)

4.4 Zero-Shot Cross-Country Classification

4.4.1 All languages

We evaluate `mBERT` on zero-shot cross-country transfer, i.e., training on one country and testing on the rest (results are shown in Table 8). Performance is in general poor, indicating that `mBERT` is not able to generalize from one country to another. Trained on Brazil, the model is unable to make any inferences on other countries. From Kenya to India, we see some transferability potential, with the model correctly identifying passages in all three classes (although at a non-competitively low rate). These results confirm our intuition that detecting extreme speech depends on social and cultural information, so zero-shot transfer, without access to specific information about the target country, is not a promising approach.

4.4.2 English

We investigate cross-country transfer of `BERT`, an English model. We only experiment with the two countries that have a nontrivial number of English passages, India (IN) and Kenya (KE), restricting the datasets to their English part only (denoted by IN_{en} and KE_{en}, respectively). While cross-country performance is low for both countries, we see that $KE_{en} \rightarrow KE_{en}$ performance is high. We note that performance is better in $KE_{en} \rightarrow KE_{en}$ than in the previously examined $KE_{all} \rightarrow KE_{all}$ (where KE_{all} is the entire Kenyan set). This shows that for a single language within one country, `BERT` can indeed classify extreme speech with adequate accuracy.

4.5 Prediction analysis with LIME

To shed light on predictions of `mBERT` in the EXTREMITY task (described in §4.1) we extract top-contributing words with LIME (Ribeiro et al., 2016). Specifically, we compute the words that contribute the most to `mBERT`'s predictions (alongside their weights) for each passage and then average the weights, returning the top 10 words with at least 5 occurrences in the examined set. This list is shown in Table 10.

Brazil	Germany	India	Kenya
fechar	Politiker	muslims	cows
Ucranizar	Grünen	Muslim	ruto
ucranizar	Mohammedaner	muslim	luo
safada	Juden	Muslims	wajinga
prender	Merkels	ko	kikuyu
lixo	Merkel	mullo	stupid
coisa	Regierung	Rohingyas	idiot
kkkkk	Opfer	ड	looting
Vagabundo	Islam	suvar	tangatanga
traveco	Moslems	डर	ujinga

Table 10: Top words contributing to predictions of `mBERT` for EXTREMITY

The Indian and German sets are dominated by religious groups (“Moslems”, “Muslims”). In India, ethnic terms (“Rohingyas”) are also present while in Germany we see extreme speech targeting politicians (“Merkel”). In Brazil we see politically divisive terms (“Ucranizar”, a term originally meaning “Ukrainian Brazilian” which has now been appropriated to denounce opponents to the right-wing as “communists”) as well as insults like “traveco” (for “cross-dresser”, used here as a slur). In Kenya, we see direct insults such as “idiot” and “wajinga” (meaning “foolish”), as well as expressions referring to ethnic group such as “luo” and “kikuyu”.

5 Conclusion

We have presented XtremeSpeech, an extreme speech dataset, containing 20,297 passages from Brazil, Germany, India and Kenya. We capture both granular levels of extremity and targets of extreme speech by engaging a team of annotators from within the affected communities. In a collaboration of anthropologists and computational linguists, we established a community-based framework, with the goal of curating data more representative of real-world harms.

We introduce baselines for three novel tasks, including extreme speech and target group classification. We give experimental support for the intuition that extreme speech classification is dependent on cultural knowledge and that current NLP models do not capture this. Finally, we perform interpretability analysis on `BERT`'s predictions to reveal potential deficiencies, showing that models rely heavily on keywords and names of marginalized groups.

We hope our community-driven work will contribute to the effective elimination of extreme speech against target groups, not just in Western democracies, but in a greater variety of countries worldwide.

6 Acknowledgments

This research has received funding from the European Research Council Proof of Concept grant (Agreement Number: 957442). For more about the project see `https://www.ai4dignity.gwi.uni-muenchen.de`.

7 Ethical Considerations and Limitations

7.1 Ethics Statement

The data provided here contains extreme speech that can be shocking and harmful. We present this dataset as a way to peel back the veil of extreme speech against the selected under-represented communities around the world. We want to motivate the analysis of this overlooked area as a whole and the investigation of the various levels of extreme speech (derogatory, exclusionary and dangerous) as found in online social media. This data is not intended and should not be used for pretraining models applied to real-world tasks, since a model pretrained on this data could potentially exhibit and propagate the extreme speech found in the passages we collected.

Further, while we endeavored to include as many communities around the world as possible, the data we collected and the list of communities we included are of course non-exhaustive. For each country, we had a close circle of annotators, therefore it is possible other marginalized groups in these countries were not covered (although we made efforts to keep this to a plausible minimum).

7.2 Limitations

Due to limitations of both time and budget, we only gathered extreme speech without negative passages (ie. neutral language). These neutral passages form the majority of content on social media (Founta et al., 2018; Sap et al., 2020). Despite the abundance of such passages, annotating them using our current scheme would be time and effort-consuming (our annotators collect data on their own, from their own networks, without us querying and supplying data to them). Thus, to keep control in the hands of annotators while at the same time keeping their workload to a reasonable minimum, we decided to only collect extreme speech passages.

A Data Statement

CURATION RATIONAL In our project, we venture to present a dataset on extreme speech across different countries (Brazil, Germany, India and Kenya). Fact-checkers from these countries were requested to gather and annotate data. These fact-checkers searched online platforms and communities to identify extreme speech based on their contextual language. The choice of sources was left to the fact-checkers, since they have intimate knowledge of the spread of extreme speech. Sources include social media (e.g., Twitter), fora (e.g., groups on Telegram) and direct messaging.

LANGUAGE VARIETY Data was collected for Brazilian Portuguese (pt-BR), German (de-DE), Hindi (hi-IN, either in the Devangari or Latin script), Swahili (sw-KE) and English used as a second language alongside these native languages.

SPEAKER DEMOGRAPHICS Speaker demographics were not recorded (and anonymized where necessary). Data was collected from Brazil, Germany, India and Kenya, so a fair assumption is that speakers come from these countries.

ANNOTATOR DEMOGRAPHICS Annotators were accredited fact-checkers in their respective countries. There were 8 female and 5 male annotators (per country, female/male counts are 2/1 in Brazil, 4/0 in Germany, 2/2 in India and 0/2 in Kenya). They were native speakers of (Brazilian) Portuguese, German, Hindi and Swahili. Ages were not recorded. Further (self-disclosed) information on annotators can be found at `https://www.ai4dignity.gwi.uni-muenchen.de/partnering-fact-checkers/`.

SPEECH SITUATION Speech consists entirely of text, posted and collected in 2020 and 2021. Text is mainly asynchronous, informal and spontaneous. Certain passages were posted as responses to other text (which was not collected) in a more synchronous manner. By the nature of this project, all passages contain a level of extremity.

TEXT CHARACTERISTICS Text comes from social media in the form of user comments. Length was limited to approximately two paragraphs (at the discretion of the annotators).

OTHER The team spanned multiple disciplines, ages and ethnicities.

	Brazil	Germany	India	Kenya	*Total*

Table 11: Average passage length statistics

B Data Analysis

B.1 Institutions of Power

Statistics of institutions of power are shown in Table 15. These groups can only be the target of derogatory speech, since we want to avoid censoring of speech aimed at these groups. Across all countries, we see that politicians are the predominant targets.

B.2 Average Passage Length

In Table 11 we show the average length of passages per label for each country. All sets show similar lengths, except Brazil where passages are overall shorter. Also, across sets, the more extreme a passage is, the longer it is on average.

C Annotation Details

C.1 Logistics

There are at least two annotators from each country. In some countries, we worked with fact-checker teams which themselves employ multiple fact-checkers. In these instances, annotation work was split according to the requirements and resources of the particular team. We ensured that all involved members were accredited fact-checkers and were interviewed by our anthropology team to verify they are familiar with extreme speech and are capable of identifying it. Payment was 1.5 Euros per passage provided for the original dataset and 1 Euro per passage for the re-annotation task.

C.2 Cross-annotation

In Table 12 we show the number of passages cross-annotated by each annotator. Annotators were split into two groups, A and B, according to availability and were tasked with cross-annotating the passages provided by the other group.

C.3 Inter-annotator agreement details

In Table 14 we show inter-annotator agreement scores per country. While Germany and Kenya have acceptable scores, the other two countries have low scores.

	Group A	Group B
Brazil	834 833	833
Germany	834 833	833
India	1250	417 417 416
Kenya	1250	1250

Table 12: Number of passages each group of annotators cross-annotated, evenly split among the members of each group. Details in Appendix C.2.

C.4 Online Interface

In Figure 2 we see the interface annotators used to enter and annotate data.

D Reannotation

After discussion with the annotators from Kenya, we found that there was disagreement surrounding two ethnic groups and the power dynamics around them. Namely, the Kikuyu and Kalenjin, two ethnic groups currently in power in Kenya. They make up around 17% (largest group) and 13% (third largest group) of the population of Kenya, respectively. Because of their position of power, in a lot of sociopolitical issues these two ethnic groups (either jointly or individually) get pitted against the rest of the population. So, in that binary perspective (e.g., Kikuyus vs. "others"), the ethnic group in power was considered an ethnic minority by one annotator. The other annotator did not share this perspective and labeled these ethnic groups as indigenous groups. After a series of discussions with the annotators, a consensus was reached that the ethnic groups in power will be labeled neither as ethnic minorities nor as indigenous groups, but as a new target label: "large ethnic groups". This entailed that re-labeling of the extremity of these passages should take place.

E Model Details

Transformer models were finetuned for 3 epochs (5 minutes each), LSTMs for 5 and SVMs until convergence. A maximum length of 128 was used universally. For each baseline, three runs were made with results averaged. Standard deviations were minimal and were not reported for brevity.

The `BERT`-based models we used are:[6]

1. `bert-base-multilingual-cased`: `https://huggingface.co/bert-base-multilingual-cased`
2. `bert-base-portuguese-cased`: `https://huggingface.co/neuralmind/bert-base-portuguese-cased`
3. `bert-base-german-cased`: `https://huggingface.co/bert-base-german-cased`
4. `hindi-bert`: `https://huggingface.co/monsoon-nlp/hindi-bert`
5. `bert-base-uncased-swahili`: `https://huggingface.co/flax-community/bert-base-uncased-swahili`

	All

mBERT	84.9	55.1	50.4
	M	R	
mBERT	85.5	56.8	
	Target Group		
mBERT	91.4		

Table 13: Combined multilingual setting results.

F Combined Multilingual Setting

We perform an ablation study by combining all sets across countries and repeating our `mBERT` experiments in this new multilingual task (Table 13).

Even though the use of a "catch-all" model that is able to work on all languages sounds enticing, care should be taken to ensure that the model has sufficient understanding for each language and culture instead of making predictions based on dubious statistical cues (McCoy et al., 2019). This is a task out of scope for this work, but we are adding such a model to our baselines for completion.

G Test Set Results

In Tables 16, 17, 18, 19 and 20 we show results on the test set for tasks defined in §4.

Abstract

Warning: This paper contains examples of language that some people may find offensive.

Natural Language Processing (NLP) models risk overfitting to specific terms in the training data, thereby reducing their performance, fairness, and generalizability. E.g., neural hate speech detection models are strongly influenced by identity terms like *gay*, or *women*, resulting in false positives, severe unintended bias, and lower performance. Most mitigation techniques use lists of identity terms or samples from the target domain during training. However, this approach requires a-priori knowledge and introduces further bias if important terms are neglected. Instead, we propose a knowledge-free Entropy-based Attention Regularization (EAR) to discourage overfitting to training-specific terms. An additional objective function penalizes tokens with low self-attention entropy. We fine-tune BERT via EAR: the resulting model matches or exceeds state-of-the-art performance for hate speech classification and bias metrics on three benchmark corpora in English and Italian. EAR also reveals overfitting terms, i.e., terms most likely to induce bias, to help identify their effect on the model, task, and predictions.

1 Introduction

Online hate speech is growing at a rapid pace, with effects that can result in dangerous criminal acts offline. Due to its verbal nature, various Natural Language Processing approaches have been proposed (Qian et al., 2018; Indurthi et al., 2019; Attanasio and Pastor, 2020; Kennedy et al., 2020; Vidgen et al., 2021, inter alia). Recently, detection performance has significantly improved with the use of large pre-trained language models based on Transformers (Vaswani et al., 2017), such as Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019). However, several works have shown that by fine-tuning neural language models on hate speech detection, the classifiers obtained contain severe *unintended bias* (Dixon et al., 2018), i.e. they perform better or worse when texts mention specific *identity terms* (such as *gay*, *Muslim*, or *woman*). As a result, a sentence like “As a Muslim woman, I agree” would be wrongly classified as hate speech, purely due to the presence of two identity terms, i.e., terms referring to specific groups based on their socio-demographic features. One cause of false positives is selection bias in the keyword-driven collection of corpora (Ousidhoum et al., 2020). Figure 1 shows a false positive example for a fine-tuned BERT model on hate speech detection. Ideally, the model should rely on the words *adore* and *you*. Instead, BERT overfitted to the word *Girl* and associated it with a hateful context. This unwanted effect demonstrates the issues of lexical overfitting, and how they cause uninteded bias on identity terms.

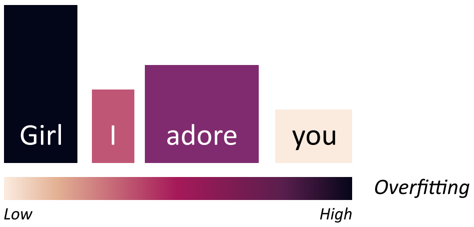

Figure 1: False positive from BERT as a hate speech detector. The darker and taller the bar, the higher the overfitting on the term.

Various methods have been proposed to mitigate and measure (unintended) bias (Elazar and Goldberg, 2018; Park et al., 2018; Dixon et al., 2018; Nozza et al., 2019; Kennedy et al., 2020; Vaidya et al., 2020). However, all those methods rely on the availability of a set of *identity terms*. This is a severe limitation, which hinders the generalizability and applicability of hate detection models

Findings of the Association for Computational Linguistics: ACL 2022, pages 1105 - 1119
May 22-27, 2022

to real-world contexts. For example, a model designed to reduce the unintended bias on gender-related terms (such as *woman*, *wife*) will not address unintended bias for religious affiliation. So practitioners must decide a-priori *"which vulnerable groups are present in our data?"*

We propose an Entropy-based Attention Regularization (EAR) that forces the model to build token representations by attending to a wider context, i.e., consider a larger number of tokens from the rest of the sentence. We measure the attended context as the entropy of the self-attention weight distribution over the input sequence. We use EAR as a regularization term in the loss computation to maximize each token's entropy. We apply EAR to BERT. The resulting model (BERT+EAR) significantly improves performance on unintended bias mitigation in English and Italian. In addition, it requires no a-priori knowledge (e.g., sets of identity terms), making it fairer and more general. The contextualized representations EAR induces avoid basing the classification on individual terms and, ultimately, mitigate lexical overfitting and intrinsic bias from pre-trained weights.

As a training by-product, EAR lets us extract the overfitting terms, i.e., terms accounting for narrower context that most likely induce unintended bias. These terms can highlight possible weaknesses in the model: from the over-sensitivity of pre-trained weights to specific words (Sheng et al., 2019; Nangia et al., 2020; Vig et al., 2020), to over-specialization of training corpora on the keywords used for collecting data (Ousidhoum et al., 2020).

Note that while we show results on BERT, EAR is applicable to any attention-based architecture.

Contributions. EAR is a novel entropy-based attention regularization method to mitigate unintended bias by reducing lexical overfitting. It is applied to all terms, so it *does not need a-priori domain knowledge* (e.g, predefined term lists). Independent of domain-specific information, EAR *generalizes better to different languages and contexts* compared to similar approaches. Attention entropy is used to extract a list of the most likely *biased terms*. EAR code is available at `https://github.com/g8a9/ear`.

2 Entropy-based Attention Regularization

Attention was originally designed for aligning target and source sequences in machine translation (Graves, 2013; Bahdanau et al., 2015). However, in the Transformer architecture (Vaswani et al., 2017), it has become a means to account for lexical influence and long-range dependencies. It also provides useful information about the importance of a term for the output (Wiegreffe and Pinter, 2019; Brunner et al., 2020; Sun and Marasović, 2021). Here, we use the notion of attention entropy, and EAR's use of it in BERT. Note, though, that EAR can be used with *any* attention-based architecture.

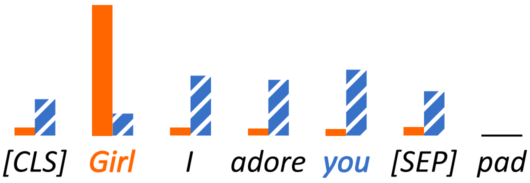

Figure 2: Self-attention distribution on tokens *Girl* (solid orange) and *you* (shaded blue). Attention for *Girl* is concentrated on its representation: its entropy is low. Attention for *you* is spread: its entropy is high.

Self-attention in Transformers. The Transformer model consists of two connected units, an encoder and a decoder, designed for sequence-to-sequence tasks.

A transformer encoder applies scaled-dot product self-attention over the input tokens to compute N independent attention heads.[1] Let $E = [\boldsymbol{e_0}, ..., \boldsymbol{e_{d_s}}]$ be the sequence of input embeddings, with $\boldsymbol{e_i} \in \mathbb{R}^{d_m}$. For the h-th attention head and i-th position, each embedding $\boldsymbol{e_i}$ is projected into a query $\boldsymbol{q_{h,i}}$, a key $\boldsymbol{k_{h,i}}$ and value $\boldsymbol{v_{h,i}}$. So each token expresses an attention distribution over all input embeddings as

$$a_{h,i} = \text{softmax}\left(\frac{\boldsymbol{q}_{\boldsymbol{h},\boldsymbol{i}}^T K_h}{\sqrt{d_k}}\right) \tag{1}$$

where K_h is the matrix of keys and d_k their dimension.

Attention weights $a_{h,i} = [a_{h,i,0}, ..., a_{h,i,d_s}]$, where $a_{h,i,j} \in [0,1]$ and $\sum_j a_{h,i,j} = 1$, can be seen as a soft-indexing over the values. Since the values are projections of the tokens themselves, each weight in self-attention measures the contribution of its token to the attention head and, in turn, to the new token representation. We provide additional details to the self-attention mechanism in Appendix A.

---

[1] In the following, we use *token* and *embedding* interchangeably. We represent vectors with lowercase bold letters.

Attention entropy. Information *entropy* was first introduced in Shannon (1948), and measures the average information content of a random variable X with the set $[x_0, ..., x_n]$ of possible outcomes. It is defined as

$$H(X) = -\sum_i P(x_i) \log P(x_i) \tag{2}$$

Following Ghader and Monz (2017), we compute the entropy in the self-attention heads by interpreting each token's attention distribution as a probability mass function of a discrete random variable. The input embeddings are the possible outcomes, and the attention weights their probability.

For the sake of simplicity, we now discuss the computation of attention entropy of a single token in a standard transformer encoder. Attention weights are first averaged over heads by defining $a'_{i,j} = \frac{1}{h} \sum_h a_{h,i,j}$ as the mean attention that the token at position i pays to the token at position j. Then, we define a probability mass function by applying a softmax operator:

$$a_{i,j} = \frac{e^{a'_{i,j}}}{\sum_j e^{a'_{i,j}}} \tag{3}$$

We define the attention entropy as follows

$$H_i = -\sum_{j=0}^{d_s} a_{i,j} \log a_{i,j} \tag{4}$$

Intuitively, attention entropy measures the degree of contextualization while constructing the model's upper level's embedding. A large entropy suggests that a wider context contributes to the new embedding, while a small entropy tells the opposite: only a few tokens are deemed relevant. From a broader viewpoint, contextualized tokens improve the information passage between continuous layers by re-distributing the information content for every unit involved.

Figure 2 shows a toy example of self-attention distributions for two arbitrary tokens. Solid orange bars correspond to $a_{\text{Girl},j}$, while shaded blue bars correspond to $a_{\text{you},j}$. The toy example illustrates the correlation between attention distributions and entropy. The representation of *you* uses a wider context and, thus, it has a higher attention entropy. Note that, if present, we discard padding tokens from the attention entropy computation. Conversely, we include special tokens when required by the downstream task.

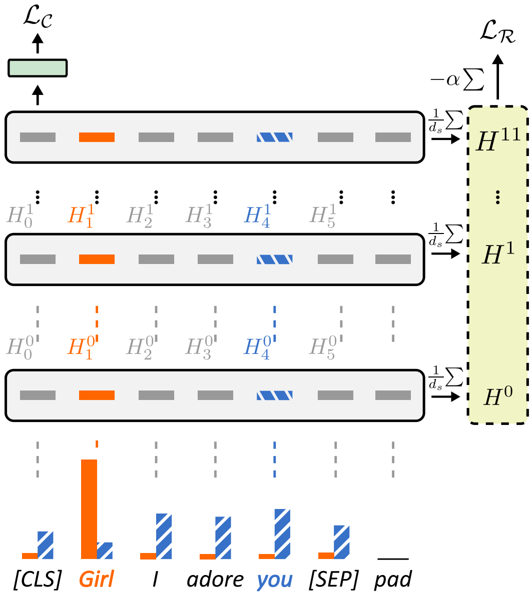

Figure 3: Overview of BERT+EAR. Grey boxes are Transformer layers. Each builds a token with attention entropy H_i^ℓ. Right green box pools layer-wise contextualization contributions and outputs regularization loss. First layer self-attention distribution (bottom) shown for *you* (shaded blue) and *Girl* (solid orange).

EAR in BERT. We introduced attention entropy as a proxy for the degree of contextualization of token representations above. Following this intuition, we propose BERT with EAR mitigation (BERT+EAR), a novel model trained to learn tokens with maximal self-attention entropy over the input sequence. We fine-tune BERT+EAR in the downstream task of hate speech detection. Note, though, that the approach is feasible for any classification task. In classification models, having more contextualized tokens avoids individual terms driving the classification outcome because they got over-attentioned.

Although EAR is applicable to any Transformer-based model, we base our approach here on the BERT (Devlin et al., 2019) base architecture. BERT provides an informative case study, given the number of architectures it has spawned and the recent interest in its attention patterns (Clark et al., 2019b; Kovaleva et al., 2019; Serrano and Smith, 2019). BERT consists of twelve stacked transformer encoders, each running self-attention on the output of the previous encoder. In BERT+EAR, we build new tokens with the maximal information content coming from the previous layer for every transformer layer in the architecture. Using Equation 4, we first compute the attention entropy of each token in the input sentence. We then take their mean and define the *average contextualization* for the ℓ*-th* layer as

$$H^\ell = \frac{1}{d_s} \sum_{i=0}^{d_s} H_i^\ell \tag{5}$$

where H_i^ℓ is the attention entropy of the token at position i, and d_s is the length of the input sequence (excluding the padding tokens but including the [CLS] and [SEP] special tokens). Finally, we introduce a new regularization term to the model loss to maximize the entropy at each layer:

$$\mathcal{L} = \mathcal{L}_C + \mathcal{L}_R, \quad \mathcal{L}_R = -\alpha \sum_l H^\ell \tag{6}$$

$\mathcal{L}$ is the total loss, $\mathcal{L}_C$ and $\mathcal{L}_R$ are the classification and regularization loss, respectively, and $\alpha \in \mathbb{R}$ is the regularization strength. As in previous work, $\mathcal{L}_C$ is the Cross Entropy loss obtained with a linear layer on top of the last encoder as a classification head. It receives the [CLS] embedding and outputs the probability of the positive class (Hate).

The new regularization term $\mathcal{L}_R$ frames the task of maximal contextualization learning in the network. This framing has several advantages over existing approaches. First, it is a sum of differentiable terms and is hence differentiable. We can thus optimize BERT+EAR with classical back-propagation updates. Second, the regularization is agnostic to specific identity terms. It instead induces the network to learn contextualized tokens globally. This induction is crucial to regularize biased terms that might not be known in advance. Finally, note that the $\mathcal{L}_R$ pools each layer's entropy-based contributions H^ℓ. Each term H^ℓ is in turn dependent on the sole attention entropy defined in Equation 4. This makes the setup a general framework not limited to BERT. $\mathcal{L}_R$ can be used to evaluate and maximize the token contextualization in any attention-based architecture.

Figure 3 shows a graphical overview of BERT+EAR. Each layer provides a contextualization contributing to the loss independently, where layers with a low average contextualization increase the loss the most. Note also that, similarly to He et al. (2016), $\mathcal{L}_R$ introduces skip connections between layers and the classification head, so shorter paths for the contextualization information to flow.

Insights from attention entropy. On the one hand, we use attention entropy maximization to train BERT+EAR and test its classification and bias mitigation performance. On the other hand, we can leverage attention entropy to automatically extract the tokens with the lowest contextualization, which are the most likely to induce unintended bias. When a sentence is fed through a model like BERT, we can inspect the attention distribution of its terms[2].

We propose to exploit entropy, and hence contextualization, to gain insights into any attention-based model. Given a corpus and a model we want to inspect, we repeatedly query the model with sentences from the corpus and collect each token's attention entropy. Finally, we take each token's mean to measure the impact it has on bias, where lower is worse. Note that the same term can impact bias differently depending on the sentence.

While our approach works for any attention-based model and data set, we test it on fine-tuned classifiers to extract the biased terms learned on the training data set. We discuss this functionality in Section 5.

3 Experimental settings

In this work, we consider the problem of *unintended bias* (Dixon et al., 2018): "*a model contains unintended bias if it performs better for comments containing some particular identity terms than for comments containing others*".

Datasets. Unintended bias is measured on synthetic test sets, artificially generated by filling manually defined contexts with identity terms (e.g., *I hate all* ___, *I love all* ___) . By construction, each identity term appears 50% of the time in hateful contexts and 50% in non-hateful ones. If a model then classifies the instances related to one identity term differently than the others, it means that the model contains unintended bias towards that term, e.g., if every instance containing the term *women* is labelled hateful, independently of the context. Synthetic test sets simulate new data, so a model that has low performance on this set demonstrates low generalization abilities and incapacity to be used in real-world contexts and applications.

We test BERT+EAR on hate speech datasets with associated synthetic test sets to measure unintended bias.

MISOGYNY (EN) (Fersini et al., 2018) is a state-of-the-art corpus for misogyny detection in English.

---

[2] For complex terms, we average the attention entropy of their sub-words.

	MISOGINY (EN)	MISOGINY (IT)	MLMA
# Train	4,000	5,000	5082
# Test	1,000	1,000	565
% Validation	10	10	10
% Hate (train, test)	45, 46	47, 53	88, 88
B_2	0.858	0.852	0.881
# Synthetic	1,464	1,908	77,000
# Identity terms	12	18	50
% Hate (Synthetic)	50	50	50

Table 1: Statistics of the data sets.

The related synthetic test set (Nozza et al., 2019) was created via several manually defined templates and synonyms for "woman" as identity terms.

MISOGYNY (ITA) (Fersini et al., 2020) is the benchmark corpus for misogyny detection in Italian. The synthetic test set has been generated similarly to the English one. This dataset allows us to study EAR's impact on cross-lingual adaptation.

MULTILINGUAL AND MULTI-ASPECT HATE SPEECH (MLMA) (Ousidhoum et al., 2019) consists of tweets with various hate speech targets. We choose to work on its English part. We use the synthetic test provided in Dixon et al. (2018), generated by slotting a wide range of identity terms into manually defined templates.

Table 1 reports statistics of the data sets. Alongside the size of train, test, and validation sets, we report also the percentage of hateful instances to show the class balance. Note that MLMA is highly unbalanced with 88% of instances associated with the hateful class. Note that the original MULTILINGUAL AND MULTI-ASPECT dataset comes in a multi-label, multiple class setting. Following Ousidhoum et al. (2021), we used the *Hostility* dimension of the dataset as target label and created a *Hate* binary from it as follows. We considered single-labeled "Normal" instances to be non-hate/non-toxic and all the other instances to be toxic.

To further characterize our data sets, we explore the aspect of selection bias, reporting the measure B_2 (Ousidhoum et al., 2020). The metric ranges from 0 to 1 and evaluates how likely topics of the data set are to contain keywords of the data collection. Values above 0.7 demonstrate high selection bias, implying the need for unbiasing procedures.

We report also the size and number of identity terms used in the synthetic test sets. The percentage of hateful content is perfectly balanced (50%) since each identity term should appear exactly in the same context as the others to measure the unintended bias. See Appendix B for the list of identity terms and further preprocessing details.

3.1 Metrics

We use the weighted and binary F1-score of the hateful class ($\mathbf{F1_w}$ and $\mathbf{F1_{hate}}$) as classification metrics. We consider both due to the class imbalance of test sets (see Table 1).

We compute the unintended bias metrics from Dixon et al. (2018) and Borkan et al. (2019). They are computed from differences in the score distributions between instances mentioning a specific identity-term (*subgroup distribution*) and the rest (*background distribution*). The three per-term AUC-based bias scores are:

1) $AUC_{subgroup}$ calculates AUC only on the data subset of a given identity term. A low value means the model performs poorly in distinguishing between hateful and non-hateful comments that mention the identity term.

2) *Background Positive Subgroup Negative* (AUC_{bpsn}) calculates AUC on the hateful background examples and the non-hateful subgroup examples. A low value means that the model confuses non-hateful examples that mention the identity term with hateful examples that do not.

3) *Background Negative Subgroup Positive* (AUC_{bnsp}) calculates AUC on the non-hateful background examples and the hateful subgroup examples. A low value means that the model confuses hateful examples that mention the identity with non-hateful examples that do not.

We report the averaged metrics across identity terms, i.e., $\mathbf{AUC_{subgroup}}$, $\mathbf{AUC_{bpsn}}$, and $\mathbf{AUC_{bnsp}}$.[3]

3.2 Baselines

We compare BERT+EAR against the following existing approaches: (1) *BERT* (Devlin et al., 2019), (2) *BERT+SOC mitigation* (Kennedy et al., 2020), where the authors modify BERT's loss to lower the importance weight of identity terms, computed with the Sampling-and-Occlusion (SOC) algorithm (Jin et al., 2019), (3) Nozza et al. (2019), a single-layer neural network architecture based on the Universal Sentence Encoder (USE) representation (Cer et al., 2018), (4) Lees et al. (2020), a multilingual BERT model fine-tuned on the training data, (5) Ousidhoum et al. (2021), a classifier based on TF-

IDF and Logistic Regression, and (6) Zhang et al. (2020), a debiasing training framework based on instance weighting.

The *debiased* version proposed in Lees et al. (2020) is obtained by training the model on additional samples from Wikipedia articles (assumed to be non-hateful) to balance the distribution of specific identity terms. Nozza et al. (2019) extracted these additional non-hateful samples from an external Twitter corpus (Waseem and Hovy, 2016).

To address the impact of different term lists, we also consider two different versions of BERT+SOC mitigation, one where we test the effect of *missing identity terms* and the other where the identity terms are *translated* for adapting to a new language.

4 Experimental Results

Table 2 shows classification and bias metrics on both synthetic and test set for the three corpora, i.e., MISOGYNY (EN) (top), MISOGYNY (ITA) (middle), and MLMA (bottom). The top rows in each table section report the performance of hate speech detection models specifically proposed for the respective dataset. The lower rows show the results of baselines and BERT+EAR. BERT+SOC mitigation uses the identity terms from Kennedy et al. (2020) (see Appendix C), unless a different identity terms lists is specified (e.g., "BERT+SOC mitigation, translated ITs").

BERT+EAR obtains comparable and, in most cases, better performance on all three datasets than all state-of-the-art debiasing approaches, which are based on (i) the knowledge of identity terms and (ii) data augmentation techniques. However, identity terms are not always readily available, which severely limits the generalization of those approaches. Similarly, there are several drawbacks to data augmentation with (assumed) non-hateful samples containing the identity terms. 1) Data augmentation is expensive. It requires filtering a large dataset (usually Wikipedia) and retraining the model with a much larger set of instances. 2) Data augmentation with task-specific identity terms requires prior knowledge of those terms, and is therefore limited by the authors' knowledge. 3) The overlap between identity terms in the evaluation set and the augmented data inevitably (but somewhat unfairly) improves the performance on the synthetic dataset.

BERT+EAR is overall the best debiasing model considering the proposed bias metrics. The only exception is MISOGYNY (EN), for which BERT+EAR has lower **AUC$_{\text{bnsp}}$** and **AUC$_{\text{bpsn}}$** than BERT+SOC mitigation. The latter's advantage, however, comes with high variability in the results. BERT+SOC mitigation seems more sensitive to random initialization. The standard deviation over 10 runs is 37%, compared to 13% of BERT+EAR. Figure 4 shows the AUC$_{\text{subgroup}}$ metric separately by identity term on MISOGYNY (EN). We compare

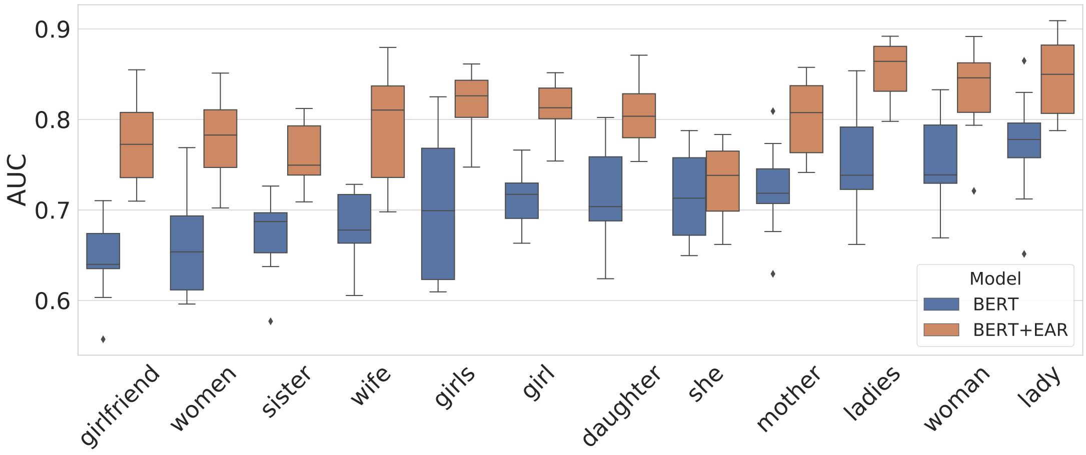

Figure 4: $\text{AUC}_{\text{subgroup}}$ results broken down by identity term on MISOGYNY (EN).

BERT and BERT+EAR over 10 different initialization runs. EAR improves BERT across all identity terms

Most existing models and AUC-based metrics for unintended bias focus only on the false positives (i.e., hateful instances wrongly recognized as non-hateful). While correctly recognizing hateful instances is important, we believe that the problem of false negatives is equally important. Since BERT+EAR does not rely on identity term lists, it regularizes terms that impact *both* the positive and negative class. BERT+EAR obtains an average decrease of 15.04% in false negative rate compared to BERT and BERT+SOC mitigation. Indeed, the performance difference between BERT+EAR vs. BERT and BERT+SOC is mainly due to non-hateful instances (∼95% of the time). Reducing the impact of overfitting terms like *f*ck* and *p*ssy* in MISOGYNY (EN) causes BERT+EAR to consider a larger context, and correctly labels them as non-hateful.

4.1 Error Analysis

Table 3 shows tweets from the MISOGYNY (EN) data set which have been correctly predicted by BERT+EAR but misclassified by BERT or BERT+SOC. These tweets serve as qualitative examples of the effectiveness of forcing the model to attend to a wider context and not overfit to training-specific terms, exploiting the richness of information (Nozza et al., 2017). The examples are an excerpt of the most common cases where BERT+EAR classifies the non-hateful examples correctly: (1) when slurs or negative words (such as *sk*nk*) are used in a non-hateful context, like slang or lyrics, (2) when many words associated with misogyny appear in the sentence (e.g., *rape*, *abuse*) and (3) when the hateful target is male and the instance should not be classified as misogynous. The use of a wider context by BERT+EAR allows the model identify such non-misogynous instances compared to BERT and BERT+SOC. In particular, BERT+SOC is even more biased in these cases because its debiasing techniques overly rely on specific terms (e.g. *woman*) and increase overfitting to training-specific examples.

4.2 Impact of predefined identity terms

We also analyze the impact of predefined identity term lists on performance by evaluating the effect of (i) missing identity terms, and (ii) adapting to a new language where the list is unavailable.

First, we remove every identity term of BERT+SOC from MISOGYNY (EN) that appears at least once in the evaluation set, here *women* and *woman* out of 24 terms. This reflects the real-world case where the identity term list does not contain a specific group present in the data. The significant performance drop resulting from this case (Table 2, top, “missing ITs”) highlights a strong weakness of term-based mitigation strategies.

Second, we analyze the case where identity terms need to be adapted to a new language, e.g., Italian. We translated the English identity terms from BERT+SOC to Italian via Google Translate.[4] Table 2 (middle, “translated ITs”) shows that the performance is lower than BERT+EAR. A simple translation of predefined identity terms is therefore not an option for cross-lingual settings. This aligns with the findings by Nozza (2021), that demon-

---

[4] For gendered Italian words, we kept both the masculine and the feminine (e.g., *muslim* → *musulmana*, *musulmano*).

strated that cross-lingual hate speech detection is limited by the use of non-hateful, language-specific taboo interjections that are not directly translatable.

In sum, we demonstrated that relying on a predefined list of identity terms is a strong limitation for performance and generalizability of the model. In contrast, BERT+EAR's independence from any predefined terms makes it the ideal model in real-world scenarios.

5 Extracting overfitting terms

While being the core of EAR, attention entropy serves another purpose. Once standard fine-tuning is concluded (i.e., with no regularization involved), models have overfitted specific terms. We identify these terms using attention entropy.

To extract the most indicative terms, we replicate training conditions. Specifically, we run inference using all the training data using a fine-tuned checkpoint and a standard BERT tokenizer. We collect attention entropy values for each term and average them over all training instances. Terms with lowest average entropy show the highest overfitting as the model learned them with a narrow context.[5]

Retrieving these terms after training allows us to gain insights into the domain and language-specific aspects driving the outcome.

Table 4 shows the top 10 terms with highest lexical overfitting on the studied datasets extracted from the corresponding fine-tuned model. We extract terms strongly correlated with the positive class, e.g., *womens*ck* (97%), *shut* (96%), *n*gger* (92%), *sb*rro* (97%), *c*lone* (95%). Note that these terms are *not* frequent in the corpus. Overfitting terms appear with an average document frequency of only 4.7%, while the most frequent terms have 32.5% average document frequency across datasets. These results suggest that the higher the class polarization of a token, the narrower the context BERT will use to learn its representation, and the higher the overfitting.

6 Related Work

The first works to study bias measurement and mitigation in neural representation aimed at removing implicit gender bias from word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017; Garg et al., 2018; Romanov et al., 2019; Ravfogel et al., 2020). More recently, researchers have started to focus on contextualized sentence representations and effective neural models for understanding the presence and resolution of bias (Nozza et al., 2021; Ousidhoum et al., 2021).

While the majority of proposed approaches focus on data augmentation (Dixon et al., 2018; Nozza et al., 2019; Sharma et al., 2020; Bartl et al., 2020; de Vassimon Manela et al., 2021), different approaches have been proposed for bias mitigation intervening directly in the objective function. Kennedy et al. (2020) proposed to apply regularization during training to the explanation-based importance of identity terms, obtained with Sampling-and-Occlusion (SOC) explanations (Jin et al., 2019). Kaneko and Bollegala (2021) pro-

posed a method for debiasing pre-trained contextual representation by retaining the learned semantic information for gender-related words (e.g., *she*, *woman*, *he*, *man*) and simultaneously removing any stereotypical biases in the pre-trained model. Zhou et al. (2021) exploited debiasing methods for natural language understanding (Clark et al., 2019a) to explicitly determine how much to trust the bias given the input. Vaidya et al. (2020) proposed a multi-task learning model for predicting the presence of identity terms alongside the toxicity of a sentence.

The main drawback of all aforementioned works is their strict reliance on a set of predefined identity terms. This list can be either defined manually by experts or extracted a-priori from the data set. In both cases, the subsequent debiasing models will be strongly affected by these biased terms, limiting the applicability of the trained model to new data. This is a severe limitation, since it is not always possible to retrain a model on new data to reduce bias, resulting in limited use in real-world cases.

7 Conclusion

We introduce EAR, a regularization approach applicable to any attention-based model. Our approach does not require any a-priori knowledge of identity terms, e.g., lists. This feature (i) allows us to generalize to different languages and contexts, and (ii) avoids neglecting important terms. Thus, it prevents the introduction of further bias. As part of the training procedure, EAR also discovers the impact of relevant domain-specific terms. This automatic term extraction provides researchers with an analysis tool to improve data collection and bias mitigation approaches.

EAR, applied to BERT, reliably classifies data with competitive performance and substantially improves various bias metrics. BERT+EAR generalizes better to new domains and languages than similar methods.

In future work, we will apply EAR-based models to different downstream tasks to both improve bias mitigation and automatically extract biased terms.

Acknowledgments

We would like to thank the anonymous reviewers and area chairs for their suggestion to strengthen the paper. This research is partially supported by funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (No. 949944, INTEGRATOR), and by Fondazione Cariplo (grant No. 2020-4288, MONICA). DN, and DH are members of the MilaNLP group, and of the Data and Marketing Insights Unit at the Bocconi Institute for Data Science and Analysis. EB is member of the DataBase and Data Mining Group (DBDMG) at Politecnico di Torino. GA did part of the work as a member of the DBDMG and is currently a member of MilaNLP. Computing resources were partially provided by the SmartData@PoliTO center on Big Data and Data Science.

Ethical Considerations

In this paper, we propose term attention entropy as a proxy for unintended bias in attention-based architectures. Our approach allows us to extract, for a given classifier and data set, a list of terms that induce most of the bias in the model. While this list is intuitive and easy to obtain, we would like to point out some ethical dual-use considerations.

The process of collecting the list is a data-driven approach, i.e., it is strongly dependent on the task, collected corpus, term frequencies, and the chosen model. Therefore, the list might lack specific terms or include terms that do not strictly perpetrate harm, but are prevalent in the sample. Because of these twin issues, the resulting lists should *not* be read as complete or absolute. We discourage users from developing new models based solely on the extracted terms. We want, instead, the terms to stand as a starting point for debugging and searching for potential bias issues in the task at hand, be it in data collection or model development.

Further, while the probability is low, we can not exclude the possibility that future users run EAR on other tasks and data sets to derive private information or profile vulnerable groups.

A Details on self-attention in Transformers

The Transformer (Vaswani et al., 2017) is the building block of many recent neural language models. A Transformer model consists of two connected encoder and a decoder units which align a source and a target sequence. Differentiating from the original formulation, large language models, such as BERT, drop the encoder and use the remaining encoder to process a single input sequence.

A transformer encoder consists of a multi-head self-attention block and a position-wise, fully connected feed forward neural network. Both the self-attention block and the feed forward network adopt a residual skip connection and batch normalization. We provide details for a standard forward pass in the encoder. In attention blocks, the multi-head output is computed with Scaled Dot-Product Attention between a set of queries and keys of dimension d_k, and a set of values of dimension d_v. Let Q, K and V be the respective matrix representations. The attention is then computed as

$$\mathrm{Attention}(Q, K, V) = \mathrm{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V$$

To improve expressiveness, the operation is performed on N different, independent linear projections of the same queries, keys and values, so that N attention heads are produced. The heads are then concatenated, projected back to the original input space, and finally fed through the fully connected neural network to produce the next layer embeddings. Let $E = [e_0, ..., e_{d_s}]$ be the sequence of input embeddings[6], with $e_i \in \mathbb{R}^{d_m}$. In the specific case of a transformer encoder, queries, keys and values correspond to the input embeddings - i.e. $Q = K = V = E$. As such, the output of the multi-head self-attention block is computed applying the previously presented Equation to the N token projections, concatenating and projecting back to the original space:

$$\mathrm{MultiHead}(Q, K, V) = (\mathrm{o}_0 || \dots || \mathrm{o}_N)\, W^O$$

where

$$\mathrm{o}_h = \mathrm{Attention}\left(QW_h^Q, KW_h^K, VW_h^V\right)$$

and W^O and each W_h^Q, W_h^K, W_h^V are projection matrices.

B Experimental setup

Hyper-parameters All our experiments use the Hugging Face transformers library (Wolf et al., 2020). We base our models and tokenizers on the `bert-base-uncased` checkpoint for English tasks and on the `dbmdz/bert-base-italian-uncased` checkpoint for Italian. We pre-process and tokenize our data using the standard pre-trained BERT tokenizer, with a maximum sequence length of 120 and right padding. We train all models with the following hyperparameters: batch size=64, learning rate=0.00002, weight decay=0.01, learning rate warmup steps=10%, full precision, maximum number of training epochs=30, and early stopping on non-improving validation loss after 5 epochs. Table 2 report results of BERT+EAR trained for 20 epochs with no early stopping, and regularization strength $\alpha = 0.01$. We chose the latter parameters with grid search on $\alpha \in [0.0001, 0.001, 0.01, 0.1, 1]$ and epochs $\in [10, 20, 30, 40, 50]$. When fine-tuning on MULTILINGUAL AND MULTI-ASPECT, we use a weighted cross-entropy classification loss ($\mathcal{L}_C$) to discount class unbalance. Specifically, we normalize the loss for data points belonging to class C by the prior probability of C, evaluated as its relative frequency in the training set.

For Kennedy et al. (2020), Nozza et al. (2019), Lees et al. (2020), and Ousidhoum et al. (2021), we kept all the parameters as specified by the respective authors. Please refer to our repository (`https://github.com/g8a9/ear`) for further details or the respective publications.

We trained all models with 10 different initialization seeds per parameter configuration and averaged over them to obtain stable results and meaningfully compute significance.

Statistical significance We compute the statistical significance of BERT+EAR over BERT and BERT with SOC mitigation via bootstrap sampling, following Søgaard et al. (2014), using ° and △ (and their filled counterparts for a stronger significance) symbols, respectively. We use 1000 bootstrap samples and a sample size of %20. For Hate Speech, significance can only be computed on F1-scores, since bias metrics require an assumption about the label distribution across identity terms that is not given.

---

[6] The input embeddings for the first layer are the static token embeddings plus their position encoding.

Selection bias We computed the $\mathbf{B_2}$ metric following Ousidhoum et al. (2020). Specifically, we run the authors' code on each of our training dataset, using the query keywords used to sample each dataset. In case of queries composed of multiple words, we split and considered them separate keywords.

Dataset preprocessing The original MULTILINGUAL AND MULTI-ASPECT dataset comes in a multi-label, multiple class setting. Following Ousidhoum et al. (2021), we used the *Hostility* dimension of the dataset as target label and created a *Hate* binary from it as follows. We considered single-labeled "Normal" instances to be non-hate/non-toxic and all the other instances to be toxic.

Computation time We report NVIDIA Tesla V100 PCIE-16GB -equivalent computation time for the tested models. Averaging across the three presented data sets, training and evaluating 10 seeds of BERT+EAR (without early stop) requires 22 hours, compared to 72 hours for BERT+SOC and 7 hours for BERT. The regularization of attention entropy does not affect the computation time by a significant amount.

$\mathbf{CO_2}$ emission Experiments were conducted using a private infrastructure, which has an estimated carbon efficiency of 0.432 $kgCO_2eq/kWh$. A cumulative of 319 hours of computation was performed on the hardware of type Tesla V100-PCIE-16GB (TDP of 300W). Total emissions are estimated to be 41.34 $kgCO_2eq$.

Estimations were conducted using the Machine Learning Impact calculator presented in (Lacoste et al., 2019).

C List of identity terms

In the following, we report the list of identity terms used in the considered data sets and methods.

From BERT's Point of View:
Revealing the Prevailing Contextual Differences

Carolin M. Schuster
Technical University of Munich
carolin.schuster@tum.de

Simon Hegelich
Technical University of Munich

Abstract

Though successfully applied in research and industry large pretrained language models of the BERT family are not yet fully understood. While much research in the field of BERTology has tested whether specific knowledge can be extracted from layer activations, we invert the popular probing design to analyze the prevailing differences and clusters in BERT's high dimensional space. By extracting coarse features from masked token representations and predicting them by probing models with access to only partial information we can apprehend the variation from 'BERT's point of view'. By applying our new methodology to different datasets we show how much the differences can be described by syntax but further how they are to a great extent shaped by the most simple positional information.

1 Introduction

By taking on the perspective of BERT and presenting the methodology to explore this point of view we contribute a new approach to BERTology research, a field that has emerged for a number of good reasons.

Ever since the original BERT paper (Devlin et al., 2019) combined masked language modeling (MLM) with massive pretraining and the transformer architecture (Vaswani et al., 2017), models of the BERT family have achieved a variety of new Natural Language Processing (NLP) benchmarks. While their success is driven by the contextualization of words it is clear that these models do not yet have a real understanding of language (Bender and Koller, 2020). Still, researchers are struggling to find out what it is exactly that they learn and how they perform so well. Challenges are the high number of parameters over which the model knowledge is distributed, and the innumberable different patterns the models can potentially gather from text.

BERTology takes on this quest of understanding the inner workings of these large pretrained models to drive further improvements and identify the next steps towards general AI. Though the training of ever greater models with ever more data has been criticized because of the societal costs and risks these models bring with, including bias and discrimination (Bender et al., 2021). Nevertheless, because of their high performance they are already employed in research but also industry-applications, which exacerbates the need for their explainability.

The black box of Bidirectional Encoder Representations from Transformers (BERT) and its relatives commonly consists of 6-24 identical transformer encoder layers. Each layer comprises a multi-head-attention block followed by a fully connected block, with both being bypassed by residual connections (Vaswani et al., 2017). This stack of layers is primarily pretrained with MLM, the task of predicting a randomly masked (or replaced) word in an input text, and can afterwards be fine-tuned to specific tasks. Next to attention scores, layer activations are a popular choice for analysis, as they conflate the information from attention heads and skip-connections and represent the stages of the contextualization process.

BERT layer activations are most prominently scrutinized by the so-called edge probing design, in which they are treated as the fixed input to another neural network trained on specific NLP tasks (Tenney et al., 2019). Previous research has employed this method to test them for information on word senses or grammatical properties, but this does not reveal how much the information shapes the space.

By inverting the probing design we present a new way to analyze layer activations, specifically their prevailing patterns, complementing the existing methodology. In contrast to the regular process, we do not use them as input but as the output of

Findings of the Association for Computational Linguistics: ACL 2022, pages 1120 - 1138
May 22-27, 2022 ©2022 Association for Computational Linguistics

a model. We reduce their dimensionality by clustering and principal component extraction to capture the predominating differences within a dataset. By declaring these differences as our ground truth and explaining them in a second step, we can render visible the salient patterns and groupings from 'BERT's point of view'. We chose this term to signal the shift of the perspective, from any contextual information a human might deem important to the information that actually predominates the representative space of the models.

For different datasets we extract the layer activations of masked tokens, meaning that all analyzed tokens start out with identical representations. With this setup we can be sure that the differences we analyze are derived from context and are not caused by different pretrained embeddings. As masked language modeling continues to be a popular and successful pretraining objective, it is of particular interest which patterns are exploited when a model is determining the identity of a masked token.

For the prediction of the representative features we train three types of probing models that receive as input a simplified version of the token context: bag-of-words, ordered part-of-speech tags and simply the position of the token in a sentence. By the disentanglement of these information types, the probing results provide indications about their importance for shaping the representative space.

Social science shows that contrastive explanations are more relevant to humans than complete explanations (Miller, 2019), which affirms the necessity of methods that focus on the contrasts perceived by black box models. For a specific dataset of masked tokens our methodology reveals the most salient differences between their contexts.

Contributions With our methodology we offer a new perspective on the contextual representations inside masked language models: The contrasts within a dataset from BERT's point of view.

By its application we render visible how well syntax describes the coarse patterns of the space but further how much of this description is possible by mere simplistic positional information.

Finally we demonstrate the danger of misinterpreting the learned patterns of the models due to the correlational nature of separated information types which may also lead to an overestimation of the models' sophistication.

2 Related Work

In the field of BERTology (see Rogers et al., 2020 for a general overview) much research has focused on three components; the self-attention mechanism, a key component of the transformer architecture that provides intuitive explanations (see e.g. Kovaleva et al., 2019, Manning et al., 2020, Clark et al., 2019), individual neurons (e.g. Luo et al., 2021) and the layer activations that are scrutinized in our work. Frequently the edge probing design (Tenney et al., 2019) has been deployed to analyze the contents of these activations, in different settings such as after finetuning (Merchant et al., 2020) and with various modifications. Amnesic probing measures what information gets used in the probing tasks by removing selected properties (e.g. part-of-speech) from the activations (Elazar et al., 2021). Similarly O'Connor and Andreas (2021) measured usable information when increasing context size and ablating features of this additional context, e.g. by shuffling. In a parameter-free approach Wu et al. (2020) analyzed the output representation of a masked token by additionally masking other tokens in its proximity to determine their impact.

Another stream of research explores the geometrical space of layer activations. A common approach is the direct measurement of similarities, e.g. between instances of the same token and tokens of the same sentences (Ethayarajh, 2019; Peters et al., 2018) or between instances of homonyms and synonyms (Garcia, 2021). Further work analyzes the separability of predefined categories (e.g. word senses) by manifold analysis (Mamou et al., 2020), by measuring categorical cohesion with silhouette scores (Mickus et al., 2020) or a nearest-neighbor classifier (Coenen et al., 2019), or by searching for clustering solutions that correspond to the categories (Yenicelik et al., 2020). The similarities to our work are the focus on word level representations and the search for categories, though our clusters are not predefined by us but are the groupings inherent to our datasets from BERT's point of view.

Much of the described work concerns only representations of unmasked tokens, except for e.g. Wu et al. (2020) and Mamou et al. (2020), but as masked language modeling continues to be a popular training objective the study of contextual information of masked tokens is highly relevant.

3 Experimental Setup

Because of the various components of probing classifiers and their respective interactions, the design of such is non-trivial (Belinkov, 2021). This is also true for this new, inverted type of probing process that we present here.

3.1 Data

For this analysis of salient differences between large numbers of datapoints the composition of the dataset determines what can potentially be found. Differences may be related to semantics, syntax but also to artifacts that humans are unaware of. Which of the existing distinctions shape the representations in turn depends on if and how these patterns are utilized by the studied model.

The prevailing differences thus depend on:

- The availability of different patterns
- The frequency of available patterns
- BERT's attention to available patterns
- BERT's integration of available patterns

The choice of data is contingent on the objective; it thus can be a specific NLP dataset to understand a model's task performance or a new dataset that we wish to interpret. For an explorative analysis of BERT's view the data can be used as is, but for an analysis of the relevance of specific patterns it is necessary to control their availability and frequency within the dataset. Patterns that are the same across all examples do not influence the feature extraction process.

The tokens to be masked can be one or more frequent words, word senses or syntactical functions, e.g. Part-of-Speech, depending on the selected dataset and the contexts of interest. The diversity of contexts and contextual representations may differ much depending on the token, especially as contextual information not only gives clues about the word behind the mask but also about its interpretation - additional meaning that is attached to it. This is especially true for tokens that signify entities as they are subject to opinions, e.g. "person". This is also reflected by the great amount of sensible candidate words, e.g. named entities, professions or even insults, compared to a masked determinator token "the" or other stopwords.

We selected four datasets from two sources and with different masked tokens to demonstrate the varying patterns that are salient in different kinds of datasets. Data collection and preprocessing steps are listed in Appendix C.

SemCor&OMSTI noun-synsets Our first dataset stems from the combined word-sense annotated corpus (Raganato et al., 2017) of SemCor (Sense-tagged Semantic Corpus) (Miller et al., 1991) and OMSTI (One Million Sense-Tagged Instances) (Taghipour and Ng, 2015). We selected three frequent noun synsets for masking: person.n.01, manner.n.01 and line.n.16, and stratified according to synset, which resulted in a dataset of 6048 masked tokens. While these words are all nouns, they are still used in different syntactic settings.

SemCor&OMSTI person.n.01 From the same combined, sense-annotated corpus we masked all 7702 instances of the synset person.n.01. This includes instances of the word "person" but also named entities.

cctweets-random Our cctweets data consists of tweets about climate change activism that were collected during and after the UN Climate Change Conference in 2019. Ethical considerations of data privacy are elucidated in Appendix A. The discourse was highly polarized, containing diverging representations of the same issues, posing the question of what differences would be salient in the presence of such polarization. We masked random tokens for explorative analysis and as comparison to the cctweets-activist dataset. This dataset comprises 155952 instances.

cctweets-activist Our last dataset consists of climate change related tweets with 132710 masked mentions of a prominent climate change activist, as this person was the center of attention of the discourse. Therefore we could extract thousands of lexically identical instances with different depictions. This dataset represents the use case of searching for semantic groupings based on interpretations from context.

3.2 Feature Extraction

For the investigation of salient differences between the masked token representations we chose k-means clustering and principal component analysis to produce both categorical and continuous features. The appropriateness of either method depends on the properties of the data and we show the results for both, for all of our datasets.

input type	example tokenization	example tensor
Bag-of-Words	who is mask	[0 1 0 0 1 0 1 0 0]
Part-of-Speech	[PAD] [PAD] WP VBZ [MASK] [PAD] [PAD] [PAD] [PAD]	[0 0 4 6 1 0 0 0 0]
Position	[PAD] [PAD] [MASK] [MASK] [MASK] [PAD] [PAD] [PAD] [PAD]	[0 0 1 1 1 0 0 0 0]

Table 1: Input Format: Bag-of-Words, Part-of-Speech and position.

However it is achieved the dimensionality reduction helps humans to grasp the coarse patterns of the space, which is not possible with the raw distributions of meaning over 768 dimensions (bert-base-uncased). Categorizing and aligning datapoints along a single dimension, e.g. ranking them according to some quality, are furthermore tasks that humans not only understand but perform themselves on a daily basis, which underlines the importance of representing the data accordingly.

It has been shown that none of the layer representations of BERT are uniformly distributed with respect to direction (Ethayarajh, 2019) and it is thus important to note that the methods applied here are susceptible to this anisotropy. This does not contradict our design, as we want to describe distances as they are, also showing possible causes for anisotropy. The goal is not to tune our feature extraction methods but to understand how we may want to change the language models themselves.

K-Means Clustering The purpose of clustering is finding distinct groups of similar contexts and it is performed directly on the raw, extracted layer representations. We chose a robust, widely-used algorithm to capture obvious clusters, namely k-means, which we ran with the default configuration of the scikit-learn library. This means 10 runs with different centroid initializations, returning the best solution. We leave the experimentation with different clustering algorithms for future work, but it should be noted that feature extraction methods should remain simple, as complex features will take away from the explainability power of the method.

As we do not know the correct numbers of clusters we cluster for different values of k (2-30) and also utilize silhouette scores to identify the optimal value, thus showing what might be a useful granularity from BERT's point of view. Silhouette scores are a measure of how similar datapoints are to points within their cluster as opposed to points of neighboring clusters (Rousseeuw, 1987). We select common values 2 and 5 to perform the probing for better comparability between settings.

Principal Component Analysis By rotating our axes with principal component analysis (PCA) we obtain the uncorrelated dimensions along which there is the most variation. Thus they are continuous representations of the biggest divergences that are perceived by the BERT models. This is a useful, straightforward alternative to the categorization by clustering when the clusterability of the representative space is low. We choose to analyze the first two principal components with our probing method.

3.3 Pretrained Models

For the extraction of the masked representations we chose two models of the BERT family. First bert-base-uncased (Devlin et al., 2019), which is the standard sized original BERT model and second, deberta-base (He et al., 2020), a modification that has recently been a prominent name on NLP benachmark leaderboards, e.g. SuperGLUE (Wang et al., 2019). The models were retrieved from the Huggingface Transformers library (Wolf et al., 2020).

3.4 Probing

Our reversed probing methodology predicts the features we extracted from BERT representations and takes as inputs simpler features that we obtain from the texts. These inputs are chosen to provide different kinds of contextual information to our probing models. By optimizing these models we can then find out how well our coarse BERT features are described by this information.

To find out how much co-occurences — unordered meaning — and how much syntax shape our coarse BERT features, we disentangle these types of information from our context sentences by creating two input types. The first is a bag-of-words vector that considers all context words of a masked token, while the second input type is a part-of-speech embedding that retains the original order of the context tokens. Because a preliminary qualitative analysis of clusters showed that much of the performance of the syntax classifier may be due to the positional information it receives, we added a third position-only input type. This list of classifiers is not conclusive, but rather a starting point and may also be expanded depending on what additional information is available. Table 1 shows the overview of the selected information and input formats.

For better comparability and similar optimization, we chose to build the architecture of these classifiers identically except for the input layer. While the first layer of the BOW model is fully-connected and accepts a multi-hot vocabulary vector, the POS architecture requires an actual embedding layer. Position is retained simply by centering the masked token and padding on both sides until maximum sequence length. A linear layer aggregates the information over the sequence dimension, arriving at a fixed-length syntax embedding. The position classifier functions similarly, without the additional embedding dimension. For all probing models we append one hidden and one output layer with ReLU activations in-between.

Implementation The probing classifiers were implemented with the Huggingface Transformers Trainer Loop (Wolf et al., 2020) with AdamW optimizer (Loshchilov and Hutter, 2019) and a linear learning rate schedule. Hyperparameter search was realized with Optuna (Akiba et al., 2019) and is described in Appendix D. For the cluster prediction models the cross-entropy loss was calculated with balanced class weights and the best model was selected by Macro-F1 score, as we care equally about all identified clusters. The best models for the regression of principal components were determined by MSE-loss.

4 Results

For the investigation of prevailing differences discerned by the models, we are starting with a manual inspection of the PCA plots for bert-base-uncased in Figure 1 and deberta-base in Figure 3, observing that the contextual space for some combinations of datasets and layers exhibits quite distinct clusters. The presence of further clusters is indicated by their optimal number as determined by silhouette scores, shown in the lower right corner of the individual plots. The datapoints are colored according to positional information, here simply defined as the first character of the masked token divided by the number of characters in the sentence. From these visuals alone we can already learn that positional information greatly shapes the principal components and visible clusters. Some clusters are completely defined by a specific position while others are internally arranged by this feature.

The probing results for the test datasets are shown in Figure 2 for bert-base-uncased and Figure 4 for deberta-base (evaluation results can be found in Appendix E). For almost all studied representations the Part-of-Speech models perform best or are on par to the Bag-Of-Words models. The performance gap is more distinct for the explained variance of the principal components with an 0.21 average difference in R^2 but only 0.1 for the Macro-F1 scores of the cluster predictions. Notably, while the position models can never outperform the POS models, as they receive only the position-related subset of their contextual inputs, they achieve a large percentage of their performance for many settings, corroborating the finding of the visibly prevailing positional information. Here the performance gaps are 0.40 for R^2 and 0.26 for the Macro-F1 scores, averaged over all studied settings, showing how much the part-of-speech tags add to the explanations.

For some datasets the plots of BERT and deBERTa closely resemble one another, especially for the noun-synsets. Strikingly, though the data consists of three equally-sized groups of synsets, there are exactly two clusters visible in 2D. The cluster assignment plots for best values of k in Appendix F show that for some layers of BERT and deBERTa the k-means algorithm does manage to differentiate all three of the synsets. Since the probing results are similar as well, we can conclude that BERT's and DeBERTa's point of view do correspond for this dataset. Qualitative inspection found that the synsets person.n.01 and manner.n.01 adjoin while line.n.16 is spatially far removed. While positional information visibly permeates the clusters the distance between them is described almost perfectly by the POS models, thus by syntactic contextual differences. However, the almost equal performance of the BOW models shows the correlation of part-of-speech with bag-of-words patterns that can be exploited.

For the dataset of masked person.n.01 synsets the BERT and deBERTa 2D-projections appear less alike, especially for layer 6. In this setting the POS model's performance for the regression of BERT's principal components greatly exceeds all others with 88% of their variances explained. Further analysis showed that the cluster in the upper half of the plot contains only instances of masked to-

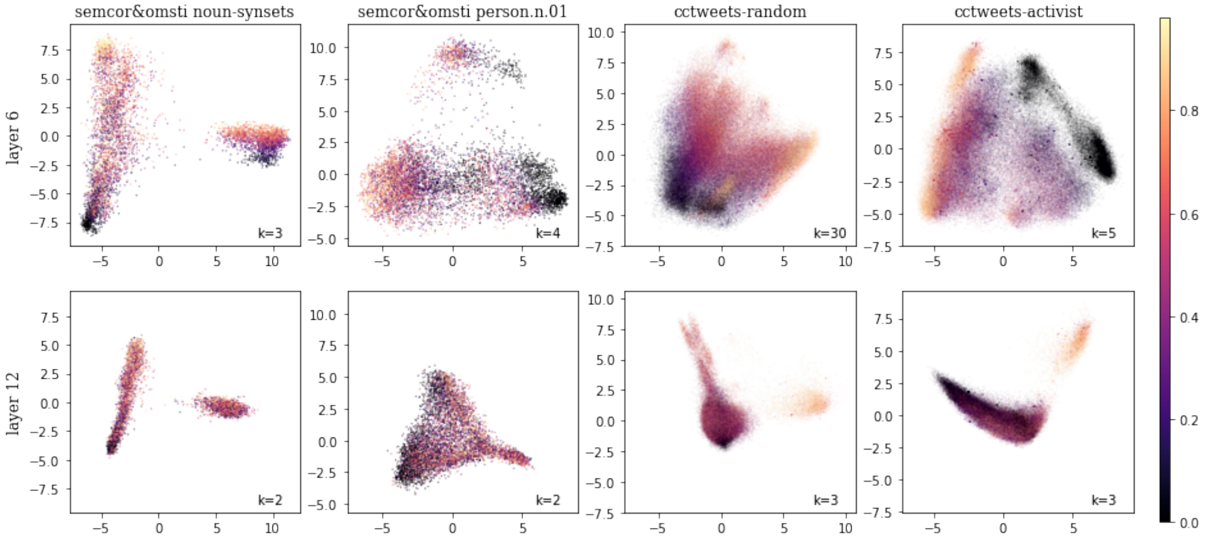

Figure 1: BERT-base-uncased 2D Principal Components. Datapoints are colored by positional information, calculated by the first character of the masked token divided by the number of characters of the sentence. K indicates the number of clusters with the best silhouette score. Extended plot with additional layers: Appendix 5.

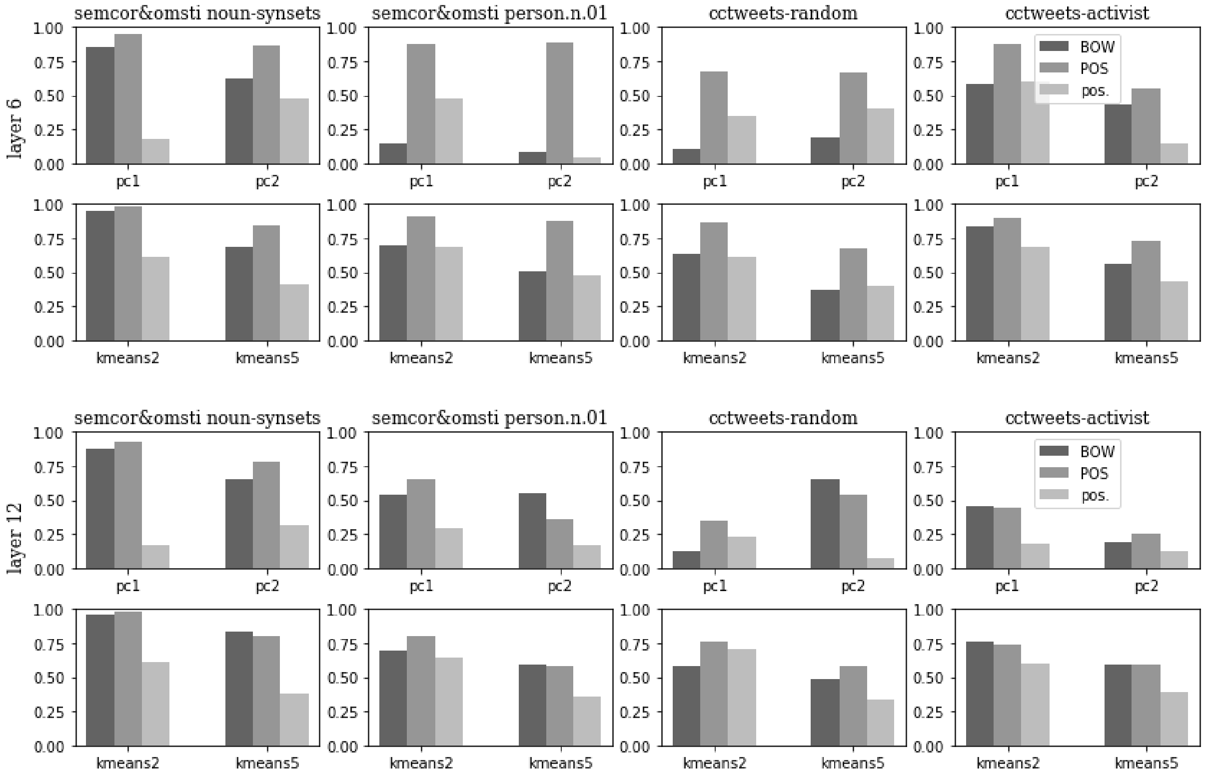

Figure 2: BERT-base-uncased Probing Test Results. Reported scores are Macro-F1 for k-means prediction and R² for the regression of principal components.

kens that were followed by an apostrophe, showing that his specific syntactic pattern is perceived as significantly different. Because of the very low performance of the BOW regression model, we can be sure that this difference is indeed caused by syntax and not by co-occurences. The diverging results for the k-means-2 model expose that the clustering algorithm found a different one than the visible grouping solution (see also plots with cluster assignments for k=2 in Appendix 6).

For both the twitter datasets of random masks and masked activist tokens the final layer of BERT

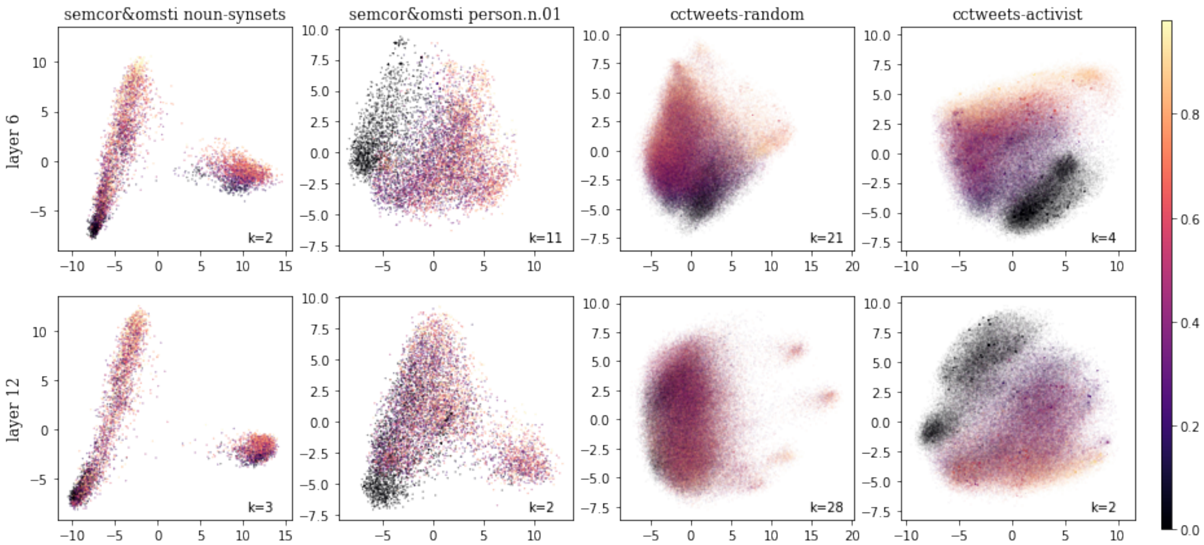

Figure 3: DeBERTa-base 2D Principal Components. Datapoints are colored by positional information, calculated by the first character of the masked token divided by the number of characters of the sentence. K indicates the number of clusters with the best silhouette score. Extended plot with additional layers: Appendix 8.

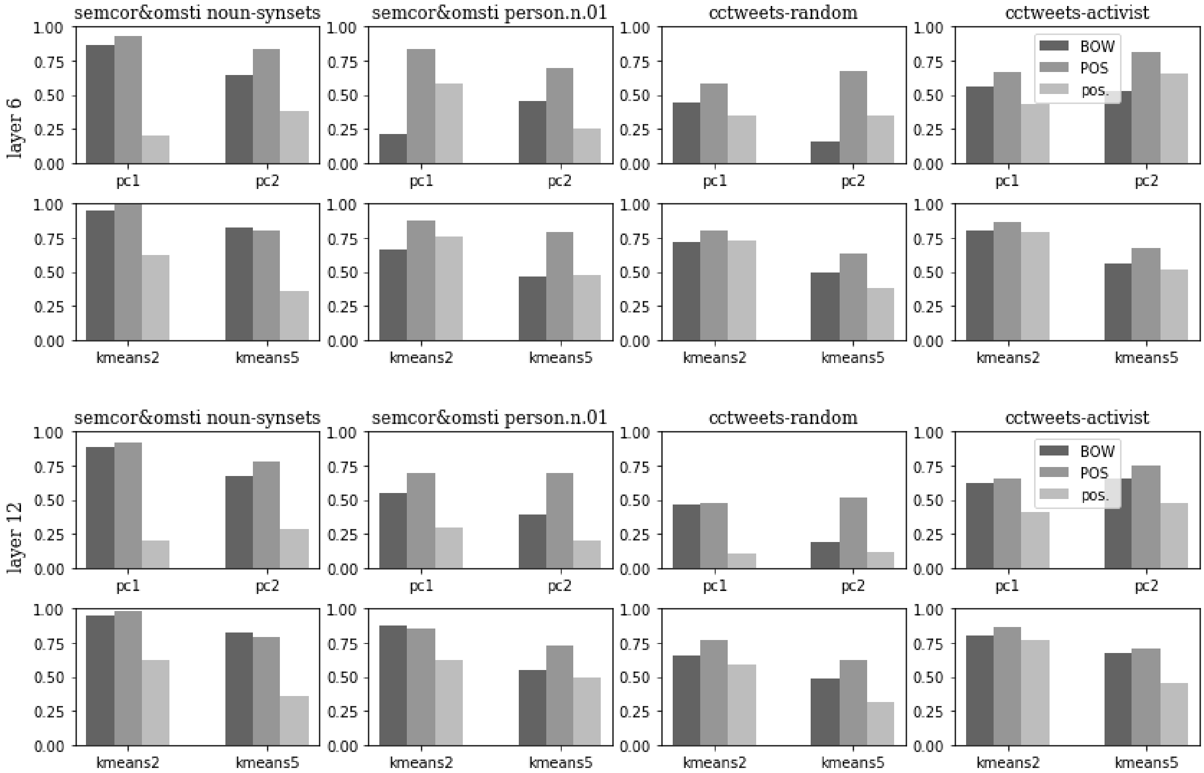

Figure 4: DeBERTa-base Probing Test Results. Reported scores are Macro-F1 for k-means prediction and R² for the regression of principal components.

singles out those that appeared at the end of the sentence. Qualitative investigation showed that this is the case regardless if the token was the final one or followed by a punctuation character. For DeBERTa the space of cctweets-activist is characterized by position to a greater extent than that of cctweets-random, as evident from the visuals and the performances of the position models. The numbers of clusters as suggested by silhouette scores are much higher for the random masks. While the BERT and DeBERTa perspectives on the dataset with equally sized groups of synsets seem quite identical, the cases of one synset or random masks reveal rather different perceived contextual differences.

5 Discussion & Conclusion

In contrast to much recent BERTology work of predicting specific syntactic and semantic information from layer activations, we invert the probing design to instead predict features of the representative space itself. From masked token representations we extract clusters and principal components of contextual information and explore their nature by probing models that receive as input detangled types of information. We thus paint a picture of the dissimilarities and groupings within a dataset from BERT's point of view, thereby expanding existing probing methodology by a crucial perspective.

Our analysis shows that the representative space of contextual information does exhibit clusters. Most clusters and principal components of our datasets are best described by the Part-of-Speech models, however, for many settings the positional probing models can achieve 50% or more of the POS performance. This shows how the representative space of both BERT and DeBERTa is greatly shaped by the most simple positional information, even though these models handle positional embeddings differently. As demonstrated by Geirhos et al. (2020), neural networks are prone to shortcut learning, and thus position may be one such shortcut. On the other hand, for the standard BERT it was shown that the representative space is anisotropic due to outlier neurons capturing positional information, which was attributed to Layer Normalization (Luo et al., 2021).

The usual probing classifier architecture that receives representations as input and predicts a specified linguistic property cannot clarify, if the representations are actually informed by the linguistic property of interest or by other, correlating properties of the training data (Belinkov, 2021). In our analysis the for some cases equal performance of detangled semantics (Bag-of-Words) and syntax (ordered Part-of-Speech tags) shows as well their correlational nature and the difficulty of pinpointing which features are actually utilized by large masked language models. When simplistic and meaningful features correlate this provides the danger of assuming that the models are much more sophisticated than they actually are.

We do not attempt to answer the question of what information should predominate the representational space, but it is likely that the optimum is not reached with features as simple as the position of a token in a sentence. We expect the best solutions to be defined by more sophisticated features that are not obtainable with simple string analysis, and which might even be utilizable for data analysis and hence other fields of research.

Concluding, our methodology delivers clues about the shortcomings of language models and the shortcuts that they are exploiting, to highlight directions of further adjustments of training objectives and processes in the future.

We hope that this work inspires more researchers to look at the world from BERT's point of view, to understand how it differs from ours. By recognizing the nature of their current primitivity we can generate new ideas on how to improve these large language models, gradually moving in the direction of a more general AI.

Limitations The prevailing contextual patterns that are revealed by this method are not universal but are always contingent on the analyzed datasets. Accordingly these have to be chosen and controlled depending on the research objective.

For the extraction of categories by clustering, selecting the appropriate number of clusters is nontrivial. Here the number of clusters was set to equal numbers to allow for a comparison between datasets and layers, but these may not reflect the inherent number of groupings.

Lastly this method, as with any method that analyzes individual parts of a network in isolation, does not explain how the identified prevailing information is utilized during task performance.

Future Work A promising extension of this work will be to enlarge the set of probing models to even better partition the different types of information, to better understand their contributions. Examples of further relevant input types are a windowed Bag-of-Words or Bag-of-Words filtered by word types. Furthermore it would be highly interesting to compare the POS model to other embedding models (e.g. simply word embeddings) with identical structures.

The settings that may be analyzed by this method are various, such as the finetuning process, to explore how the prevailing patterns shift when models adapt to particular tasks. A comparison between models of different languages may reveal different focuses and varying correlations of information types.

The described method is applicable also for the analysis of unmasked tokens though then the process of contextualization will differ from the very first layer depending on the token. The masked and unmasked contextualizations are moreover shaped by different objectives, predicting masked tokens and predicting potentially perturbed tokens, which may result in attention to different contextual patterns.

Finally it may be fruitful to utilize gradient-based attribution methods to pinpoint not just the relevance of input types but the relevance of specific inputs and positions from BERT's point of view.

A Ethical Considerations

This work utilizes public discussions by private individuals on Twitter. The tweets were collected with the Twitter streaming API and all information of the tweeting users, including user names and ids, was discarded. However, sensitive information is also found within the analyzed texts, none of which are made public. The tweets are stored with restricted access and will be deleted upon research conclusion. Afterwards only the tweet ids will be available, which can be hydrated through the Twitter API only for tweets that still are public.

B Computing Infrastructure & Runtimes

A Nvidia GeForce RTX 2080 Ti graphics card was used for the training and evaluation of the probing models. The hyperparameter search with 50 runs lasted 28 minutes on average and the final models were optimized with an average of 6 minutes training time.

C Data Collection & Preprocessing

The unified sense-tagged corpus of SemCor and OMSTI was obtained from `http://lcl.uniroma1.it/wsdeval/training-data` (Raganato et al., 2017).

The Part-of-Speech tags for the POS probing models were obtained by the nltk python package. Specialized taggers for Twitter data are available but were not deemed necessary as most of the twitter-specific artefacts were removed during preprocessing.

For probing the datasets were split randomly into training, evaluation and test sets by the ratio 70:15:15.

Twitter datasets Tweets were collected through the Twitter Streaming API with keywords related to climate change and activism. The timeframe of collection was during and after the United Nations Climate Change Conference in 2019 (COP25): 2.-19.12.2019 As per Twitter policy only the ids of tweets are made available, which can be rehydrated with the Twitter API.

- Filters:
  - only English tweets
  - no replies
  - at least three words
  - only sentences / sentence-like phrases
  - duplicates removed
- Preprocessing:
  - removing URLs
  - removing hashtag and mention sequences if n > 1
  - pruning repeating characters and words if n > 3
  - random masking /masking first token that matches activist pattern
  - obtaining sentences / sentence-like phrases containing the mask token

D Hyperparameter Search

Hyperparameter search was performed for a sample of the analyzed probing settings: For each combination of the 4 datasets, 3 input types (bag-of-words, part-of-speech and position) and 2 output types (k-means, principal component), 3 settings were sampled and hyperparameter search was conducted with Optuna for 50 runs. The search results were then pooled for each combination.

The search space and pooling strategy are shown in Table 2. Preliminary experiments had shown that one hidden layer was a generally good choice for network depth, but network width was included as a search parameter. The determined values for the hyperparameters stayed within the search boundaries, except for two cases where n_hidden was equal to the maximum value. Thus additional trials were run to find out if representational capacity had to be increased further with the maximum value found to be 2060.

hyperparameter	search space	pooling
hidden_layer_size	128 - 2048	max
batch_size	8 - 64	mean
learning_rate	1e-5 - 1e-1	mean
n_steps	5000 - 50000	max + 5000

Table 2: Hyperparameter Search Space and Pooling Strategy.

For batch_size and learning_rate the values were aggregated by averaging, but to ensure a sufficient capacity of the network layer_size was set to the maximum. The number of training steps was set to the maximum plus additional 5000 steps to ascertain sufficient training for any configuration. As the best checkpoint is selected for testing, this does not hurt the performance of faster converging models.

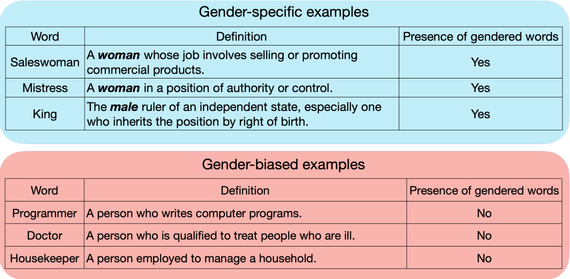
Abstract

Pre-trained word embeddings, such as GloVe, have shown undesirable gender, racial, and religious biases. To address this problem, we propose DD-GloVe, a train-time debiasing algorithm to learn word embeddings by leveraging dictionary definitions. We introduce dictionary-guided loss functions that encourage word embeddings to be similar to their relatively neutral dictionary definition representations. Existing debiasing algorithms typically need a pre-compiled list of seed words to represent the bias direction, along which biased information gets removed. Producing this list involves subjective decisions and it might be difficult to obtain for some types of biases. We automate the process of finding seed words: our algorithm starts from a single pair of initial seed words and automatically finds more words whose definitions display similar attributes traits. We demonstrate the effectiveness of our approach with benchmark evaluations and empirical analyses. Our code is available at `https://github.com/haozhe-an/DD-GloVe`.

1 Introduction

Word embeddings can meaningfully capture semantic and syntactic similarities between words. Popular embeddings are Word2Vec (Mikolov et al., 2013b), GloVe (Pennington et al., 2014), and FastText (Bojanowski et al., 2017). Although contextual word embeddings, like BERT embeddings (Devlin et al., 2019) and ELMo (Peters et al., 2018), gain increasing popularity, some recent research keeps using static word embeddings as input to their state-of-the-art algorithms in downstream natural language processing and computer vision applications (Guan et al., 2021; Gao et al., 2021).

Despite the effectiveness of word embeddings, biases in them reflect undesirable association between some concepts. Bolukbasi et al. (2016) first identify that the distance between $\overrightarrow{\text{man}}$ and $\overrightarrow{\text{woman}}$ is close to that between $\overrightarrow{\text{programmer}}$ and $\overrightarrow{\text{homemaker}}$. Similar phenomena in word embeddings lead to biased interpretations in the word analogy task, associating certain words with gender, racial, and religious stereotypes (Manzini et al., 2019). Deploying such biased word embeddings in downstream tasks would cause allocational and representational harms (Blodgett et al., 2020). It is important to learn bias-reduced word embeddings.



Gender-specific examples

Word	Definition	Presence of gendered words
Saleswoman	A ***woman*** whose job involves selling or promoting commercial products.	Yes
Mistress	A ***woman*** in a position of authority or control.	Yes
King	The ***male*** ruler of an independent state, especially one who inherits the position by right of birth.	Yes

Gender-biased examples

Word	Definition	Presence of gendered words
Programmer	A person who writes computer programs.	No
Doctor	A person who is qualified to treat people who are ill.	No
Housekeeper	A person employed to manage a household.	No

Figure 1: Definitions of example gender-specific and gender-biased words. Gender-specific words typically contain gendered words in their definitions, whereas gender-biased words tend to have neutral definitions.

Dictionary definitions, however, are a neutral source for mitigating biases in word embeddings. The objective, impartial, and concise definitions of words in a dictionary could be unbiased reference points. We propose to encourage word embeddings to be similar to their relatively neutral representations in a dictionary for bias reduction. We simultaneously train and debias the word embeddings from a new initialization point, so as to learn distributional representations and mitigate biases using dictionary definitions concurrently. In addition, several gender-debiasing algorithms rely on a list of pre-compiled seed words to approximate the gender direction, along which the vector component is removed for bias mitigation. We find that, given one pair of the initial seed words, dictionary definitions can help automatically search relevant seed words. Thus, the compilation of seed

---

Findings of the Association for Computational Linguistics: ACL 2022, pages 1139 - 1152
May 22-27, 2022

words becomes automated. We also find that the automatically generated seed words better capture the notion of gender in the word embedding space.

Our contributions Leveraging the advantages of dictionary definitions, we propose DD-GloVe, a train-time debiasing algorithm to learn bias-reduced GloVe word embeddings. In summary, we make the following contributions:

1. We propose four dictionary-guided loss functions that encourage word embeddings to contain less biased information and richer semantic knowledge by referencing to their relatively neutral dictionary definition representations. (Sec. 3.1)
2. DD-GloVe automatically approximates the bias direction given only one pair of initial seed words. This method finds the most attribute-specific definitions by computing the definition embeddings' projection onto the difference of the initial seed words' definition embeddings. We average the embeddings of the most attribute-specific words to approximate the bias direction. (Sec. 3.2)
3. We empirically demonstrate that DD-GloVe effectively learns bias-reduced word embeddings as we achieve state-of-the-art results in WEAT. Also, our experiments show that debiasing is achieved without sacrificing semantic meanings. (Sec. 4)

2 Motivations

We analyze the limitations in current debiasing algorithms for word embeddings and present our corresponding solutions.

Debiasing algorithms Existing mainstream gender-debiasing algorithms are projection-based post-processing (Bolukbasi et al., 2016; Wang et al., 2020). They need a list of manually selected words (e.g. "she" and "he", "girl" and "boy", "woman" and "man") to compute a gender direction in the word embedding space. They then project the pre-trained word embeddings onto the gender direction and remove the vector component living in this direction. The resultant word vectors preserve useful semantic meanings but contain less gender information. However, these algorithms do not consider the possible usage of additional knowledge like dictionary definitions. Furthermore, there is a limitation in this projective post-processing approach. The manually compiled list to approximate the bias direction might be difficult to obtain for other types of biases. It would be helpful to find an alternative that involves less human labor.

Our approach: using dictionary definitions Using dictionary definitions to train bias-reduced word embeddings could address the above limitation and gives us additional advantages.

(1) Dictionary definitions provide a source of unbiased word representations for debiasing. We define *gender-specific words* as words that are supposedly associated with a particular gender by their definitions. Some examples of gender-specific words are "countryman", "countrywoman", "fraternal", and "sororal." We define *gender-biased words* as words that could refer to a person of any gender but tend to be stereotypically recognized as one gender due to human biases. For example, "nurse", "cashier", and "driver" are gender-biased words. *Gendered words* are a list of 1,441 words compiled by Wang et al. (2020) that explicitly define or describe a gender. Examples of gendered words are like "man", "woman", "he", and "she." In a dictionary, gender-specific words typically contain gendered words in their definitions, whereas gender-biased words tend to have neutral definitions. Example words and their definitions from Oxford online dictionary[1] are shown in Fig. 1. We further obtain 379 gender-specific words, compiled by Wang et al. (2020), and 40 words of gender-biased occupations, compiled by Zhao et al. (2018a), to verify if this trend is general. For each definition of the words, we check whether any gendered words are present. We find that gendered words are absent from 39 out of 40 gender-biased occupations. This result shows dictionary definitions are almost bias-free. In contrast, gendered words are present in 327 out of 379 gender-specific words' definitions. This shows that if a definition contains a gendered word, it is highly likely that the word defined is gender-specific. Dictionary definitions can thus act as a reliable guidance for bias mitigation.

(2) Dictionary definitions could automate the process of finding seed words that approximate the bias direction. We compare definition similarities to find words that commonly associate with some attribute. It is relatively easy to obtain one pair of seed words that describe two opposite concepts associated with a protected attribute (e.g. "she" and "he" for gender). We then look into the definitions of these initial seed words, and find other words whose definitions are similar to theirs. As a measure of similarity, we compute the projection onto

---

[1] https://www.lexico.com/

the difference between the definition embedding of one initial seed word and the definition embedding of the other. Detailed algorithm is described in Sec. 3.2. This method avoids using manually compiled words to approximate the bias direction.

(3) Dictionary definitions offer additional semantic knowledge. Researchers improve word embeddings using dictionary definitions (Faruqui et al., 2015; Tissier et al., 2017). These works primarily enhance semantic meanings of word embeddings rather than reduce biases in them. Nevertheless, their successes indicate the possibility to preserve, or even enhance, the semantic meaning representations of word embeddings as we use dictionary definitions to debias them.

Existing dictionary debiasing algorithm A recent work makes the first attempt to debias word embeddings using dictionary definitions via post-processing (Kaneko and Bollegala, 2021). They compute a weighted average of pre-trained word vectors as the definition embeddings. They assume these definition embeddings are the "neutral" reference points for word embeddings. However, this is a major flawed assumption in post-processing debiasing. Due to the biases in pre-trained word vectors, the definition embeddings also contain biases. Partially owing to this flawed assumption, their resultant embeddings show limited effectiveness in several benchmark evaluations like the Word Embedding Association Test (Caliskan et al., 2017).

Our approach: training from scratch Training from scratch addresses the problem of biased definition embeddings computed from pre-trained, biased word vectors. As word embeddings are initialized randomly, they contain virtually no biases. Correspondingly, the definition embeddings obtained at this point will contain minimal biases. As training proceeds, the debiasing algorithm can continuously apply corrections, so as to learn distributional semantics and reduce biased information simultaneously. In Sec. 5.1, we empirically demonstrate that training from scratch could produce substantially more neutral definition embeddings that lead to improved debiasing.

3 DD-GloVe

We propose four dictionary-guided loss functions, namely (1) **orthogonal loss**, which mitigates general biases by diminishing the redundant component in word vectors that disagree with their definition embeddings, (2) **projection loss**, which directly reduces a specific type of bias by minimizing the difference between word vectors' projection and definitions' projection onto the bias direction, (3) **definition loss**, which injects semantic meanings from definitions into word embeddings, and (4) **bias-aware GloVe loss**, which dynamically adjusts weights of co-occurrences for bias reduction.

In addition, we introduce a novel algorithm that automatically searches seed words for bias direction approximation with only one pair of initial seed words as the input.

Notations We use $w \in \mathbb{R}^d$ to denote word vectors with dimension d. We overload the symbol w to represent a word in some contexts. $s(w)$ denotes the definition embedding of word w. A word can have multiple definitions in a dictionary. Since GloVe does not distinguish word meanings, we choose to use all available definitions for w when computing $s(w)$. Previous works compute definition embeddings by smoothed inverse frequency (Arora et al., 2017; Kaneko and Bollegala, 2021). We propose a simpler but empirically effective method that averages the definitional words. Therefore, our definition embedding is

$$s(w) = \frac{1}{K}\sum_{i=1}^{K} h(w)_i \tag{1}$$

where h is the function that returns all definitional words (excluding stop words) of w, and $K = |h(w)|$ is the number of definitional words.

3.1 Dictionary-guided Loss Functions

Orthogonal loss for general debiasing The definition embedding $s(w)$ reflects the redundant encoding in w, which is defined as

$$\phi\left(w, s(w)\right) = w - \frac{w \cdot s(w)}{s(w) \cdot s(w)} s(w) \tag{2}$$

where $(\cdot)$ is the dot product of vectors. $\phi\left(w, s(w)\right)$ represents the unnecessary, and likely biased, meaning encoded in the word vector w, because $\phi\left(w, s(w)\right)$ is the component in w that lives in the subspace orthogonal to $s(w)$.

We minimize the squared dot product between $\phi\left(w, s(w)\right)$ and w by

$$J_{ortho}(w) = \left(\phi\left(w, s(w)\right) \cdot w\right)^2 . \tag{3}$$

This loss term is ignored if a word does not have definitions in the dictionary. The orthogonal loss mitigates almost all general types of biases because it signals word embeddings to drop any information that is absent from their definition embeddings.

Projection loss for specific debiasing We design a projection-based loss to further enhance the debiasing effectiveness for a specific type of bias. The type of bias depends on use cases. With the definition embedding $s(w)$ as an unbiased reference for w, we want the projection of w onto the bias direction g (g is explained in Sec. 3.2) to be similar to that of $s(w)$. Thus,

$$J_{proj}(w) = \left\| \frac{w \cdot g}{g \cdot g} g - \frac{s(w) \cdot g}{g \cdot g} g \right\|_1 . \tag{4}$$

If the dictionary does not define w, we assume w should be a neutral word and $s(w) \cdot g = 0$. Dictionary definitions would indicate if a word vector should express the meaning associated with a protected attribute. This loss function thus avoids human intervention or using an additional classifier to decide what word to debias.

Definition loss for semantic meaning This loss function aims to inject the semantic meaning represented in dictionary definitions into word embeddings. The definition loss encourages a word vector to be similar to its definition embedding. As a result, it signals word embeddings about what to keep and what is lacking in their semantic meaning representations. We propose to minimize the $l1$-norm difference between w and its definition embedding $s(w)$ via definition loss

$$J_{def}(w) = \| w - s(w) \|_1 . \tag{5}$$

If a word is not defined in the dictionary, we skip its gradient update for this loss term.

Bias-aware GloVe loss The original GloVe loss is a log-bilinear regression of word co-occurrences. Each co-occurrence composes a word and its context word $(w, \tilde{w})$. It is evident that if the training corpus has more balanced word co-occurrences over the protected attributes, the trained word embeddings show a smaller extent of bias (Hall Maudslay et al., 2019; Lu et al., 2020). For example, if "nurse" occurs equally likely with gendered words like "she" and "he", the embedding of "nurse" would be more neutral with respect to genders. To equivalently create more balanced word co-occurrences, we introduce the bias-aware Glove loss. Different from static co-occurrence weights in the original Glove, bias-aware Glove loss adjusts co-occurrence weights according to the bias of a word and its context word.

What co-occurrences should be assigned new weights? If either w or $\tilde{w}$ is biased, we modify its weight, so that the number of co-occurrences containing biased words are equivalently modified. To decide if w (similarly for $\tilde{w}$) is biased in training, we quantify its genderedness by

$$u(w) = \frac{w \cdot v_1}{\|w\| \|v_1\|} - \frac{w \cdot v_2}{\|w\| \|v_2\|} \tag{6}$$

where v_1, v_2 are initial seed words like "she" and "he" (explained in Sec. 3.2). We then compare $u(w)$ with its neutral reference point $s(w)$. Hence, the bias of a word is

$$d(w) = |u(w) - u(s(w))| . \tag{7}$$

Increase or decrease the weights? If a biased w and $\tilde{w}$ are associated with opposite genders (i.e. $u(w)$ and $u(\tilde{w})$ have opposite signs), we assign a higher weight, equivalently increasing such co-occurrences; if a biased w and $\tilde{w}$ are associated with the same gender (i.e. $u(w)$ and $u(\tilde{w})$ have the same sign), we assign a lower weight, equivalently decreasing such co-occurrences.

By how much? The magnitude of the weight change is proportional to the maximum extent of bias in a given co-occurrence pair, which is computed by $\max(d(w), d(\tilde{w}))$.

The proposed weight for a co-occurrence pair is

$$f'(w, \tilde{w}) = \\ 1 - \alpha \cdot \mathrm{sgn}(u(w)) \cdot \mathrm{sgn}(u(\tilde{w})) \cdot \max(d(w), d(\tilde{w})) \tag{8}$$

where we multiply a constant α to keep $f'(w, \tilde{w})$ within a reasonable range, about $[0.9, 1.1]$, for stable performance. The modified GloVe loss is

$$J_{G-bias} = \sum_{i,j=1}^{|V|} f'(w_i, \tilde{w_j}) f(X_{ij}) (w_i^T \tilde{w}_j \\ + b_i + \tilde{b}_j - \log X_{ij})^2 \tag{9}$$

where V is the set of vocabulary, and $b, \tilde{b}$ are scalar bias terms. f is a function that assigns weights to co-occurrence pairs based on their frequency (introduced in GloVe). If a co-occurrence pair contains at least one word that is not defined, we set $f' = 1$.

DD-GloVe loss function Putting all the proposed loss functions together, we have the loss function

$$J = J_{G-bias} + \beta J_{ortho} + \gamma J_{proj} + \lambda J_{def} \quad (10)$$

where β, γ, λ are hyperparameters.

3.2 Approximating the Bias Direction g

Algorithm 1 approximates the bias direction g with a single pair of initial seed words. Let a pair of attribute-specific words be (v_1, v_2) such that word vector difference $v_1 - v_2$ is similar to the true bias direction associated with the protected attributes $\mathcal{A}_1$ and $\mathcal{A}_2$. For example, (v_1, v_2) could be "she" and "he" for gender debiasing, and the corresponding $\mathcal{A}_1$ and $\mathcal{A}_2$ are female and male respectively. We find two sets of most attribute-specific definitions $Q_{\mathcal{A}_1}$ and $Q_{\mathcal{A}_2}$ along $s(v_1) - s(v_2)$ by looking at definition embeddings' projection onto this direction. The sizes of $Q_{\mathcal{A}_1}$ and $Q_{\mathcal{A}_2}$ are determined empirically based on the availability of words associated with a certain concept. For instance, in our experiment that focuses on gender-debiasing, we set $N = 30$. One can run Algorithm 1 once at the beginning of training to obtain a set of seed words that will be used throughout the training, or run Algorithm 1 multiple times to update seed words periodically. We find that the former works better with attributes that have a large number of words associated with them, such as gender. The latter tends to fit attributes that have a smaller number of associated words, such as races.

Algorithm 1 Find seed words automatically and approximate the bias direction

```
Input: Initial seed words $(v_1, v_2)$, desired total number of seed words $N$ for each attribute
Output: Two sets of seed words $Q_{\mathcal{A}_1}, Q_{\mathcal{A}_2}$, the approximated bias direction $g$
  $Q_{\mathcal{A}_1} \leftarrow \{v_1\}, Q_{\mathcal{A}_2} \leftarrow \{v_2\}, R \leftarrow \emptyset$
  ▷ Get each word's definition projection onto the difference between the definition embeddings of $v_1, v_2$ i.e. projection along $s(v_1) - s(v_2)$.
  for all $w \in V$ do
      $r(w) \leftarrow \frac{s(w) \cdot s(v_1)}{\|s(w)\| \|s(v_1)\|} - \frac{s(w) \cdot s(v_2)}{\|s(w)\| \|s(v_2)\|}$
      $R \leftarrow R \cup \{(w, r(w))\}$
  end for
  ▷ Find top $N$ most attribute-specific words and approximate the bias direction.
  $R_{sorted} \leftarrow$ Sort $R$ by $r(w)$ in descending order
  for $n \in \{1, 2, \ldots, N\}$ do
      $w_1, r(w_1) \leftarrow R_{sorted}[n]$
      $w_2, r(w_2) \leftarrow R_{sorted}[|R_{sorted}| - n]$
      $Q_{\mathcal{A}_1} \leftarrow Q_{\mathcal{A}_1} \cup \{w_1\}, Q_{\mathcal{A}_2} \leftarrow Q_{\mathcal{A}_2} \cup \{w_2\}$
  end for
  $g \leftarrow \frac{1}{|Q_{\mathcal{A}_1}|} \sum_{w \in Q_{\mathcal{A}_1}} w - \frac{1}{|Q_{\mathcal{A}_2}|} \sum_{w \in Q_{\mathcal{A}_2}} w$
```

4 Experiments

We present two settings for DD-GloVe. (1) In DD-GloVe$_{gender}$, we mainly mitigate gender bias, thus using "she" and "he" as the initial seed words. (2) DD-GloVe$_{race}$, we focus on reducing racial bias. The initial seed words are "black" and "white".

For each word in the vocabulary of Glove, we try to find its definitions from the Oxford online dictionary. If the word has multiple definitions, we simply concatenate them into one definition. Stopwords are removed for pre-processing. We average the definitional words to obtain $s(w)$ by following Eqn. 1. Words that are not present in the Oxford dictionary are skipped. In total, we have 92,140 words with definitions.

We run GloVe (Pennington et al., 2014), Double Hard Debias (DHD) (Wang et al., 2020), dictionary-based debiasing (Dict Debias) (Kaneko and Bollegala, 2021), and GN-GloVe (Zhao et al., 2018b) as baselines for comparison. The detailed experimental setup is described in the appendix (A.1).

4.1 WEAT

To evaluate bias in word embeddings, researchers commonly use Word Embedding Association Test (WEAT) (Caliskan et al., 2017). This test quantifies the strength of association between a set of target words (such as science and arts) and a set of attribute words (such as male and female names). The test result produces effect size d and p-value. If there exist strong associations between target and attribute words, d would be large and p-value would be small. Bias-reduced word embeddings should ideally have low d and high p-values.

We report WEAT results in Table 1. We observe that DD-GloVe$_{gender}$ outperforms all the baselines in gender-related tests. DD-GloVe$_{race}$ performs as effectively as the state-of-the-art dictionary-based debiasing algorithm in racial association test. DD-GloVe$_{race}$ also shows some effects of gender debiasing in Gender-2 test and produces the best result in the nature test. It is evident that DD-GloVe can reduce multiple types of biases simultaneously with an emphasis on the bias we want to mitigate to the greatest extent. This phenomenon benefits

Embeddings	Gender-1		Gender-2		Race		Age		Nature	
	$d \downarrow$	$p \uparrow$	$d \downarrow$	$p \uparrow$	$d \downarrow$	$p \uparrow$	$d \downarrow$	$p \uparrow$	$d \downarrow$	$p \uparrow$
GloVe	1.74	0.00	1.07	0.013	1.18	0.0029	1.03	0.0090	1.15	0.0029
DHD	1.38	0.0014	0.45	0.19	1.06	0.0076	0.88	0.023	1.22	0.0017
Dict Debias	1.68	0.00	1.15	0.0081	0.82	0.033	**0.62**	**0.086**	1.27	0.0012
GN-GloVe	1.80	0.00	1.18	0.0063	1.01	0.010	0.96	0.014	1.21	0.0018
DD-GloVe$_{gender}$	**1.25**	**0.0029**	**0.083**	**0.44**	1.01	0.011	0.94	0.017	1.01	0.0088
DD-GloVe$_{race}$	1.75	7.8e-5	0.77	0.063	**0.80**	**0.037**	0.64	0.078	**0.99**	**0.0099**

Table 1: WEAT results for various word embeddings. The gender attribute set contains male and female names. Gender-1 tests gender v.s. career & family. Gender-2 tests gender v.s. math & arts. The race set consist of European American names and African American names. The age set contains stereotypically young and old names (Nosek et al., 2002). The nature set composes flower and insects vocabulary (Greenwald et al., 1998). Attributes sets of race, age, and nature are tested against pleasant and unpleasant words (Caliskan et al., 2017). For GN-GloVe, we exclude the gender dimension in word embeddings for these tests.

Embeddings	Pro	Anti	Avg	Diff
GloVe	67.03	55.96	61.50	11.07
DHD	60.56	57.99	59.28	2.57
Dict Debias	66.30	57.22	61.76	9.08
GN-GloVe	64.67	60.78	62.73	3.89
DD-GloVe	65.53	57.59	61.56	7.94

Table 2: Coreference resolution F1-score (%) using models trained with different embeddings. We also report the average F1-score (Avg) and the difference (Diff) between pro-stereotype and anti-stereotype subsets in WinoBias. We use all dimensions in GN-GloVe embeddings in this experiment.

from our design of loss functions: orthogonal loss reduces general types of biases while projection loss mitigates the chosen type of bias along g.

4.2 Coreference Resolution

We verify the effects of bias-reduced word embeddings on a downstream task – coreference resolution. WinoBias (Zhao et al., 2018a) is a dataset tailored to measure a model's gender bias when clustering the denotative noun phrases referring to the same entity. It consists of pro-stereotype and anti-stereotype sentences. Every sentence in pro-stereotype subset has a counterpart in the anti-stereotype subset with the gendered pronoun replaced with the opposite one. Models should ideally have similar performance in these two subsets. We train the end-to-end coreference resolution model proposed by Lee et al. (2017) with OntoNotes 5.0 (Weischedel et al., 2012) using various word embeddings. The coreference resolution model is implemented using AllenNLP (Gardner et al., 2017). We evaluate each model using WinoBias Type 1 set.

Model F1-scores are shown in Table 2 and training F1-scores are reported in the appendix. Compared to post-processing dictionary-based debiasing, DD-GloVe produces a lower F1-score difference, indicating less biased information is used to make coreference resolution predictions. DHD outperforms DD-GloVe in terms of F1-score difference, but DD-GloVe enjoys overall higher average. GN-GloVe performs the best in this task, likely because the occupations in WinoBias are found in their manually compiled male and female words. Their model could easily force these words to be completely neutral, whereas DD-GloVe would depend on dictionary definitions to decide the genderedness of words. The occasional noise in definitions may cause DD-GloVe to not outperform.

4.3 Semantic Meaning Preservation

We conduct experiments in word analogy and concept categorization to ensure semantic meaning of word embeddings are well preserved after bias mitigation. The word analogy task tests "A is to B as C is to what?" We find a word vector w that is nearest to $w_A - w_B + w_C$ as the solution. We use Google word analogy (Mikolov et al., 2013a) and MSR (Mikolov et al., 2013c) for evaluation. Concept categorization aims to group words into various categories based on their semantic meanings. The metric for this task is purity (Schütze et al., 2008). We evaluate various embeddings with Almuhareb-Poesio (AP) (Almuhareb, 2006), ESSLLI (Baroni et al., 2008), Battig (Battig and Montague, 1969), and BLESS (Baroni and Lenci, 2011).

Embeddings	Word analogy (%)				Concept categorization (%)			
	G-Sem	G-Syn	G-Total	MSR	AP	ESSLI	Battig	BLESS
GloVe	79.26	63.19	70.48	**54.10**	57.71	66.91	49.42	**83.50**
DHD	79.77	61.65	69.87	53.25	59.20	67.00	46.57	79.50
Dict Debias	79.46	**63.22**	70.59	53.89	**60.95**	66.91	**53.31**	83.00
GN-GloVe	77.11	61.88	68.79	50.55	57.96	60.47	46.68	81.00
DD-GloVe	**80.27**	62.67	**70.66**	53.69	58.71	**67.78**	48.06	76.00

Table 3: Experiments to verify semantic meaning preservation of debiased word embeddings. G-Sem, G-Syn, and G-Total refer to Google-Semantic subset accuracy, Google-Syntactic subset accuracy, and Google word analogy total accuracy respectively.

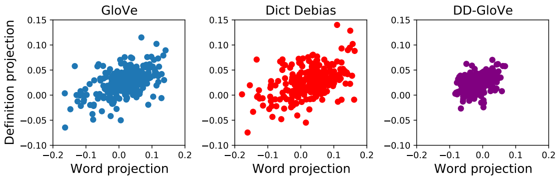

Figure 2: Scatter plots of definition embedding projections against word embedding projections for gender-neutral profession vocabularies. Both the definition embeddings and word embeddings in DD-GloVe consistently have closer-to-zero projection values.

KMeans clustering is run for categorization.

We obtain the top-1 accuracy for word analogy task and purity for concept categorization shown in Table 3. We see that there is minimal degradation in performance in most datasets we have tested. Sometimes, DD-GloVe achieves marginally higher top-1 accuracy or purity than the baseline GloVe. Two reasons lead to the improvement: it is partially due to the trend that using additional knowledge to train word vectors enhances their semantic meaning representations; also, reducing biased information enables fairer predictions in these tasks.

In addition to these experiments, we conduct more extrinsic evaluations for semantic meaning preservation in the appendix (A.2). We find that DD-GloVe preserves useful semantic meanings that help models to perform well in a variety of downstream tasks such as coreference resolution, sentiment analysis, and document classification.

5 Discussion

5.1 Benefit of Training from Scratch

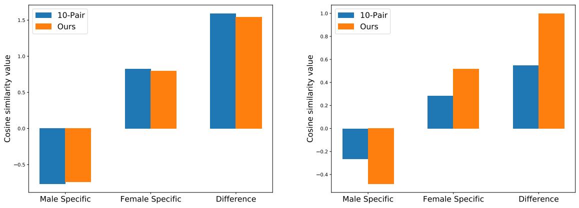
Training from scratch plays a key role in DD-GloVe because it significantly reduces the biases in definition embeddings, which are used as reference points for word embedding debiasing. We use the gender-neutral profession words provided by Bolukbasi et al. (2016). We project their definition embedding and word embedding onto the direction $\overrightarrow{\text{he}} - \overrightarrow{\text{she}}$. We present the scatter plots for three embeddings in Fig. 2. We fix the scale for both axes for easy comparison. In GloVe, a more biased occupation word tends to have a more biased definition embedding. This trend is visible from the strong linear correlation between definition embedding projections and word embedding projections ($p = 1.16 \times 10^{-18}$). Due to the biases in definition embeddings, using the GloVe definition embeddings as the optimization objective in post-processing would not effectively mitigate word embedding biases. Consequently, Dict Debias exhibits a similar trend in its definition embeddings and word embeddings. However, training from scratch allows word vectors to learn semantic meanings from a new random initialization, at which word vectors do not contain meaningful biased information. The definition embeddings will thus contain negligible biases. During training, these more neutral definition embeddings can consistently function as relatively neutral reference points for word embeddings to drop redundant information and keep useful semantic meanings. Shown in Fig. 2, DD-GloVe generates more neutral word and definition embeddings.

5.2 Bias Direction Approximation

We present part of the word list produced by Algorithm 1 in Table 4. Most choices are interpretable by human as they specifically refer to or describe a particular gender. We also quantitatively evaluate the quality of gender direction approximation. Similar to Antoniak and Mimno (2021)'s argument, a good gender direction should have large magnitude in cosine similarity with gender specific words while the signs are opposite for the two gen-

Female	ex-wife, girl, jane, woman, wife, witch, women, she, pilipinas, heroine, maids, hens, dona, wives
Male	he, son, brother, brothers, boys, sons, boy, businessman, yang, gentleman, wizard, headmaster, statesman

Table 4: Sample words chosen by our dictionary-guided algorithm (Algorithm 1) to approximate the gender direction. The full list can be found in the appendix (A.3)



(a) GloVe embeddings (b) DD-GloVe embeddings

Figure 3: Average cosine similarities between gender specific words and gender directions. "10-Pair" refers to the gender direction computed using the 10 pairs of seed words provided by Bolukbasi et al. (2016). We normalize the cosine values so that their mean is 0 and standard deviation is 1.

Initial seed	G-Sem (%)	$d\downarrow$	$p\uparrow$
she-he	80.47	1.25	0.0029
herself-himself	79.63	1.30	0.0012
her-his	80.25	1.50	7.8e-5
girl-boy	81.18	1.38	0.0011
mother-father	80.81	1.71	7.8e-5
woman-man	80.20	1.69	7.8e-5

Table 5: Performance of DD-GloVe on Google-Sem (%) and WEAT gender tests with different initial seed words. We finetune the hyper-parameter for each setting.

ders. This phenomenon would imply that the male-specific words and female-specific words are far apart from the other set when they are projected onto the gender direction.

We borrow 190 male-specific words and 177 female specific words used by Wang et al. (2020) and compute their average cosine similarities with different gender directions. Fig. 3a shows that gender-specific words have similar cosine similarities with both the gender direction used by Bolukbasi et al. (2016) and the gender direction found by our Algorithm 1. This indicates that, in the GloVe embedding space, our gender direction is as effective as the baseline to capture the notion of gender. In DD-GloVe embeddings, our gender direction has greater magnitude of average cosine similarities for both genders. Consequently, the difference between male and female cosine similarity is larger, indicating a clearer manifestation of gender.

5.3 Choice of Initial Seed Words

We conduct experiments to understand if different initial seed words affect the performance of DD-GloVe. We report our results in Table. 5. While all settings show similarly good semantic meaning preservation, we see that the choice of initial seed words gives rise to varying debiasing results. This is mainly due to the fact that some words have more diverse definitions than others. For example, definition of "he" contains mainly gendered words like *"man", "boy", and "male"*, whereas the definition of "man" can be far more general, where it has definitions like *"a human being of either sex; a person."* As a result, the gender direction approximated by Algorithm. 1 may suffer from the noisy definitional words, leading to less effective debiasing results.

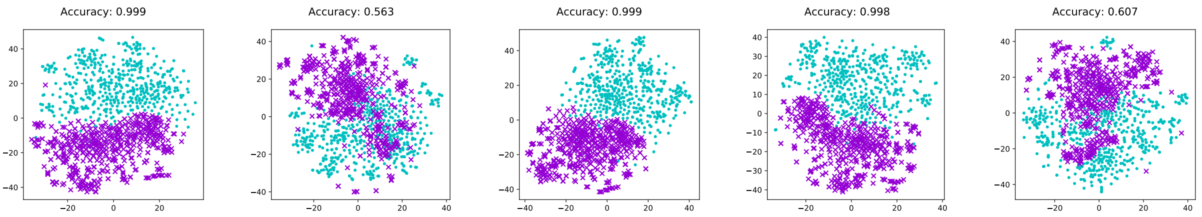
5.4 Does DD-GloVe Simply Hide Biases?

We use the neighborhood metric (Gonen and Goldberg, 2019) to evaluate if the debiased word embeddings actually reduce biases. We cluster these most biased words using the classical KMeans algorithm for different embeddings. We expect effective bias-mitigated word embeddings to achieve a classification accuracy close to 0.5, which indicates word embeddings do not encode any useful information regarding the protected attributes in these words and the clustering algorithm can only make random guesses. Fig. 4 illustrates tSNE projections of the word embeddings of top 500 most gender-biased words in GloVe. The visualization shows that DD-GloVe$_{gender}$ mixes up the embeddings in a similar fashion as Double Hard Debias. In contrast, using dictionary definitions for post-processing debiasing and GN-GloVe tend to hide biases since the two clusters remain easily separable.

5.5 Ablation Study

We carry out an ablation study to better understand the role of each loss in DD-GloVe. Detailed discussions are in the appendix (A.4). We summarize our findings from the ablation study here.

J_{ortho} contributes to both semantic meaning enhancement and general bias reduction in word embeddings when its weight is small. Nonetheless,



(a) GloVe (b) DHD (c) Dict Debias (d) GN-GloVe (e) DD-GloVe$_{gender}$

Figure 4: tSNE projections of word vectors for neighborhood metric evaluation. The most biased words in GloVe are found by projecting word vectors onto the difference between $\overrightarrow{\text{boy}}$ and $\overrightarrow{\text{girl}}$.

this loss term reduces biases at the expense of semantic meaning preservation as its weight gets higher. Hence, the weight for J_{ortho} should be kept relatively low. We also find that J_{ortho} is not the most effective component for bias mitigation but it is still a crucial part for reducing general biases. J_{proj} is essential for effective bias reduction. We find the projection-based loss function largely contributes to debiasing. J_{def} enhances semantic meaning representation but does not help much in bias mitigation. J_{G-bias} further mitigates bias, suggesting that adjusting word co-occurrence weights could help learn bias-reduced word embeddings.

6 Related Work

6.1 Biases in Word Embeddings

Biases in embeddings can cause harms in downstream tasks. Gender bias is found in coreference resolution (Rudinger et al., 2018; Zhao et al., 2018a), dialogue systems (Henderson et al., 2018) and machine translation models (Escudé Font and Costa-jussà, 2019). Researchers also find pretrained word embeddings exhibit racial and religious biases (Manzini et al., 2019).

6.2 Debiasing Word Embeddings

Algorithms to debias word embeddings can be classified into projection-based post-processing, dictionary-based post-processing, and train-time algorithms. **Projection-based post-processing** subtracts a word vector's projection onto the bias direction. Bolukbasi et al. (2016), Wang et al. (2020), Ravfogel et al. (2020), Kumar et al. (2020), Kaneko and Bollegala (2019), Dev and Phillips (2019), and Karve et al. (2019)'s works fall into this category. **Dictionary definitions** have been largely overlooked by debiasing algorithms. Kaneko and Bollegala (2021) uses dictionary definitions via post-processing, but its effectiveness is limited due to using biased definition embeddings as reference points. **Train-time algorithms** either introduce bias-decreasing objectives (Zhao et al., 2018b) or counter-factually augment training data (Lu et al., 2020; Hall Maudslay et al., 2019).

6.3 Using Additional Knowledge

Researchers have attempted to learn word embeddings with resources outside the training corpora. Faruqui et al. (2015); Mrkšić et al. (2017); Tissier et al. (2017); Bosc and Vincent (2018); Zhang et al. (2020) are successful in enhancing semantic meaning representations with the aid of semantic relationships in word graphs or dictionaries. However, these works do not mitigate biases. In DD-GloVe, we specifically design loss functions that utilize dictionary definitions for bias alleviation.

7 Conclusion

In this paper, we propose DD-GloVe, a train-time debiasing algorithm to learn word embeddings leveraging dictionary definitions. We achieve effective debiasing results while preserving semantic meanings. The bias direction in DD-GloVe is automatically approximated using our dictionary-guided algorithm given a single pair of initial seed words. Our current implementation is based on GloVe, but the idea of using dictionary definitions to mitigate biases can be generalized to other word embeddings since our dictionary-guided losses are orthogonal to word embedding objectives. It is also likely that incorporating dictionary definitions can alleviate biases in contextualized word embeddings. This is out of the scope of this paper and remains an open research problem.

A Appendix

A.1 Experimental Set-up

We give a more detailed description of our experimental set-up in this section.

We use Wikipedia dump available on Hugging Face[2] as our training corpora. We follow the same pre-processing procedure in the original GloVe implementation. We build a vocabulary of 400,000 most frequently occurring words. We set the dimension of word vector to be 300. Although the baseline GloVe is trained with 100 iterations, we find that training about 40 iterations yields excellent debiasing result while keeping the quality of word embeddings in other semantic tasks. We clip the the values in word vectors to be within $[-1, 1]$ to avoid numerical difficulties.

In the setting of DD-GloVe$_{gender}$, we place major emphasis on minimizing gender bias while mitigating other types of biases. We use one pair of initial seed words, “she” and “he”. We run Algorithm 1 once at the beginning with $N = 30$. We then use the same set of seed words throughout. Gender direction is approximated once in each iteration. We choose the hyperparameter values in Eqn. 10 to be $\beta = 1\times10^{-4}, \gamma = 0.2, \lambda = 1\times10^{-4}$. Note that the difference in the magnitude is caused by the trend that definition loss and orthogonal loss have considerably larger values because the losses are not normalized by the vector dimension. We set α in Eqn. 8 to be 0.4.

We also conduct experiments that targets to mitigate racial bias In this experiment DD-GloVe$_{race}$, we find seed words using Algorithm 1 in the first 5 iterations and update them every 10 iterations. The initial seed words are “black“ and “white.” We choose the hyperparameter values $\beta = 1 \times 10^{-4}, \gamma = 0.05, \lambda = 1 \times 10^{-4}$. α in Eqn. 8 remains 0.4.

We run GloVe (Pennington et al., 2014), Double Hard Debias (DHD) (Wang et al., 2020), dictionary-based debiasing (Dict Debias) (Kaneko and Bollegala, 2021), and GN-GloVe (Zhao et al., 2018b) as baselines for comparison. When reproducing the baselines, we follow the default hyperparameter settings in their released code. Each baseline algorithm represents a major debiasing

Embeddings	OntoNotes 5.0
GloVe	60.50
DHD	59.61
Dict Debias	60.66
GN-GloVe	60.78
DD-GloVe	60.44

Table 6: Coreference resolution F1-score (%) using models trained with different embeddings. These results show that Dd-GloVe keeps useful semantic meanings in embeddings since the F1-score on OntoNotes 5.0 is similar to the baseline and its counterparts.

Word Embeddings	Sentiment Analysis	Document Classification
GloVe	87.94	74.16
DD-GloVe	88.34	74.45

Table 7: F-1 score (%) of models in two downstream tasks. These results show that DD-GloVe well preserve semantic meaning of word vectors after debiasing.

technique: DHD uses projective correction via post-processing; Dict Debias uses dictionary definitions in post-processing. GN-GloVe trains GloVe from scratch with new objectives for debiasing.

A.2 Additional Experimental Results

We report coreference resolution models' F1-score on the training set OntoNotes 5.0 in Table 6. These results indicate that DD-GloVe is able to preserve useful semantic meanings that help train coreference resolution models.

We conduct additional experiments to evaluate model F-1 scores in downstream tasks. We train an LSTM model with pre-trained word embeddings for sentiment analysis on an IMDB dataset[3]. We also train a CNN model with pre-trained word embeddings for document classification using the 20 Newsgroups data set[4]. We report F-1 scores of models in both tasks' test set in Table. 7. We see that DD-GloVe performs marginally better than the baseline GloVe in these two tasks. These results demonstrate that DD-GloVe preserves semantic meanings in the debiased word embeddings.

Female	ex-wife, girl, jane, woman, wife, witch, women, she, pilipinas, heroine, maids, hens, dona, wives, fiancee, goddess, bint, sheila, hostess, hen, nun, sisters, girls, waitress, doe, sister, actress, businesswoman, chairwoman, goddesses
Male	he, son, brother, brothers, boys, sons, boy, businessman, yang, gentleman, wizard, headmaster, statesman, nobleman, policeman, salesman, bahadur, stallion, fiance, manny, englishman, beau, widower, chicano, workmen, councilman, stallions, schoolmaster, scotsman, horseman

Table 8: Full lists of words chosen by our dictionary-guided algorithm (Algorithm 1) to approximate the gender direction.

A.3 Full List of Seed Words

We report the full list of chosen seed words by running Algorithm 1 for approximating gender direction in Table. 8.

A.4 Ablation Study

To understand the role of each dictionary-guided loss in DD-GloVe, we conduct an ablation study that only uses one of the proposed losses, and an experiments that avoid using one of the losses but optimizes the other two in Table. 10. We have made the following observations.

J_{ortho} contributes to both semantic meaning preservation and general bias reduction Both word analogy accuracy and WEAT results improve as the weight of J_{ortho} increases from $1e-5$ to 0.01, as shown in Table. 10. However, if the weight of J_{ortho} gets large, it debiases word embeddings at the expense of semantic meaning representations. We should keep its weight low for both semantic meaning preservation and bias mitigation. We see that J_{ortho} is not the most effective component for bias mitigation because the debiasing effect does not suffer a significant drop when J_{ortho} is not used to train DD-GloVe, shown in Table. 10. However, J_{ortho} remains an important component in the loss function because of its ability to reduce general types of biases. In Table. 9, we report the WEAT results of DD-GloVe without using J_{ortho} and com-

Table 10: Ablation study to understand the effects of each loss in DD-GloVe. The table shows the performance of DD-GloVe in Google-sem word analogy (G-Sem) and WEAT Gender-1 test (effect size d and p-value). In the experiment without J_{G-bias}, we replace J_{G-bias} with the original GloVe loss function.

pare them with the baseline GloVe and DD-GloVe with all losses used. It is evident that the absence of J_{ortho} causes race, age, and nature WEAT test to have worse results.

J_{proj} is essential for effective bias reduction Table. 10 shows that WEAT results improve significantly as we increase the weight of J_{proj}. When the projection loss is not used, there is a significant degradation in debiasing performance in Table. 10.

J_{def} enhances semantic meaning representation In Table. 10, we see that the word analogy task enjoys higher accuracy when the weight of J_{def} increases. This benefits from the additional semantic meaning injected from dictionary definitions. In terms of debiasing, J_{def} does not help much as illustrated in Table. 10. This finding explains why simply doing retrofitting with dictionary definitions does not mitigate biases.

J_{G-bias} further mitigates bias We find that when J_{G-bias} is replaced with the original GloVe loss function, there remains evidence of debiasing but it is less effective, as shown in Table. 10. This suggests that adjusting co-occurrence weights according to the word bias and context word bias can learn more neutral word embeddings.

Knowledge Graph Embedding by Adaptive Limit Scoring Loss Using Dynamic Weighting Strategy

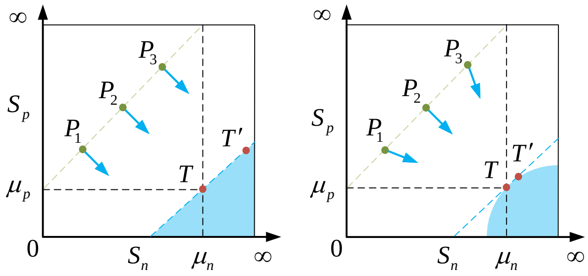
Abstract

Knowledge graph embedding aims to represent entities and relations as low-dimensional vectors, which is an effective way for predicting missing links in knowledge graphs. Designing a strong and effective loss framework is essential for knowledge graph embedding models to distinguish between correct and incorrect triplets. The classic margin-based ranking loss limits the scores of positive and negative triplets to have a suitable margin. The recently proposed Limit-based Scoring Loss independently limits the range of positive and negative triplet scores. However, these loss frameworks use equal or fixed penalty terms to reduce the scores of positive and negative sample pairs, which is inflexible in optimization. Our intuition is that if a triplet score deviates far from the optimum, it should be emphasized. To this end, we propose Adaptive Limit Scoring Loss, which simply re-weights each triplet to highlight the less-optimized triplet scores. We apply this loss framework to several knowledge graph embedding models such as TransE, TransH and ComplEx. The experimental results on link prediction and triplet classification show that our proposed method has achieved performance on par with the state of the art.

1 Introduction

Knowledge graphs are usually collections of factual triplets — (head entity, relation, tail entity), also known as (subject, predicate, object), which represent human knowledge of the real world in a structured way. There are some outstanding knowledge graphs, such as WordNet (Miller, 1995), Freebase (Bollacker et al., 2008), DBpedia (Lehmann et al., 2015), YAGO (Suchanek et al., 2007). They have gained widespread attention for their successful usage in various applications, *e.g.*, question answering (Bordes et al., 2014; Huang et al., 2019), recommendation systems (Zhou et al., 2020), medical science (Hasan et al., 2020), *etc*.



(a) (b)

Figure 1: Comparison between the popular optimization manner of reducing (S_n, S_p) and the proposed reducing $(\alpha_n S_n, \alpha_p S_p)$. (a) Reducing (S_n, S_p) is prone to inflexible optimization (P_1, P_2 and P_3 all have equal gradients with respect to S_n and S_p), as well as potential overlapping problem (both T and T' on the decision boundary are acceptable). (b) With $(\alpha_n S_n, \alpha_p S_p)$, the L_{AS} dynamically adjusts its gradients on S_p and S_n, and thus benefits from a flexible optimization process. For P_1, it emphasizes on increasing S_n; for P_3, it emphasizes on reducing S_p. Moreover, it aggregates T and T' on the circular decision boundary, which can alleviate the overlap problem.

Similar to word embedding, knowledge graph embedding is one of the basic research fields of knowledge graph, which can be applied to tasks such as knowledge graph completion (Bordes et al., 2013; Sun et al., 2019), triplet classification (Socher et al., 2013; Nguyen et al., 2020), search personalization (Lu et al., 2020). For a knowledge graph embedding model, there are two major components, the scoring triplets and the optimizing loss function. In the last few years, negative sampling with margin-based ranking loss framework has been commonly used for modelling knowledge graph embedding. In this framework, a positive triplet (h, r, t) can get its score $S_p = f_r(h, t)$, and the corresponding negative triplet (h', r, t') score value is $S_n = f_r(h', t')$, where f_r is the scoring function. Finally, optimize the margin-based

---

May 22-27, 2022

ranking loss function $max(0, \mu + S_p - S_n)$. In $max(0, \mu + S_p - S_n)$, increasing S_p is equivalent to reducing S_n. We argue that this symmetric optimization manner is prone to the following two problems.

Lack of flexibility in optimization. The penalty strength on S_p and S_n is restricted to be equal or fixed. Given the specified loss function, the gradients of S_p and S_n have the same amplitude or fixed multiples . In some corner cases, *e.g.*, when both S_p and S_n are small ("P_1" in Figure 1a), we expect positive samples S_p to be small and negative samples S_n to be large, so we need a smaller penalty for S_p and a larger penalty for S_n. However, the aforementioned loss framework also retains a large gradient magnitude for S_p, which is inefficient and irrational.

Overlapping between S_p and S_n. Under a margin-based ranking loss(exclude$\{S_p^h, S_n^l\}$ here), there are three kinds of value distributions for a pair of positive and negative triplets $\{(h,t),(h',t')\}$, including $\{S_p^{l0}, S_n^{h0}\}, \{S_p^{l1}, S_n^{l1}\}, \{S_p^{h2}, S_n^{h2}\}$, where the superscript l indicates a low value, h indicates a high value, and the number indicates three cases. As long as $S_p^{*i} - S_n^{*i} < -\mu, i = 1, 2, 3$ is satisfied, there may be an overlap phenomenon of $S_p^{h2} > S_n^{l1}$. For example, T (one of the optimized states) has $\{S_p, S_n\} = \{1, 4\}$ and T' has $\{S'_p, S'_n\} = \{5, 8\}$. They are both satisfied with the margin of $\mu = 3$. However, when comparing them against each other, we find $S'_p > S_n$. The overlap between S_p and S_n damages the separability of positive and negative triplets.

Limit-based scoring loss (Zhou et al., 2017) proposes to add an upper-limit scoring loss on $f_r(h,t)$ to guarantee low scores for the positive triplets, which can effectively avoid $\{S_p^{h2}, S_n^{h2}\}$ case; Double limit scoring loss (Zhou et al., 2021) adds a lower-limit score for negative triplets on this basis, and finally alleviates the overlap problem. However, neither method can solve the problem of inflexible optimization. Our intuition is that if a triplet score deviates far from the optimum, it should be emphasized. To this end, we propose Adaptive Limit Scoring Loss, which simply reweights each triplet to highlight the less-optimized triplet scores. The main contributions of this paper are summarized as follows:

- We propose adaptive limit scoring loss, which benefits knowledge graph embedding with flexible optimization and definite positive and negative triplet separation.
- Compared with the recent knowledge graph embedding negative sample loss framework limit-based scoring loss and double limit scoring loss (Zhou et al., 2017, 2021), our method not only reduces the amount of tuning parameters but also improves the performances.
- Experiments are carried out on WordNet and Freebase datasets with link prediction and triplet classification task, and the results show the superiority of our proposed method with performance on par with the state of the art.

2 Related Works

2.1 Knowledge Graph Embedding Models

Roughly speaking, we can divide knowledge graph embedding models into translational distance models and semantic matching models

Translational distance models describe relations as translations from source entities to target entities. TransE (Bordes et al., 2013) is the most widely used translation distance constraint model. It assumes that entities and relations satisfy $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$, where $\mathbf{h}, \mathbf{r}, \mathbf{t} \in \mathbb{R}^k$. However, TransE cannot handle 1-N, N-1, and N-N relations well (Wang et al., 2014). TransH (Wang et al., 2014) is proposed to compensate for the shortcomings of TransE. It projects entities onto relation-specific hyperplanes with $\mathbf{h}_\perp = \mathbf{h} - \mathbf{w}_r^\top \mathbf{h} \mathbf{w}_r$ and $\mathbf{t}_\perp = \mathbf{t} - \mathbf{w}_r^\top \mathbf{t} \mathbf{w}_r$. TransR (Lin et al., 2015) has a very similar idea to TransH, which introduces relation-specific spatial transformations instead of hyperplanes. TransE_AT (Yang et al., 2021) improves TransE's ability to express symmetric relations by introducing affine transformation. TranSparse (Ji et al., 2016) simplifies TransR by forcing the projection matrix to be sparse. Moreover, RotatE (Sun et al., 2019) defines each relation as a rotation from the source entity to the target entity in a complex vector space, which can represent various relation patterns including symmetry/asymmetry, inversion and composition.

Semantic matching models use the similarity scoring function to evaluate the latent semantics of entities and relations. RESCAL (Nickel et al., 2011) is a tensor factorization model which represents each relation as a full-rank matrix and defines score function as $f_r(\mathbf{h}, \mathbf{t}) = \langle \mathbf{h}^\top \mathbf{M}_r \mathbf{t} \rangle$. DistMult (Yang et al., 2015) simplifies the embedding of relations $\mathbf{M}_r$ as a diagonal matrix, which can reduce the number of parameters and make the model easier to train. However, Distmult assumes that all relations are symmetric, and is not friendly to other types of relations, such as antisymmetry and composition. To solve this problem, ComplEx (Trouillon et al., 2016) extends DistMult to complex space: $\mathbf{h}, \mathbf{r}, \mathbf{t} \in \mathbb{C}^k$, and uses conjugate-transpose $\bar{\mathbf{t}}$ to model asymmetric relations. MLP (Dong et al., 2014) and NTN (Socher et al., 2013) use a fully connected neural network to calculate the scores of given triplets. ConvE (Dettmers et al., 2018), ConvR (Jiang et al., 2019) and CoPER-ConvE (Stoica et al., 2020) employ convolutional neural networks to build score functions.

2.2 Loss Functions

For knowledge graph embedding models optimized with negative sampling, we summarize the related loss functions as follows.

Margin-based ranking loss L_R is a widely used loss function for KG embedding models, which has successfully been used for NTN (Socher et al., 2013), TransE (Bordes et al., 2013), TransH (Wang et al., 2014), TransR (Lin et al., 2015), *etc.* The L_R is formulated by :

$$L_R = \sum_{\substack{(h,r,t)\in\mathcal{G} \\ (h',r,t')\in\mathcal{G}'}} [\mu + S_p - S_n]_+, \qquad (1)$$

where $[x]_+ = max(0, x)$ is a rectified linear unit that denotes the positive part of x. μ is the margin between positive and negative triplets, $S_p = f_r(h,t), S_n = f_r(h',t')$ represents the score of the positive and negative triplets respectively. $\mathcal{G}$ denotes the set of positive triplets, and $\mathcal{G}' = \{(h',r,t) \notin \mathcal{G} | h' \in \mathcal{E}\} \cup \{(h,r,t') \notin \mathcal{G} | t' \in \mathcal{E}\}$ denotes the set of corrupted triplets.

Limit-based scoring loss (Zhou et al., 2017) adds an upper-limit scoring loss term $[S_p - \mu_p]_+$ to guarantee low scores for positive triplets. The loss framework has been proved to be successfully applied in TransE and TransH, and its formula is:

$$L_{RS} = \sum_{\substack{(h,r,t)\in\mathcal{G} \\ (h',r,t')\in\mathcal{G}'}} [\mu + S_p - S_n]_+ + \lambda[S_p - \mu_p]_+, \quad (2)$$

where $\lambda, \mu_p > 0$. On this basis, Double Limit Scoring Loss (Zhou et al., 2021) proposes to replace $[\mu + S_p - S_n]_+$ of L_{RS} with lower-limit scoring loss for negative triplets $[\mu_n - S_n]_+$. The loss framework is:

$$L_{SS} = \sum_{\substack{(h,r,t)\in\mathcal{G} \\ (h',r,t')\in\mathcal{G}'}} [S_p - \mu_p]_+ + \lambda[\mu_n - S_n]_+, \quad (3)$$

where $\mu_n > \mu_p > 0$. Compared with L_R and L_{RS} losses, L_{SS} loss expects not only marginal discrimination between positive and negative triplets' scores but also low scores for positive triplets and high scores for negative triplets.

Some other negative sampling losses of the knowledge graph embedding model also try to improve the discrimination between positive and negative triplets. HolE (Nickel et al., 2016) suggests to use logistic function instead of rectified linear unit to distinguish the probabilities of positive and negative triplets. ComplEx (Trouillon et al., 2016) propose a negative log-likelihood loss to learn compact representations. ProjE (Shi and Weninger, 2017) uses the pointwise ranking method to optimize the list of candidate entities collectively, so that the probability ranking of positive triplets is higher than that of negative triplets. RotatE (Sun et al., 2019) defines a log-sigmoid function to make the positive and negative triplets away from the same margin in the opposite direction. Sun *et al.* (Sun et al., 2020) propose the pair similarity optimization and successfully apply the method in visual tasks such as face recognition. Inspired by this, we refine the scoring and weighting strategies and apply them to knowledge graph embedding. Except for negative sampling methods, neural network frameworks with cross-entropy loss (Lacroix et al., 2018) and 1-N binary cross-entropy loss (Dettmers et al., 2018) have been developed for knowledge graph embedding in recent years. In this paper, our work mainly focuses on improving the marginal ranking loss L_R and the limited loss $L_{RS}\&L_{SS}$ for knowledge graph embedding.

3 The Proposed Methods

In this section, we firstly present adaptive limit scoring loss L_{AS} for optimizing Knowledge graph embedding models. Secondly, we introduce different metrics of our loss for optimization according to the positioning method of the circle center.

3.1 Adaptive Limit Scoring Loss

We consider enhancing the optimization flexibility by allowing each triplet score to learn at its own pace, depending on its current optimization status. Then, we add adaptive penalty items to the positive and negative triplets scoring respectively. Equation (3) can be changed to:

$$L_{AS} = \sum_{\substack{(h,r,t)\in\mathcal{G} \\ (h',r,t')\in\mathcal{G}'}} \alpha_p[S_p - \mu_p]_+ + \alpha_n[\mu_n - S_n]_+. \tag{4}$$

Where α_n and α_p are non-negative weighting factors. During training, when back propagating to S_p (S_n), the gradient with respect to $\alpha_p[S_p - \mu_p]_+ + \alpha_n[\mu_n - S_n]_+$ will be multiplied by $\alpha_p(\alpha_n)$. When the triplet score deviates far from its optimum (i.e., v_p for S_p and v_n for S_n. v_p and v_n are intermediate variables), it should obtain a large weighting factor in order to obtain effective update with large gradient. To this end, we define α_p and α_n in an adaptive way:

$$\begin{cases} \alpha_p = [S_p - v_p]_+ \\ \alpha_n = [v_n - S_n]_+, \end{cases} \tag{5}$$

Overall, the adaptive limit scoring loss in Equation (4) expects $S_p < \mu_p$ and $S_n > \mu_n$. We further analyse the settings of μ_p and μ_n by deriving the decision boundary. In the optimization process, the decision boundary is realized at $\alpha_p(S_p - \mu_p) + \alpha_n(\mu_n - S_n) = 0$. Combined with Equation (5), we can get:

$$(S_p - \frac{v_p + \mu_p}{2})^2 + (S_n - \frac{v_n + \mu_n}{2})^2 = C, \tag{6}$$

where $C = \left((v_p - \mu_p)^2 + (v_n - \mu_n)^2\right)/4$. Equation (6) shows that the decision boundary is the arc of a circle, as shown in Figure 1b. The center of the circle is at $S_n = (v_n + \mu_n)/2$, $S_p = (v_p + \mu_p)/2$, and the radius equals $\sqrt{C}$. Here we have four hyperparameters μ_p and μ_n from Equation (4), v_p and v_n from Equation (5). After Positioning the center of the circle, the four hyperparameters can be reduced to two, which is less than L_{RS} and L_{SS}.

3.2 Positioning the Center of Circle

The center of circle is the ideal optimization target for (S_n, S_p), and the arc is the actual decision boundary. Usually, we expect lower score for S_n and higher for S_p. However, our model training is based on the open world assumption, which states that knowledge graphs contain only true facts and non-observed facts can be either false or just missing (Drumond et al., 2012). It means that the generated negative triplets may be correct, but they do not appear in the original knowledge graph. Therefore, we do not want S_n to be infinite but a finite value. Here we consider two options:

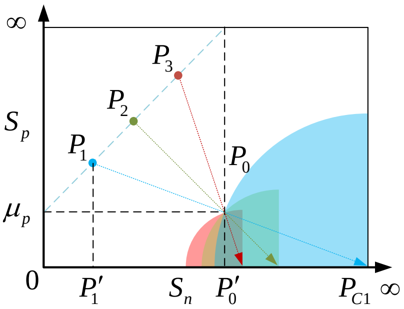

Figure 2: Different embedding states have different optimization trajectories. P_1, P_2, and P_3 have different ideal optimization goals and derive three decision boundary arcs (located in light blue, green and red sectors).

Constant Adaptive Limit Scoring Loss (CAS). We set the center of the circle as a constant $(0, \mu_p + \mu_n)$. Correspondingly, the two hyper-parameters v_p, v_n in Equation (5) can be reduced by setting $v_p = -\mu_p$, $v_n = \mu_n + 2\mu_p$. And the decision boundary in Equation (6) can be degraded into:

$$(S_p - 0)^2 + (S_n - (\mu_p + \mu_n))^2 = 2\mu_p^2. \tag{7}$$

The decision boundary defined in Equation (7) aims to optimize $S_p \rightarrow 0$ and $S_n \rightarrow \mu_p + \mu_n$ (Actually $(0, \mu_p + \mu_n)$ cannot be reached, in Equation (4) we limit $S_p \geq \mu_p, S_n \leq \mu_n$). The choice of the constant $(\mu_p + \mu_n)$ is inspired by the value range of the dynamic weighting in Equation (5). When the model embedding needs to be optimized (that is, $S_p > \mu_p, S_n < \mu_n$), substituting $v_p = -\mu_p$ into Equation (5), we can get the positive triplet dynamic weight range $\alpha_p > 2\mu_p$. Similarly, substituting $v_n = \mu_n + 2\mu_p$ into Equation (5), we can get the same range of negative triplets dynamic weight $\alpha_n > 2\mu_p$.

Independent Adaptive Limit Scoring Loss (IAS). When the model embedding is in different states (such as P_1, P_2 and P_3 in Figure 2), it should have different optimized trajectories. We expect to find the optimal trajectory for each independent embedding state. Taking point P_1 (assume its coordinates are (S_n, S_p)) in Figure 2 as an example, its corresponding decision boundary is the largest arc (located in light blue sector), and the center of the circle is $P_{C1}(C_{1n}, 0)$. Based on triangle similarity $\triangle P_{C1}P_0P'_0 \sim \triangle P_{C1}P_1P'_1$ we can get:

$$C_{1n} = \mu_n + \mu_p \frac{\mu_n - S_n}{S_p - \mu_p}, \tag{8}$$

where $S_n < \mu_n, S_p > \mu_p$. Combing the center of circle defined by Equation (6), the two hyper-parameters v_p, v_n in Equation (5) can be reduced by setting $v_p = -\mu_p$, $v_n = \mu_n + 2\mu_p\ (\mu_n - S_n)/(S_p - \mu_p)$. Compared with L_{CAS}, L_{IAS} can independently set the circle center of each sample to obtain an independent optimized trajectory.

Adaptive Limit Scoring L_{AS} further improves double scoring loss L_{SS} by adding adaptive penalty terms to dynamically adjust the optimization process. In the early stage of model training, the scores of the positive and negative triplets are far from optimization, which increases the weight of the penalty item and obtains a larger gradient. This is conducive to the early rapid convergence for the model. During training, when there is a bias in the optimization of the paired positive and negative triplets, *e.g.*, the positive triplet is close to the optimum while the negative triplet is still far from the requirement, the penalty term will increase the weight of the negative triplet so that the negative triplet can be adjusted in time. In addition to the separate limits for the positive and negative scores, the differentiated pace adjustment with penalty items can also alleviate the overlap problem (see T' in Figure 1 a and b).

4 Experiments

We comprehensively evaluate the effectiveness of Adaptive Limit Scoring Loss for link prediction (Bordes et al., 2013) and triplet classification (Socher et al., 2013) tasks under different knowledge graph embedding models. Our experiments are carried out on two popular knowledge graphs FreeBase (Bollacker et al., 2008) and WordNet (Miller, 1995). Freebase contains a large number of world facts such as movies, sports. WordNet is a large-scale lexical knowledge graph. Some subsets of the two knowledge graphs are used in our experiments, including WN18, WN18RR and WN11 from WordNet, and FB15k, FB15K-237 and FB13 from Freebase. The statistics of these subsets are shown in Table 1. FB15k-237 (Toutanova and Chen, 2015) and WN18RR (Dettmers et al., 2018) are subsets of FB15k and WN18, respectively, where inverse relations are deleted.

Dataset	#En	#Re	#train	#valid	#test
WN18	40,943	18	141,442	5,000	5,000
FB15K	14,951	1,345	483,142	50,000	59,071
WN18RR	40,943	11	86,835	3,034	3,134
FB15k-237	14,541	237	272,115	17,535	20,466
WN11	38,696	11	112,581	2,609	10,544
FB13	75,043	13	316,232	5,908	23,733

Table 1: Number of entities, relations, and observed triplets in each split for benchmarks.

Parameters Settings. We compare the series of TransE, TransH, RotatE and ComplEx with different losses. The ranges of the main hyperparameters for the grid search are set as follows: learning rate $\alpha \in$ {0.00005, 0.0001, 0.0005, 0.001, 0.005, 0.01}, the embedding dimension $m \in$ {50, 80, 100, 150, 200}, the batch size $B \in$ {50, 100, 200, 500, 1000, 2000, 5000}, $\{L1, L2\}$ distances for loss functions. For TransE and TransH with Adaptive Limit Scoring, upper limit score for positive triplets $\mu_p \in$ {0.25, 1, 2, 3, 4, 5, 6, 7, 8, 10, 15}, and lower limit score for negative triplet $\mu_n \in \{\mu_p +$ {0.1, 0.25, 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11}}. Parameter C for TransH series from {0.0005, 0.0625, 0.25, 1.0}. For ComplEx, upper limit μ_p score for positive triplets is $log(p_+)$, $p_+ \in$ {0.1, 0.2, 0.3, 0.4, 0.5, 0.6}, and lower limit score μ_n for negative triplet $log(p_-)$, $p_- \in \{p_+ +$ {0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9}}. We train WN18 and FB15K with 1000 times, WN18RR and FB15K237 with 3000 times for Link prediction, WN11, FB13 and FB15K with 1000 times for triplet classification. For RotatE, we use the parameters recommended by Sun et al. (2019) (with larger epoch, embedding dim and self-adversarial negative sampling) and the same μ_p, μ_n parameter search range as TransE and TransH. We use SGD for TransE, TransH and Adam (Kingma and Ba, 2014) for RotatE, ComplEx as the optimizer and fine-tune the hyperparameters on the validation dataset.

4.1 Link Prediction

Link prediction (Bordes et al., 2012, 2013) aims to predict the missing triplets such as head entity prediction $(?, r, t)$ or tail entity prediction $(h, r, ?)$ based on the known triplets. For a testing triplet (h, r, t), either the head entity h or the tail entity t will be replaced with the total list of the embedding entities to construct the predicted triplets. Then

Table 2: Evaluation results on WN18 and FB15k datasets. In each column, the top-1 result with bold marker and top-2-4 results with underline markers are given.

such triplets are ranked in descending order according to the scoring function. Based on the score rank, several metrics are usually reported: mean rank (MR), Mean Reciprocal Rank (MRR) and the proportion of top-k rank (Hits@k) for correct entities. A good model should have low "MR", high "MRR" and high "Hits@k". For constructing the corrupted triplets, "unif" means that the head or tail entity is replaced with equal probability traditionally, and "bern" denotes reducing false negative labels by replacing head or tail with different probabilities (Wang et al., 2014). The settings "raw" and "filt" for the metrics distinguish whether or not to consider the impact of a corrupted triplet existing in the correct Knowledge graph.

4.1.1 Results on WN18 and FB15K

Firstly, we follow the experimental procedures of most negative sampling knowledge graph embedding models (such as Bordes et al. (2013); Wang et al. (2014), *etc.*), and use MR and Hits@10 to evaluate WN18 and FB15K. The optimal configurations are illustrated in Appendix A Table 5.

Table 2 shows the evaluation results on two datasets WN18 and FB15K. The original results of TransE, TransH and ComplEx are from the references (Bordes et al., 2013; Wang et al., 2014; Trouillon et al., 2016). And their extension with limit-based scoring loss (-RS), double limit scoring Los (-SS) are from Zhou et al. (2017, 2021) For the other compared models, we report the original results from Lin et al. (2015); Ji et al. (2016); Yang et al. (2014); Nguyen et al. (2016).

From Table 2, we can see that models with L_{AS} (Including CAS and IAS refer to Section 3.2) loss have improved in different degrees. Compared to WN18 (95% + on hit@10) whose results are already high, FB15K has been improved significantly. On FB15K, the results (Compare in the best results for Hit@10) are increased by TransE 6.4%,

4.1.2 Results on WN18RR and FB15K-237

FB15K-237 (Toutanova and Chen, 2015) and WN18RR (Dettmers et al., 2018) are two more challenging datasets for Knowledge graph completions, where the inverse relations are deleted and the main relation patterns are symmetry/antisymmetry and composition patterns. In recent years, many embedding models (Dettmers et al., 2018; Sun et al., 2019) are tested on FB15K-237 and WN18RR by five metrics, MR, MRR, Hits@1, Hits@3 and Hits@10. In this experiment, by the five metrics, we compare our loss framework on TransE, TransH, ComplEx and RotatE with their former loss models Zhou et al. (2017, 2021); Bordes et al. (2013); Wang et al. (2014); Trouillon et al. (2016); Sun et al. (2019) and some baseline models Rescal (Nickel et al., 2011), DisMult (Yang et al., 2015) and ConvKB (Nguyen et al., 2018). We evaluate the models in the "bern" and "filt" settings. The optimal configurations are illustrated in Appendix A Table 6.

The experimental results on FB15K-237 and WN18RR are given in Table 3. In each column, the top-1 result with bold marker and top-2-4 results with underline markers are given. Our presented models with L_{AS} loss outperform the corresponding former models with L_R, L_{RS} and L_{SS} on all the metrics. The results also prove the effectiveness of our L_{AS} loss. Detailed improved results for MRR (Compare in the best results) metric are as follows. On WN18RR, the results are increased by TransE 1.5%, TransH 1.1%, ComplEx 3.0% and RotatE 1.2% than corresponding L_{SS} loss models. On FB15K237, the results are increased by TransE 0.8%, TransH-SS 1.2%, ComplEx-SS 2.9% and RotatE 0.6%.

Table 4: Accuracies(%) on Triplets Classification.

4.2 Triplet Classification

Triplet classification is a binary classification problem used to decide whether a given triplet (h,r,t) is correct or not. This task is usually tested by translation models, but it is rarely validated by nonlinear models (Bordes et al., 2013; Dettmers et al., 2018). Therefore, in this experiment, we only test the series of the compared translation models. We use three datasets, WN11, FB13 and FB15K (see Table 1) for the experiment. The training procedures are the same as the experiments of link predictions. For a testing triplet (h, r, t), it will be predicted positive if the score $f_r(h, t)$ is below a relation-specific threshold, otherwise negative. The relation-specific threshold is optimized by maximizing classification accuracies on the validation set.

We compare our loss framework L_{AS} used in TransE and TransH with baseline methods reported in Wang et al. (2014); Ji et al. (2015); Lin et al. (2015) who used the same datasets. TransE-SS and TransH-SS (Zhou et al., 2021) are retrained with the best configure in our framework. In the test phase, we need negative triplets for the binary classification evaluation. The datasets WN11 and FB13 released by NTN (Socher et al., 2013) with negative triplets. For FB15k, we construct the negative triplets following (Socher et al., 2013). The optimal configurations are illustrated in Appendix A Table 7.

The experimental results on triplet classification are shown in Table 4. In each column, the top-1 result with bold marker and top-2-3 results with underline markers are given. On WN11, models with L_{AS} all can reach an accuracy of 84%. On FB13, models with L_{AS} are comparable to former loss models. On FB15K, models with L_{AS} have significant improvement compared to former models, and TransH-CAS performs best resulting 91.6% accuracy among the compared models.

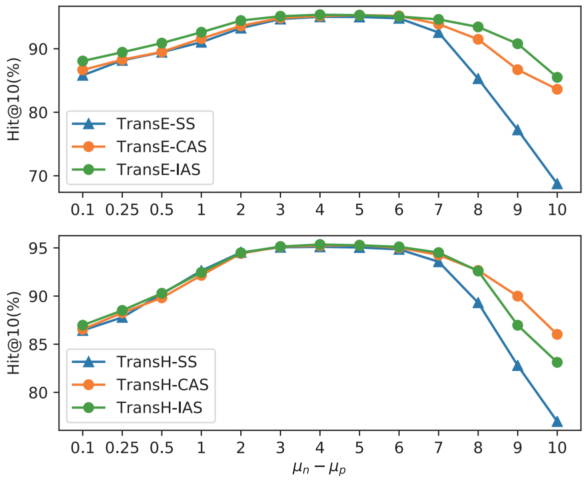

Figure 3: The impact of hyper-parameter $\mu_n - \mu_p$.

4.3 Discussion

Impact of the hyper-parameters. We analyze the impact of two hyper-parameters μ_p (the upper score margin for all positive triplets) and μ_n (the lower score margin for all negative triplets). On the WN18 dataset, we first select a fixed value of μ_p, and test the impact of different values of $\mu_n = \mu_p + \{0.1, 0.25, 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10\}$ on the experimental results. Figure 3 shows that good results can be obtained when $\mu_p - \mu_n$ is in the range of 2-7. Compared with L_{SS}, L_{AS} is more robust when $\mu_p - \mu_n$ takes a larger value.

Analysis of the convergence. We analyze the convergence of L_{AS} and L_R, L_{RS}, L_{SS} with TransE model on the FB15K dataset. Figure 4a shows the convergence curve of different loss functions after normalization. From the figure, we can see that L_{AS} can converge more quickly and reach lower states. This phenomenon confirms that L_{AS} has a more definite convergence target, which promotes separability for positive and negative triplets.

Analysis of the dynamic weight. We analyze the mean valid weights of positive and negative triplets ($S_p - v_p > 0$ and $S_p - \mu_p > 0$ for α_p, $v_n - S_n > 0$ and $\mu_p S_p > 0$ for α_p). Figure 4b shows the dynamic changes of α_p, α_n of TransH on the WN18 dataset (i donates IAS, c donates CAS). Normally, the positive triplets are further away from optimization at the beginning, so the value of α_p is larger. From Figure 4b we can see that the weight change of L_{IAS} is more sensitive than L_{CAS}, and the overall weight dynamic changes of the two are closer. For practical applications, we recommend using the simpler L_{CAS} first, and L_{IAS} may bring some better results.

5 Conclusion

In this paper, we propose a novel adaptive limit scoring loss framework for learning knowledge graph embeddings. The key idea of our proposal adaptive scoring loss is to re-weight each triplet and highlight the less-optimized triplet scores. For the setting of dynamic weights, we propose constant adaptive and independent adaptive methods according to the positioning of the circle center. We apply our loss framework on several knowledge graph embedding models such as TransE, TransH, ComplEx and RotatE, and conduct experiments on WordNet and Freebase datasets with link prediction and triplet classification tasks. The experimental results show the superiority of our proposed method.

OCR Improves Machine Translation for Low-Resource Languages

Abstract

We aim to investigate the performance of current OCR systems on low resource languages and low resource scripts. We introduce and make publicly available a novel benchmark, OCR4MT, consisting of real and synthetic data, enriched with noise, for 60 low-resource languages in low resource scripts. We evaluate state-of-the-art OCR systems on our benchmark and analyse most common errors. We show that OCR monolingual data is a valuable resource that can increase performance of Machine Translation models, when used in backtranslation. We then perform an ablation study to investigate how OCR errors impact Machine Translation performance and determine what is the minimum level of OCR quality needed for the monolingual data to be useful for Machine Translation.

1 Introduction

Despite many recent successes, Machine Translation still lacks support or fails to achieve good performance for most low-resource languages, which represent a very large fraction of the languages spoken by the world's population (Fan et al., 2020; Wenzek et al., 2020; Goyal et al., 2021).

The poor performance in these settings can largely be attributed to the lack of training data. Many techniques for improving Machine Translation, such as backtranslation (Sennrich et al., 2016; Edunov et al., 2018; Zhang et al., 2020) and approaches which make use of pre-trained language models (Gao et al., 2019; Chen et al., 2021; Liu et al., 2021), rely heavily on high quality monolingual data, which is not readily available for low-resource languages. Fortunately, many books and other resources in these languages have been digitized and made available online. However, this textual data is "locked" away in formats such as PDFs and images, which are not readily accessible. As a result, there are large unexplored collections of data in many languages which could be used as a source for monolingual data. For example, one Nepali books corpus[1], contains around 342M tokens, which would potentially make it one of the largest sources of monolingual data for this language.

A solution to this problem is to rely on modern Optical Character Recognition (OCR) tools to extract the text. Unfortunately however, most of the OCR models have only been evaluated on a handful of languages, and public benchmarks for low-resource scripts and languages are lacking (Smith, 2007a; Wick et al., 2020). As a result, a comprehensive evaluation of OCR tools, particularly for low-resource languages and scripts, is still an open problem. Moreover, there is little-to-no understanding of the downstream effect that recognition errors will have on the data augmentation techniques that make use of high-quality monolingual data, such as the methods that low-resource language translation typically relies upon.

In this paper, we pose the question of what is the minimum level of OCR quality needed for OCR-extracted monolingual text to be useful for Machine Translation, particularly in low-resource scenarios. To this end, in this work: (*i*) we create and release an OCR benchmark, OCR4MT, first of its kind, based on real and synthetic data, enriched with noise, for 60 low-resource languages in low resource scripts; (*ii*) we evaluate commercial and research state-of-the-art OCR models on our benchmark, analyse their performance and extract their common errors for many languages; and (*iii*) we investigate how the most frequent OCR errors impact Machine Translation performance and determine what is the minimum level of OCR quality needed for monolingual data to be useful for Machine Translation.

From our results, we observe that the best avail-

May 22-27, 2022

able OCR systems work well on Latin scripts and perform significantly worse on non-Latin and non-European scripts (e.g., Perso-Arabic, Khmer).

Our findings also show that monolingual data from OCR is a valuable source of data for improving Machine Translation for low resource languages, paving the way for future research on data augmentation for Machine Translation based on monolingual data extracted from OCR-ed documents.

2 Related Work

Despite extensive progress, Machine Translation for low resource languages is still an unsolved problem. This is mainly due to two different aspects: model architecture and lack of training data. In our work we focus on addressing the latter aspect.

One effective method to increase training data is to augment the parallel training corpus with back-translations of target language sentences (Sennrich et al., 2016; Edunov et al., 2018).

There are large collections of unexplored scanned documents (i.e., PDFs) and images in low resource languages, that can be used as monolingual data for backtranslation, such as online repositories of books[2] or online archives[3]. Works like Rijhwani et al. (2020a) or Bustamante et al. (2020) also acknowledge that textual data for most low-resource languages often exists in formats that are not machine-readable, such as paper books and scanned images. They address the task of extracting text from these resources and create benchmark datasets of transcriptions for several endangered languages: Ainu, Griko, Yakkha (Rijhwani et al., 2020a) and Shipibo-konibo, Ashaninka, Yanesha, Yine (Bustamante et al., 2020). A summary of current benchmarks and data resources for low-resource languages in Table 1. Observe that the related benchmarks contain few languages and few data compared to ours.

	#languages	**#lines**
Rijhwani et al. (2020a)	3	1,782
Bustamante et al. (2020)	4	60,000
Gupte et al. (2021)	4	not specified
OCR4MT	60	186,060

Table 1: Summary of some current benchmarks for low resource and endangered languages.

Our research can be applied on large data resources of endangered and low resource languages, such as AILLA[4] or ELAR[5]. Rijhwani et al. (2020a) find that endangered language linguistic archives contain thousands of scanned documents — the Archive of the Indigenous Languages of Latin America (AILLA) contains around 10,000 such documents and the Endangered Languages Archive (ELAR) has around 7,000. Rijhwani et al. 2020a find that endangered language documents often contain a translation into another (usually high-resource) language. Multilingual documents represent the majority in the archives they examined: AILLA contains 4,383 scanned documents with bilingual text and 1,246 scanned documents with trilingual text, while ELAR contains around 5,000 multilingual documents.

This monolingual data can be collected using Optical Character Recognition (OCR) tools. However, we don't know what is the quality of OCR tools, particularly for low-resource languages and low resource scripts. We aim to address this problem, by building a benchmark of 60 low resource languages with the goal of testing OCR systems and analyse how their errors impact backtranslation performance.

Rijhwani et al. 2020a also show how general-purpose OCR tools such as (Fujii et al., 2017; Ingle et al., 2019) are not robust to the data-scarce setting of endangered languages. They address this problem, by developing an OCR post-correction method tailored to ease the training in this data-scarce setting.

The work most similar to ours is the recent research by Gupte et al. 2021. They also built a pipeline to generate analog synthetic documents on which they run a commercial OCR model and analyse the OCR errors. Unlike our work, however, their focus is on improving Named Entity Recognition (NER) accuracy and on only 4 different languages: (English, German) from CoNLL 2003 (Sang and Meulder, 2003) and (English, Chinese and Arabic) from CoNLL 2012 (Pradhan et al., 2012).

Our work's novelty consists in providing the first large-scale benchmark of 60 low resource languages and low resource scripts, with the purpose of evaluating OCR performance on each language and it's downstream impact on Machine Translation.

3 OCR4MT Benchmark

To build a benchmark useful for multiple low-resource languages and low resource scripts, we proposed the use of texts that are freely-available in multiple languages. To this end, we chose the Universal Declaration of Human Rights (UDHR) database[6] which represents a legal domain, and the Flores 101 dataset (Goyal et al., 2021) which is based on Wikipedia. Moreover, we chose these datasets because they provide data in many languages, and have plain text we can evaluate OCR models on. Our benchmark contains *real* and *artificially-created* PDFs[7].

UDHR is composed of articles on fundamental human rights to be universally protected and it has been translated into over 500 languages. For each language, UDHR contains documents in different formats: plain text, PDF, XML and HTML. There are currently 460 translations fully converted to Unicode and available as text. Each document is composed of 30 short articles, on average 3 sentences each. We used the plain text and corresponding PDF files as validation data for the OCR systems.

The Flores 101 dataset consists of text data: 3,001 sentences extracted from English Wikipedia, for 101 languages, covering a variety of different topics and domains. We artificially created PDFs from the text documents by saving/exporting the text documents as PDF.

Language Selection. We select 60 languages which are both in Flores 101 and the UDHR datasets. We prioritize low resource languages, with low resource scripts. The scripts, together with the corresponding languages present in our benchmark can be seen in Table 2.

Table 2: Scripts and their corresponding languages in our benchmark. The languages are grouped into 8 groups, according to their location and script.

Annotation Process. The UDHR data is composed of one document image per language (PDF), and each document contains a preface and around 30 articles. In addition, each document has an accompanying text version. To build the benchmark, we first manually annotate the bounding boxes for each of the 30 PDF documents. Using the bounding boxes, we split each document image into individual articles of about 40 words in average. This allows to accurately compare the ground truth text version with the OCR output for each article.

Each article was labeled by a single annotator. We had a total of 10 annotators in total. In the tutorial we showed how to crop a bounding box around each article and how to name the images with their corresponding language code and number.

Data validation. We then validate the quality of annotations, both automatically and manually.

---

[6] `https://www.unicode.org/udhr/translations.html`

[7] We call *real*, the PDFs that had this format originally and we call *artificially-created*, the PDFs that were originally text documents and were converted into PDF format. We *artificially created* PDFs in order to increase our benchmark data size, as by applying augmentation techniques (i.e., adding noise) they can resemble the *real* PDFs.

We automatically validate each article by measuring the CER per article. If the CER between the PDF labeled version and the text version is greater than two standard deviations away from the mean, the article is marked as anomalous (Cousineau and Chartier, 2010). We manually check and re-annotate all the anomalous articles until no anomalies were detected.

During the manual anomaly check process, we found cases when for some languages, i.e., Malayalam and Pashto, some articles were missing in the original PDF document. In such cases, we removed those articles from the benchmark. We also found and removed all articles for which the PDF and text versions had different contents (i.e., they were paraphrases of each other). In total, we removed 141 articles, which is ∼7.8% of the total number of initial articles. Finally, we obtain 1,659 pairs of PDF and corresponding text versions of articles.

Data Augmentation. To make the artificial data closer to real life PDFs, we apply different augmentation techniques: changing font, color, size, letter spacing, opacity, italic, bold and image: skewing, adding salt & pepper noise. We choose common fonts for the data scripts: Times New Roman (for Arabic, Latin), Arial (for Arabic, Cyrillic), Verdana (for Cyrillic), Noto Sans Devanagari (for Devanagari), Calibri (for Pashto), Jameel Noori Nastaleeq (for Urdu), Browalia New (for Thai), Korean (for Korean), PMingLiu (for Traditional Chinese). The letter spacing, opacity, skewing and noise levels can be adjusted. A sample augmented document from Flores 101 is shown in Figure 1.

4 OCR Evaluation

To estimate the impact of recognition errors in downstream tasks, namely Machine Translation, we perform a *black-box* evaluation of two SOTA OCR systems, one commercial and one research. These represent reasonable choices for an non-OCR expert, such as MT practitioners. Below, we describe our experimental setup in detail.

4.1 OCR SOTA systems

Following Rijhwani et al. (2020b), for the commercial use case, we evaluate the Google Vision API OCR system (Fujii et al., 2017; Ingle et al., 2019) as provided by the Google Vision AI toolkit[8]. For the research system, we use the Tesseract OCR engine (Smith, 2007b).

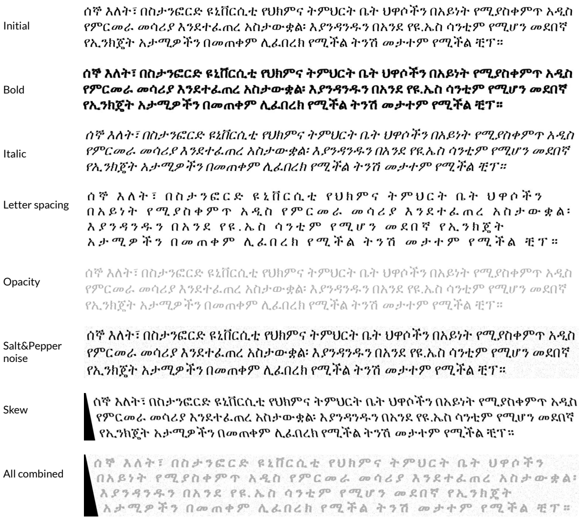

Figure 1: Data augmentation sample on Amharic artificial PDF from Flores 101: adding bold, italic, increasing letter spacing, decreasing opacity, adding salt and pepper, skewing and all combined.

Google Vision OCR system is highly performant and covers 60 major languages in 29 scripts. It also provides script-specific OCR models in addition to language specific ones. Per-script models are more robust to unknown languages because they are trained on data from multiple languages and can act as a general character recognizer without relying on a single language's model (Rijhwani et al., 2020a).

Tesseract is one of the most accurate open-source OCR engines (Smith, 2007b). In our experiments, we run Tesseract version 4, which is based on an LSTM architecture (Hochreiter and Schmidhuber, 1997). Tesseract can recognize more than 100 languages and it can be trained to recognize other languages.

4.2 Metrics

The metrics we use for measuring OCR performance is character error rate (CER) (Berg-Kirkpatrick et al., 2013; Schulz and Kuhn, 2017). The metrics are based on the Levenshtein or edit distance, which is the minimum number of single-character edits (insertions, deletions or substitutions) required to change one word into the other. CER is the edit distance between the OCR-ed data and the gold standard/initial data, divided by the total number of characters in the initial data. CER is not always between 0 and 100, in particular when there is a high number of insertions. This value is often associated to the percentage of characters that

---

[8] `https://cloud.google.com/vision`

were incorrectly predicted.

Word error rate (WER), CER's word-based counterpart, is also used in related work (Rijhwani et al., 2020a; Rigaud et al., 2019; Chiron et al., 2017). In this work, we choose to report only CER, as word boundaries are not comparable across languages.

There is no single benchmark for defining a *good* CER value, as it is highly dependent on the use case. Different scenarios and complexity (e.g., printed vs. handwritten text, type of content, etc.) can result in varying OCR performances. In Holley (2009), a review of OCR accuracy in large-scale Australian newspaper digitization programs came up with these benchmarks, for printed text:

- **Good** OCR accuracy: CER 1-2% (i.e., 98–99% accurate)
- **Average** OCR accuracy: CER 2-10%
- **Poor** OCR accuracy: CER > 10% (i.e., below 90% accurate)

4.3 General Results

We evaluate each model on the 60 languages from our benchmark, on both artificially created PDFs (Flores 101) and real PDFs (UDHR).

From the results in Table 3, we can see that the commercial system from Fujii et al. (2017) performs overall better than Tesseract across languages and data types: 20% more languages have good performance on artificial data and 15% more languages have good performance on real data. In Table 5 we also provide the results for each language, OCR system and data.

As expected, we also observe that the OCR performance is higher on artificially created PDFs (average CER 5.9 and 2.0) compared to real PDFs (average CER 12.1 and 8.5). We want to verify this is not due to the content, but to the format of the data. Therefore, we create artificial PDFs from the real ones in UDHR data, and run the OCR models on each of the 3 datasets. The results can be seen in Figure 2.

4.4 Group analysis

We also observe that the performance of the OCR systems vary based on script and location. Therefore, we group the 60 languages into 8 groups, as in Table 2, according to their script and location: Latin, Cyrillic, Perso-Arabic, North Indic, South Indic, Southeast Asian (SEA), China-Japan-Korea (CJK) and Other/Unique (Armenian, Amharic, Georgian, Greek, Hebrew). We run the overall best OCR system (Fujii et al., 2017) on these 8 groups of languages and compare the performance between language groups and also between the different data types: real PDFs (UDHR) and artificial PDFs (Flores 101). The results can be seen in Figure 3. Our observations and takeaways from this evaluation are the following:

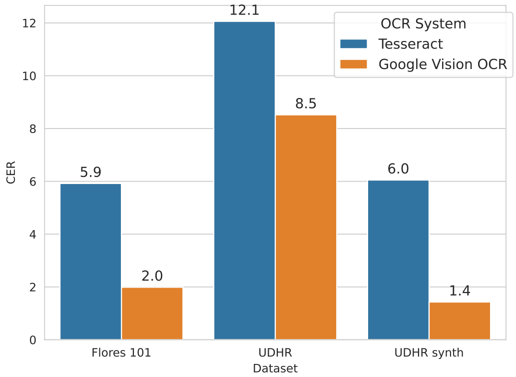

Figure 2: Average CER (the lower, the better) of the SOTA OCR systems: Tesseract and Fujii et al. 2017, across datasets, over 60 languages. UDHR synth contains artificially created PDFs from UDHR.

- **Artificially created data is easier to recognize**. As expected, the OCR SOTA model performs overall better on artificially created PDFs (Flores 101) than on real PDFs (UDHR). This holds for each group of languages, with the exception of the Perso-Arabic group where the OCR accuracy is slightly poorer (13.7 CER on Flores 101 and 13.2 CER on UDHR).
- **Latin and Cyrillic achieve the best performance**. The OCR SOTA model accuracy is the highest for European scripts such as Latin and Cyrillic. The OCR accuracy on Latin and Cyrillic is good (< 2% CER) on both Flores 101 and UDHR data. Therefore, we conclude that efforts for improving OCR models should focus on groups of languages other than Latin and Cyrillic.
- **Perso-Arabic performs badly**. Given that the Perso-Arabic group has a poor performance on both Flores 101 and UDHR data (> 10% CER), we conclude that the Perso-Arabic group needs considerable attention when improving OCR models.
- **Performance varies per languages/type of data**. The North Indic, South Indic, SEA and Other/Unique (Armenian, Amharic, Georgian,

OCR accuracy	**Flores 101**		**UDHR**	
	Tesseract	Fujii et al. 2017	Tesseract	Fujii et al. 2017
Good (CER $<$ 2%)	60%	80%	35%	50%
Average (CER 2-10%)	28.3%	15%	31.7%	23.3%
Poor (CER $>$ 10%)	11.6%	5%	33.3%	26.7%

Table 3: Evaluation of SOTA models on our benchmark: percentage of languages with a good, average and poor OCR accuracy, on artificial PDFs (Flores 101) and real PDFs (UDHR).

Greek, Hebrew) groups have a good or average OCR accuracy on artificially created data (Flores 101) and a poor OCR accuracy on real data (UDHR). This shows that OCR models need more real training data from the North Indic, South Indic, SEA and Other/Unique (Armenian, Amharic, Georgian, Greek, Hebrew) groups. A notable exception is the performance for the CJK group, which has a similar performance on both datasets.

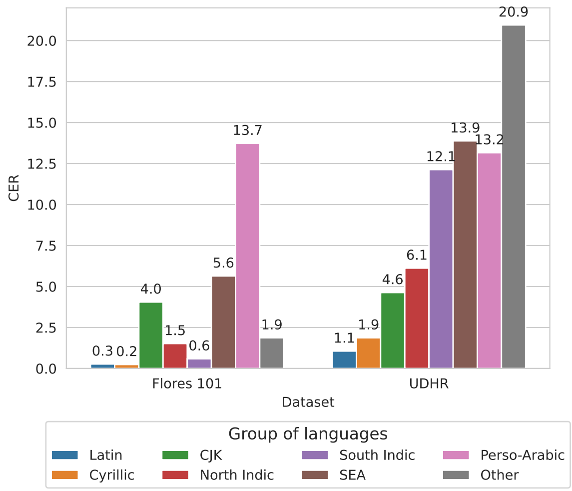

Figure 3: Average CER (the lower, the better) of best performing OCR model (Fujii et al. (2017)), across groups of languages in UDHR and Flores 101 datasets.

5 OCR impact in Machine Translation

Monolingual data is a valuable resource for Machine Translation, particularly for data augmentation techniques such as backtranslation. While there is plenty of monolingual data available for a few languages, there is a lack of data for very low resource languages. Fortunately, we have observed that there exist collections of monolingual data for low resource languages available as PDFs and images.

However, we still do not know whether the quality of the OCR-ed data is good enough to be used for training and improve the performance of a Machine Translation (MT) model. In this section, we explore the performance of an MT model after being trained on backtranslated OCR-ed (OCR+BT) data. In particular, we explore the setup in which a pre-trained multilingual model is fine-tuned on backtranslated data obtained from OCR-ed monolingual data. We use this setup to understand the cases in which OCR data improves or hurts performance.

5.1 The Nepali case

One of the languages with a promising number of documents is Nepali, which contains around 342M tokens from the corpus of Nepali books[9], which potentially makes it the largest sources of monolingual data for this language. To understand how valuable is the data and the validity of our evaluation setup, we explore adding OCR+BT data in small increments.

Setup. We collect the OCR-ed Nepali data using the open-source model Tesseract (Smith, 2007b). We then perform backtranslation, where we translate the OCR-ed Nepali data into English synthetic data using a SOTA MT model and use the data to fine-tune the model. As SOTA MT model, we use the pre-trained model M2M-124 with 615M parameters from Goyal et al. 2021 which was extended to 124 languages from the M2M-100 multilingual model (Fan et al., 2020).

We fine-tune the model on 10k, 20k and 30k sentences and obtain significant gains in performance. The results can be seen in Figure 4. Observe how the performance significantly increases (+7 BLEU) with the additional 30K pairs of OCR+BT data.

5.2 The impact of OCR errors on MT

As seen in Figure 4, the performance of the SOTA MT model increased significantly when fine-tuned on OCR-ed data. Therefore, we want to explore in more depth what is the level of quality needed for

---

[9] `https://pustakalaya.org/en/`

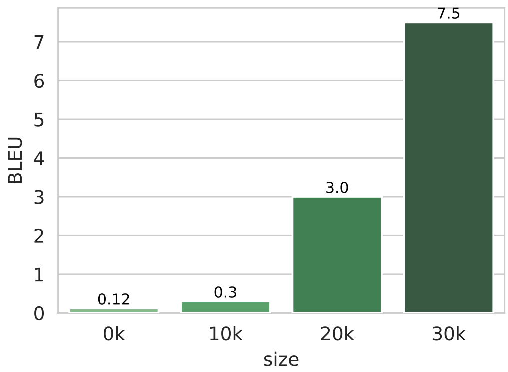

Figure 4: English to Nepali Machine Translation results from fine-tuning on OCR-ed monolingual data collected from Nepali books corpus.

the OCR-ed data to be useful for Machine Translation. Specifically, we want to measure the impact of OCR errors on MT performance: i) which error types affect it the most; ii) if there is an error threshold after which the OCR-ed data is detrimental to the MT model/hurts the performance; iii) if this threshold depends on data size or language.

To measure these, we first learn automatically the most frequent recognition errors that happen in each language. Then inject these errors to clean monolingual data to simulate an imperfect OCR process. Finally, we run several backtranslation experiments using the error-injected data and vary the data size and rate of OCR errors applied to the data.

Monolingual Data. We select three languages, with diverse scripts, based on their high error rates on the OCR-ed UDHR data: Khmer, Pashto and Tamil. We apply the OCR errors on large scale monolingual data from WikiMatrix (Schwenk et al., 2021) and CC100 (Wenzek et al., 2020; Conneau et al., 2020). To determine how the size of the monolingual data influence translation performance, we vary the data size to be 10,000 and 20,000 sentences.

OCR errors. We insert the 10 most frequent OCR errors from the best performing model on the UDHR test set. The errors are insertions, deletions and substitutions[10]. Some examples of most common character deletions and substitutions are shown in Table 4. The errors are applied randomly to the monolingual data, based on the frequency they appear in the UDHR data. We vary the rate at which we apply the errors on the monolingual data from 0 to 20. We then measure CER. A CER of 20 means that around 20% of the characters are incorrect.

Language	Substitution	Deletion
Khmer	ឌ → ត	ឌ
Lao	ໃ→ ໄ ; ລ→ ຣ	ຣ
Pashto	ګ → گ ; ي → ی	ي

Table 4: Examples of most common substitutions and deletions from UDHR OCR-ed data in Khmer, Lao and Pashto.

Backtranslation. We use the same MT model that we used in the Nepali experiment, the pre-trained M2M-124 model with 615M parameters from Goyal et al. 2021. The source language is English and target languages are Khmer, Pashto and Tamil.

We train a separate model for each target language. In order to measure how the OCR errors affect backtranslation performance, we run the experiments on both the initial/non OCR-ed monolingual data and the OCR-ed monolingual data. We use the M2M-124 pre-trained model in backtranslation as following. First, we translate the monolingual corpus into English, using the M2M-124 pre-trained model. Then, we fine-tune the model on the generated noisy English corpus and target monolingual data. For testing the fine-tuned model we use the the Flores devtest set and for validation, the Flores dev set (Goyal et al., 2021).

5.3 Evaluation

We compare the performance of the M2M-124 fine-tuned on OCR-ed monolingual data with the M2M-124 pre-trained model and with the M2M-124 fine-tuned on initial/non OCR-ed monolingual data. The evaluation metric used is BLEU score over tokenized text with an spm model (Goyal et al., 2021). The results can be seen in Figure 5.

Our observations and takeaways from this ablation are the following.

- **Translation quality is robust to small amounts of noise**. When comparing performance of fine-tuning MT models on the OCR-ed data vs. initial/non OCR-ed, the MT performance varies per language, but on average, until CER 4%, there is very few difference in

---

[10] One interesting fact is that the most common insertion and deletion across languages is the white-space.

BLEU score. Therefore, OCR-ed data with average OCR acuracy ($\leq$ 4% CER) can be effectively used for fine-tuning MT models. Beyond that threshold, more degradation can be expected. However, in absense of any other data, noisy OCR-ed data still provides an advantage.

- **Replacements are more damaging than other errors.** The different types of OCR errors (insertion, deletion and replacement) have different effects on the overall MT performance. On average, the replacement OCR error affects MT performance more than insertions and deletions: e.g., for fine-tuning data size 20k, until CER ~10, the drop in performance caused by deletions or insertions is negligible and reaches -2 BLEU by CER 20, while replacements reduce the BLEU score much faster than the other error types (~-2 BLEU at CER 10 and -6 BLEU at CER 20). Therefore, OCR-ed data with average OCR accuracy (CER $\leq$ 10) with mostly insertion and deletion errors can be effectively used for fine-tuning MT models.
- **More data results on higher or more rapid decreases in BLEU scores.** This trend is observed mostly for replacement errors. The insertions and deletions affect the OCR performance about the same amount (-2 BLEU at CER 20) in both 10k and 20k fine-tuning data size.

6 Conclusion

In this paper, we proposed a new benchmark with real and synthetic data, enriched with noise, for 60 low-resource languages in low resource scripts. We group the 60 languages into groups according to their scripts and location, evaluate SOTA OCR models on our benchmark and extract their most common errors. We use the SOTA OCR errors to measure their impact on Machine Translation models by comparing the MT models fine-tuned with OCR-ed data with pre-trained MT models and MT models fine-tuned with initial/non OCR-ed data.

Our most important takeaway is that OCR-ed monolingual data improves Machine Translation (MT) through backtranslation. This augmentation is robust to most types of errors, except replacements, and in general most current OCR models produce good enough recognition to be able to train MT models, with the exception of a few scripts like Perso Arabic.

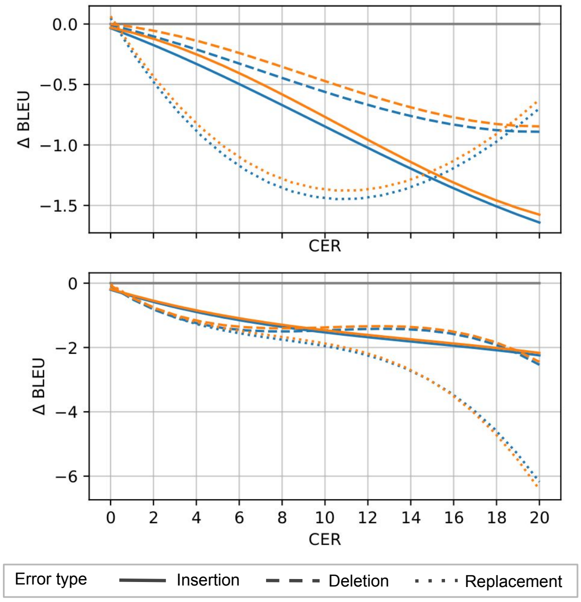

Figure 5: Ablation studies on OCR errors impact on MT performance. Upper graph (fine-tuning on 10k data) and lower graph (fine-tuning on 20k data) show the difference in BLEU scores between the M2M-124 MT model fine-tuned on OCR-ed data and the pre-trained M2M-124 MT model (shown in orange) and the difference in BLEU scores between the M2M-124 MT model fine-tuned on OCR-ed data and the M2M-124 MT model fine-tuned on non OCR-ed data (shown in blue).

Our work paves the way for future research on data augmentation for Machine Translation based on OCR documents.

The scripts to download and process the benchmark introduced in this paper are available at `https://github.com/facebookresearch/flores`.

Abstract

Large-scale pre-trained language models have demonstrated strong knowledge representation ability. However, recent studies suggest that even though these giant models contain rich simple commonsense knowledge (e.g., bird can fly and fish can swim.), they often struggle with complex commonsense knowledge that involves multiple eventualities (verb-centric phrases, e.g., identifying the relationship between "Jim yells at Bob" and "Bob is upset"). To address this issue, in this paper, we propose to help pre-trained language models better incorporate complex commonsense knowledge. Unlike direct fine-tuning approaches, we do not focus on a specific task and instead propose a general language model named CoCoLM. Through the careful training over a large-scale eventuality knowledge graph ASER, we successfully teach pre-trained language models (i.e., BERT and RoBERTa) rich discourse-level commonsense knowledge among eventualities. Experiments on multiple commonsense tasks that require the correct understanding of eventualities demonstrate the effectiveness of CoCoLM.

1 Introduction

Recently, large-scale pre-trained language representation models (LMs) (Devlin et al., 2019; Liu et al., 2019) have demonstrated the strong ability to discover useful linguistic properties of syntax and remember an impressive amount of knowledge with self-supervised training over a large unlabeled corpus (Petroni et al., 2019; Jiang et al., 2020). On top of that, with the help of the fine-tuning step, LMs can learn how to use the memorized knowledge for different tasks, and thus achieve outstanding performance on many downstream natural language processing (NLP) tasks.

As discussed in Verga et al. (2020), while language models have already captured rich knowledge, they often only perform well when the semantic unit is a single token while poorly when the semantic unit is more complex (e.g., a multi-token named entity or an **eventuality**, which is a linguistic term for verb-centric phrases covering *activities*, *states* and *events* (Bach, 1986; Araki and Mitamura, 2018)). For example, as shown in Table 1, if we follow LAMA (Petroni et al., 2019) to analyze the knowledge contained in BERT-large (Devlin et al., 2019) with a token prediction task, we can find out that BERT can understand that birds can fly, and a car is used for transportation, but it fails to understand the relation between "Jim yells at Bob" and relevant eventualities. An important reason behind this is that current language models heavily rely on token-level masked language models (MLMs) as the loss function, which can effectively represent and memorize token co-occurrence statistics[1] but struggle at perceiving multi-token concepts.

Query	Answer
Birds can [MASK]. Cars are used for [MASK].	fly transport
Jim yells at Bob, [MASK] Jim is upset. Jim yells at Bob, [MASK] Bob is upset.	but but

Table 1: Exploring knowledge contained in pre-trained language models following LAMA (Petroni et al., 2019). Queries and prediction returned by BERT-large are presented. Semantically plausible and implausible prediction are indicated with blue and red colors.

To address this problem and equip LMs with complex and accurate human knowledge, several recent works attempt to integrate entity representations from external knowledge graphs. While those approaches have been proved effective in merging structured knowledge into the LMs, they still have two limitations when applying to eventuality representations: (1) The first line of work (Verga

Type	Sequences
Temporal	I had a dream. *Precedence* (**Before**) I met with you yesterday. *Succession* (**After**) There were so many matters.
Casual	I go to supermarket. *Reason* (**Because**) I have a coupon. *Result* (**So**) The price is great.
Others	You can come with me. *Alternative* (**Or**) You can stand here. *Contrast* (**But**) The situation remains unchanged.

Table 2: Examples of eventuality sequences with different types of discourse relations (highlighted with pink) and connectives (bolded). Note there may exist multi-relational eventuality pairs

et al., 2020; Shen et al., 2020; Févry et al., 2020) restricts a fixed set of named entities or concepts to be linked to KGs while the eventualities are not easily canonicalized. There are enormous eventualities, which many of them refer to similar meanings such as "Tom is upset" and "Alice is upset". (2) The second class of methods uses powerful contextualized representations to encode one-hop triplets from KGs (Bosselut et al., 2019; Yao et al., 2019) for the task of KG completion. However, it is not sufficient for tasks that require the understanding of complex discourse relations in the event sequences or chains. For example pretrained LMs on the story ending prediction task (Mostafazadeh et al., 2016) have gaps with human performance (Li et al., 2019). Besides that, different types of relations (*casual* or *temporal*) make high-order inference over eventualities difficult and challenging.

In this paper, to effectively inject eventuality knowledge into pre-trained language representation models, we propose a knowledge injection framework CoCoLM, which requires no concept or eventuality linking and encodes multi-hop eventuality information as well as their discourse relations. The starting point is a large-scale eventuality knowledge graph, ASER (Zhang et al., 2020b), where the edges are discourse relations among eventualities (e.g., "being hungry" can cause "eat food" and "being hungry" often happens at the same time as "being tired"). First, we go beyond one-hop modeling (Yao et al., 2019; Bosselut et al., 2019) and carefully conduct weighted random walk over ASER to harvest multi-hop eventuality sequences connected by discourse relations (§2.1). Individual eventualities are contextualized by coherent sequences (examples in Table 2). Second, we fine-tune pretrained LMs on the sampled sequences and reformulate the masked language modeling objective to new *eventuality-level* masking to perceive the eventualities as independent semantic units (§ 2.2). In addition, two auxiliary tasks of discourse relation prediction are proposed to make implicit commonsense inferences (§ 2.3). For example, the new tasks explicitly reinforce the casual relation prediction between "I have a coupon" and "The price is great". By doing so, we successfully expose and inject fruitful high-order information between eventualities to pretrained LMs. To understand the impact of our proposed CoCoLM, we conduct experiments on three tasks that require the understanding of temporal, causal, mixed (multiple) relations respectively. The results show that our method achieves substantial improvements on the multiple-relation task while competitive performance on single-relation tasks. Extensive analyses are conducted to show the effect and contribution of all components in CoCoLM. Our main contributions are as follows:

- We propose CoCoLM, a new contextualized language model enhanced by complex commonsense knowledge from high-order discourse relations. CoCoLM is trained to predict the whole eventuality among the sequences using a large-scale eventuality KG.
- We introduce two auxiliary discourse tasks to help incorporate discourse-related knowledge into pre-trained language models, which complement the special eventuality masking strategy.
- CoCoLM achieves stronger performance than the baseline LMs on multiple datasets that require the understanding of complex commonsense knowledge about eventualities.[2]

2 Methods

The overall framework of CoCoLM is presented in Figure 1. Given a pre-trained language model, we inject complex commonsense knowledge about eventualities by adding one adaptive pre-training stage (Gururangan et al., 2020). Specifically, we first generate eventuality sequences based on carefully controlled walks over existing eventuality knowledge graphs and then use the sequences as

---

[2] Our code and models are available at `https://github.com/HKUST-KnowComp/Co2LM`.

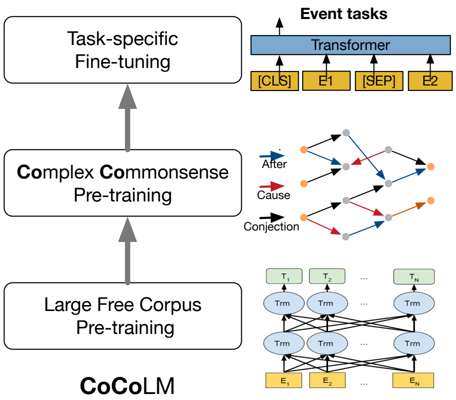

Figure 1: The overall framework of CoCoLM. On top of base pre-trained LMs, complex commonsense knowledge from the eventuality sequences is injected by fine-tuning MLMs and auxiliary discourse tasks.

the context to help LMs handle eventualities. Besides the original token-level MLM objective, we also introduce the *eventuality-level* masking strategy and several auxiliary tasks to assist the training. As the training is not task-specific, the resulting LM can be easily applied to any downstream tasks via another task-specific fine-tuning stage.

2.1 Eventuality Sequence Generation

Multi-hop path information have been shown useful and interpretable to provide extra context knowledge by connecting the concepts from ConceptNet (Speer et al., 2017) for commonsense reasoning tasks (Lin et al., 2019; Wang et al., 2020a). Similarly, we generate eventuality sequences by leveraging ASER, which uses eventualities as nodes and the discourse relations as edges. ASER extracts rich eventuality knowledge from diverse corpus, such as "being hungry" and "being tired" often happen together and people often "make a call" before they go. It contains much larger scale of discourse relations than DisSent (Nie et al., 2019). Interestingly, beyond the single edges, higher-order connections over ASER can also reflect insightful eventuality knowledge. For example, "sleep" and "go" are not likely to happen at the same time because "sleep" can be caused by "being tired" and there exist *contrast* connections between "being tired" and "go". To include higher-order knowledge into the model, we propose to take the whole graphical structure into consideration rather than single-hop edges. Motivated by DeepWalk (Perozzi et al., 2014), we randomly sample paths to simulate the overall graph structure and generate eventuality-level co-occurrence information.

Given the initial knowledge graph $\mathcal{G} = (\mathcal{E}, \mathcal{R})$, where $\mathcal{E}$ is the eventuality set and $\mathcal{R}$ is the relation set, we conduct the weighted random walk based on the edge weights over $\mathcal{G}$ to sample eventuality paths. We denote each path as $(E_0, r_0, E_1, r_1, ..., r_{l-1}, E_l)$, where E means an eventuality, r a discourse edge connecting two eventualities, and l the numbers of eventualities along the sequence. To convert the sampled sentence into a token list, we keep all words in each event as a sentence and use representative connectives for each discourse relation to connect them (examples in the Table 2; full list in the Appendix Table 9). As ASER is automatically extracted from raw corpus, it may contain noise. To minimize the influence of the noise and improve the informativeness, the selected paths should fulfill:

1. To filter out rare eventualities, the frequency of starting eventualities has to be larger than five.

2. Other than the relations that have the transitive property (e.g., *Precedence*, *Result*), each selected path should not contain successive edges with repeated relations.

3. We manually improve the sampling probability of selecting sub-sequence patterns like "E_i **Condition** E_j **Reason** E_k". Since it has been proven that *if-then* rules (Sap et al., 2019) and *if-then-because* rules (Arabshahi et al., 2020) are crucial for reasoning.

2.2 Eventuality-Level Mask

Masking strategy plays a crucial role in the training of language representation models. Besides the random token-level masking strategy, many other masking strategies have been explored by previous literature such as the-whole-word masking (Devlin et al., 2019; Cui et al., 2019), entity masking (Sun et al., 2019; Shen et al., 2020) or text span masking (Joshi et al., 2020)[3]. Similarly, to effectively help the model view each eventuality as an independent semantic unit, we propose the following two masking strategies: (1) **Whole Eventuality Masking**: Similar to the whole word masking or entity masking strategies, the whole eventuality masking aims to reduce the prior biases of eventuality tokens. For example, given an eventuality sequence "I feel sleepy because I drink a cup of [MASK].",

---

[3] Unlike `SpanBERT`, we have discourse connectives as span boundaries and do not need the SBO objective.

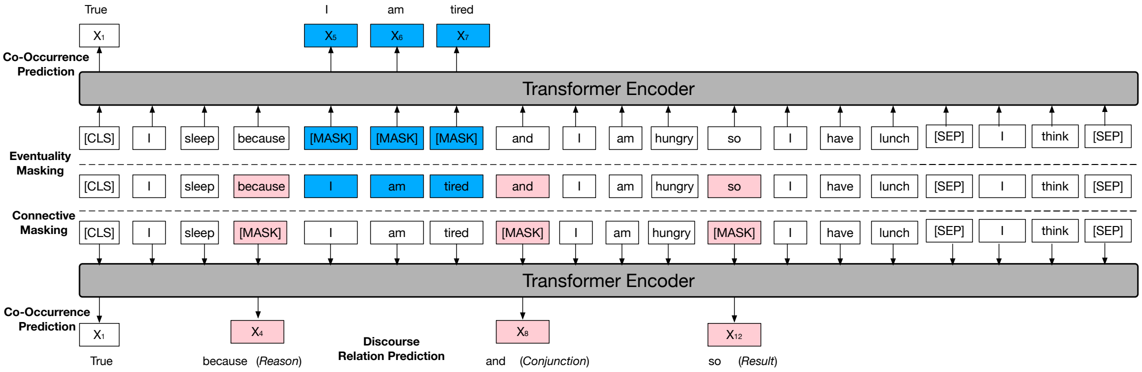

Figure 2: Illustration of CoCoLM-(Complex commonsense pre-training stage). Given an eventuality sequence, it is either masked by the whole eventuality masking (`in blue`) or discourse connective masking strategy (`in pink`). Besides the regular masked language model, the discourse relation labels are jointly predicted for masked connective tokens (on $\mathbf{x}_4$, $\mathbf{x}_8$ and $\mathbf{x}_{12}$). Co-occurrence prediction (on $\mathbf{x}_1$) is conducted for both masking strategies.

BERT would easily predict "coffee" or "tea" because of the prior knowledge of "cup of" inside the eventuality. Instead of that, masking the whole "I drink a cup of coffee" would encourage the prediction to treat each eventuality as an independent semantic unit and focus on the relations between them. For each sampled sequence, we randomly mask at most one eventuality to fulfill the masking budget, which is typically 25% of the sequence token length. (2) **Discourse Connective Masking**: Besides masking the eventualities, to effectively encode the discourse information, we also tried masking the discourse connectives.

Examples of two masking strategies are shown in Figure 2. It is worth mentioning that for each sequence, we only randomly select one type of masking strategy to guarantee that enough information is kept in the left tokens for the prediction. The formal masking objective is defined as follows. Given a tokenized sampled sequence $X = (x_1, x_2, ..., x_n)$, after masking several tokens, we pass it to a transformer encoder (Vaswani et al., 2017) and denote the resulting vector representations as $\mathbf{x_1}, \mathbf{x_2}, ...\mathbf{x_n}$. The training loss $\mathcal{L}_{mlm}$ can thus be defined as:

$$\mathcal{L}_{mlm} = -\frac{1}{|\mathbf{M}|}\sum_{i \in \mathbf{M}} \log P(x_i|\mathbf{x_i}), \tag{1}$$

where $\mathbf{M}$ means the set of masked tokens following the aforementioned masking strategies.

2.3 Auxiliary Tasks

A limitation of the MLM loss is that the prediction is over the entire vocabulary, and as a result, the model could not effectively learn the connection between eventualities and connective words. To remedy this and force the model to learn the discourse knowledge, we propose to add an additional classification layer after the last layer of transformer encoder and it feeds the output vector $\mathbf{x_i}$ of connective token x_i into a softmax layer over the set of discourse relation labels as follows.

$$P(l_i|\mathbf{x_i}) = \text{softmax}(\mathbf{x_i W} + \mathbf{b}), \tag{2}$$

$$\mathcal{L}_{rel} = -\sum_{i \in \mathbf{M}_R} \log P(l_i = \widetilde{l_i}|\mathbf{x}_i), \tag{3}$$

where $\mathbf{M}_R$ is the index set of masked discourse connective tokens (e.g., *because*, *and*, *so*) in Figure 2, l_i is the predicted discourse relation label, and $\widetilde{l_i}$ the label provided by ASER (10 relations in Table 9). $\mathbf{W}$ and $\mathbf{b}$ are trainable parameters.

Besides the aforementioned discourse relations, ASER also provides the *Co-occurrence* relations between eventualities, which mean that two eventualities appear in the same sentence, but there are no explicit discourse markers between them. Co-occurrence information has been used for narrative event prediction (Chambers and Jurafsky, 2008) Though *Co-occurrence* relations are less informative, high frequency pairs still reflect rich knowledge about eventualities. Motivated by this, we propose another auxiliary task to help the model to learn such knowledge. Specially, given an eventuality sequence $S = (E_0, r_0, E_1, r_1, ..., r_{l-1}, E_l)$ and an eventuality E_c, we format the input[4] as "[CLS] S [SEP] E_c [SEP]". We set 50% of the time E_c to

---

[4] The special tokens are based on the base model, i.e., we add "[CLS]" and "[SEP]" for `BERT` models and add "<s>" and "</s>" for `RoBERTa` models. All notations in the rest of this paragraph are based on `BERT`.

be the positive *co-occurred* eventuality with one of the eventualities in the sequence while 50% of the time E_c is randomly sampled negative in ASER. Similar to the next sentence prediction in the original BERT, on top of the vector representation of token [CLS], i.e., $\mathbf{x}_{cls}$, we add another classification layer to predict whether the *Co-occurrence* relations hold or not. The training objective $\mathcal{L}_{occur}$ for binary classification is similar to $\mathcal{L}_{rel}$:

$$\mathcal{L}_{occur} = -\log P(l_i = \widetilde{l_i}, |\mathbf{x}_{cls}), \tag{4}$$

where $\widetilde{l_i}$ is the true co-occurrence label (positive or negative) for the sequence.

Merging all three losses together, we can then define the overall loss function $\mathcal{L}$ as:

$$\mathcal{L} = \mathcal{L}_{mlm} + \mathcal{L}_{rel} + \mathcal{L}_{occur}. \tag{5}$$

3 Experiments

3.1 Implementation Details

In this work, we use the released ASER-core version[5] extracted from multi-domain corpora, which contains over 27.6 million eventualities and 8.8 million relations. We follow the heuristic rules in Sec. 2.1 to sample eventuality sequences for pretraining. Overall we generated 4,041,572 eventuality sequences (sentences), ranging from one to five hops and the one-hop sequence means the direct (first-order) edge in the ASER. We also downsample eventuality nodes with extremely high frequency such as *I see*. Sequence examples are listed in Table 2 and more examples as well as sequence distribution over different lengths are appended in the Appendix.

We select base and large version of `BERT` (Devlin et al., 2019), `RoBERTa` (Liu et al., 2019) as the base LM. For the continual complex commonsense pre-training phase, we use the Adam optimizer for 10 epochs with batch size 128, learning rate 1e-5 and weight decay 0.01. Considering the relative longer span of masked eventualities, we enlarge the masking proportion from 15% to 25%, which averagely add 1.7 more masked tokens in the sequences. We implemented the pretraining with Huggingface library (Wolf et al., 2020) and running CoCoLM pretraining on eight Nvidia V100 32GB GPUs took four days. Pretraining introduces two classification layers with thousands of parameters.

Dataset	Type	# Train	# Dev	# Test
ROCStories	Narrative (Multiple)	1,771	100	1,871
MATRES	Temporal	231*	25	20
COPA	Causal	400	100	500

Table 3: The statistics of evaluation datasets (See examples in A.1). The tasks are binary or multiple classification problems. Note the dataset of MATRES is split at the article level following Ballesteros et al. (2020).

3.2 Datasets and Evaluations

In this section, we introduce evaluation datasets and settings as follows:

ROCStories (Mostafazadeh et al., 2016) is widely used for story comprehension tasks such as Story Cloze Test. It contains 98,162 five-sentence coherent stories as the unlabeled training dataset, 1,872 four-sentence story contexts along with two candidate ending sentences in the dev and test datasets. The dataset split for the story ending prediction task is the same as Li et al. (2019).

MATRES (Ning et al., 2018b) is a pairwise event temporal ordering dataset, where each event pair in one document is annotated with a temporal relation (*Before, After, Equal, Vague*). It contains 13,577 event pairs extracted from 256 documents for training (25 left for dev) and 20 for testing.

COPA (Gordon et al., 2012) is a binary-choice commonsense causal reasoning task, which requires models to predict which the candidate hypothesis is the plausible effect/cause of the given premise. We follow the training/dev/test split in SuperGLUE (Wang et al., 2019).

The statistics of the three selected datasets are presented in Table 3. For fine-tuning experiments, we select the learning rate from {2e-5, 1e-5, 5e-6}, and maximize the sequence length and batch size such that they can fit into GPU memory. Fine-tuning was much faster due to fewer new parameters from classification layers.

Different from MATRES and COPA, solving the story ending tasks of ROCStories requires multi-type relation inferences including causal, temporal etc. Moreover, as mentioned in Sharma et al. (2018), there is a strong bias about the human-created negative endings such that the model can distinguish the positive and negative endings without seeing the first four events. Even though Sharma et al. (2018) tried to filter the annotations, the bias still cannot be fully relieved. As a result, to clearly show the effect of adding complex

Table 4: Evaluation results on three commonsense task (top scores in boldface). We report the accuracy of `ROCStories` dataset under normal supervised setting and debiased (D) setting mentioned in the §3.2.

knowledge about events into the LM, besides the most widely used supervised setting, we also report the performance of a *debiased setting*, where the model randomly selects events from other stories as the negative ending during the training. The debiased setting is indicated with “D”. Following previous works, we report accuracy for the ROCStories, MATRES and COPA tasks. For MATRES, we also report F1 scores by considering the task as general relation extraction and treating the label of *vague* as *no relation* (Ning et al., 2019). All models are trained until convergence and the best model on the dev set is selected to be evaluated.

4 Experimental Results

The results are presented in Table 4, from which we can see that CoCoLM consistently outperforms all the baselines on all three commonsense tasks, especially on the debiased setting of ROCStories.

Besides that, we can make the following observations. First, the improvement of our model is more significant on ROCStories than COPA and MATRES, which is mainly because multiple relation combinations in the eventuality sequences bring high-order information and thus help complex reasoning. Second, CoCoLM achieves significant improvement on lower-capacity LMs trained on small corpora. For example, CoCoLM brings up to 59.2% improvement over BERT-base on the ROCStories dataset. Third, compared with the original supervised setting, the debiased setting is more challenging for all models, which helps verify our assumptions that previous models might benefit from the bias. Here the debiased setting should be more fair for comparison. When we dig into the MATRES dataset, event pairs (typically verb pairs) are associated with the context, which some of could be easily inferred from the local context with obvious clues (Ballesteros et al., 2020) while the others may need external commonsense knowledge that can be memorized by the language models. As a comparison, both the ROCStories and COPA do not have any extra context, and thus require the pre-trained LMs to know the essential knowledge to solve those problems.

Method	Accuracy	Δ	Accuracy (D)	Δ (D)
CoCoLM	91.9	-	71.2	-
w/o *occur loss*	91.3	-0.6	70.4	-0.8
w/o *eventuality mask*	91.1	-0.8	70.2	-1.0
w/o *rel loss*	90.5	-1.4	69.6	-1.6
w/o *occur & rel losses*	90.3	-1.6	69.3	-1.9
w token-level *mlm* only	89.2	-2.7	69.2	-2.0

Table 5: Ablation study on ROCStories test set by removing different model components. *occur* and *rel* are discourse relation and co-occurrence loss respectively.

In the rest of this section, we conduct extensive experiments and case studies to demonstrate the contribution of different components. In all following analysis experiments, we use `BERT-large` as the base language model and `ROCStories` as the evaluation dataset.

4.1 Ablation Study

We conduct an ablation study in Table 5 via LM pretraining with different settings and then fine-tuning. We can see that all components contribute to the final success of our model, especially the *Relation loss*. This result again verified that discourse connective prediction is a much more challenging pretraining task as shown in Malmi et al. (2018). CoCoLM is optimized to memorize high-order discourse knowledge that strongly correlates with downstream tasks and thus brings

Resource	Accuracy	Δ	Accuracy (D)	Δ (D)
ASER (M)	91.9	-	71.2	-
ASER (S)	85.4	-6.5	67.5	-3.7
ATOMIC (S)	88.2	-3.7	68.2	- 3.0

Table 6: Effect of different event knowledge resources. "M" and "S" pertain to "multi-hop" and "single-hop".

more performance boost. Besides, when replacing the whole eventuality masking with random token masking, we can observe 0.8% (1.0%) accuracy drop, which indicates the usefulness of eventuality-level masking. The relative better improvement of *Co-occurrence loss* suggests our previous assumption that even though compared with other discourse relations (e.g., *Before* and *Cause*), the *Co-occurrence* relations have relatively weaker semantic, it still can help models to better understand events due to its large scale.

To further verify the effectiveness of proposed methods, we compare with the baseline that the `BERT-large` models are fine-tuned with only token-level MLM objective on syntactic eventuality sequences. The performance dropped close to finetuning over original `BERT-large`, which shows that the gains of CoCoLM are not simply from the MLM objective and the new proposed objectives as well as masking strategies contributed largely.

4.2 Effect of Different Knowledge Resources

To access the effect of high-order ASER commonsense knowledge, we compare with the performance of directly integrating single-hop edges from ASER. We decompose the multi-hop sequences into single-hop edges and keep the comparable size of single-hop edges with multi-hop ones. The results are shown in Table 6, from which we can see that there is still a notable gap between multi-hop and single-hop knowledge injection at the comparable size. Hence multi-hop knowledge is crucial for LMs to understand eventualities. Besides ASER, another important event knowledge resource is ATOMIC (Sap et al., 2019), which is a crowdsourced commonsense knowledge graph that contains nine types of *if-then* casual relations between social-centric events. However, it is a bipartite graph, which symbolically random walk over ATOMIC is impossible like normal graphs. Nevertheless, we are interested in the differences of injecting human-annotated and auto-extracted triplets into LMs. Though relation types and triplet size[6] may vary from other other, Fang et al. (2021) successfully converts discourse knowledge in ASER to *if-then* knowledge in ATOMIC and shows the former might roughly cover the latter. When injecting into LMs, we can see in Table 6 that ATOMIC can outperform the single-hop version of ASER since ATOMIC is cleaner with human annotations. We leave how to combine ASER and other event knowledge resources (Mostafazadeh et al., 2020; Hwang et al., 2020) to get more high-quality multi-hop event knowledge as our future work.

4.3 Effects of Knowledge Retrieval

We also study the effect of other knowledge injection methods, for example simple retrieving relevant nodes from ASER. We use the BM25 algorithm to retrieve Top 5 relevant nodes for each event in the ROCStories. Following Petroni et al. (2020), retrieved nodes are appended at the end of story context and separated by the `[SEP]` token. The results show no obvious improvements over baselines. The reason might be that single event nodes could not provide more information and all the tasks require relational knowledge. Advanced integration methods with retrieved knowledge like Lv et al. (2020) and Guu et al. (2020) are worthy to be deeply explored in the future.

4.4 Probing Experiments

We present one case study from the probing analysis experiment in Table 7 to further investigate the discourse-aware nature of our proposed language models. Motivated by Petroni et al. (2019), we put a `[MASK]` token between two events and try to ask the model to predict the connective. Take the case from COPA dataset as an example, connectives predicted by CoCoLM clearly show the *effect* relation between two events. However predictions from the baseline models reveal weaker (*temporal, conjunction*) or wrong (*contrast*) relations. Similar observations could be drawn from another two datasets. Like Table 1, we also sample 300 high-frequency pairs from ASER to predict connectives. The P@1 for CoCoLM (`BERT-large`) has 15.2% improvement over `BERT-large`. These observations show that CoCoLM manages to memorize richer discourse knowledge about daily events (Note that connective probing analysis does not mean strong correlations with downstream task performance).

---

[6] The detailed comparison is included in the AppendixA.4

Dataset	Example	BERT [MASK]	CoCoLM [MASK]
ROC Stories	Context: Ed made beef jerky for a living. He ran the business out of his garage. One day he woke up and noticed his garage jarred open. He looked inside and noticed everything in disarray Positive Ending: Ed was delighted to see this. Negative Ending: Ed was shocked called the police for an investigation.	Context + [MASK] + Ending: **P: when, then, while** **N: and, but, so**	Context + [MASK] + Ending: **P: so, hence, therefore** **N: or, and, though**
MATRES	The last surviving member of the team which first conquered Everest in 1953 has {e_1: died} in a Derbyshire nursing home. George Lowe, 89, {e_2: died} in Ripley on Wednesday after a long-term illness, with his wife Mary by his side.	S1, +[MASK] + S2: **and, sir, Dr**	S1, +[MASK] + S2: **then, afterwards, till**
COPA	Premise: The girl found a bug in her cereal. Positive Hypothesis: She lost her appetite. Negative Hypothesis: She poured milk in the bowl.	Pre+ [MASK] + Hypo: **P: then, but, and** **N: then, next, so**	Pre + [MASK] + Hypo: **P: so, therefore, thus**. **N: but, instead, and**.

Table 7: Examples from evaluation datasets. Connectives in blue are predicted by the `BERT-large` model and ones in pink are predicted by CoCoLM (`BERT-large`). "P" and "N" represent the positive and negative candidates.

5 Related Work

Understanding Events. It is important to represent and learn the commonsense knowledge for deeply understanding the causality and correlation between events. Recently various kinds of tasks requiring multiple dimensional event knowledge are proposed such as story ending prediction (Mostafazadeh et al., 2016), event temporal ordering prediction (Ning et al., 2018a), and event casual reasoning (Gordon et al., 2012). Prior studies have incorporated external commonsense knowledge from ConceptNet (Speer et al., 2017) and ATOMIC (Sap et al., 2019) for solving event representation (Ding et al., 2019), story generation tasks (Guan et al., 2020), KG completion (Bosselut et al., 2019). However, their event-level knowledge is sparse and incomplete due to the human-annotated acquisition, which thus limits the model capacity, especially when injecting into LMs. Zhang et al. (2020b) builds a large-scale eventuality knowledge graph, ASER, by specifying eventuality relations mined from discourse connectives. It explicitly provides structural high-order discourse information between events spanning from temporal, casual to co-occurred relations, which has been proven to be transferable to human-defined commonsense (Zhang et al., 2020a; Fang et al., 2021) and help with script learning (Lv et al., 2020). In this work, we aim at making full use of multi-dimensional high-order event knowledge in the ASER to help pretrained LMs understand events.

Injecting Knowledge into LMs. Though Petroni et al. (2019) shows that pre-trained LMs store factual knowledge without fine-tuning, still, LMs can not handle knowledge-intensive tasks such as open-domain question answering or commonsense reasoning. Previous works explore different ways to inject various knowledge into pre-trained LMs for downstream tasks. They mainly differ from knowledge resources, masking strategies, and training objectives. From the resource side, entity-centric KGs are infused into LMs in the form of linked entities (Zhang et al., 2019; Peters et al., 2019; Xiong et al., 2020). triplets (Yao et al., 2019; Liu et al., 2020; Wang et al., 2020b) or descriptions (Wang et al., 2021b; Yu et al., 2020). Besides that, linguistic knowledge (e.g.,synonym/hypernym relations (Lauscher et al., 2020), word-supersense (Levine et al., 2020), dependency parsing (Wang et al., 2020b), and constituent parsing (Zhou et al., 2019)) also plays a critical role to improve LMs. Simple commonsense knowledge from ConceptNet (Speer et al., 2017) is injected into LMs via linked entity-level MLMs and a new distractor loss function (Shen et al., 2020). Last but not least, domain-specific knowledge is also customized to improve relevant tasks such as mined sentiment word (Tian et al., 2020), event temporal patterns (Zhou et al., 2020), and numerical reasoning data (Geva et al., 2020). We refer readers to Safavi and Koutra (2021) for the comprehensive survey. In this work, we aim at injecting complex commonsense into pre-trained LMs with two significant difference against previous works: 1) we use the event rather than tokens as the semantic unit, and propose to use an eventuality-based masking strategy as well as two auxiliary tasks to help LMs understand events; 2) We first leverage the random walk process on a large-scale knowledge graph to include multi-hop knowledge.

6 Conclusion and Future Work

In this work, we aim at helping pre-trained language models understand complex commonsense about eventualities. Specifically, we first conduct the random walk over a large-scale eventuality-based knowledge graph to collect multi-hop event knowledge and then inject the knowledge into the pre-trained LMs with an eventuality-based mask strategy as well as two auxiliary tasks. Experiments on three downstream tasks as well as extensive analysis demonstrate the effectiveness of the proposed model. As our approach is a general solution, we believe that it can also be helpful for other tasks that require complex commonsense about events.

For future work, we would sample sub-graph structures to explore more meaningful event-centric commonsense knowledge (Wang et al., 2021a). Moreover, we will equip our models with generative abilities by finetuning powerful T5 (Raffel et al., 2020) or BART (Lewis et al., 2020) models to help narrative story completion (Ji et al., 2020), commonsense inference (Gabriel et al., 2021), event infilling tasks (Lin et al., 2021). Unified event-aware language models like Zhou et al. (2022) would be promising and interesting directions.

A Appendices

A.1 Examples of Evaluation Datasets

We select one example for each commonsense evaluation dataset and list in Table 8. In terms of MATRES, it has 13,577 event pairs among 256 articles with 4 temporal relations, i.e., *Before* (6,874), *After*(4,570), *Equal* (470) and *Vague* (1,656). Compared with MATRES and COPA, solving the ROCStories requires more complex commonsense knowledge to understand the whole narrative and multiple types of relations across events.

Dataset	**Example**
ROC Stories	Context: The Mills next door had a new car. The car was stolen during the weekend. They came to my house and asked me if I knew anything. I told them I didn't, but for some reason they suspected me. Positive Ending: They called the police to come to my house. Negative Ending: They liked me a lot after that.
MATRES	Fidel Castro {e_1: invited} John Paul to {e_2: come} for a reason. *Label*: **BEFORE**
COPA	Premise: I knocked on my neighbor's door. Positive Hypothesis: My neighbor invited me in. Negative Hypothesis: My neighbor left his house.

Table 8: The examples for all commonsense evaluation datasets.

A.2 ASER Discourse Relations

In the Table 9, we list ten discourse relations as well as representative connectives (markers) used to train CoCoLM. We further categorize them into three types: "temporal", "casual" and "others". We refer the readers to original ASER papers (Zhang et al., 2020b) for detailed relation analysis.

Types	Relations	Connectives
Temporal	Precedence	before
	Succession	after
	Synchronous	meanwhile
Casual	Reason	because
	Result	so
	Condition	if
Others	Conjunction	and
	Contrast	but
	Alternative	or
	Concession	although

Table 9: The discourse relations as well as representative markers in the ASER knowledge graph.

A.3 Eventuality Sequences

We append more sampled eventuality sequences from random walk. Also we organize the sequences into several meta-paths (the paths with same relation patterns). Here only 2-hop and 3-hop sequences are listed and we could observe meaningful high-order connections between eventualities.

The sequence distributions with different lengths and types of relations are shown in the Figure 3. We can see that casual relations take up a small share, which again show that causal knowledge tends to be implicit and hard to acquire.

A.4 ATOMIC V.S. ASER

In this section, we summarize the nine casual/effect relations from ATOMIC (Sap et al., 2019) in the Table 2. Fang et al. (2021) shows ASER's discourse relations could be converted to causal knowl-

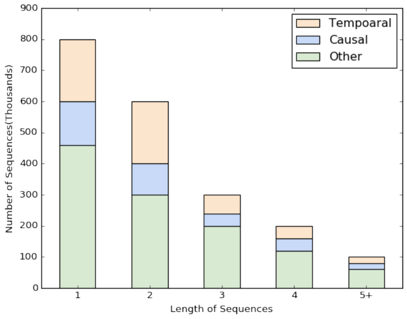

Figure 3: The distribution of lengths along with relation edges for generated eventuality sequences.

edge in the ATOMIC. Thus ASER might roughly cover the knowledge in the ATOMIC. Moreover, ASER also covers agentless events such as "the weather is good", which was partially covered by GLUCOSE (Mostafazadeh et al., 2020) However it contains noise compared with ATOMIC. CoCoLMexperiments show ATOMIC (877K edges) performs better than ASER(4.4 M - $5\times larger)$.

If-Then Types	Relations	Causal Types
If-Event-Then-State	xIntent	Cause
	xReact	Effect
	oReact	Effect
If-Event-Then-Event	xNeed	Cause
	xEffect	Effect
	xWant	Effect
	oEffect	Effect
	oWant	Effect
If-Event-Then-Persona	xAttr	Stative

Table 10: The *if-then* types and causal relations between events in the ATOMIC knowledge graph. For relations, "x" and "o" refer to PersonX and others while "xAttr", "xIntent", "xReact" mean the attribute, intent, reaction of PersonX *etc.*

Learning to Robustly Aggregate Labeling Functions for Semi-supervised Data Programming

Abstract

A critical bottleneck in supervised machine learning is the need for large amounts of labeled data which is expensive and time-consuming to obtain. Although a small amount of labeled data cannot be used to train a model, it can be used effectively for the generation of human-interpretable *labeling functions* (LFs). These LFs, in turn, have been used to generate a large amount of additional noisy labeled data in a paradigm that is now commonly referred to as data programming. Previous methods of generating LFs do not attempt to use the given labeled data further to train a model, thus missing opportunities for improving performance. Additionally, since the LFs are generated automatically, they are likely to be noisy, and naively aggregating these LFs can lead to suboptimal results. In this work, we propose an LF-based bi-level optimization framework WISDOM to solve these two critical limitations. WISDOM learns a *joint model* on the (same) labeled dataset used for LF induction along with any unlabeled data in a semi-supervised manner, and more critically, reweighs each LF according to its goodness, influencing its contribution to the semi-supervised loss using a robust bi-level optimization algorithm. We show that WISDOM significantly outperforms prior approaches on several text classification datasets. The source code can be found at `https://github.com/ayushbits/robust-aggregate-lfs`.

1 Introduction

Supervised machine learning approaches require large amounts of labeled data to train robust machine learning models. Human-annotated *gold* labels have become increasingly important to modern machine learning systems for tasks such as spam detection, (movie) genre classification, sequence labeling, *etc.* The creation of labeled data is, however, a time-consuming and costly process that requires large amounts of human labor. Together with the heavy reliance on labeled data for training models, this serves as a deterrent to achieving comparable performance on new tasks. As a result, various methods such as semi-supervision, distant supervision, and crowdsourcing have been proposed to reduce reliance on human annotation.

In particular, several recent data programming approaches (Bach et al., 2019; Maheshwari et al., 2021; Chatterjee et al., 2020; Awasthi et al., 2020) have proposed the use of *human-crafted* labeling functions to *weakly* associate labels with the training data. Typically, users encode supervision as rules/guides/heuristics in the form of labeling functions (LFs) that assign noisy labels to the unlabeled data, thus reducing dependence on human-labeled data. The noisy labels were aggregated using Label aggregators, which often employ generative models, to assign a label to the data instance. Examples of label aggregators are SNORKEL (Ratner et al., 2016) and CAGE (Chatterjee et al., 2020). These models provide consensus on the noisy and conflicting labels assigned by the discrete LFs to help determine the correct labels probabilistically. We could use the obtained labels to train any supervised model/classifier and evaluate on a test set. Apart from the cascaded approach described above, recently proposed semi-supervised paradigm (Awasthi et al., 2020; Maheshwari et al., 2021) learns to aggregate labels using both features and a very small labeled set in addition to labeling functions. Such approaches have been shown to outperform the completely unsupervised data programming approaches described above.

Data programming (unsupervised or semisupervised) requires *carefully* curated LFs, generally expressed in the form of regular expressions or conditional statements. Even though creating LFs can potentially take less time than creating large amounts of supervised data, it requires domain experts to spend considerable time identifying and determining the patterns that should be incorpo-

Table 1: Illustration of induced LFs, including examples of the issue of conflicting LFs, on the TREC dataset. Learning importance (weights) of LFs can be used to reduce the conflicts among LFs.

rated into LFs. In this paper, we circumvent the requirement of human-curated LFs by instead automatically generating human-interpretable LFs as compositions of simple propositions on the data set by leveraging SNUBA (Varma and Ré, 2018) which utilizes a small *labeled-set* to induce LFs automatically. However, as we will show, SNUBA suffers from two critical limitations, which keep it from outperforming even a simple supervised baseline that is trained on the same *labeled-set*. First, SNUBA only uses the *labeled-set* to generate the LFs but does not make effective use of it in the final model training. Secondly, as it naively aggregates these LFs, it is not able to distinguish between very noisy LFs and more useful ones. This work addresses both of these limitations.

In Table 1, we present a sample set of induced LFs and assigned labels for the TREC dataset (Li and Roth, 2002). The induced LFs are likely to be less precise compared with those created by humans, and they are likely to have more mutual conflicts. Since the LFs are incomplete and noisy, existing label aggregators that merely consume their outputs do not perform well when dealing with such noisy LFs (*c.f.* Table 1). For instance, the sentence `How long does a dog sleep ?` will be assigned both **DESCRIPTION** and **NUMERIC** labels due to the LFs *how* and *how long*.

As a solution, *how* should be given less importance due to its noisy and conflicting nature, whereas *how long*, associated with the **NUMERIC** label, should be given higher importance. In this paper, we present a bi-level optimization framework for reweighting the induced LFs, which effectively reduces the weights of noisy labels while simultaneously increasing the weights of the more useful ones.

In Figure 1, we present an overview of our approach. We leverage semi-supervision in the feature space for more effective data programming using the induced (automatically generated) labeling functions. To enable this, we split the same *labeled-set* (which was used to generate the LFs) into a *supervised set* and *validation set*. The *supervised set* is used for semi-supervised data programming, and *validation set* is used to tune (reweight) the LFs. As a basic framework for semi-supervised data programming, we leverage SPEAR (Maheshwari et al., 2021), which has achieved state-of-the-art performance. While the semi-supervised data programming approach helps in using the labeled data more effectively, it does not solve the problem of noise associated with the LFs. To address this, we propose an LF reweighting framework, WISDOM[1], which learns to reweight the labeling functions, thereby helping differentiate the noisy LFs from the cleaner and more effective ones.

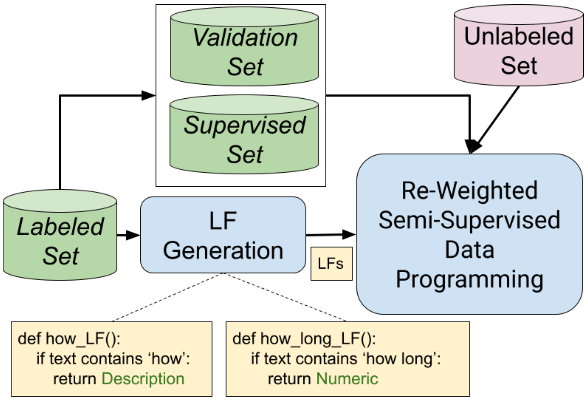

Figure 1: Pictorial depiction of our WISDOM workflow. A small *labeled-set* is used to automatically induce LFs. This labeled set is split equally into *supervised set* and *validation set* to be used by our re-weighted semi-supervised data programming algorithm along with the unlabeled set.

The reweighting is achieved by framing the problem in terms of bi-level optimization. We argue that using a small *labeled-set* can help improve label prediction over hitherto unseen test instances when the *labeled-set* is bootstrapped for (i) inducing LFs, (ii) semi-supervision, and (iii) bi-level optimization to reweight the LFs. For most of this work, the LFs are induced automatically by leveraging part of the approach described in (Varma and Ré, 2018). The LFs are induced on the entire *labeled-set*, whereas the semi-supervision and reweighting are performed on the *supervised set* and *validation set* respectively (which are disjoint partitions of *labeled-set*).

Our Contributions are as follows: While leveraging SNUBA (Varma and Ré, 2018) only for *au-*

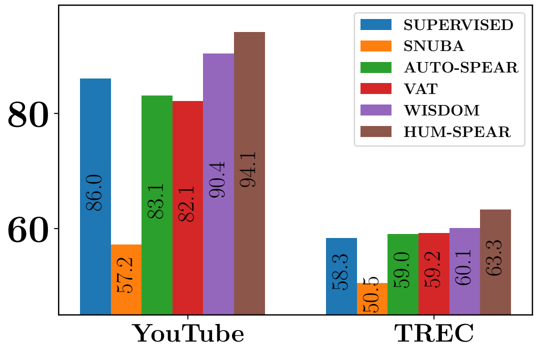

Figure 2: A summary plot contrasting the performance gains obtained using WISDOM on previous state-of-the-art approaches on YouTube and TREC (using Lemma features). WISDOM outperforms other learning approaches with auto-generated LFs.

tomatically generating LFs, we address the important limitations of SNUBA by (i) effectively using the labeled set in a semi-supervised manner using SPEAR (Maheshwari et al., 2021), and (ii) critically making the labeling function aggregation more *robust* via a reweighting framework. We do the reweighting by using our proposed bi-level optimization algorithm that weighs each LF separately, giving low importance to noisy LFs and high importance to relevant LFs. We present evaluations on six text classification datasets and show that WISDOM demonstrates better performance than current label aggregation approaches with automatically (or even human) generated labeling functions.

A summary of the results are presented in Figure 2. As mentioned, SNUBA performs worse than a simple supervised baseline that trained only on the labeled data component. Furthermore, WISDOM outperforms VAT (a state-of-the-art semi-supervised learning algorithm) and HUM-SPEAR sometimes (a state-of-the-art semi-supervised data programming algorithm with human-generated LFs), demonstrating the benefit of having both semi-supervision and robust LF reweighting with the auto-generated LFs. Finally, WISDOM gets to within 2 - 4% of HUM-SPEAR (using human crafted-LFs), without having to incur the cost of generating labeling functions manually, and which can also require significant domain knowledge.

2 Background

2.1 Notations

Let us denote the feature space by $\mathcal{X}$ and the label space by $\mathcal{Y} \in \{1...K\}$ where K is the number of classes. Let the automatically (or manually) generated labeling functions be denoted by λ_1 to λ_m where m is the number of labeling functions generated. Let the vector $\mathbf{l}_i = (l_{i1}, l_{i2}, \ldots, l_{im})$ denote the firings of all the LFs on an instance $\mathbf{x}_i$. Each l_{ij} can be either 1 or 0; $l_{ij} = 1$ indicates that the LF λ_j has fired (*i.e.*, triggered) on the instance x_i and 0 indicates it has not. Furthermore, each labeling function λ_j is associated with some class k_j and for an input x_i, it outputs the label $\tau_{ij} = k_j$ when triggered (*i.e.*, $l_{ij} = 1$) and $\tau_{ij} = 0$ otherwise.

Notation	Description
$\mathbf{l}_i \in \{0,1\}^m$	Firings of all the LFs, $\lambda_1..\lambda_m$ on an instance $\mathbf{x}_i$
$\tau_{ij} \in [0, K]$	class k_j associated by LF λ_j, when triggered ($l_{ij} = 1$) on x_i
f_ϕ	The feature-based model with parameters ϕ operating on feature space $\mathcal{X}$ and on label space $\mathcal{Y} \in \{1...K\}$
P_θ	The label probabilities as per the LF-based aggregation model with parameters θ
labeled-set ($\mathcal{L}$)	The entire labeled dataset: $\mathcal{L} = \{(x_i, y_i)\}$ where $i \in \{1 \cdots N\}$. This is used to induce the LFs
supervised set ($\mathcal{S}$)	Subset of $\mathcal{L}$ that is used for semi-supervision: $\mathcal{S} = \{(x_i, y_i)\}$ where $i \in \{1 \cdots N/2\}$
validation set ($\mathcal{V}$)	Subset of $\mathcal{L}$ that is used for reweighting the LFs using a bi-level optimization formulation: $\mathcal{V} = \{(x_i, y_i)\}$ where $i \in \{N/2 + 1 \cdots N\}$
*u*nlabeled-set ($\mathcal{U}$)	Unlabeled set: $\mathcal{U} = \{x_i\}$ where $i \in \{N + 1 \cdots M\}$. It is labeled using the induced LFs
$\mathcal{L}_{ce}$	Cross Entropy Loss
H	Entropy function
g	Label Prediction from the LF-based graphical model
LL_s	Supervised negative log likelihood over the parameters θ of the LF aggregation model
LL_u	Unsupervised negative log likelihood summed over labels
KL	KL Divergence between two probability models
R	Quality Guide based loss
$\mathcal{L}_{ss}(\theta, \phi, \mathbf{w})$	The semi-supervised bi-level optimization objective with additional weight parameters $\mathbf{w}$ over the LFs

Table 2: Summary of notations used in this paper.

Let the *labeled-set* be denoted by $\mathcal{L} = \{(x_i, y_i)\}$ where $i \in \{1 \cdots N\}$ and N is the number of points in *labeled-set*. Similarly, we have an unlabeled dataset denoted as $\mathcal{U} = \{x_i\}$ where $i \in \{N + 1 \cdots M\}$ and $M - N$ is the number of unlabeled points. The *labeled-set* is further split into two disjoint sets called *supervised set* and *validation set*. Let the *supervised set* be denoted by $\mathcal{S} = \{(x_i, y_i)\}$ where $i \in \{1 \cdots N/2\}$. Let $\mathcal{V} = \{(x_i, y_i)\}$ denote the *validation set*, where $i \in \{N/2 + 1 \cdots N\}$.

2.2 SNUBA: Automatic LF Generation

Varma and Ré (2018) present SNUBA, a three step approach that (i) automatically generates candidate LFs (referred to as heuristics) using a *labeled-set*, (ii) filters heuristics based on diversity and accuracy metrics to select only relevant heuristics, and (iii) uses the final set of filtered LFs (heuristics) and a label aggregator to compute class probabilities for each point in the unlabeled set $\mathcal{U}$. Steps (i) and (ii) are repeated until the labeled set is exhausted or a limit on the number of iterations is reached. Each LF is a basic composition of propositions on the labeled set. A proposition could be a word, a phrase, or a lemma (*c.f.*, the second column of

Table 1), or an abstraction such as a part of speech tag. The composition is in the form of a classifier such as a decision stump (1-depth decision tree) or logistic regression.

Our WISDOM framework utilizes SNUBA for generating the LFs and thereafter reweigh the LFs via our reweighting framework while jointly learning the model parameters and the LF aggregation in a semi-supervised manner.

2.3 SPEAR: Joint SSL Data Programming

Maheshwari et al. (2021) propose a joint learning framework called SPEAR that learns the parameters of a feature-based classification model and of the label aggregation model (the LF model) in a semi-supervised manner. SPEAR has a feature-based classification model $f_\phi(\mathbf{x})$ that takes the features as input and predicts the class label. SPEAR employs two kinds of models: a logistic regression and a two-layer neural network model. For the LF aggregation model, SPEAR uses an LF-based graphical model inspired from CAGE (Chatterjee et al., 2020). CAGE aggregates the LFs by regularizing parameters such that learned joint distribution of y and τ_j matches the user provided quality guides over all y.

$$P_\theta(i, y) = \frac{1}{Z_\theta} \prod_{j=1}^{j=m} \psi_\theta(\tau_{ij}, y) \tag{1}$$

There are K parameters $\theta_{j1}, \theta_{j2} ... \theta_{jK}$ for each LF λ_j, where K is the number of classes. The potential ψ_θ used in the CAGE model is defined as:

$$\psi_\theta(\tau_{ij}, y) = \begin{cases} \exp(\theta_{jy}) & \text{if } \tau_{ij} \neq 0 \\ 1 & \text{otherwise} \end{cases} \tag{2}$$

The loss function of SPEAR has six terms. These include the cross entropy on the labeled set, an entropy SSL term on the unlabeled dataset, a cross entropy term to ensure consistency between the feature model and the LF model, the LF graphical model terms on the labeled and unlabeled datasets, a KL divergence again for consistency between the two models, and finally a regularizer. The objective function is:

$$\sum_{i \in \mathcal{L}} \mathcal{L}_{ce}(f_\phi(x_i), y_i) + \sum_{i \in \mathcal{U}} H(f_\phi(x_i)) +$$
$$\sum_{i \in \mathcal{U}} \mathcal{L}_{ce}(f_\phi(x_i), g(l_i)) + LL_s(\theta|\mathcal{L}) + LL_u(\theta|U) +$$
$$\sum_{i \in \mathcal{U} \cup \mathcal{L}} KL(P_\theta(l_i), f_\phi(x_i)) + R(\theta|\{q_j\}) \tag{3}$$

where g is the label prediction from the LF-based graphical model. The second component $H()$ models semi-supervision (Grandvalet and Bengio, 2005) in the form of minimization of the entropy of the predictions on the unlabeled dataset $\mathcal{U}$. It provides some semi-supervision by trying to increase the confidence of the predictions made by the model on the unlabeled dataset. (Refer Table 2 for notations used in the objective function). In the objective function above, the LF model parameters are θ while the feature model parameters are ϕ. The learning problem in SPEAR is simply to optimize the objective jointly over θ and ϕ. (We refer readers to Maheshwari et al. (2021) for details.)

CAGE loss formulation: The learning problem proposed in CAGE (Chatterjee et al., 2020) is a special case of SPEAR where they just use the fifth loss term $LL_u(\theta|U)$ along with the quality guide $R(\theta|\{q_j\})$. The specific loss formulation of CAGE is as given below:

$$LL_u(\theta|U) + R(\theta|\{q_j\}) \tag{4}$$

3 The WISDOM Workflow

In this section, we present our robust aggregation framework for automatically generated LFs. We present the LF generation approach followed by our reweighting algorithm, which solves a bi-level optimization problem. In the bi-level optimization, we learn the LF weights in the outer level, and in the inner level, we learn the feature-based classifier's and labeling function aggregator's parameters jointly. We describe the main components of the WISDOM workflow below (see also Figure 1). A detailed pseudocode of WISDOM is provided in Algorithm 1. We describe the different components of WISDOM below.

Automatic LF Generation using SNUBA: Our WISDOM framework utilizes steps (i) and (ii) from SNUBA (*c.f.*, Section 2.2) for automatically inducing LFs. That is, it initially iterates between i) candidate LF generation on *labeled-set* $\mathcal{L}$ and ii) filtering them based on diversity and accuracy based criteria, until a limit on the number of iterations is reached (or until the labeled set is completely covered). We refer to these steps as SNUBALFGEN.

Re-Weighting CAGE: To deal with noisy labels effectively, we associate each LF λ_j with an additional weight parameter $w_j \in [0, 1]$ that acts as its reliability measure. The w's are optimized on the validation set and have interactions amongst themselves, unlike θ which is learned on the combination of unlabeled and training sets. The discrete potential in CAGE (*c.f.*, eq.(2)) can be modified to include weight parameters as follows:

$$\psi_\theta(\tau_{ij}, y) = \begin{cases} \exp(w_j \theta_{jy}) & \text{if } \tau_{ij} \neq 0 \\ 1 & \text{otherwise} \end{cases} \tag{5}$$

We observe that if the weight of the j^{th} LF is zero (*i.e.*, $w_j = 0$), the corresponding weighted potential in eq. (5) becomes one, which in turn implies that the j^{th} LF is ignored while maximizing the log-likelihood during label aggregation. Similarly, if all the LFs are associated with a weight value of one (*i.e.*, $w_j = 1$), the above weighted potential will degenerate to the discrete potential used in CAGE. The re-weighted CAGE is implicitly invoked on lines 12, 13, 17 and 18 of Algorithm 1 where $\mathcal{L}_{SS}(\theta, \phi, \mathbf{w})$ is invoked. We compare performance of CAGE with a bi-level variation in Table 5.

13         $\phi_t^* = \phi_t - \alpha \nabla_\phi \mathcal{L}_{ss}(\theta_t, \phi_t, \mathbf{w}_t)$
14         **** Outer level ****
15         $\mathbf{w}_{t+1} = \mathbf{w}_t - \beta \nabla_\mathbf{w} \frac{1}{|\mathcal{V}|} \sum_{i \in \mathcal{V}} \mathcal{L}_{ce}(f_{\phi_t^*}(x_i), y_i)$
16     **** Update net parameters $\phi, \theta$ ****
17         $\theta_{t+1} = \theta_{t+1} - \alpha \nabla_\theta \mathcal{L}_{ss}(\theta_t, \phi_t, \mathbf{w}_{t+1})$
18         $\phi_{t+1} = \phi_{t+1} - \alpha \nabla_\phi \mathcal{L}_{ss}(\theta_t, \phi_t, \mathbf{w}_{t+1})$
19         $t = t + 1$
20 until convergence
21 return $\theta_{t+1}, \phi_{t+1}, \mathbf{w}_{t+1}$
```

The Reweighted Joint SSL: Since the label aggregator graphical model is now dependent on the additional LF weight parameters $\mathbf{w}$, the joint semi-supervised learning objective function is modified as follows:

$$\begin{aligned} \mathcal{L}_{ss}(\theta, \phi, \mathbf{w}) &= \sum_{i \in \mathcal{S}} \mathcal{L}_{ce}(f_\phi(x_i), y_i) + \sum_{i \in \mathcal{U}} H(f_\phi(x_i)) \\ &+ \sum_{i \in \mathcal{U}} \mathcal{L}_{ce}(f_\phi(x_i), g(l_i, \mathbf{w})) + LL_s(\theta, \mathbf{w}|\mathcal{S}) \\ &+ LL_u(\theta, \mathbf{w}|\mathcal{U}) + \sum_{i \in \mathcal{U} \cup \mathcal{S}} KL(P_{\theta, \mathbf{w}}(l_i), f_\phi(x_i)) \\ &+ R(\theta, \mathbf{w}|\{q_j\}) \end{aligned} \tag{6}$$

In Section 7, we present the somewhat intuitive expansions of terms that are dependent on $\mathbf{w}$.

Bi-Level Objective: WISDOM jointly learns the LF weights and weighted labeling aggregator and feature classifier parameters for the objective function defined in Equation (6). The LF weights are learned by WISDOM by posing a bi-level optimization problem for this objective function as defined in eq. (7) and employing alternating one-step gradient updates. As evident in eq. (7), WISDOM uses a *validation set* ($|\mathcal{V}|$) which is a subset of *labeled-set* ($|\mathcal{L}|$) to learn the LF weights. Furthermore, the introduced weight parameters allow filtering of LFs based on the feature model and a bilevel objective in the form of a cross-entropy loss of feature model predictions on the validation set. In essence, WISDOM tries to learn LF weights that result in minimum validation loss on the feature model that is jointly trained with weighted labeling aggregator.

$$\begin{aligned} \mathbf{w}^* &= \underset{\mathbf{w}}{\operatorname{argmin}} \frac{1}{|\mathcal{V}|} \sum_{i \in \mathcal{V}} \mathcal{L}_{ce}(f_{\phi^*}(x_i), y_i) \\ \text{where } \boldsymbol{\phi}^*, \boldsymbol{\theta}^* &= \underset{\boldsymbol{\phi}, \boldsymbol{\theta}}{\operatorname{argmin}} \mathcal{L}_{ss}(\theta, \phi, \mathbf{w}) \end{aligned} \tag{7}$$

However, determining the optimal solution to the above Bi-level objective function is computationally intractable. Hence, inspired by MAML (Finn et al., 2017), WISDOM adopts an iterative alternative minimizing framework, wherein we optimize the objective function at each level using a single gradient descent step. As shown in Algorithm 1, lines 12 and 13 are the inner level updates where the parameters θ, ϕ are updated using the current choice of weight parameters $\mathbf{w}$ for one gradient step, and in line 15, the weight parameter $\mathbf{w}$ is updated using the one-step updates from lines 12 and 13. Finally, the net parameters ϕ, θ are updated in lines 17 and 18. This procedure is continued till convergence (*e.g.*, no improvement in the outer-level loss) or for a fixed number of epochs.

Table 3: Summary statistics of the datasets and the automatically generated LFs using SNUBA. The test set contains 500 instances for each dataset.

4 Experiments

We present evaluations across six datasets that we describe in the following Section 4.1. In Table 3, we present summary statistics of these datasets, including the sizes of *supervised set*, *validation set* (with *labeled-set* being the union of these disjoint sets) and the number of (auto-generated) LFs used in the experiments.

4.1 Datasets

We use the following datasets in our experiments: (1) **TREC** (Li and Roth, 2002): A question classification dataset with six categories: `Description, Entity, Human, Abbreviation, Numeric, Location.` (2) **YouTube Spam Classification** (Alberto et al., 2015): A spam classification task over comments on YouTube videos. (3) **IMDB Genre Classification**[2]: A plot summary based movie genre binary classification dataset. (4) **SMS Spam Classification** (Almeida et al., 2011): A binary spam classification dataset to detect spam in SMS messages. (5) **Twitter Sentiment** (Wan and Gao, 2015): This is a 3-class sentiment classification problem extracted from Twitter feed of popular airline handles. Each tweet is either labeled as negative, neutral, and positive labels. (6) **Stanford Sentiment Treebank (SST-5)** (Socher et al., 2013) is a single sentence movie review dataset, with each sentence labeled as either negative, somewhat negative, neutral, somewhat positive, or positive.

4.2 Baselines

In Table 4, we compare our approach against the following baselines:

Snuba (Varma and Ré, 2018): Recall from Section 2.2 that SNUBA iteratively induces LFs from the count-based raw features of the dataset in the steps (i) and (ii). For the step (iii), as in (Varma and Ré, 2018), we employ a generative model to assign probabilistic labels to the unlabeled set. These probabilistic labels are obtained by training a 2-layered NN model.

Supervised (SUP): This is the model obtained by training the classifier $P_\theta(y|x)$ only on *labeled-set*. This baseline does not use the unlabeled set.

Learning to Reweight (L2R) (Ren et al., 2018): This method trains the classifier using a meta-learning algorithm over the noisy labels in the unlabeled set obtained using the automatically generated labeling functions and aggregated using SNORKEL. It uses an online algorithm that assigns importance to examples based on the gradient.

Posterior Regularization (PR) (Hu et al., 2016): This is a method for joint learning of a rule and feature network in a teacher-student setup. Similarly to L2R, it uses the noisy labels in the unlabeled set obtained using the automatically generated labeling functions.

Imply Loss (IL) (Awasthi et al., 2020): This method leverages both rules and labeled data by associating each rule with exemplars of correct firings (*i.e.*, instantiations) of that rule. Their joint training algorithms de-noise over-generalized rules and train a classification model. This is also run on the automatically generated LFs.

SPEAR (Maheshwari et al., 2021): This method employs a semi-supervised framework combined with a graphical model for consensus amongst the LFs to train the model. We compare against two versions of SPEAR. The first that (just like L2R, PR, IL, and VAT) uses auto-generated LFs (which we call AUTO-SPEAR), and the second, *viz.*, HUM-SPEAR, which uses the human LFs.

VAT: Virtual Adversarial Training (Miyato et al., 2018) is a semi-supervised approach that uses the virtual adversarial loss on the unlabeled points, thereby ensuring robustness of the conditional label distribution on the unlabeled points.

4.3 Experimental Setting

To train our model on the *supervised set*, we use a neural network architecture with two hidden layers (512 units) and ReLU activation function as our feature-based model f_ϕ. We choose our classification network to be the same as SPEAR (Maheshwari et al., 2021). We consider two types of features: a) raw words and b) lemmatizations, as an input to our supervised model (lemmatization is a technique to reduce a word, *e.g.,* ‘walking,’ into its root form, ’walk’). Additionally, these features are used as basic propositions over which composite LFs are built.

Each experimental run involves training WISDOM for 100 epochs with early stopping based on *validation set*. Our model is optimized using mini-

---

[2] `www.imdb.com/datasets`

batch gradient descent with the Adam optimizer. We tuned the hyperparameters on the *validation set*, and the optimal configuration was found to have a dropout probability of 0.80 and a batch size of 32. Further, the optimal configuration learning rates for the classifier and LF aggregation models were 0.0003 and 0.01, respectively. Performance numbers for each experiment are obtained by averaging over five independent runs, each having a different random initialization. For evaluation on the test set, the model with the best performance on the *validation set* was chosen. On all datasets, macro-F1 is employed as the evaluation criterion. We implement all our models in PyTorch[3] (Paszke et al., 2019). We run all our experiments on Nvidia RTX 2080 Ti GPUs with 12 GB RAM set within Intel Xeon Gold 5120 CPU having 56 cores and 256 GB RAM. Model training times range from 15 mins (YouTube) to 100 mins (TREC).

4.4 Results

In Table 4, we compare the performance of Wisdom against different baselines (all using auto-generated labeling functions except VAT), for both raw and lemmatized count features (*c.f.* Section 2.2) across multiple datasets. We observe that Snuba performs worse than the *Supervised* baseline on all datasets, exhibiting high variance over different runs (surprisingly, Varma and Ré (2018) did not compare the performance of Snuba against the *supervised* baseline). Learning to Reweight (L2R) performs worse than *Supervised* on all datasets except YouTube. Posterior regularization, imply loss and Spear show gains over *Supervised* on a few datasets, but not consistently across all datasets and settings. Finally, Vat obtains competitive results in some settings (*e.g.*, TREC dataset) but performs much worse on others (*e.g.*, IMDB and SST-5). In contrast, Wisdom achieves consistent gains over *Supervised* and the other baselines in almost all datasets (except TREC with raw features where Vat does slightly better than Wisdom). Additionally, Wisdom yields smaller variance over different runs compared to other semi-supervised approaches. Recall that the main difference between Wisdom and Auto-Spear is that the former reweighs the LFs in both the label aggregator as well as in the semi-supervised loss, as against Auto-Spear which does not reweigh the LFs at all. Consequently, the aforementioned empirical gains illustrate the robustness of the bi-level optimisation algorithm. Note that these numbers are all reported using only 10% labeled data, and hence, results for some datasets (starting with *Supervised*) might appear lower than those reported in the literature. Note that, we compare Wisdom (using automatically induced LFs) against the Hum-Spear which uses *the human crafted* LFs in conjunction with the state-of-the-art Spear approach (Maheshwari et al., 2021). Although Wisdom uses auto-generated LFs, it sometimes performs better than Hum-Spear, which utilizes human-curated LFs. On careful analysis (presented in Section 8 of the supplementary), we observe that the human curated LFs tend to be more generic abstractions of possible patterns without assessing how precise they are for the end task. Consequently, these abstract human-LFs tend to have not only higher collective coverage but also high mutual conflicts and lower average individual precision values than the automatically induced LFs. Given the individual strengths of both *h*uman-lfs and *a*uto-lfs, it might be interesting to consider using them in conjunction with each other in order to improve performance as future work. An ablation test in Figure 3 reveals that Wisdom performs well even for small-sized *labeled-set* unlike other baselines, demonstrating its robustness in scenarios with only few labeled examples.

4.5 Importance of the Bi-Level formulation

A label aggregation approach, such as Cage, Snorkel, may improve the consensus labeling across LFs, but not necessarily their agreement with the ground truth. Further, when LFs are noisy (or induced automatically), the performance of the Cage model can suffer. However, the bi-level framework of Cage can alleviate these problems since it implicitly reduces the noise in LFs. In order to demonstrate effectiveness of the bi-level formulation, we compare Cage(Eq (4)) with two variants (i) Cage$_{\text{val}}$[4] that considers validation set feedback in the loss formulation for promoting LF agreement with ground-truth label and (ii) Cage$_{\text{Bi-level}}$ with the proposed bi-level formulation that tries to do the same[5]. We present our results in Table 5. The performance of our Cage$_{\text{Bi-level}}$ is clearly superior to the original Cage model, as well as to the Cage$_{\text{val}}$ model. Thus, the bi-level formulation more effectively incorporates validation set feedback than other formulations as demonstrated by application of bi-level on both Spear as well as on Cage. In Table 1, we had presented some illustrative examples (from the TREC dataset) of

---

[3] `https://pytorch.org/`

[4] Cage$_{\text{val}}$ - equivalent to using only $LL_s(\theta|\mathcal{L}) + LL_u(\theta, \mathbf{w}|\mathcal{U}) + R(\theta, \mathbf{w}|\{q_j\})$ in Eq (3)

[5] In other words, Cage$_{\text{Bi-level}}$ is equivalent to using only $LL_u(\theta, \mathbf{w}|\mathcal{U}) + R(\theta, \mathbf{w}|\{q_j\})$ in Eq (6)

Table 4: Performance of different approaches on six datasets, *viz.*, IMDB, YouTube, SMS, TREC, Twitter, and SST-5. Results are shown for both 'Raw' or 'Lemmatized' features. The numbers reported are macro-F1 scores over the test set averaged over 5 runs, and for all methods after the double-line are reported as gains over the baseline (*Supervised*). L2R, PR, IL, Auto-Spear, and Wisdom all use the automatically generated LFs; *Supervised* and Vat do not use LFs; and Hum-Spear uses the human generated LFs. 'NA' in Hum-Spear column is when human LFs are not available. Numbers in brackets '()' represents standard deviation of the original scores and not of the gains.

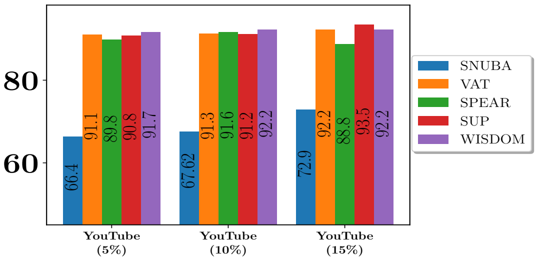

Figure 3: Ablation study with different *labeled-set* sizes on the YouTube dataset.

	Youtube	SMS	TREC
Cage	62.45	18.1	14.1
Cage$_{\text{val}}$	84.62	39.61	37.99
Cage$_{\text{Bi-level}}$	87.11	43.22	39.34

Table 5: Comparison of Cage model with two variants. Cage$_{\text{val}}$ includes validation set feedback in the original Cage loss function and Cage$_{\text{Bi-level}}$ is bi-level formulation of Cage objective using Eq 5.

automatically induced LFs whose weights are relatively higher based on the bi-level formulation along with those that are down-weighted owing to their conflicting signals. We present additional examples as well as further qualitative analysis in Section 9 of the supplementary.

5 Related Work

In this section, we describe some additional related work that was not covered in Section 2.

Automatic Rule Generation: The programming by examples paradigm produces a program from a given set of input-output pairs (Gulwani, 2012; Singh and Gulwani, 2012). It synthesises those programs that satisfy all input-output pairs. RuleNN (Sen et al., 2020) learns interpretable first-order logic rules as composition of semantic role attributes. Many of these approaches, however, learn more involved rules (using *e.g.*, a neural network) which may not work in the realistic setting of very small labeled data. In contrast, Snuba and Wisdom use more interpretable models (Rudin, 2019) like logistic regression and decision trees for rule induction.

Semi-supervised Learning (SSL): The goal of SSL is to effectively use unlabeled data while training. Early SSL algorithms used regularization-based approaches like margin regularization, and laplacian regularization (Chapelle et al., 2010). Most recent SSL approaches like Mean Teacher (Tarvainen and Valpola, 2017), VAT (Miyato et al., 2018), UDA (Xie et al., 2020), MixMatch (Berthelot et al., 2019) and FixMatch (Sohn et al., 2020) introduced various kinds of perturbations and augmentations that can be used along with consistency loss. Even though the current SSL approaches perform well even with minimal labels, they are computationally intensive and cannot be easily implemented in low-resource scenarios. Furthermore, it is tough to explain the discriminative behavior of the semi-supervised models.

Bi-level Optimization: The concept of bi-level optimization has been discussed in (von Stackelberg et al., 1952; Bracken and McGill, 1973; Bard, 2006). Since then, the framework of bi-level optimization has been used in various machine learning applications like hyperparameter tuning (Mackay et al., 2019; Franceschi et al., 2018; Sinha et al., 2020), robust learning (Ren et al., 2018; Guo et al., 2020), meta-learning (Finn et al., 2017), efficient learning (Killamsetty et al., 2021) and continual learning (Borsos et al., 2020). Previous applications of the bi-level optimization framework for robust learning have been limited to supervised and semi-supervised learning settings. To the best of our knowledge, WISDOM is the first framework that uses a bi-level optimization approach for robust aggregation of labeling functions.

6 Conclusion

While induction of labeling functions (LFs) for data-programming has been attempted in the past by Varma and Ré (2018), we observe in our experiments that the resulting model in itself does not perform well on text classification tasks, and turns out to be even worse than the supervised baseline. A more recent semi-supervised data programming approach called SPEAR (Maheshwari et al., 2021), when used in conjunction with the induced LFs, performs better, though it fails to consistently outperform the supervised baseline. In this paper, we introduce WISDOM, a bi-level optimization formulation for reweighting the LFs, which injects robustness into the semi-supervised data programming approach, thus allowing it to perform well in the presence of noisy LFs. On a reasonably wide variety of text classification datasets, we show that WISDOM consistently outperforms all other approaches, while also coming close to the skyline of SPEAR using human-generated LFs.

Appendix

7 Explanation of loss terms

First Component (L1): The first component (L1) of the loss $L_{CE}\left(P^f_\phi(y|\mathbf{x}_i), y_i\right) = -\log\left(P^f_\phi(y = y_i|\mathbf{x}_i)\right)$ is the standard cross-entropy loss on the labelled dataset $\mathcal{L}$ for the model P^f_ϕ.

Second Component (L2): The second component L2 is the semi-supervised loss on the unlabelled data $\mathcal{U}$. In our framework, we can use any unsupervised loss function.

Third Component (L3): The third component $L_{CE}\left(P^f_\phi(y|\mathbf{x}_i), g(\mathbf{l}_i), w\right)$ is the cross entropy of the classification model using the hypothesised labels from CAGE (Chatterjee et al., 2020) on $\mathcal{U}$. Given that $\mathbf{l}_i$ is the output vector of all labelling functions for any $\mathbf{x}_i \in \mathcal{U}$, we specify the predicted label for $\mathbf{x}_i$ using the LF-based graphical model $P_\theta(\mathbf{l}_i, y)$ as: $g(\mathbf{l}_i) = \underset{y}{\text{argmax}} P_{\theta,w}(\mathbf{l}_i, y)$

Fourth Component (L4): The fourth component $LL_s(\theta|\mathcal{L})$ is the (supervised) negative log likelihood loss on the labelled dataset $\mathcal{L}$: $LL_s(\theta, w|\mathcal{L}) = -\sum\limits_{i=1}^{N} \log P_{\theta,w}(\mathbf{l}_i, y_i)$

Fifth Component (L5): The fifth component $LL_u(\theta, w|\mathcal{U})$ is the negative log likelihood loss for the unlabelled dataset $\mathcal{U}$. Since the true label information is not available, the probabilities need to be summed over y: $LL_u(\theta, w|\mathcal{U}) = -\sum\limits_{i=N+1}^{M} \log \sum\limits_{y\in\mathcal{Y}} P_{\theta,w}(\mathbf{l}_i, y)$

Sixth Component (L6): The sixth component $KL(P^f_{\phi,w}(y|\mathbf{x}_i), P_\theta(y|\mathbf{l}_i))$ is the Kullback-Leibler (KL) divergence between the predictions of both the models, *viz.*, feature-based model f_ϕ and the LF-based graphical model P_θ summed over every example $\mathbf{x}_i \in \mathcal{U} \cup \mathcal{L}$. Through this term, we try and make the models agree in their predictions over the union of the labelled and unlabelled datasets.

Quality Guides (QG): As a last component in our objective, we use quality guides $R(\theta, w|\{q_j\})$ on LFs which have been shown (Chatterjee et al., 2020) to stabilise the unsupervised likelihood training while using labelling functions. Let q_j be the fraction of cases where λ_j correctly triggered. And let q^t_j be the user's belief on the fraction of examples $\mathbf{x}_i$ where y_i and l_{ij} agree. If user's beliefs weren't available, we consider precision of LFs on validation set as the user's beliefs. Except SMS dataset, we take precision of LFs on validations set as quality guides. If $P_{\theta,w}(y_i = k_j|l_{ij} = 1)$ is the model-based precision over the LFs, the quality guide based loss can be expressed as $R(\theta, w|\{q^t_j\}) = -\left(\sum_j q^t_j \log P_{\theta,w}(y_i = k_j|l_{ij} = 1) + (1 - q^t_j)\log(1 - P_{\theta,w}(y_i = k_j|l_{ij} = 1))\right)$.

8 LF Analysis

We compare statistics of automatically induced LFs and human-curated LFs in Table 6. While developing LFs, humans generally tend to design LFs based on generalizibility of the pattern without worrying much about the conflicts among the patterns. Whereas the LF induction in WISDOM focuses on inducing individually precise LFs without necessarily focusing on the overall coverage. Except in the case of the SMS dataset, collective coverage of human designed LFs is much higher than that of the automatically induced LFs. We also observe in Table 6 that higher coverage leads to higher conflicts. Whereas, on an average, the precision is higher for each of the automatically induced LFs in the case of every dataset.

9 Qualitative Analysis of Automatically Induced LFs

For the six datasets used for experimentation, we automatically induce LFs using Snuba (Varma and Ré, 2018). We show the automatically induced LFs and their respective weights assigned by WISDOM for three datasets TREC, IMDB, and SMS below.

In Table 7, we present LFs produced by the Snuba for the TREC dataset sorted in descending order of weights for each class along with the weights assigned by WISDOM to each of the LFs. From analysis, we observe that WISDOM does a good job of reweighting LFs. For instance, `how many` was given higher weightage than `how` and `many` for class Numeric; this sounds logical as well since sentences containing the keyword `how many` are more likely to belong to class Numeric than sentences containing

	Auto LFs				**Human LFs**			
	#LFs	**Precision**	**Conflict**	**Cover (%)**	**#LFs**	**Precision**	**Conflict**	**Cover(%)**
YouTube	11	94.3	8.1	63.4	10	79.8	28.7	88.0
SMS	25	94.9	3.2	47.9	73	92.3	1.0	33.3
TREC	13	70.1	2.3	62.3	68	59.9	22.3	95.1

Table 6: Comparison of automatically generated LFs with human-curated LFs. Coverage is fraction of instances in $\mathcal{U}$ covered by at least one rule. Precision refers to micro precision of rules. Conflict denotes the fraction of instances covered by conflicting rules among all the covered instances.

Class	LF	Weights
NUM	how many	1
NUM	how	1
NUM	many	0.62
DESC	what kind	1
DESC	what was	0.54
LOC	city	1
LOC	country	0.84
LOC	where	0.05
ENTY	what does	1
ENTY	def	1
ENTY	why	0.8
ENTY	what is	0.65
HUM	who	0.00012

Table 7: Automatically induced LFs by Snuba (Varma and Ré, 2018) for the TREC dataset sorted in descending order of weights per class assigned by WISDOM. Column 1 refers to the class associated with the induced LF. No LFs were induced for class `Abbreviation`.

the keyword `how` or `many`. Another example is among LFs associated with Location class, LFs `city` and `country` were given higher weightage than `where`. However, WISDOM does a poor job by assigning a very small weight value to the single LF `who` associated with the Human class.

In Table 8, we present LFs produced by the Snuba for the IMDB dataset sorted in descending order of weights for each class along with the weights assigned by WISDOM to each of the LFs. For the IMDB dataset as well, we can see that WISDOM does a good job of reweighting LFs. For instance,among the LFs associated with the class ROMANCE, `wife` and `love` were given higher weightage than other LFS like `friendship`, `wealthy`, `town`; this sounds logical as well since ROMANCE is often associated with the sentences containing the keywords `wife`, `love` than sentences containing the keyword `friendship`, `town`, `wealthy`. One more key observation is that apart from LFs `wife` and `love`, all other LFs associated with the class ROMANCE are given weights of 0(equivalent to ignoring them). However, assigning 0 weights is controversial for LFs like `boyfriend` since there is a possibility of ROMANCE associated with the sentence containing keyword `boyfriend`. Similarly for LFs associated with Action class, LFs `government`, `agent`, and `plan` were given higher weightage than `race`, and `team`.

In Table 9, we present LFs produced by the Snuba for the SMS dataset sorted in descending order of weights for each class along with the weights assigned by WISDOM to each of the LFs. For the SMS dataset, we can see that WISDOM did not do as good a job of reweighting as done on other datasets. For instance,among the LFs associated with the class SPAM, `ur`, `video` and `cam` were given higher weightage while completely ignoring(i.e., assigned a weight of zero) to other important LFS like `free`, `claim`, `won`. Whereas for LFs associated with the class NOT SPAM, WISDOM did a good job. One possible reason for the poor job of WISDOM for reweighting LFs associated with the class SPAM is that class imbalance present in the unlabeled set, where the sample count of samples of the class SPAM is

Class	LF	Weights
ROMANCE	wife	0.412
ROMANCE	love	0.042
ROMANCE	boyfriend	0
ROMANCE	friendship	0
ROMANCE	wealthy	0
ROMANCE	story	0
ROMANCE	town	0
ROMANCE	friend	0
ACTION	government	1
ACTION	plan	0.985
ACTION	agent	0.913
ACTION	team	0.753
ACTION	race	0.685

Table 8: Automatically induced LFs by Snuba (Varma and Ré, 2018) for the IMDB dataset sorted in descending order of weights per class assigned by WISDOM. Column 1 refers to the class associated with the induced LF.

Class	LF	Weights
SPAM	ur	1
SPAM	video	1
SPAM	com	1
SPAM	contact	0.2213
SPAM	holiday	0.1593
SPAM	free	0
SPAM	claim	0
SPAM	stop	0
SPAM	won	0
SPAM	win	0
SPAM	uk	0
SPAM	text	0
SPAM	urgent	0
NOTSPAM	come	1
NOTSPAM	ok	1
NOTSPAM	got	1
NOTSPAM	like	1
NOTSPAM	sorry	0.03731254

Table 9: Automatically induced LFs by Snuba (Varma and Ré, 2018) for the SMS dataset sorted in descending order of weights per class assigned by WISDOM. Column 1 refers to the class associated with the induced LF.

eight times smaller than the sample count of the class SPAM. From our LF analysis results across the three datasets, we observe that WISDOM tries to up weigh LFs that are more specific and precise and downweigh LFs that are abstract and less precise.

Multi-Granularity Semantic Aware Graph Model for Reducing Position Bias in Emotion-Cause Pair Extraction

Abstract

The Emotion-Cause Pair Extraction (ECPE) task aims to extract emotions and causes as pairs from documents. We observe that the relative distance distribution of emotions and causes is extremely imbalanced in the typical ECPE dataset. Existing methods have set a fixed size window to capture relations between neighboring clauses. However, they neglect the effective semantic connections between distant clauses, leading to poor generalization ability towards position-insensitive data. To alleviate the problem, we propose a novel **M**ulti-**G**ranularity **S**emantic **A**ware **G**raph model (MGSAG) to incorporate fine-grained and coarse-grained semantic features jointly, without regard to distance limitation. In particular, we first explore semantic dependencies between clauses and keywords extracted from the document that convey fine-grained semantic features, obtaining keywords enhanced clause representations. Besides, a clause graph is also established to model coarse-grained semantic relations between clauses. Experimental results indicate that MGSAG surpasses the existing state-of-the-art ECPE models. Especially, MGSAG outperforms other models significantly in the condition of position-insensitive data.

1 Introduction

Emotion Cause Analysis (ECA) has attracted increasing research interest in recent years (Wei et al., 2020; Sun et al., 2021; Singh et al., 2021; Yu et al., 2021), because of the great potential of applying in consumer review mining, public opinion monitoring, and online empathetic chatbot building. Its goal is to detect causes or stimuli for a certain emotion expressed in text.

Emotion Cause Pair Extraction (ECPE) (Xia and Ding, 2019) is a new task related to ECA, which is concerned with causal relationships between emotions and causes. It's a much more challenging task. Because we need a comprehensive understanding of document content and structure to perform emotion-cause co-extraction and discriminate emotion-cause clause pairs from negative ones (Wei et al., 2020). As shown in the following example, an emotion clause c_7 and a cause clause c_2 construct an emotion-cause pair (c_7, c_2) which is needed to be extracted by an ECPE model.

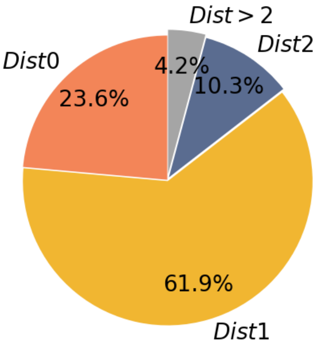

Figure 1: The distribution of the relative distance of an emotion clause and a cause clause that comprise a pair in the ECPE dataset (Xia and Ding, 2019). $Dist0$, $Dist1$, and $Dist2$ mean the relative distances between the two clauses are 0, 1, and 2 respectively. $Dist > 2$ means the relative distances are larger than 2.

Example. *When the driver was about to start the bus to leave the station* (c_1), *an old lady ran to the front of the bus with a fast speed and sat down on the ground* (c_2). *Passengers standing in the front of the bus can see this scene clearly* (c_3). *Seeing this scene* (c_4), *the passengers in the car immediately became restless* (c_5), *and had a heated debate* (c_6). *Some of the passengers were* ***angry*** (c_7), *and told the driver he shouldn't be meddlesome* (c_8).

In general, the number of candidate emotion-cause pairs is the square of the number of clauses in a document. However, most documents contain only one emotion-cause pair. Due to the problem of the tremendous search space, most existing

May 22-27, 2022

methods have fully exploited relative position features to decrease the number of candidate pairs. For instance, ECPE-MLL (Ding et al., 2020b) and SLSN (Cheng et al., 2020) set a fixed size window around a certain clause, and the central clause and other clauses inside the window comprise candidate pairs. However, models heavily relying on the relative position features ignore the distant semantic cues, resulting in poor generalization ability towards position-insensitive data in which the cause clause is not in proximity to the emotion clause.

According to Figure 1, we can observe that there is a position bias problem in ECPE. For the most 85% emotion-cause pairs, the relative distances between its emotion clauses and corresponding cause clauses are less than 2. It means that most cause clauses either appear immediately preceding/following their corresponding emotion clauses or are the emotion clauses themselves. Existing methods mainly focus on the position-sensitive data (majority) and neglect the position-insensitive data (minority). How to improve the performance on the two parts of data instead of only focusing on one of them, has become an intractable challenge.

Some proposed methods (Xia and Ding, 2019; Chen et al., 2020a) without relative position information seem to be position-insensitive, but overlook the effective semantic connections between distant clauses which convey causal cues. Thus, they can not alleviate the position bias problem.

To alleviate this problem, we propose a multi-granularity semantic aware graph model (MGSAG). We assume that fine-grained semantic features conveyed by global keywords in a document are conducive to exploring causal cues, especially cues implied in distant clauses. Besides, coarse-grained semantics between clauses is also important to find causal relations implied in the context. From the two perspectives, we realize multi-granularity semantic enhanced clause relationships modeling based on two graphs: clause-keyword bipartite graph and fully connected clause graph, utilize fine-grained and coarse-grained semantic features jointly. Experimental results show that MGSAG outperforms all of the state-of-the-art baselines. Especially, it achieves a significant improvement on position-insensitive test data. In summary, our contributions are three-fold:

- To alleviate the position bias problem in ECPE, we propose MGSAG to achieve fine-grained and coarse-grained semantic enhanced clause representation learning.
- To value model performance on emotion-cause clause pairs consisting of distant clauses, we split the original test set into two parts according to the relative distances of emotion clauses and cause clauses, and evaluate models on them.
- Experimental results prove that our model achieves remarkable improvement over best-performing approaches on the original test set. Especially, it outperforms other methods in the condition of position-insensitive data.

2 Related Work

According to whether the relative position information is used explicitly or not, existing ECPE works can be divided into two categories: position-sensitive approaches and position-insensitive approaches.

Position-Sensitive Approaches. Most methods (Ding et al., 2020a; Cheng et al., 2020; Ding et al., 2020b) have set a fixed size window to reduce the number of candidate pairs according to the inherent position bias in the dataset, because of the sparsity of true emotion-cause pairs compared with candidate emotion-cause pairs. Besides, Chen et al. (2020b) leveraged the relative position information explicitly in the process of pair representation learning. The ECPE-MLL model proposed by Ding et al. (2020b) is the state-of-the-art method in the ECPE task. An over-reliance on relative position information makes these methods have poor generalization ability towards position-insensitive data.

Position-Insensitive Approaches. Some sequence-based methods without relative position information (Xia and Ding, 2019; Chen et al., 2020a; Fan et al., 2020) seem to be position-insensitive. Xia and Ding (2019) proposed a RNN-based framework and generate candidate pairs by applying the Cartesian product. Chen et al. (2020a) reformulated the ECPE task as a unified sequence labeling problem. Fan et al. (2020) modeled the extraction of emotion-cause pairs as performing a sequence of transitions and actions. However, these methods have shown poor performance on position-insensitive data due to the neglect of effective semantic connections between distant clauses.

Different from the above methods, our model incorporates fine-grained and coarse-grained semantic features jointly, which can alleviate the position bias problem well.

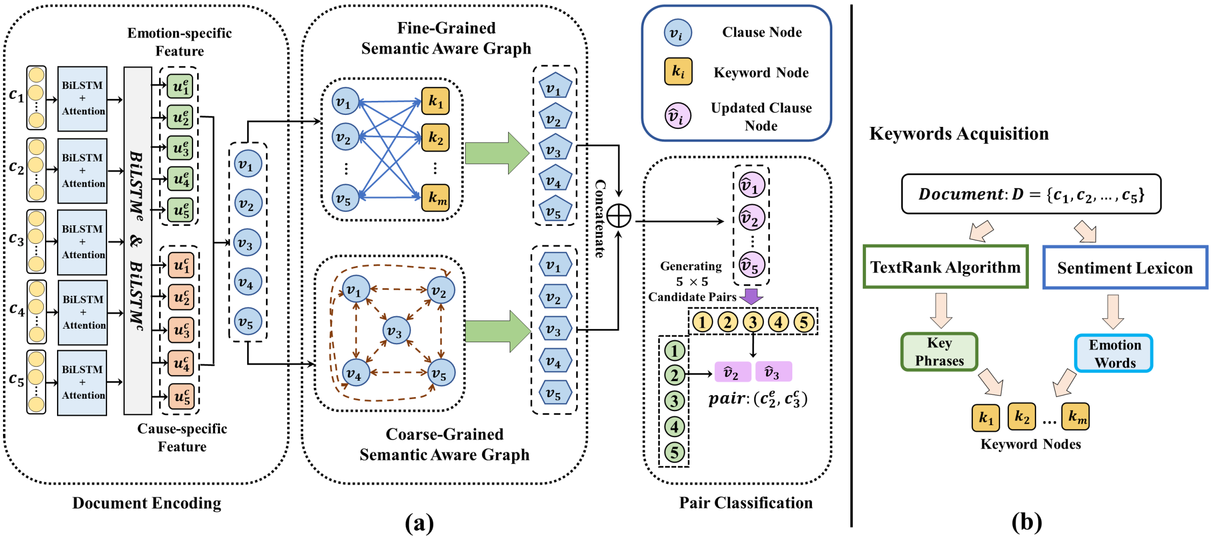

Figure 2: (a) shows an overview of MGSAG. (b) shows the process of keywords acquisition.

3 Problem Formulation

Given a document $D = \{c_1, c_2, ..., c_{|D|}\}$ where $|D|$ is the number of clauses, the clauses are formed into $|D| \times |D|$ candidate emotion-cause pairs using Cartesian product: $P = \{..., (c_i^e, c_j^c), ...\}$, where c_i^e is clause c_i serving as a candidate emotion clause, c_j^c is clause c_j serving as a candidate cause clause. The ECPE task is to assign a binary label to each candidate pair (c_i^e, c_j^c), where "1" means that clause c_i is an emotion clause and clause c_j provides the cause of it, otherwise "0".

4 Methodology

We propose a multi-granularity semantic aware graph model to alleviate the position bias problem in ECPE. More concretely, we obtain fine-grained semantic aware clause representations based on a clause-keyword bipartite graph. Simultaneously, coarse-grained semantic aware clause representations are generated based on a fully connected clause graph. As shown in Figure 2, the model consists of four components: 1) document encoding, 2) fine-grained semantic aware graph (FGSAG), 3) coarse-grained semantic aware graph (CGSAG), 4) pair classification.

4.1 Document Encoding

Given a document $D = \{c_1, c_2, ..., c_{|D|}\}$ consisted of $|D|$ clauses, we adopt a hierarchical recurrent neural network to encode context information and generate emotion-specific and cause-specific clause representations for each clause in the document.

Word-Level Encoder. For each clause $c_i = \{w_1^i, w_2^i, ..., w_{|c_i|}^i\}$, we first adopt a word-level BiLSTM network to encode the context by passing words' information along the clauses forwards and backwards, and then obtain the clause's hidden state sequence $(h_1^i, h_2^i, ..., h_{|c_i|}^i)$. An attention layer is adopted to combine them and return a state vector $\mathbf{h}_i = \sum_{j=1}^{|c_i|} \alpha_j h_j^i$ for clause c_i, where $\alpha_j = \mathbf{softmax}(\mathbf{W}_a h_j^i)$ is the attention weight of the j-th word in clause c_i, $\mathbf{W}_a$ is a trainable weight matrix for attention score calculation.

Clause-Level Encoder. In order to extract the emotion features and the cause features respectively, the clause-level encoder consists of two BiLSTM networks. The document D's clause state sequence $(\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_{|D|})$ is fed into two clause-level BiLSTM networks to produce emotion-specific and cause-specific clause representations, respectively:

$$\begin{aligned} \mathbf{u}_i^e &= \mathbf{BiLSTM}^e(\mathbf{h}_i)\,, \\ \mathbf{u}_i^c &= \mathbf{BiLSTM}^c(\mathbf{h}_i)\,, \end{aligned} \tag{1}$$

where $\mathbf{BiLSTM}^e$ and $\mathbf{BiLSTM}^c$ generate the emotion-specific and cause-specific clause representation $\mathbf{u}_i^e, \mathbf{u}_i^c \in \mathbb{R}^{2d_h \times 1}$ of clause c_i, respectively. d_h means the number of hidden units in BiLSTM.

Afterwards, we use a gate mechanism to fuse the emotion feature $\mathbf{u}_i^e$ and the cause feature $\mathbf{u}_i^c$ to obtain clause representation $\mathbf{v}_i \in \mathbb{R}^{2d_h \times 1}$:

$$\begin{aligned} \mathbf{g}_i &= \sigma(\mathbf{W}_g \mathbf{u}_i^e + \mathbf{b}_g)\,, \\ \mathbf{v}_i &= \mathbf{g}_i \mathbf{u}_i^c + (1 - \mathbf{g}_i) \mathbf{u}_i^e\,, \end{aligned} \tag{2}$$

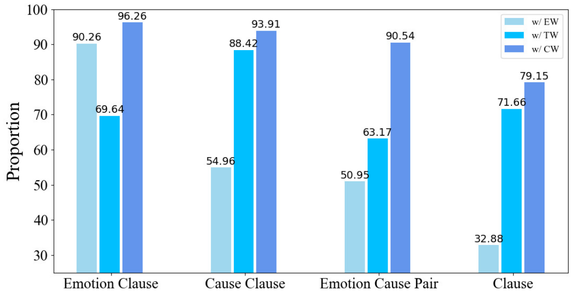

Figure 3: The influence of the two types of keywords from an intuitive aspect. It shows the proportion of emotion clauses, cause clauses, emotion-cause pairs, and clauses that are covered by the extracted key phrases or emotion words or both of them. "w/ EW", "w/ TW", and "w/ CW" means using emotion words, key phrases obtained by TextRank or both of them, respectively.

where $\mathbf{W}_g \in R^{1\times 2d_h}$ and $\mathbf{b}_g$ are parameters; σ is the sigmoid function.

In the training process, we leverage the emotion labels and cause labels as auxiliary supervision signals to facilitate the clause representation learning in the clause-level encoder:

$$\begin{aligned} \hat{\mathbf{y}}_i^e &= \mathbf{softmax}(\mathbf{W}_e\mathbf{u}_i^e + \mathbf{b}_e)\,, \\ \hat{\mathbf{y}}_i^c &= \mathbf{softmax}(\mathbf{W}_c\mathbf{u}_i^c + \mathbf{b}_c)\,, \end{aligned} \tag{3}$$

where $\mathbf{W}_e, \mathbf{W}_c \in \mathbb{R}^{1\times 2d_h}$ are trainable parameters and $\mathbf{b}_e, \mathbf{b}_c$ are bias terms.

4.2 Fine-Grained Semantic Aware Graph

To obtain fine-grained semantic enhanced clause representations, we leverage external knowledge to extract keywords in the document first. Then, we build a clause-keyword bipartite graph to model the relations between clauses. In this way, the keywords which convey fine-grained semantic features can help highlight the potential causal features contained in the clause representations.

Keywords Acquisition. We use the TextRank algorithm (Mihalcea and Tarau, 2004) to extract key phrases and a sentiment lexicon (Xu et al., 2008)[1] to obtain emotion words in a document. We take the union of the two sets as the final keyword set.

To measure the influence of the two types of keywords from an intuitive view, we count the proportions of emotion clauses, cause clauses, emotion-cause pairs, and clauses that are covered by the emotion words or key phrases or both of them. Noted that if emotion clause and cause clause that comprise a pair both contain any keyword, we think that the pair is covered by the keywords.

From Figure 3 we observe that if we use the key phrases extracted by TextRank alone, only about 69% of emotion clauses can be found; if we use the emotion words alone, only about 54% of cause clauses can be identified. With the use of emotion words or key phrases, only about 50% or 63% of emotion-cause pairs can be figured out. Consequently, we take the union of the two sets as the final keyword set. However, given the complete keyword set, clauses that contain keywords account for a large proportion (79%), which means that the imported keywords may introduce noise as well. To this end, it's necessary to measure the importance of different keywords when modeling the interaction between clauses and keywords.

Clause-Keyword Bipartite Graph Construction. Given a document D, we denote the clause-keyword bipartite graph as $\mathcal{G}_b = (\mathcal{V}, \mathcal{E}_b)$, where $\mathcal{V} = \mathcal{V}_c \cup \mathcal{V}_k$ represents a node set composing of clause nodes and keyword nodes and $\mathcal{E}_b$ denotes edges between nodes. $\mathcal{V}_k = \{k_1, k_2, ..., k_m\}$ and $\mathcal{V}_c = \{c_1, c_2, ..., c_{|D|}\}$ mean there are m keywords and $|D|$ clauses in the document D. We establish edges between each node in $\mathcal{V}_c$ and each node in $\mathcal{V}_k$, which means every element e_{ij} in $\mathcal{E}_b \in \mathbb{R}^{|D|\times m}$ is 1. It is because the average length of clauses is too short, many keywords only appear once in one clause. Thus, an adjacency matrix based on keyword-clause co-occurrence is extremely sparse.

For keywords in $\mathcal{V}_k$, their feature vectors are initialized by the word embedding vectors released by Xia and Ding (2019). As for clause nodes $c_i \in \mathcal{V}_c$, they are initialized with the corresponding context-aware clause representation $\mathbf{v}_i$ generated from the clause-level encoder. We denote the feature matrices of keyword and clause nodes as $\mathbf{X}_k = \{\mathbf{k}_1, ..., \mathbf{k}_m\} \in \mathbb{R}^{m\times d_w}$ and $\mathbf{X}_c = \{\mathbf{v}_1, ..., \mathbf{v}_{|D|}\} \in \mathbb{R}^{|D|\times 2d_h}$ respectively, where d_w is the dimension of the word embedding and is equal to $2d_h$ in our setting.

Attention Guided Clause Representations Update. We propose a graph attention module to model the semantic interaction between clauses and keywords, aiming to utilize the fine-grained semantic features implied in keywords to facilitate clause representation learning.

Intuitively, the clause-keyword bipartite graph realizes fine-grained semantic connections between distant clauses, which is helpful to extract emotion-

---

[1] We download the sentiment lexicon from this link: `https://github.com/ZaneMuir/DLUT-Emotionontology`.

cause pairs composed of distant clauses. Nevertheless, for a specific clause, the importance of various keywords is different. Therefore, we use the graph attention mechanism (Velickovic et al., 2018) to measure the document-level keyword preference-degree of each clause, where the attention weight is computed as the edge weight between the clause node c_i and the keyword node k_j in a document:

$$\alpha_{ij} = \frac{\mathbf{exp}(w^\top[\mathbf{W}_1\mathbf{v}_i;\mathbf{W}_2\mathbf{k}_j])}{\sum_{t=1}^{|D|}\mathbf{exp}(w^\top[\mathbf{W}_1\mathbf{v}_t;\mathbf{W}_2\mathbf{k}_j])}\,, \qquad (4)$$

where $\mathbf{v}_i$ and $\mathbf{k}_j$ are features of clause c_i and keyword k_j respectively; $[\cdot;\cdot]$ is the concatenation operation; $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{d_w \times d_w}$ and $w \in \mathbb{R}^{2d_w \times 1}$ are trainable parameters.

Then, clause c_i is encoded as the fine-grained semantic enhanced representation $\mathbf{v}_i^b$ as follows:

$$\mathbf{v}_i^b = \mathbf{tanh}((\mathbf{v}_i + \sum_{j=1}^{m}(\alpha_{ij}(\sum_{t=1}^{|D|}\alpha_{tj}\mathbf{W}_3\mathbf{v}_t))) + \mathbf{b})\,, \qquad (5)$$

where $\sum_{t=1}^{|D|}\alpha_{tj}\mathbf{W}_3\mathbf{v}_t$ means the representation of the keyword $\mathbf{k}_j$, and $\sum_{j=1}^{m}(\alpha_{ij}(\sum_{t=1}^{|D|}\alpha_{tj}\mathbf{W}_3\mathbf{v}_t))$ is the weighted added of keyword representations for generating fine-grained semantic enhanced clause representation. $\mathbf{W}_3 \in \mathbb{R}^{d_w \times d_w}$ is a trainable parameter and $\mathbf{b}$ is a bias term.

4.3 Coarse-Grained Semantic Aware Graph

Coarse-grained semantic relationships between clauses are useful for finding causal cues implied in the context. We establish a fully connected clause graph and leverage graph attention mechanism to model the coarse-grained semantic relationships between clauses.

Given a document D, we define the clause graph as $\mathcal{G}_c = (\mathcal{V}_c, \mathcal{E}_c)$, where $\mathcal{V}_c$ represents a node set and $\mathcal{E}_c$ denotes an edge set. Each node in the fully connected graph is a clause in D, and every two nodes have an edge. Self-loop edge is added to every node because a clause can be an emotion clause and a cause clause simultaneously. We use clause representation $\mathbf{v}_i$ generated from the clause-level encoder for node feature initialization. Based on the self-attention mechanism (Vaswani et al., 2017) which aggregated neighboring clauses' information, the graph attention network propagates information among clauses by stacking multiple graph attention layers. The representation of clause c_i in the t-th layer is updated as follows:

$$\mathbf{v}_i^{(t)} = \mathbf{ReLU}(\sum_{j\in\mathcal{N}(i)}\alpha_{ij}^{(t)}\mathbf{W}_1^{(t)}\mathbf{v}_j^{(t-1)} + \mathbf{b}^{(t)})\,, \qquad (6)$$

where $\mathbf{W}_1^{(t)} \in \mathbb{R}^{d_w \times d_w}$ is a transform matrix and $\mathbf{b}^{(t)}$ is a bias term; $\mathcal{N}(i)$ represents the neighbouring clauses of c_i; $\mathbf{v}_i^{(0)} = \mathbf{v}_i$. The attention weight $\alpha_{ij}^{(t)}$ is learned as follows:

$$e_{ij}^{(t)} = {w^{(t)}}^\top \mathbf{tanh}([\mathbf{W}_2^{(t)}\mathbf{v}_i^{(t-1)};\mathbf{W}_3^{(t)}\mathbf{v}_j^{(t-1)}])\,,$$
$$\alpha_{ij}^{(t)} = \frac{\mathbf{exp}(\mathbf{LeakyReLU}(e_{ij}^{(t)}))}{\sum_{k\in\mathcal{N}(i)}\mathbf{exp}(\mathbf{LeakyReLU}(e_{ik}^{(t)}))}\,, \qquad (7)$$

We stack two graph attention layers and obtain $\mathbf{v}_i^c = \mathbf{v}_i^{(2)}$ as the updated representation for c_i.

4.4 Pair Classification

We concatenate the two types of clause representations and obtain $\hat{\mathbf{v}}_i = [\mathbf{v}_i^b; \mathbf{v}_i^c]$ as the final representation of clause c_i.

Emotion Cause Pair Extraction. For a candidate pair $(c_i^e, c_j^c) \in P$, we pass its representation $\mathbf{v}_{ij}^p = [\hat{\mathbf{v}}_i; \hat{\mathbf{v}}_j]$ to a fully-connected layer with softmax activation function to predict the label of it:

$$\hat{\mathbf{p}}_{ij} = \mathbf{softmax}(\mathbf{W}_p^\top \mathbf{v}_{ij}^p + \mathbf{b}_p)\,, \qquad (8)$$

where $\mathbf{W}_p \in \mathbb{R}^{4d_w \times 2}$ and $\mathbf{b}_p \in \mathbb{R}^{2\times 1}$ are trainable parameters. We obtain the predicted label $\hat{\mathbf{EC}}_{ij}$ for the candidate pair (c_i^e, c_j^c) according to the probability distribution $\hat{\mathbf{p}}_{ij}$.

During model training, we use two cross-entropy loss functions $\mathcal{L}_{emo}$ and $\mathcal{L}_{cau}$ to supervise the clause representation learning in the clause-level encoder and a cross-entropy loss function $\mathcal{L}_{pair}$ to supervise the final emotion-cause pair prediction. The loss function $\mathcal{L}$ is formulated as follows:

$$\mathcal{L} = \mathcal{L}_{pair} + \mathcal{L}_{emo} + \mathcal{L}_{cau}\,. \qquad (9)$$

Emotion Extraction and Cause Extraction. Following Chen et al. (2020b), we implement emotion extraction and cause extraction based on the predictions of all candidate pairs. For emotion extraction, the predicted label $\hat{\mathbf{E}}_i$ for clause c_i can be obtained as follows:

$$\hat{\mathbf{E}}_i = \begin{cases} 1, & if \sum_{j=1}^{|D|}(\hat{\mathbf{EC}}_{ij}) > 0 \\ 0, & otherwise \end{cases}\,. \qquad (10)$$

For cause extraction, the predicted label $\hat{\mathbf{C}}_i$ for clause c_i can be obtained similarly.

5 Experiments

We conduct a series of experiments to verify the effectiveness of MGSAG.

5.1 Experimental Setup

5.1.1 Dataset and Evaluation Metrics

We use the benchmark dataset released by Xia and Ding (2019) for experiments. This typical and widely used dataset is constructed based on an emotion cause extraction corpus (Gui et al., 2016) that contains 1,945 Chinese documents from SINA city news[2]. To obtain statistically credible results, we adopt the same data split setting (10-fold cross-validation) used by Xia and Ding (2019), repeat the experiments 10 times, and report the average results of precision (P), recall (R), and F_1-score (F_1) on the main task: emotion-cause pair extraction (**ECPE**), and two sub-tasks: emotion extraction (**EE**) and cause extraction (**CE**), following existing works (Xia and Ding, 2019; Ding et al., 2020b,a; Chen et al., 2020a,b; Cheng et al., 2020).

5.1.2 Redistricting of Original Test Set

As ECPE is a newly proposed task, there is only one typical and widely used dataset. Because of the inherent position bias in ECPE, how to improve the performance on both position-sensitive (majority) and position-insensitive data (minority), has become one of the challenges. Therefore, it is essential to measure the reliance of existing methods on the relative position information.

To this end, we split the original test set ($Test_{all}$) of each fold into two parts according to the relative distance between emotions and causes. The first part ($Test_{Bias}$) contains documents with only one pair and the relative distance between the two clauses is less than 2. The second part ($Test_{NoBias}$) is the complement of the first part, which means $Test_{all} = Test_{Bias} \cup Test_{NoBias}$ and $Test_{Bias} \cap Test_{NoBias} = \emptyset$. We conduct experiments on the original test set first, and then use $Test_{Bias}$ and $Test_{NoBias}$ to evaluate various methods respectively. To ensure fairness, we use the same model parameters which produce results on $Test_{all}$ to obtain the results on the two subsets: $Test_{Bias}$ and $Test_{NoBias}$.

5.1.3 Comparative Approaches

We compare MGSAG with the following methods, which can be divided into two types: position-insensitive and position-sensitive methods.

Position-insensitive Methods. Following methods haven't utilized the relative position information explicitly. **Indep / Inter-CE / Inter-EC** (Xia and Ding, 2019): these two-step approaches first extracted emotions and causes separately to form candidate emotion-cause pairs and then trained a classifier to recognize true pairs. **IE-CNN** (Chen et al., 2020a) reformulated the ECPE task as a sequence labeling task and extracted pairs in an end-to-end fashion.

Position-sensitive Methods. Following methods take relative position information as a crucial feature to recognize pairs. **PairGCN** (Chen et al., 2020b) is a method highly dependent on position information when modeling relations between pairs. **ECPE-2D** (Ding et al., 2020a) extracted pairs through 2D representation, interaction, and prediction. The window-constrained 2D Transformer achieved the best performance. **SLSN-U** (Cheng et al., 2020) extracted pairs through a process of local search which was defined by the setting of the local context window. **RankCP** (Wei et al., 2020) utilized kernel-based relative position embedding to enhance the clause representations obtained from inter-clause modeling module. **ECPE-MLL** (Ding et al., 2020b) used a multi-label learning method inside each sliding window which was defined manually.

5.1.4 Implementation Details

To conduct a fair comparison with the baselines, we utilize the same word embeddings followed Xia and Ding (2019). The dimension of word embedding is 200. The numbers of hidden units of BiLSTM in the word-level and clause-level encoder are set to 200 and 100, respectively. We stack two graph attention layers to build a graph attention network and add dropout (Srivastava et al., 2014) with the rate of 0.1 for each layer to reduce overfitting. During the training process, we use the Adam (Kingma and Ba, 2015) optimizer to update all parameters. We report the results of BERT (Devlin et al., 2019) in the appendix.

5.2 Experimental Results

5.2.1 Results on Original Test Set

Table 1 reports the comparative results on emotion cause pair extraction and two sub-tasks. We can observe that position-sensitive models perform better than position-insensitive models on average, indicating the effectiveness of using relative position

Table 3: F_1 results of ablation study on $Test_{Bias}$, $Test_{NoBias}$, and $Test_{all}$, focusing on EC Pair Ext.

information. However, our method MGSAG hasn't utilized relative position information, aiming to alleviate the position bias problem in ECPE. In spite of this, MGSAG still outperforms the existing state-of-the-art methods. Especially, MGSAG achieves the best F_1 on the main task: emotion-cause pair extraction. The F_1 score of MGSAG on ECPE is **1.06%** higher than that of ECPE-MLL, which indicates the efficiency of capturing multi-granularity semantic relations between clauses.

For the two sub-tasks, MGSAG outperforms other baselines in terms of cause extraction compared with emotion extraction. This indicates that the effective clause representation learning based on MGSAG is beneficial to extract cause clauses and further facilitate the extraction of emotion-cause pairs.

5.2.2 Results on $Test_{Bias}$ and $Test_{NoBias}$

To evaluate if MGSAG is vulnerable when the causes are not in proximity to the emotion, we evaluate it on the two subsets as shown in 5.1.2. Table 2 shows the results on $Test_{Bias}$ and $Test_{NoBias}$. Noted that when we get the best results on the original test set as shown in Table 1, we use the same parameters to evaluate models on the two subsets ($Test_{Bias}$ and $Test_{NoBias}$).

From Table 2 we observe that there is a significant gap (34∼41%) between the results on $Test_{Bias}$ and $Test_{NoBias}$, for all of the methods. One of the reasons should be the imbalanced data of $Test_{Bias}$ and $Test_{NoBias}$, which means the proportion of position-insensitive data is very small. More importantly, most of the methods exploit the relative position information explicitly or implicitly, leading to poor performance on $Test_{NoBias}$.

However, MGSAG outperforms existing state-of-the-art baselines on both of the two subsets ($Test_{Bias}$ and $Test_{NoBias}$), proving its generalization ability towards position-sensitive and position-insensitive data. Specially, the F_1 score of MGSAG on $Test_{NoBias}$ is **3.13%** higher than that of ECPE-MLL. The results verify the effectiveness of capturing causal relations between clauses via multi-granularity semantics encoding.

5.3 Discussions

We conduct ablation studies to analyze the effects of different components and settings in our method MGSAG.

5.3.1 Influence of Different Components

As shown in Table 3, we remove FGSAG, CGSAG, and both of them respectively to verify the effectiveness of the proposed two graphs with the semantics of different granularity.

(c_1) When Mr. Chen drove from south to north on Yangtze River Avenue,
(c_2) it was dark and there was no street lamp.
(c_3) His slight was not clear.
(c_4) He ran into a stone and overturned.
(c_5) After that,
(c_6) he was trapped in the car,
(c_7) broke the window glass,
(c_8) and climbed out of the car.
(c_9) He said that,
(c_{10}) because of the sudden incident,
(c_{11}) he was shocked and injured.

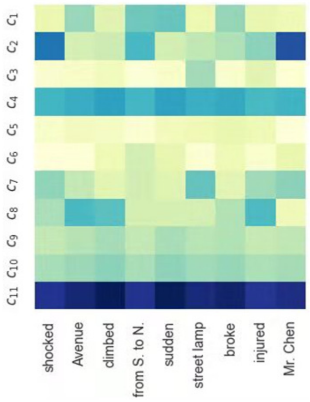

Figure 4: An example that MGSAG extracts the emotion cause pair (c_{11}, c_4) correctly, while ECPE-MLL fails. Words shaded in yellow are keywords. The heatmap presents attention scores in the clause-keyword bipartite graph. Rows of c_{11} and c_4 are the top-two darkest rows, means that keywords pay more attention to them and facilitate MGSAG to extract pair (c_{11}, c_4) correctly.

Effect of Fine-Grained Semantic Aware Graph. We remove the FGSAG to verify the effect of fine-grained semantic enhanced relations. Table 3 shows that removing FGSAG results in significant performance degradation, indicating that it is indeed useful for pair prediction. Especially, the result of F_1 on $Test_{NoBias}$ decreases **4.07%** without the FGSAG, proving its efficiency of alleviating position bias.

Effect of Coarse-Grained Semantic Aware Graph. We remove CGSAG which is used for coarse-grained semantic enhanced relations to verify its effect. Table 3 reports that model without CGSAG results in a clear drop (**2.74%/3.17%**) on $Test_{NoBias}$ and $Test_{all}$, but a limited drop (**0.76%**) on $Test_{Bias}$. It shows that modeling the coarse-grained semantic relations between clauses can alleviate position bias as well.

Effect of Semantic Aware Graph Model. We further evaluate the effect of dual graph-based modules by removing FGSAG and CGSAG simultaneously. As shown in Table 3, the model without the two graphs performs worse than without any one of them. The significant performance decline of the F_1 score on all of the test sets verifies that the fine-grained semantics and coarse-grained semantics are complementary to each other. Thus, it's necessary to take both of them into account.

Loss Function	P	R	F_1
$\mathcal{L}_{pair}$	0.6940	**0.6533**	0.6720
$\mathcal{L}_{pair} + \mathcal{L}_{emo} + \mathcal{L}_{cau}$	**0.7243**	0.6507	**0.6846**

Table 4: Comparison of different supervised signals for our method.

Model	$Test_{Bias}$	$Test_{NoBias}$	$Test_{all}$
w/ RW	0.7596	0.4078	0.6674
w/o EW	0.7669	0.3920	0.6686
w/o TW	0.7658	0.4271	0.6771
MGSAG	**0.7730**	**0.4301**	**0.6846**

Table 5: Comparative F_1 results on $Test_{Bias}$, $Test_{NoBias}$, and $Test_{all}$ of our variant models, focusing on EC Pair Ext. "w/ RW" means using random embeddings for keyword feature initialization. "w/o EW" and "w/o TW" means removing emotion words and key phrases obtained by TextRank, respectively.

5.3.2 Influence of Two-Level Supervision

We use the two-level supervised signals to train MGSAG. A low-level signal $\mathcal{L}_{emo} + \mathcal{L}_{cau}$ supervises the clause representation learning at the clause-level encoder and a high-level signal $\mathcal{L}_{pair}$ supervises the pair representation learning at the classification stage. To evaluate the effectiveness of low-level supervision, we only use $\mathcal{L}_{pair}$ to train the model, and the results are shown in Table 4. It shows that training with low-level supervision brings an improvement mainly on precision, which indicates that the low-level supervision is helpful to learn more accurate emotion-specific and cause-specific features and eventually facilitates the performance on emotion-cause pair extraction.

5.3.3 Influence of Different Keyword Settings

As shown in Table 5, we use different keyword settings to verify the effectiveness of our proposed keywords, which is the union of emotion words obtained from a sentiment lexicon (Xu et al., 2008) and key phrases obtained by TextRank (Mihalcea and Tarau, 2004). Removing any one of them results in a performance decline on all of the test sets. It proves that it's necessary to take both of them into account. Moreover, we replace the keyword features with randomly initialized embeddings, showing a significant drop on $Test_{NoBias}$. It indicates that the fine-grained semantics implied in keywords does help to alleviate the position bias problem.

5.3.4 Case Study

As shown in Figure 4, the distance between the emotion clause c_{11} and the cause clause c_4 is 7. Although the cause clause c_4 doesn't contain any keywords, global keywords in the document convey crucial fine-grained semantics, helping MGSAG extracts (c_{11}, c_4) correctly.

6 Conclusion and Future Work

In this paper, we propose MGSAG to alleviate the position bias problem in the ECPE task. Our approach implements clause representation learning via fine-grained semantics introduced by keywords and coarse-grained semantics among clauses. Experimental results show that MGSAG surpasses the state-of-the-art baselines, and outperforms other methods significantly on the position-insensitive data. In the future, we would like to tackle the problem of imbalanced data by reducing non-emotion-cause pairs, based on a position-insensitive approach.

[3] We download the pre-trained model from this link: `https://s3.amazonaws.com/models.huggingface.co/bert/bert-base-chinese.tar.gz`

nal test set, which shows the effectiveness of utilizing the pre-trained BERT. As shown in Table 6, results of models with BERT on $Test_{Bias}$ and $Test_{NoBias}$ indicate that using BERT as the encoder cannot make up for the deficiency caused by position bias. MGSAG still outperforms other methods on $Test_{all}$ and $Test_{NoBias}$. The results verify the effectiveness of capturing the causal semantic relations between clauses via fine-grained and coarse-grained semantics encoding.

Cross-lingual Inference with A Chinese Entailment Graph

Abstract

Predicate entailment detection is a crucial task for question-answering from text, where previous work has explored unsupervised learning of entailment graphs from typed open relation triples. In this paper, we present the first pipeline for building Chinese entailment graphs, which involves a novel high-recall open relation extraction (ORE) method and the first Chinese fine-grained entity typing dataset under the FIGER type ontology. Through experiments on the Levy-Holt dataset, we verify the strength of our Chinese entailment graph, and reveal the cross-lingual complementarity: on the parallel Levy-Holt dataset, an ensemble of Chinese and English entailment graphs outperforms both monolingual graphs, and raises unsupervised SOTA by 4.7 AUC points.

1 Introduction

Predicate entailment detection is important for many tasks of natural language understanding (NLU), including reading comprehension and semantic parsing. Suppose we wish to answer a question by finding a relation **V** between entities **A** and **B**. Often, **V** cannot be found directly from the reference passage or database, but another relation **U** can be found between **A** and **B**, where **U** entails **V** (for instance, suppose **U** is *buy*, **V** is *own*). If we can identify this with predicate entailment detection, we can then answer the question.

To detect predicate entailments, previous work has explored unsupervised learning of typed entailment graphs (Szpektor and Dagan, 2008; Berant et al., 2011, 2015; Hosseini et al., 2018, 2019, 2021). Entailment graphs are directed graphs, where each node represents the predicate of a relation, and an edge from node **U** to node **V** denotes "**U** entails **V**". Entailment graphs are built based on the Distributional Inclusion Hypothesis (DIH) (Dagan et al., 1999; Geffet and Dagan, 2005; Herbelot and Ganesalingam, 2013; Kartsaklis and Sadrzadeh, 2016). Predicates are disambiguated according to their arguments' types, predicates taking the same types of arguments go into one subgraph.

While previous work on entailment graphs has mostly been limited to English, building entailment graphs in other languages is interesting and challenging. The importance is two-fold: for that language, a native entailment graph would facilitate NLU in it; for cross-lingual inference, entailment graphs in different languages host exploitable complementary information. In particular, we argue that by jointly consulting strong entailment graphs in multiple languages, improvements can be gained for inference in **all** participant languages.

In this paper, we choose Chinese as our target language to build entailment graphs, as it is distant enough from English to exhibit rich complementarity, while relatively high-resource. The main challenge for building Chinese entailment graphs, is to extract reliable **typed relation triples** from raw corpora as strong input. This involves open relation extraction (ORE) and fine-grained entity typing (FET), which we discuss below.

ORE extracts predicate-argument triples from sentences, where previous work has used rule-based methods over syntactic parsers either directly (Fader et al., 2011; Etzioni et al., 2011; Angeli et al., 2015), or for distant supervision (Cui et al., 2018; Stanovsky et al., 2018; Kolluru et al., 2020). The challenge in ORE can be largely attributed to the poor definition of "open relations". The situation worsens in Chinese, as the parts of speech are more ambiguous and many linguistic indicators of relations are poorly represented. Previous work on Chinese ORE (Qiu and Zhang, 2014; Jia et al., 2018) has defined narrow sets of open relations, failing to identify many relational constructions. Conversely, we propose a novel dependency-based ORE method, which we claim provides comprehensive coverage of relational constructions.

Findings of the Association for Computational Linguistics: ACL 2022, pages 1214 - 1233
May 22-27, 2022

FET assigns types to the arguments of extracted relations, so that word-senses of predicates can be disambiguated. The challenge in Chinese FET lies mainly in the lack of datasets over a suitable type ontology: too coarse a type set would be insufficient for disambiguation, too granular a type set would result in disastrous sparsity in the entailment graph. Following Hosseini et al. (2018), we use the popular FIGER type set (Ling and Weld, 2012), and build CFIGER, the first FIGER-labelled Chinese FET dataset via label mapping. Entity typing models built on this dataset show satisfactory accuracy and are helpful for predicate disambiguation.

We evaluate our Chinese entailment graph on the Levy-Holt entailment dataset (Levy and Dagan, 2016; Holt, 2019) via translation. Results show that our Chinese entailment graph outperforms baselines by large margins, and is comparable to the English graph. We verify our cross-lingual complementarity hypothesis with an ensemble between English and Chinese graphs, where we show a clear advantage over both monolingual graphs[1], and set a new SOTA for unsupervised predicate entailment detection.

Our contributions are as follows: 1) we present a novel Chinese ORE method sensitive to a much wider range of relations than previous SOTA, and a Chinese FET dataset, the first under the FIGER type ontology; 2) we construct the first Chinese entailment graph, comparable to its English counterpart; 3) we reveal the cross-lingual complementarity of entailment graphs with an ensemble.[2]

2 Background and Related Work

Predicate entailment detection has been an area of active research. Lin (1998); Weeds and Weir (2003); Szpektor and Dagan (2008) proposed various count-based entailment scores; Berant et al. (2011) proposed to "globalize" typed entailment graphs by closing them with transitivity constraints; Hosseini et al. (2018) proposed a more scalable global learning approach with soft transitivity constraints; Hosseini et al. (2019, 2021) further refined the entailment scores with standard and contextual link prediction.

Our work is closely related to Hosseini et al. (2018), with key adaptations for Chinese in ORE and FET. Their ORE method is based on a CCG parser (Reddy et al., 2014), while ours is based on a dependency parser (Zhang et al., 2020); their FET is done by linking entities to Wikipedia entries, while we use neural entity typing for the task.

Dependency parses are less informative than CCG parses, and require heavier adaptation. However, Chinese dependency parsers are currently more reliable than CCG parsers (Tse and Curran, 2012). Previous Chinese ORE methods (Qiu and Zhang, 2014; Jia et al., 2018) are based on dependency parsers, but they omit many common constructions essential to ORE. In §3, we present the most comprehensive Chinese ORE method so far.

Linking-based entity-typing can be more accurate than neural methods, since the type labels are exact as long as linking is correct. However, current Chinese entity linking methods require either translation (Pan et al., 2019) or search logs (Fu et al., 2020). Both hurt linking accuracy, and the latter grows prohibitively expensive with scale. On the other hand, since the seminal work of Ling and Weld (2012), neural fine-grained entity typing has developed rapidly (Yogatama et al., 2015; Shimaoka et al., 2017; Chen et al., 2020), with a common interest in FIGER type set. For Chinese, Lee et al. (2020) built an ultra-fine-grained entity typing dataset, based on which we build our CFIGER dataset via label mapping.

Weber and Steedman (2019) aligned English and German entailment graphs, and showed that the English graph can help with German entailment detection. Yet it was uncertain whether this effect comes from genuine complementarity or the mere fact that the English graph is stronger. We take one step further, and show that complementarity can be exploited in both directions: for English, the higher resource language, entailment detection can also benefit from the ensemble to reach new heights.

As a related resource, Ganitkevitch et al. (2013) created a multi-lingual database for symmetric paraphrases; in contrast, entailment graphs are directional. More recently, Schmitt and Schütze (2021) proposed to fine-tune language models on predicate entailment datasets via prompt learning. In contrast to our entailment graphs, their approach is supervised, which carries the danger of overfitting to dataset artifacts (Gururangan et al., 2018).

Another related strand of research, e.g. SNLI (Bowman et al., 2015), is concerned with the more

---

[1] This effect remains clear when both monolingual graphs are trained with parallel corpora, verifying that complementarity is behind this gain, not the additional corpus involved. See §7.2 for more discussions.

[2] Our codes and data-sets can be found at `https://github.com/Teddy-Li/ChineseEntGraph`

general NLI task, including hypernymy detection and logic reasoning like $A \wedge B \rightarrow B$, but rarely covers the cases requiring external knowledge of predicate entailment (Hosseini et al., 2018). Conversely, entailment graphs aim to serve as a robust resource for directional predicate entailments induced from textual corpora.

3 Chinese Open Relation Extraction

We build our ORE method based on DDParser (Zhang et al., 2020), a SOTA Chinese dependency parser. We mine relation triples from its output by identifying patterns in the dependency paths.

Depending on the semantics of the head verb, instances of a dependency pattern can range from being highly felicitous to marginally acceptable as a relation. Motivated by our downstream task of entailment graph construction, we go for higher recall and take them in based on the **Relation Frequency Assumption**: less felicitous relations occur less frequently, and are less likely to take part in entailments when they do occur, thus they are negligible.

Due to the lack of a commonly accepted benchmark or criterion for “relations”, we did not perform an intrinsic evaluation for our Chinese ORE method; its significant benefit to our EG_{Zh} graph, as shown in §7, should suffice to demonstrate its strength.

3.1 Parsing for Chinese ORE

The task of open relation extraction on top of LM-driven dependency parsers, is really the task of binding the relations in surface forms to the underlying relation structures. Though trivial at first sight, the definition of these underlying and essentially semantic relations demands detailed analysis.

Jia et al. (2018) is the latest to propose an ORE method on dependency paths. They defined a set of rules to extract relations patterns, which they call dependency semantic normal forms (DSNFs)[3].

However, their set of DSNFs is inexhaustive and somewhat inaccurate. We show below that many linguistic features of Chinese demand a more principled account, more constructions need to be considered as relations, some to be ruled out. These observations are made from a multi-source news corpus, which we use to build entailment graphs (§5)[4]. Below, we highlight 5 additional constructions we identify, explained with examples[5].

A. PP Modifiers as “De” Structures One key feature of Chinese is its prevalent use of *“De”* structures in the place of prepositional phrases, where *“De”* can be seen as roughly equivalent to the possessive clitic ***’s***. For instance, in “咽炎*(pharyngitis)* 成为*(becomes)* 发热*(fever)* 的*(De)* 原因*(cause); Pharyngitis becomes the cause of fever”*, the root clause in Chinese is (Pharyngitis, becomes, cause), but we *additionally* extract the underlying relation **(pharyngitis, becomes·X·De·cause, fever)**, where the true object *“fever”* is a **nominal** attribute of the direct object *“cause”*, and the true predicate subsumes the direct object[6].

The same also applies to the subject, though somewhat more restricted. For sentences like “苹果*(Apple)* 的*(De)* 创始人*(founder)* 是*(is)* 乔布斯*(Jobs); The founder of Apple is Jobs”*, we additionally extract the relation **(Apple, founder·is, Jobs)**, where the true subject *“Apple”* is a **nominal** attribute of the direct subject *“founder”*, and the true predicate subsumes the direct subject[7].

B. Bounded Dependencies In Chinese, bounded dependencies, especially control structures, are expressed with a covert infinitival marker, equivalent to English “to”. We capture the following phenomena in addition to direct relations:

- Sequences of VPs: for sentences like *“*我*(I)* 去*(go-to)* 诊所*(clinic)* 打*(take)* 疫苗*(vaccine); I go to the clinic to take the vaccine”*, the two verb phrases “去(go-to) 诊所(clinic)” and “打(take) 疫苗(vaccine)” are directly concatenated, with no overt connection words. Here we additionally extract the relation **(I, take, vaccine)** by copying the subject of the head verb to subsequent verbs.

- Subject-control verbs: for the famous example *“*我*(I)* 想*(want)* 试图*(try)* 开始*(begin)* 写*(write)* 一个*(a)* 剧本*(play); I want to try to begin to write a play”*, again the verbs are directly con-

---

[3] We refer readers to Appendix A for a brief summary.

[4] Since entailment graph construction is fully unsupervised, this source corpus is independent of the evaluation in §6. Particularly, the Levy-Holt dataset used in §6 consists of short sentences, which is a vastly different genre, involving much simpler structures, with a single relation per sentence and few subordinating constructions discussed above (see Appendix J for relevant statistics)

[5] We refer readers to Appendix H for diagram illustrations.

[6] Here and below, examples are paired with English metaphrases, and when necessary, paraphrases; relation triples are presented as English metaphrases (inflections ignored) .

[7] These relations are more felicitous with frequent predicate argument combinations, and less so for the infrequent ones. As in line with the Relation Frequency Assumption, less felicitous relations are also less statistically significant.

catenated; this time, all verbs but the first one behaves as infinitival complements to their direct antecedents. In such cases, we extract sequences of relations like **(I, want, try)**, **(I, want·try, begin)**, **(I, want·try·begin, write)**, **(I, want·begin·try·write, a play)**.

Notably, the above relations are different from Jia et al. (2018)'s conjunction constructions in Table 5: the event sequences here involve subordination (control) rather than coordination, thus require a separate account.

C. Relative Clauses Relative Clauses also take the form of modification structures in Chinese, for which additional relations should also be extracted. For example, in *"他(he) 解决(solve) 了(-ed) 困扰(puzzle) 大家(everyone) 的(De) 问题(problem); He solved the problem that puzzled everyone"*, we extract not only the direct relation **(he, solve, problem)**, but also the relation embedded in the modification structure **(problem, puzzle, everyone)**.

D. Nominal Compounds Relations can be extracted from nominal compounds, where an NP has two consecutive "ATT" modifiers: in *"德国(Germany) 总理(Chancellor) 默克尔(Merkel); German Chancellor Merkel"*, "Germany" modifies "Chancellor", and "Chancellor" modifies "Merkel". Jia et al. (2018) extracted relations like **(Germany, Chancellor, Merkel)** for these NPs.

However, they overlooked the fact that prepositional compounds in Chinese with omitted "De" take exactly the same form (see construction **A**). For example, in NPs with nested PP modifiers like "*手续(formalities) 办理(handle) 时效(timeliness); Timeliness of the handling of formalities*" , we observe the same structure, but it certainly does not mean *"the handling of formalities is timeliness"*!

We take a step back and put restrictions on such constructions: only when all 3 words in the NP are nominals (but not pronouns), the third word is the head, the second is a 'PERSON' or 'TITLE', and the first is a 'PERSON', then it is a relation, like **(Merkel, is·X·De·Chancellor, Germany)**. Otherwise, such NPs rarely host felicitous relations.

E. Copula with Covert Objects The copula is sometimes followed by modifiers ending with "*De*". Examples are *"玉米(Corn) 是(is) 从(from) 美国(US) 引进(introduce) 的(De); Corn is introduced from US"*, *"设备(device) 是(is) 木头(wood) 做(make) 的(De); The device is made of wood"*.

In these cases, there exists an object following the indicator *"的(De)"*, but the object is an empty ***pro*** considered inferable from context. In the absence of the true object, the *VOB* label is given to *"的(De)"*, leading to direct relations like **(Corn, is, De)**. However, the true predicates are rather *"is introduced from"* or *"is made of"*. To fix this, we **replace** the direct relations with ones like **(Corn, is·from·X·introduce·De·*pro*, America)**, reminiscent of the constructions **A**.

3.2 Our ORE Method

With the above constructions taken into account, we build our ORE method on top of DDParser. For part-of-speech labels, we use the POS-tagger in Stanford CoreNLP (Manning et al., 2014). We detect negations by looking for negation keywords in the adjunct modifiers of predicates: for predicates with an odd number of negation matches, we insert a negation indicator to them, treating them as separate predicates from the non-negated ones.

4 Chinese Fine-Grained Entity Typing

As shown in previous work (Berant et al., 2011; Hosseini et al., 2018), the types of a predicate's arguments are helpful for disambiguating a predicate in context. To this end, we need a fine-grained entity typing model to classify the arguments into sufficiently discriminative yet populous types.

Lee et al. (2020) presented CFET dataset, an ultra-fine-grained entity typing dataset in Chinese. They labelled entities in sentence-level context, into around 6,000 free-form types and 10 general types. Unfortunately, their free-form types are too fragmented for predicate disambiguation, and their general types are too ambiguous.

We turn to FIGER (Ling and Weld, 2012), a commonly used type set: we re-annotate the CFET dataset with FIGER types through label mapping. Given that there are around 6,000 ultra-fine-grained types and only 112 FIGER types (49 in the first layer), we can reasonably assume that each ultra-fine-grained type can be unambiguously mapped to a single FIGER type. For instance, the ultra-fine-grained type "湖 (lake)" is unambiguously mapped to the FIGER label "location / body_of_water".

Based on this assumption, we manually create a mapping between the two, and re-annotate CFET dataset with the mapping. We call the re-annotated dataset **CFIGER**, as it is the first in Chinese with FIGER labels. As with CFET, this dataset consists of 4.8K crowd-annotated data (equally divided into

Macro F1 (%)	dev	test
CFET with CFET dataset	-	24.9
CFET with CFIGER dataset	75.7	75.7
HierType with FIGER dataset	-	82.6
HierType with CFIGER dataset	74.8	74.5

Table 1: F1 scores of baseline models for CFIGER dataset, compared with the results on the datasets where they were proposed. Macro-F1 scores are reported because it is available in both baselines.

crowd-train, crowd-dev and crowd-test) and 1.9M distantly supervised data from Wikipedia[8].

For training set we combine the crowd-train and Wikipedia subsets; for dev and test sets we use crowd-dev and crowd-test respectively. We train two baseline models: *CFET*, the baseline model with CFET dataset; *HierType* (Chen et al., 2020), a SOTA English entity typing model.

Results are shown in Table 1: the F1 score of *HierType* model is slightly lower on CFIGER dataset than on FIGER dataset in English; contrarily, thanks to fewer type labels, the F1 score of *CFET* baseline increases on CFIGER, bringing it on par with the more sophisticated *HierType* model. This means our CFIGER dataset is valid for Chinese fine-grained entity typing, and may contribute to a benchmark for cross-lingual entity typing.

For downstream applications, we nevertheless employ the *HierType* model, as empirically it generalizes better to our news corpora. As shown in later sections, the resulting FET model can substantially help with predicate disambiguation.

5 The Chinese Entailment Graph

We construct the Chinese entailment graph from the Webhose corpus[9], a multi-source news corpus of 316K news articles, crawled from 133 news websites in October 2016. Similarly to the NewsSpike corpus used in Hosseini et al. (2018), the Webhose corpus contains multi-source non-fiction articles from a short period of time. This means it is also rich in reliable and diverse relation triples over a focused set of events, ideal for building entailment graphs.

We cut the articles into sentences by punctuations, limiting the maximum sentence length to 500 characters (the maximum sequence length for Chinese Bert). We discard the sentences shorter than 5 characters, and the articles whose sentences are all shorter than 5 characters. After applying the filter, we are left with 313,718 articles, as shown in Table 2.

	EG_{Zh}	EG_{En}
# of articles taken	313,718	546,713
# of triples used	7,621,994	10,978,438
# of predicates	363,349	326,331
# of type pairs where:		
subgraph exists	942	355
$\lvert$subgraph$\rvert > 100$	442	115
$\lvert$subgraph$\rvert > 1{,}000$	149	27
$\lvert$subgraph$\rvert > 10{,}000$	26	7

Table 2: Stats of our Chinese entailment graph (EG_{Zh}) compared with the English graph in Hosseini et al. (2018) (EG_{En}). $|\cdot|$ denotes the number of predicates.

For these 314K valid articles in Webhose, we get their CoreNLP POS tags and feed them into our ORE method in §3, to extract the open relation triples. Then, with *HierType* model (Chen et al., 2020) in §4, we type all arguments of the extracted relations; we type each predicate with its subject-object type pair, such as *person-event* or *food-law*; following previous work, we consider only the first-layer FIGER types; when multiple type labels are outputted, we consider all combinations as valid types for that predicate.

We finally employ the entailment graph construction method in Hosseini et al. (2018), taking in only binary relations [10]. The detailed statistics of our Chinese entailment graph are shown in Table 2: compared with EG_{En}, our graph is built on just over half the number of articles, yet we have extracted 70% the number of relation triples, and built a graph involving even more predicates. In general, our EG_{Zh} is of comparable size to EG_{En}.

We have also considered using another larger corpus, the CLUE corpus, for building the Chinese entailment graphs, but couldn't finish due to limits on computational resources [11]. The larger corpus is built by Xu et al. (2020), which is eight times the size of the Webhose corpus and is originally intended for training Chinese language models. We provide the typed relation triples extracted from the CLUE corpus as a part of our release, and encour-

---

[8] For detailed statistics, please refer to Appendix B.

[9] `https://webhose.io/free-datasets/chinese-news-articles/`

[10] We encourage interested readers to also check Appendix D for a brief introduction to Hosseini et al. (2018).

[11] Our computing environment is specified in Appendix I

age interested readers to build their own Chinese entailment graph on this larger corpus, as we expect it to exhibit stronger performance, and present an interesting comparison to the language-model driven models pre-trained with the same corpus.

6 Evaluation Setup

6.1 Benchmark and Baselines

We evaluate the quality of our Chinese entailment graph with the predicate entailment detection task, on the popular Levy-Holt dataset (Levy and Dagan, 2016; Holt, 2019). We use the same dev/test configuration as Hosseini et al. (2018). We convert the Levy-Holt dataset to Chinese through machine translation, then do evaluation on the translated premise-hypothesis pairs.

We are painfully aware that translation adds noise; in response, we conduct a human evaluation on 100 entries of Levy-Holt development set, as a proxy to the quality of translation. We find that for 89/100 of the entries, the annotation label remains correct; of which, for 74/100 of the entries, the meanings of the translations are precise reflections to the English originals[12]. Apart from the human evaluation, we will further discuss the effect of machine-translation in §7.

In Levy-Holt dataset, the task is: to take as input a pair of relation triples about the same arguments, one premise and one hypothesis, and judge whether the premise entails the hypothesis. For example, given the premise *"John, shopped in, Tesco"*, we would like a model to identify the hypothesis *"John, went to , Tesco"* as being entailed by it.

To convert Levy-Holt dataset into Chinese, we concatenate each relation triple into a pseudo-sentence, use Google Translate to translate the pseudo-sentences into Chinese, then parse them back to Chinese relation triples with our ORE method in §3. If multiple relations are returned, we retrieve the most representative ones, by considering only those relations whose predicate covers the HEAD word.[13]

To type the Chinese relation triples, we again use *HierType* model to collect their subject-object type-pairs. The premise and hypothesis need to take the same types of arguments, so we take the intersection of their possible type-pairs as valid pairs (unless the intersection is empty, in which case we take the union). We search the entailment subgraphs of these valid type-pairs, for entailment edges from the premise to the hypothesis, and return the entailment scores associated with these edges. When edges are found from multiple subgraphs, we take their maximum score; when no edge is found with any of the valid type-pairs, we back up to the average score from arbitrary type-pairs.

We compare our Chinese entailment graph with a few strong baselines:

BERT: We take the translated premise-hypothesis pairs (as the original pseudo-sentences), and compute the cosine similarity between their pretrained BERT representations at [CLS] token. This is a strong baseline but symmetric;
Jia: We build entailment graph in the same way as §5, but with the baseline ORE method by Jia et al. (2018); accordingly, Jia et al. (2018) method is also used in parsing the translated Levy-Holt pseudo-sentences for this evaluation;
DDPORE: Similar to *Jia* baseline, but with the baseline ORE method from DDParser (2020).

6.2 Cross-lingual Ensembles

In order to examine the complementarity between our Chinese entailment graph (EG_{Zh}) and the English graph (EG_{En}) (2018), we ensemble the predictions from the two graphs, $pred_{en}$ and $pred_{zh}$[14]. We experiment with four ensemble strategies: lexicographic orders from English to Chinese and Chinese to English, max pooling and average pooling:

$$\begin{aligned} pred_{en\_zh} &= pred_{en} + \gamma * \Theta(pred_{en}) * pred_{zh} \\ pred_{zh\_en} &= \gamma * pred_{zh} + \Theta(pred_{zh}) * pred_{en} \\ pred_{max} &= MAX(pred_{en}, \gamma * pred_{zh}) \\ pred_{avg} &= AVG(pred_{en}, \gamma * pred_{zh}) \end{aligned}$$

where $\Theta(\cdot)$ is the boolean function $IsZero$, γ is the relative weight of Chinese and English graphs. γ is a hyperparameter tuned on Levy-Holt dev set, searched between 0.0 and 1.0 with step size 0.1.

For instance, suppose our premise is *"he, shopped in, the store"*, and our hypothesis is *"he, went to, the store"*, then our Chinese relations, by translation, would be "他, 在·X·购物, 商店" and "他, 前往, 商店" respectively. Suppose we find in the English graph an edge from *"shop in"* to *"go to"*, scored $pred\_en = 0.6$, and we find in the Chinese graph an edge from "在·X·购

---

Table 3: Area Under Curve values on Levy-Holt dataset, for Chinese entailment graph (EG$_{Zh}$), its baselines, ensembles with English graphs, and ablation studies. EG$_{En}$ is the English graph from (Hosseini et al., 2018); EG$_{En}$++ is the English graph from (Hosseini et al., 2021). Entries with ⋆ uses Chinese lemma baseline; entries with ◇ uses English lemma baseline; entries with † are the best ensemble strategies by dev set results.

物” to “前往”, scored $pred\_zh = 0.7$. Then we would have $pred_{en\_zh} = 0.6$, $pred_{zh\_en} = 0.7$, $pred_{max} = 0.7$, $pred_{avg} = 0.65$.

In addition to ensembling with EG$_{En}$, we also ensembled our entailment graph with the SOTA English graph EG$_{En}$++ (Hosseini et al., 2021). We call the latter ones **Ensemble++** here and below.

7 Results and Discussions

To measure the performance of our constructed Chinese entailment graphs, we follow previous work in reporting the Precision-Recall (P-R) Curves plotted for successively lower confidence thresholds, and their Area Under Curves (AUC), for the range with $> 50\%$ precision.

A language-specific lemma baseline sets the left boundary of recall, by exact match over the lemmatized premise / hypothesis. For our Chinese entailment graph (EG$_{Zh}$) and its baselines, the boundary is set by Chinese lemma baseline. For the ensembles, in order to get commensurable AUC values with previous work instead of being over-optimistic, we use the English lemma baseline.

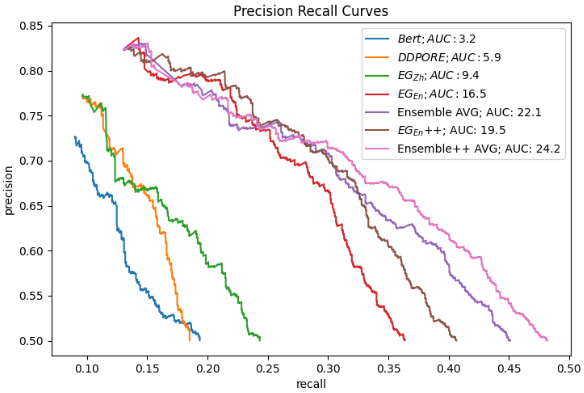

Figure 1: P-R Curves on Levy-Holt test set for EG$_{Zh}$, ensembles and baselines; *Jia(2018)* baseline is far behind others, thus omitted for the clarity of the figure.

7.1 Experiment Results

As shown in Table 3, on the Chinese Levy-Holt dataset, our EG$_{Zh}$ graph substantially outperforms the BERT pre-trained baseline. EG$_{Zh}$ is also far ahead of entailment graphs with baseline ORE methods, proving the superiority of our Chinese ORE method against previous SOTA.

EG$_{Zh}$ and EG$_{En}$ are built with the same algorithm (Hosseini et al., 2018), and evaluated on parallel datasets. Learnt from 57% the data, EG$_{Zh}$ achieves an AUC exactly 57% of its English counterpart. Note that the Chinese entailment graph is underestimated with the use of translated dataset: out of the 12,921 relation pairs in Levy-Holt test set, only 9,337 of them are parsed into valid Chinese binary relations. This means, for Chinese entailment graphs, the upper bound for recall is not 100%, but rather 72.3%, as is the upper bound for AUC. Besides, the translationese language style in Chinese Levy-Holt also poses a gap in word-choice to the natively-built entailment graph, resulting in more mismatches. Considering this additional noise, the performance of EG$_{Zh}$ means our pipeline is utilizing information in the source corpus very well.

The ensemble between Chinese and English entailment graphs sets a new SOTA for unsupervised predicate entailment detection. With all 4 ensemble strategies, improvement is gained upon both monolingual graphs; with **Ensemble AVG**, the best on dev-set, the margin of test set improvement is more than 5 points. Moreover, when ensembling with EG$_{En}$++, we get a test-set AUC of 24.2 points (**Ensemble++ AVG**), raising SOTA by 4.7 points.

7.2 Ablation Studies

In Table 3, we additionally present three **ablation studies** to verify the solidarity of our approach.

In the first ablation study, *EG$_{Zh}$ -type*, we take away entity typing and train an untyped entailment graph. In this setting, we lose 2.4 AUC points. This means, our entity typing method, as discussed in §4, is indeed helpful for disambiguating predicates in entailment graphs.

In the second ablation study, the *DataConcat* settings, we disentangle cross-lingual complementarity from the effect of extra data. We machine-translate NewsSpike corpus into Chinese, and Webhose into English[15]. We build an English graph "DataConcat En" using *NewsSpike + translated-Webhose*, and a Chinese graph "DataConcat Zh" using *Webhose + translated-NewsSpike*. Results show that while both graphs improve with data from the other side, they are still far behind our **Ensemble** settings above. Further, we ensembled the two DataConcat graphs as "DataConcat Esb", the best dev set setting in this case is MAX ensemble with $\gamma = 0.2$. On test set, this ensemble delivers an AUC of 25.0 points, this is 7.2 points higher than DataConcat En, an even wider margin than the non-DataConcat graphs. The above comparison suggests, the success of cross-lingual ensemble **cannot** be reproduced by sticking all the data together for a monolingual graph.

In the third case study, *BackTrans Esb*, we disentangle cross-lingual complementarity from the effect of machine-translation. Machine translation can be noisy, but it might also map synonyms in the source language to the same words in the target language. To single out this effect, we translate the Chinese Levy-Holt dataset back into English, and perform an ensemble between predictions on the original and the back-translated Levy-Holt. As shown in the last block of Table 3, the gain in this case is only marginal, suggesting that cross-lingual complementarity is the reason for our success, while the synonym effect is not.

In conclusion, from the entailment detection experiment, we have learnt that: 1) our Chinese entailment graph is strong in the monolingual setting, with contributions from the ORE method and entity typing; 2) a cross-lingual complementarity is clearly shown between Chinese and English entailment graphs, where the effect of ensembles is most significant in the moderate precision range (see Figure 1). We expect that ensembling strong entailment graphs in more languages would lead to further improvements.

7.3 Case Study for Cross-lingual Ensembles

Complementary to the discussions above, we further analyse our ensemble with a case study, so as to understand the reasons behind the success of our ensembles against the monolingual graphs. We compare the predictions of our Ensemble_AVG to that of the English monolingual EG$_{En}$, both thresholded over 65% precision. We categorize the prediction differences into 4 classes: *True Positives*, *False Positives*, *True Negatives*, *False Negatives*. *Positives* are cases where the ensemble switched the prediction label from negative to positive, vice versa for *negatives*; *True* means that the switch is correct, *False*, that the switch is incorrect.

Since the prediction differences between Ensemble_AVG and EG$_{En}$ is driven by EG$_{Zh}$, in Table 4, we break down each class of differences according to the direct cause of EG$_{Zh}$ making a different prediction than EG$_{En}$[16]:

- **same sentence after translation**: The premise and hypothesis become identical in relation structure; this can only happen with *positives*;
- **translation error**: The premise or hypothesis becomes unparsable into relations due to translation error; this can only happen with *negatives*;
- **lexicalization**: The difference in predictions is attributed to the cross-lingual difference in the lexicalization of complex relations;
- **ORE error**: After translation, the true relations in premise and hypothesis have the same arguments, but are mistaken due to ORE error;
- **evidence of entailment**: The difference is attributed to the different evidence of entailment in the two graphs; this is most relevant to our EG$_{Zh}$.

As shown, the majority of our performance gain comes from the additional evidence of entailment in EG$_{Zh}$; contrary to intuition, translation played a positive role in the ensemble, though not a major contributor. We attribute this to the fact that MT systems tend to translate semantically similar sentences to the same target sentence, though this similarity is still symmetric, not directional. We have singled out this effect in the third ablation

---

[15] We initially attempted to use Google Translate for translating these larger corpora as well, but turned to Baidu Translate instead for its more generous free quota.

[16] examples of each class of cause are given in Appendix E.

Direct causes of EG$_{Zh}$'s different prediction	TP (+)	FP (-)	TN (+)	FN (-)	+/-
translation-related causes, among which:	+52	-28	+42	-47	+19
· *same sentence after translation*	*+52*	*-28*	*0*	*0*	*+24*
· *translation error*	*0*	*0*	*+42*	*-47*	*-5*
lexicalization	+29	-54	+16	-12	-21
ORE error	+8	-20	+8	-5	-9
evidence of entailment	**+109**	**-95**	**+86**	**-40**	**+60**
TOTAL	+198	-197	+152	-104	+49

Table 4: Breakdown of the different predictions between our ensembles and English monolingual graph. "TP", "FP", "TN", "FN" represent *True Positive*, *False Positive*, *True Negative* and *False Negative* respectively; in the column "+/-" is the overall impact of each factor.

study above, and have confirmed that this effect is marginal to our success.

In Table 4, for both the differences from evidence of entailment, and differences in TOTAL, the precision of *positives* is lower than that of *negatives*. Namely, $TP/(TP+FP)$ is lower than $TN/(TN+FN)$. This is no surprise, as *positives* and *negatives* have different baselines to start with: *Positives* attempt to correct the false negatives from EG$_{En}$, where 17% of all negatives are false; *Negatives* attempt to correct the false positives, where 35% of all positives are false (as dictated in the setting of our case study). In this context, it is expectable that our evidence of entailment gets $109/(109+95) = 53\%$ correct for *positives*, while a much better $86/(86+40) = 68\%$ correct for *negatives*. These results support the solidarity of our contributions.

8 Conclusion

We have presented a pipeline for building Chinese entailment graphs. Along the way, we proposed a novel high-recall open relation extraction method, and built a fine-grained entity-typing dataset via label mapping. As our main result, we have shown that: our Chinese entailment graph is comparable with English graphs, where unsupervised BERT baseline did poorly; an ensemble between Chinese and English entailment graphs substantially outperforms both monolingual graphs, and sets a new SOTA for unsupervised entailment detection. Directions for future work include multilingual entailment graph alignment and alternative approaches for predicate disambiguation.

A A Brief Summary of Jia et al. (2018)

In Table 5 are the 7 rules from Jia et al. (2018) which they call Dependency Structure Normal Forms. The first rule corresponds to nominal compounds which we elaborated in constructions **D** in §3.1; the second rule corresponds to direct S-V-O relations; the third rule attends to the semantic objects hidden in adjuncts, which are always pre-verbs in Chinese; the fourth rule subsumes complements of head verbs into the predicate; the fifth rule handles the coordination of subjects, the sixth handles coordination of object, and the seventh handles coordination of predicates. These rules are reflected in our ORE method as well, but for the sake of brevity, only the constructions which have never been covered by previous work are listed in §3.1.

德国 总理 默克尔 。 German Chancellor Merkel . (German, Chancellor, Merkel)
我 看到 你 。 I see you . (I, see, you)
他 在 家 玩 游戏 。 He at home play game . (He, play-game, home)
我 走 到 图书馆 。 I walk to library . (I, walk-to, library)
我 和 你 去 商店 。 I and you go-to shop . (I, go-to, shop) (you, go-to, shop)
我 吃 汉堡 和 薯条 。 I eat burger and chips . (I, eat, burger) (I, eat, chips)
罪犯 击中 、 杀死 了 他 。 Criminal shot, kill -ed him . (criminal, shot, him) (criminal, kill, him)

Table 5: Set of DSNFs from Jia et al. (2018) exemplified. In each box, at top is an example sentence, presented in Chinese and its English metaphrase (inflection ignored); below are the relations they extract.

B Detailed Statistics of the CFIGER dataset

To test our assumption that each ultra-fine-grained type can be unambiguously mapped to a single FIGER type, we inspect the number of FIGER type labels to which each ultra-fine-grained type is mapped through manual labelling. Among the 6273 ultra-fine-grained types in total, 5622 of them are mapped to exactly one FIGER type, another 510 are not mapped to any FIGER types; only 134 ultra-fine-grained types are mapped to 2 FIGER types, and 7 mapped to 3 FIGER types. No ultra-fine-grained types are mapped to more than 3 FIGER types. Therefore, it is safe to say that our no-ambiguity assumption roughly holds.

We further inspected the number of FIGER types each mention is attached with. It turns out that among the 1,913,197 mentions in total, 59,517 of them are mapped to no FIGER types, 1,675,089 of them are mapped to 1 FIGER type, 160,097 are mapped to 2 FIGER types, 16,309 are mapped to 3 FIGER types, 1,952 are mapped to 4 FIGER types, 200 are mapped to 5 FIGER types, and 33 are mapped to 6 FIGER types. No mentions are mapped to more than 6 FIGER types. Note that each mention can be mapped to more than one ultra-fine-grained types from the start, so these numbers are not in contradiction with the above numbers.

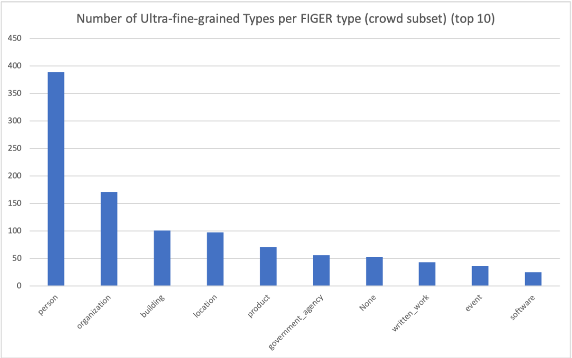

Figure 2: Number of ultra-fine-grained types in crowd-annotated subset mapped to each FIGER type; only the FIGER types with top 10 number of ultra-fine-grained types are displayed.

We also looked at the number of ultra-fine-grained types each FIGER type is mapped to, so as to understand the skewness of our mapping. Results are shown in Figure 2 and 3. Unsurprisingly, the most popular ultra-fine-grained labels are highly correlated with the ones that tend to appear in coarse-grained type sets, with "PERSON" label taking up a large portion. This distribution is largely consistent between crowd-annotated and Wikipedia subsets.

Another set of stats are the number of mentions that corresponds to each FIGER type, shown in Figure 4 and 5. The winners in terms of the number of mentions are consistent with that of the number of

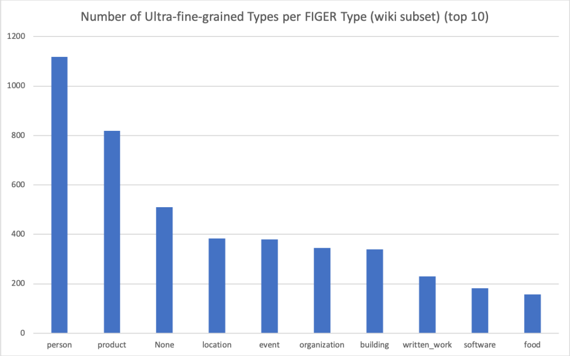

Figure 3: Number of ultra-fine-grained types in wikipedia distantly supervised subset mapped to each FIGER type; only the FIGER types with top 10 number of ultra-fine-grained types are displayed.

ultra-fine-grained types, and also consistent among themselves (between the two subsets).

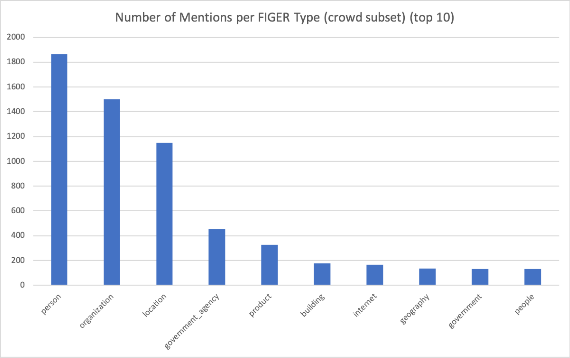

Figure 4: Number of mentions in crowd-annotated subset labelled as each FIGER type; only the FIGER types with top 10 number of mentions are displayed.

C Selecting Relation Triples for Translated Levy-Holt

To retrieve the relation triple most likely reflecting the meaning of the whole sentence, we follow this order when determining which relation triple to select:

- For the amended relations, if the predicate of any of them cover the word with HEAD token in DDParser dependency parse, we randomly choose one of these;
- If none is found, but the predicate of any non-amended relations cover the word with HEAD token in DDParser dependency parse, we randomly choose one of these;
- If none is found, but there are any other relations, we randomly choose one of these;

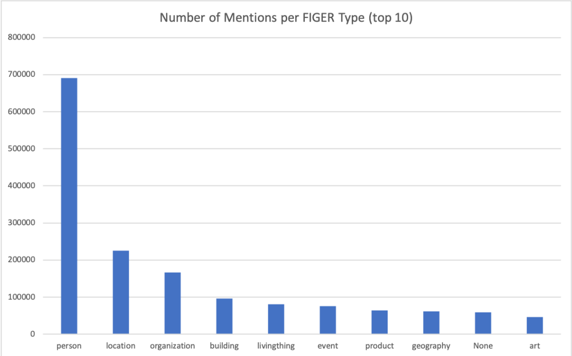

Figure 5: Number of mentions in wikipedia distantly supervised subset labelled as each FIGER type; only the FIGER types with top 10 number of mentions are displayed.

- Finally, if still none is found, we assign PREMISE_PLACEHOLDER to the premise and HYPOTHESIS_PLACEHOLDER to the hypothesis, so that no entailment relation would ever be detected between them.

D Implementation Details for Entailment Graph Construction

We have used the same entailment graph construction algorithm as Hosseini et al. (2018) to build our Chinese entailment graph from the pool of typed relation triples. When building our entailment graphs, we only feed in the relation triples whose predicate and arguments both appear at least 2 times[17]. Their approach of building entailment graphs comes in two steps, in the paragraphs below we will briefly summarize each step and discuss our implementation details.

The first step is local learning. In this step, instances of relation triples are grouped into clusters based on the arguments they take. Relations (predicates) that are seen with the same arguments of the same types are considered to have co-occurred. For each pair of predicates, based on the co-occurrence information, a few different entailment scores have been proposed, of which the BInc score (Szpektor and Dagan, 2008) was found to have the best empirical performance in (Hosseini et al., 2018). Following them, we also use the BInc score in the local learning step of our Chinese entailment graphs. Note that after the local learning step, the entailment scores between each pair of predicates are independently calculated, and there are no inter-

---

[17] We experimented with 2-2, 2-3, 3-2 and 3-3, among which this 2-2 setting is empirically favoured.

actions between entailment subgraphs of different type pairs, thus the name **local** learning.

The second step is global learning. In this step, global transitivity constraint is "softly" applied to the local graphs as an optimization problem: paraphrase predicates are encouraged to have the same pattern of entailment; different typed subgraphs are encouraged to have the same entailment score for the same (ignoring type) pair of predicates; finally, the global scores are encouraged to stay similar to the local scores as a measure of regularization. In *Jia* baseline, the local graphs are too weak for global learning to be helpful; in *DDPORE* baseline, the best dev set AUC (as reported in Table 3) is achieved after 2 epochs; in EG_{Zh}, the best dev set AUC is achieved after 3 epochs.

E Examples of Different Predictions in Case Study by Category of Direct Cause

In this section, we provide one example for each class of direct cause, as described in §7.3. Chinese sentences and relations in the examples are presented in the same format as §3.1.

Same sentence after translation

- Premise - English: (magnesium sulfate, relieves, headache)
- Hypothesis - English: (magnesium sulfate, alleviates, headaches)
- Premise - Chinese translation: "硫酸镁(magnesium) 缓解(relieves) 头痛(headache)"
- Hypothesis - Chinese translation: "硫酸镁(magnesium) 缓解(alleviates) 头痛(headache)"

The two sentences are translated to the same surface form in Chinese, as the predicates are in many cases synonyms. There are more true positives than false positives, because synonyms are simultaneously more likely true entailments and more likely translated to the same Chinese word.

Translation Error

- Premise - English: (Refuge, was attacked by, terrorists)
- Hypothesis - English: (Terrorists, take, refuge)
- Premise - Chinese translation: "避难所(refuge) 遭到(suffered) 恐怖分子(terrorists) 袭击(attack); Refuge suffered attack from terrorists."
- Hypothesis - Chinese translation: "恐怖分子(terrorists) 避难(take-shelter); Terrorists take shelter."

The hypothesis is supposed to mean "The terrorists took over the refuge". However, with translation, the hypothesis in Chinese is mistaken as an intransitive relation where take-refuge is considered a predicate.

Lexicalization

- Premise - English: (Granada, is located near, mountains)
- Hypothesis - English: (Granada, lies at the foot of, mountains)
- Premise - Chinese translation: "格拉纳达(Granada) 靠近(is-near) 山脉(mountains)"
- Hypothesis - Chinese translation: "格拉纳达(Granada) 位于(is-located-at) 山脚下(hillfoot)"

When the hypothesis is translated into Chinese, the lexicalization of the relation changed, the part of the predicate hosting the meaning of 'the foot of' is absorbed into the object. Therefore, while in English "is located near" does not entail "lies at the foot of", in Chinese "is-near" is considered to entail "is-located-at". In this way, an instance of *false positive* comes into being.

ORE Error

- Premise - English: (A crow, can eat, a fish)
- Hypothesis - English: (A crow, feeds on, fish)
- Premise - Chinese translation: "乌鸦(crow) 可以(can) 吃(eat) 鱼(fish)"
- Hypothesis - Chinese translation: "乌鸦(crow) 以(take) 鱼(fish) 为(as) 食(food)"
- Premise - extracted Chinese relation: (crow, eat, fish)
- Hypothesis - extracted Chinese relation: (crow, take·X·as·food, fish)

While the translations for this pair of relations is correct, in the subsequent Chinese open relation extraction, our ORE method failed to recognize "可以(can)" as an important part of the predicate. To avoid sparsity, most adjuncts of the head verb are discarded, and modals are part of them. While the original premise "can eat" does not entail "feeds on", the Chinese premise "eat" does in a way entail "feeds on", where another instance of *false positive* arises.

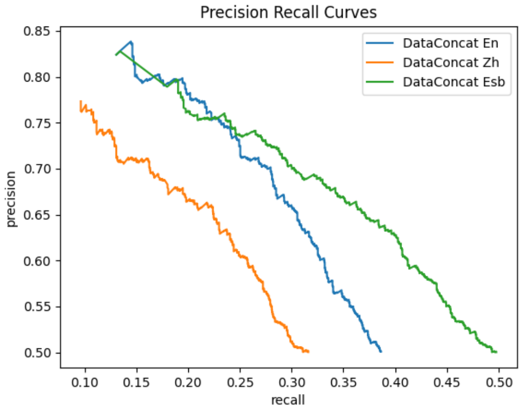

Figure 6: P-R Curves on Levy-Holt test set for DataConcat ablation study.

Evidence of Entailment

- Premise - English: (quinine, cures, malaria)
- Hypothesis - English: (quinine, is used for the treatment of, malaria)
- Premise - Chinese translation: “奎宁(quinine) 治疗(cure) 疟疾(malaria)”
- Hypothesis - Chinese translation: “奎宁(quinine) 用于(is-used-to) 治疗(cure) 疟疾(malaria)”
- Premise - extracted Chinese relation: (quinine, cure, malaria)
- Hypothesis - extracted Chinese relation: (quinine, is-used-to·cure, malaria)

In the above example, sufficiently strong evidence for “cure” entailing “is used for the treatment of” is not found in the English graph, whereas strong evidence for “治疗(cure)” entailing “用于·治疗(is-used-to·cure)” is found in the Chinese graph. In this way we get an instance of *true positive*.

F More Precision-Recall Curves

In this section, we present more precision-recall curves from the baselines and ablation studies in Table 3. These curves contain more details explaining the AUC values in the table.

Figure 6 contains the curves for the ablation study of DataConcat. Here all three models ultimately come from the same corpus, so the performance difference can be fully attributed to the cross-lingual complementarity of entailment graphs.

Figure 7 contains the curves for two sets of ablation studies: EG_{Zh} with or without entity typing; EG_{En} ensembled with back-translation predictions or not. The former study shows the clear benefit of our entity typing system, while the latter study shows that ensembling with back-translated predictions only results in a marginal gain, therefore the synonym effect from translation is not a major contributor to the success of our ensembling method.

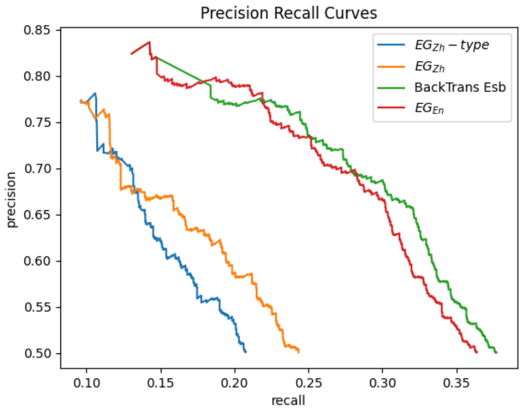

Figure 7: P-R Curves on Levy-Holt test set for EG_{Zh} $-type$, BackTrans Esb, in comparison to EG_{Zh} and EG_{En} respectively.

G Manual Examination of Chinese Levy-Holt

In order to provide a quantified evaluation for the quality of our Chinese Levy-Holt dataset from a human perspective, we manually labelled 100 proposition pairs in the Chinese Levy-Holt dev set (1-29, 1124-1136, 2031-2059, 3091-3122, 4061-4089, excluding the entries which are not parsed back into binary relation triples).

In this evaluation, we aim to answer the question of “how accurate is the translate-then-parse procedure when it claims to have successfully converted an evaluation entry”. We label each Chinese entry along two dimensions: semantic consistency, whether it has preserved the meaning of the English entry; label consistency, whether the entailment label remains correct.

Along the first dimension of semantic consistency, we summarize our findings as follows:

- Correct: 74/100. These are the Chinese entries whose Chinese **predicates** precisely reflects the meaning of the English entry[18];
- Metaphors: 3/100. These are the cases where the

---

[18] Arguments are allowed to be translated to different senses of the words, as long as the entailment label between the predicates is not affected.

English entry involves metaphorical word-senses of predicates, but such metaphorical senses of these words are infelicitous in Chinese context;

- Adjuncts: 9/100. These are the cases where a part of an English predicate is translated into an adjunct to the Chinese head-verb, and is not included in the Chinese predicate (as in the example for ORE Errors in Appendix E); examples of missed-out adjuncts are 'widely', 'should' and 'may';
- Lexical: 5/100. These are the cases where the word-segmentation of the Chinese sentence is incorrect (as Chinese sentences come with no spaces between words);
- Errors: 7/100. These are the cases where, although the Chinese ORE method outputs some binary relation triples for the translation, that relation triple is not the true relation for the sentence;
- Translation: 2/100. These are the cases where, although the translation can be parsed into some binary relation triples by our Chinese ORE method, the translation is incorrect, thus everything downstream is wrong.

Along the second dimension of label consistency, we find that: in 89 / 100 entries, the actual labels in Chinese are consistent with the English labels; in 10 / 100 entries, the actual labels in Chinese are inconsistent with the English labels; in the remaining 1 / 100 entry, the actual label in Chinese is consistent with the actual label in English, but the provided English label is corrupted.

In summary, for the portion where the conversion is successful, the entries in Chinese Levy-Holt preserves the meaning of the English entries reasonably well; more importantly, the labels of the Chinese Levy-Holt dataset remains robust.

H Diagram Illustrations of Our Syntactic Analysis

In this section, we present for interested readers a set of diagram illustrations of the set of constructions, as involved in our syntactic analysis in §3.1. For each construction, we draw a diagram to illustrate its dependency structure, an example to instantiate the dependency structure, and in the following lines, all the relations that we extract from this construction (one relation per line). Each relation comes in the form of triple-of-types (consistent with the diagram) and triple-of-words (as in the example), separated by semi-colons. The diagrams are presented in Table 7, Table 8 and Table 9.

I Ethics Considerations

Below we discuss the ethics considerations in our work.

The limitation to our work is two-fold. Firstly, our Chinese entailment graphs focus on the task of predicate entailment detection, and does not attempt to independently solve the more general problem of reasoning and inference: this more general task would also involve other resources including argument hypernymy detection, quantifier identification and co-reference resolution. These are out of the scope of this work. Secondly, while we have shown the effect of cross-lingual complementarity, adding in more languages to the ensemble is not directly straight-forward: this would require linguistic expertise and NLP infrastructure in the respective languages; including more languages, and eventually including arbitrary languages, is one of the directions for our future work.

The risk of our work mostly stems from our use of large-scale news corpora: if the media coverage itself is biased toward certain aspects of the world or certain groups of people, then these biases would be inherited by our entailment graphs. Our response to this is to include as many diverse news sources as possible to reduce such biases to the minimum: our source corpus for building Chinese entailment graphs includes 133 different news sources from a variety of countries and regions.

For the computational cost of building Chinese entailment graphs, the algorithm for open relation extraction takes roughly 140 CPU hours to process the entirety of Webhose corpus; the entity typing model takes roughly 180 GPU hours on NVidia 1080Ti GPUs to do inference on the entirety of Webhose corpus; the local learning process takes less than one hour, and, the global learning process, our major computational bottleneck, takes roughly 800 CPU hours to finish.

The major datasets of use, namely, Webhose corpus, CLUE dataset and the CFET dataset, are open corpora with no specified licenses, thus our academic use is allowed; no license was specified for the Levy-Holt dataset as well; our own CFIGER dataset as well as the constructed entailment graphs can be distributed under the MIT license.

Stats	Webhose	Levy-Holt
AVG sentence length (in # of Chinese characters)	24.9	10.1
AVG # of relations per sentence	15.6	2.72
Percentage of relations from our additional patterns in §3.1	48%	32%

Table 6: Some key statistics of Webhose corpus and Chinese Levy-Holt dataset.

J Comparison Between Webhose Corpus and Levy-Holt Dataset

In this section, we report some key statistics of the Webhose corpus in comparison to the Levy-Holt dataset, which highlight their difference in genre.

As shown in Table 6, the Webhose corpus has much longer sentences than the Chinese Levy-Holt dataset, and on average, a much larger number of open relations can be extracted from the sentences in Webhose corpus. More importantly, the relation patterns which we additionally identified in §3.1 are much better represented (constituting 48% of all relations) than in Chinese Levy-Holt (32%). Thus, it is clear that: 1) our ORE method in §3 was not tuned on the test data, namely Chinese Levy-Holt; 2) tuning on Chinese Levy-Holt would not help with building better ORE methods for news corpora. On the other hand, as a large-scale multi-source news corpus of 5 million sentences, Webhose corpus can be believed to accurately reflect the distribution of linguistic patterns in the entirety of the news genre.

Construction ID	Diagrams and Examples
A.1		Example: *“咽炎(pharyngitis) 成为(becomes) 发热(fever) 的(De) 原因(cause); Pharyngitis becomes the cause of fever”*
	Relation 1: (Subj, Pred, Direct_Object); (咽炎(pharyngitis), 成为(becomes), 原因(cause))
	Relation 2: (Subj, Pred·X·DE·Direct_Object, True_Object); (咽炎(pharyngitis), 成为·X·的·原因(becomes·X·DE·cause), 发烧(fever))
A.2		Example: *“苹果(Apple) 的(De) 创始人(founder) 是(is) 乔布斯(Jobs); The founder of Apple is Jobs”*
	Relation 1: (Direct_Subject, Pred, Object); (创始人(founder), 是(is), 乔布斯(Jobs))
	Relation 2: (True_Subject, Direct_Subject·Pred, Object); (苹果(Apple), 创始人·是(founder·is), 乔布斯(Jobs))
B.1		Example: *“我(I) 去(go-to) 诊所(clinic) 打(take) 疫苗(vaccine); I go to the clinic to take the vaccine”*
	Relation 1: (Subject, Pred_1, Object_1); (我(I), 去(go-to), 诊所(clinic))
	Relation 2: (Subject, Pred_2, Object_2); (我(I), 打(take), 疫苗(vaccine))

Table 7: The syntactic analysis in §3.1 illustrated with diagrams, examples and their extracted relations.

Construction ID	Diagrams and Examples
B.2		Example: *“我(I) 想(want) 试图(try) 开始(begin) 写(write) 一个(a) 剧本(play); I want to try to begin to write a play”*
	Relation 1: (Subject, Pred_1, Pred_2); (我(I), 想(want-to), 试图(try))
	Relation 2: (Subject, Pred_1·Pred_2, Pred_3); (我(I), 想·试图(want-to·try), 开始(begin))
	……
	Relation K: (Subject, Pred_1·...·Pred_K, Object); (我(I), 想·试图·开始·写(want-to·try·begin·write), 一个剧本(A play))
C		Example: *“他(he) 解决(solve) 了(-ed) 困扰(puzzle) 大家(everyone) 的(De) 问题(problem); He solved the problem that puzzled everyone”*
	Relation 1: (Subject, Pred_1, Object_1); (他(He), 解决(solved), 问题(problem))
	Relation 2: (Object_1, Pred_2, Object_2); (问题(Problem), 困扰(puzzled), 大家(everyone))
D	Analysis in construction D removes the infelicitous instances of the **Nominal Compound** construction; for the illustration of this construction, we refer readers to Jia et al. (2018) and do not repeat here.

Table 8: More syntactic analysis in §3.1 illustrated with diagrams, examples and their extracted relations.

Construction ID	Diagrams and Examples
E.1		Example: *“玉米(Corn) 是(is) 从(from) 美国(US) 引进(introduce) 的(De); Corn is introduced from US”*
	Relation 1: (Subject, Copula·Prep·X·True_Pred·DE, True_Object); (玉米(Corn), 是·从·X·引进·的(is·from·X·introduced·DE), 美国(US))
E.2		Example: *“设备(device) 是(is) 用(from) 木头(wood) 做(make) 的(De); The device is made of wood”*
	Relation 1: (Subject, Copula·Prep·X·True_Pred·DE, True_Object); (设备(device), 是·用·X·做·的(is·from·X·made), 木头(wood))
E.3		Example: *“设备(device) 是(is) 木头(wood) 做(make) 的(De); The device is made of wood”*
	Relation 1: (Subject, Copula·X·True_Pred·DE, True_Object); (设备(device), 是·X·做·的(is·X·made), 木头(wood))
E.4		Example: *“设备(device) 是(is) 木匠(carpenter) 做(make) 的(De); The device is made by a carpenter”*
	Relation 1: (Subject, Copula·X·True_Pred·DE, True_Object); (设备(device), 是·X·做·的(is·X·made·DE), 木匠(carpenter))

Abstract

Paraphrase generation using deep learning has been a research hotspot of natural language processing in the past few years. While previous studies tackle the problem from different aspects, the essence of paraphrase generation is to retain the key semantics of the source sentence and rewrite the rest of the content. Inspired by this observation, we propose a novel two-stage model, **PGKPR**, for **p**araphrase **g**eneration with **k**eyword and **p**art-of-speech **r**econstruction. The rationale is to capture simultaneously the possible keywords of a source sentence and the relations between them to facilitate the rewriting. In the first stage, we identify the possible keywords using a prediction attribution technique, where the words obtaining higher attribution scores are more likely to be the keywords. In the second stage, we train a transformer-based model via multi-task learning for paraphrase generation. The novel learning task is the reconstruction of the keywords and part-of-speech tags, respectively, from a perturbed sequence of the source sentence. The learned encodings are then decoded to generate the paraphrase. We conduct the experiments on two commonly-used datasets, and demonstrate the superior performance of PGKPR over comparative models on multiple evaluation metrics.

1 Introduction

The task of paraphrase generation is to rephrase a given sentence by preserving its key semantics. While the problem was solved using rule-based approaches (McKeown, 1979; Meteer and Shaked, 1988) and traditional machine learning techniques (Quirk et al., 2004; Wubben et al., 2010), recent attentions have been shifted to devising effective deep neural networks (Prakash et al., 2016; Gupta et al., 2018; Li et al., 2018), which generally adopt the encoder-decoder framework. More recently, controllable paraphrase generation has been extensively investigated and offers the mechanisms to guide the generation process by providing a reference such as a syntactic template (Iyyer et al., 2018; Goyal and Durrett, 2020; Huang and Chang, 2021), a sentential exemplar (Chen et al., 2019; Su et al., 2021) and so on.

SRC	what are good workouts to lose belly fat ?
POS	[WDT] [VBP] [TO] [.]
TGT	what is the best way to lose belly fat ?
POS	[WP] [VBZ] [DT] [TO] [.]
GNT	what are some good exercises to get rid of belly fat ?
POS	[WDT] [VBP] [DT] [TO] [.]

Table 1: A running example.

Although the problem has been studied from different aspects, the fundamental goal of paraphrase generation is to preserve the key semantics of a source sentence and rewrite the rest of the content. Taking the paraphrase pair in Table 1 as a running example, the key semantics are entailed by the words "good workouts", "lose belly fat" and "best way" in the source (SRC) and target (TGT) sentence, respectively. The rest of the content can be considered as auxiliary words that express the relations between the keywords. Inspired by the observation, we propose to enhance the representativeness of the encodings of a source sentence by learning simultaneously the possible keywords and the relations between them, before the encodings are fed into the decoder for text generation. To this end, we use a prediction attribution technique (Li et al., 2016a) to identify the possible keywords and use the part-of-speech (POS) tags to label the rest of the words, which represent the relations between the keywords. Table 1 shows the predicted keywords (in red) and the POS tags of the other words in the source sentence. Finally, the sentence

Findings of the Association for Computational Linguistics: ACL 2022, pages 1234 - 1243
May 22-27, 2022

generated (GNT) by our model successfully preserves both the semantics of the keywords using synonyms (in blue) and the relations between the keywords using the auxiliary words with similar POS tags.

Specifically, we propose a novel two-stage model, **PGKPR**, for **p**araphrase **g**eneration with **k**eyword and **p**art-of-speech **r**econstruction. In the first stage (Section 3), we fine-tune a BERT model to identify the keywords in a source sentence. The identification is based on a prediction attribution technique (Li et al., 2016a) that computes the gradient vector of each input word. We compute as the attribution score of each input word the L2-norm of the corresponding gradient vector, where the words with higher scores are more likely to be the keywords. In the second stage(Section 4), we adopt Transformer (Vaswani et al., 2017) and devise a multi-task learning model for paraphrase generation. Given a pair of paraphrase sentences, the learning tasks include 1) reconstructing the keywords and the POS tags of all words in the source sentence, 2) distinguishing the latent features of the pair from the features of non-paraphrase pairs, and 3) generating the paraphrase sentence. Finally, the objective function is the combination of the loss function in each learning task. In the experiments, we show that PGKPR outperforms the comparative models by a notable margin on both BLEU and ROUGE scores. The ablation study shows the effectiveness of each learning task, and the case study and user study show that PGKPR could produce paraphrases with higher quality.

A similar study was conducted by (Su et al., 2021), where they proposed a novel identification algorithm, PSI, to identify the primary and secondary content in a source sentence. Our work differs from theirs at least on the following three aspects. First, our strategy for keyword identification is purely data-driven, whereas the PSI algorithm uses a rule-based method and is sensitive to the similarity measurement used in the algorithm. Second, the PGKPR model is trained with multiple learning tasks, whereas the IANet model proposed in (Su et al., 2021) only has the learning task of predicting the target sentence. Third, PGKPR determines the keywords in a source sentence with the probability transformed from the attribution scores, which gives the model a more flexible way to separate the keywords and the other content, whereas the IANet model deterministically separates the primary and secondary content using a manually-tuned threshold based on the PSI scores.

2 Related Work

2.1 Paraphrase Generation

Recent studies have extensively applied various deep learning techniques for paraphrase generation. Representative studies have devised stacked residual LSTM networks (Prakash et al., 2016), copy mechanisms (Cao et al., 2017), reinforcement learning algorithms (Li et al., 2018), and unsupervised training methods (Roy and Grangier, 2019), etc. While performing much better than rule-based methods, these models do not offer user-defined mechanisms to control the paraphrase generation process. As such, (Iyyer et al., 2018) propose to generate paraphrases conditioned on a user-provided syntax template. (Chen et al., 2019) propose to extract the syntax exemplar from a given sentence instead of using a syntax template. (Goyal and Durrett, 2020) propose to perturb the preorder of the syntax structure of a source sentence for paraphrase generation. Two studies are related to our work. (Su et al., 2021) propose a Primary/Secondary Identification algorithm to separate the primary and secondary content of a source sentence. (Fu et al., 2019) propose to sample a latent bag of words from the encoder, which is an implicit way of extracting the keywords of a source sentence.

2.2 Prediction Attribution Techniques

Given a trained model, a prediction attribution technique calculates the attribution (i.e., contribution) of each input unit to a model prediction, which explains the faithfulness or reasoning process of the model (Bastings and Filippova, 2020). Representative techniques include gradient-based methods (Baehrens et al., 2010; Li et al., 2016a; Sundararajan et al., 2017), propagation-based methods (Bach et al., 2015; Arras et al., 2017; Binder et al., 2016) and occlusion-based methods (Zeiler and Fergus, 2014; Li et al., 2016b). The method used in the current work is the first-derivative saliency (i.e., the gradient) (Li et al., 2016a), which belongs to the first category. Take NLP models for example, an input unit in NLP tasks is usually the embedding of a word. Given a model's output, the method computes the gradient vector of the output with respect to the input embedding, and takes the L2-norm of the gradient vector as the contribution of the input to the output.

3 Stage One: Keyword Prediction

In the first stage, we train a BERT model to predict the keywords in a source sentence. The prediction is based on an attribution technique that computes the gradients of the input elements (Li et al., 2016a). In particular, given a binary classification model f and an input sequence $\mathcal{X} = \{x_1, x_2, \ldots, x_l\}$, where l is the number of input elements (i.e., the sequence length), the gradient vector g_i of x_i ($1 \leq i \leq l$) is computed as,

$$g_i = \nabla_{x_i} f(\mathcal{X}), \tag{1}$$

which represents how much the element x_i is responsible for the prediction $f(\mathcal{X})$. In practice, one can compute the L2-norm of g_i and normalize over all the L2-norms of the input sequence to obtain a score $p_i \in [0, 1]$, which represents the contribution (attribution) of x_i to a positive prediction for $\mathcal{X}$.

Based on the technique, we devise the following training task for keyword prediction. Denote by N the number of paraphrase pairs in the training set, and (s_i, t_i) the source sentence and the target sentence of the i^{th} pair, respectively, $1 \leq i \leq N$. We first construct N positive data points (i.e., each data point corresponds to a paraphrase pair) where the i^{th} data point consists of s_i, the special token `[SEP]` and t_i, sequentially, i.e., $(s_i,$ `[SEP]`$, t_i)$. Because during inference the target sentence is unknown, we construct another N positive data points $(s_i,$ `[SEP]`$, s_i)$ for training. Then for each s_i, we randomly select two different target sentences t_{i_1} and t_{i_2}, such that $i_1 \neq i$ and $i_2 \neq i$, and form two negative data points $(s_i,$ `[SEP]`$, t_{i_1})$ and $(s_i,$ `[SEP]`$, t_{i_2})$. As such there are in total $2N$ positive and $2N$ negative data points. Then we fine-tune a BERT model using the $4N$ data points to predict whether each data point is a paraphrase pair. After fine-tuning, given a new data point consisting of a source sentence and its paraphrase (the source sentence itself during inference), we first compute the output in the forward pass, and then compute the attribution scores of all the input words in the backward pass. Since the attribution score reflect how much each word contributes to the paraphrase prediction, the words with higher scores are more likely to be the keywords that capture the common semantics of the two sentences. For keyword prediction, we just use the attribution scores of the words in the source sentence. Figure 1 shows the inference process for predicting the keywords of the source sentence in the running example. We observe the five words "good", "workouts", "lose", "belly" and "fat" are more likely to be the keywords.

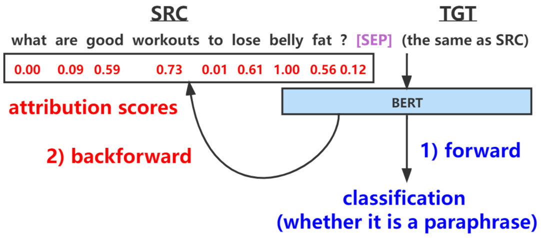

Figure 1: Stage One of PGKPR.

4 Stage Two: Multi-task Learning for Paraphrase Generation

Figure 2 shows the overview of the second stage. The model is trained simultaneously with three tasks: reconstruction of keywords and POS tags, contrastive learning for distinguishing paraphrase pairs from others, and paraphrase generation.

4.1 Task 1: Reconstruction of Keywords and POS Tags

Given a source sentence s_i, the task is learning to reconstruct the keywords of s_i and the POS tags of all the words, so that both the key semantics of s_i and the relations between the keywords are captured in the latent feature. After obtaining the attribution scores of s_i in the first stage, we consider each score as the probability that the corresponding word is a keyword. Then we flip a coin for each word with the probability and identify the final keywords of s_i. In this way, we flexibly set the keywords in each sentence and avoid overfitting the training set to some extent. On the left part of Figure 2, we observe that the five words in red are computed as the keywords based on the probabilities. Then we form an input token sequence TS_{s_i} as a two-part representation based on the perturbation to s_i, which contains the POS-tag information of s_i while also distinguishing the keywords from the non-keywords, as follows. The first part of TS_{s_i} is a perturbation of s_i, where the keywords are preserved in the sequence and the non-keywords are replaced by their corresponding POS tags. The second part is another perturbation of s_i in the other way round, where the non-keywords are preserved and the keywords are replaced by their corresponding POS tags. There is a special token `[SEP]` connecting the two parts. The idea is to use the first part to emphasize the keywords and their relations

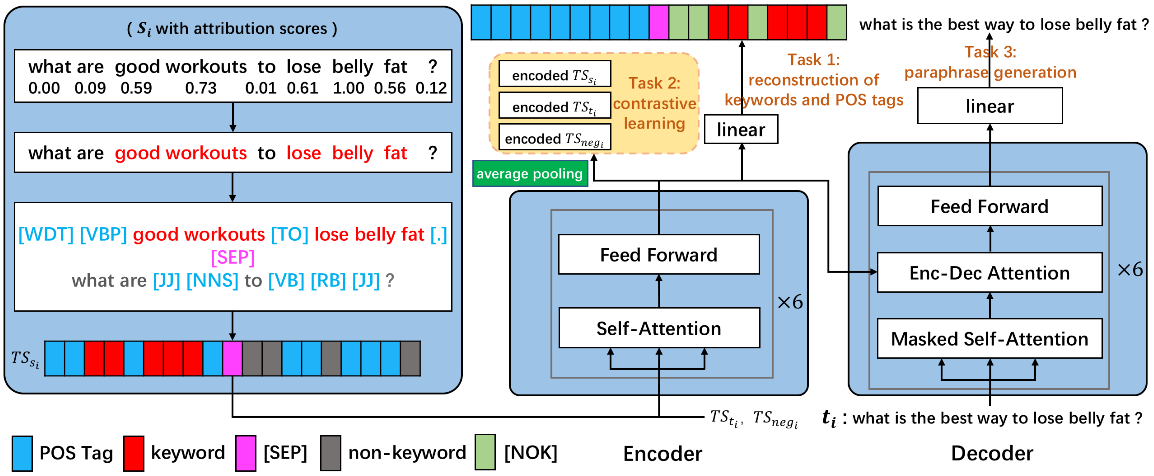

Figure 2: Stage Two of PGKPR: the Transformer-based model with three learning tasks for paraphrase generation.

(via POS tags), and use the second part to emphasize the POS information of the keywords and the content information of non-keywords. The process to form TS_{s_i} for the running example is depicted in the left part of Figure 2.

Then we feed TS_{s_i} into the Transformer's encoder. Essentially, we want to produce the encodings that preserve the POS and semantic feature of keywords, and only preserve the POS feature of non-keywords[1] of s_i. We devise the following task to achieve the goal, which attempts to reconstruct the keywords and POS tags of s_i. For each encoding in the first part of TS_{s_i}, we train it to predict the POS tag of the corresponding word in s_i. As such the output encodings could learn the syntactic feature of s_i and particularly the relations between the keywords. The encoding of the special token `[SEP]` learns to reconstruct itself, so that it still separates the output encodings into two groups with different emphasis. For each encoding in the second part of TS_{s_i}, if it corresponds to the POS tag of a keyword, we use it to reconstruct the keyword so that the encoding learns the semantic of the keyword; otherwise, it corresponds to a non-keyword and we use it to predict a special token `[NOK]` (representing "non-keyword"), which forces the encoding to downplay the semantic feature of the non-keyword and learn more the position feature. The task is depicted in the middle part of Figure 2. Denote by y_j^i the target token of the j^{th} token of TS_{s_i} and by $p(y_j^i)$ the predicted probability, the reconstruction loss function $\mathcal{L}_{rec}^i$ for s_i is computed using cross-entropy:

$$\mathcal{L}_{rec}^i = -\frac{1}{2l_s+1}\sum_{j=1}^{2l_s+1} p(y_j^i)\log(p(y_j^i)), \quad (2)$$

where l_s and $2l_s+1$ are the length of s_i and TS_{s_i}.

4.2 Task 2: Contrastive Learning for Distinguishing Paraphrase Pairs from Others

Inspired by (Yang et al., 2021; Pan et al., 2021), we devise a contrastive learning task to distinguish the syntactic and semantic features of paraphrase pairs from non-paraphrase pairs, so that the learned encodings of a source sentence are more discriminative. The general principle of contrastive learning (Chen et al., 2020) is to minimize the distances between the data point and the positive counterparts while maximizing the distances between the data point with the negative counterparts, in the latent space.

In our task, for each s_i, we use the corresponding target sentence t_i as the positive counterpart and use all other sentences in the same batch as the negative counterparts. We denote the negative counterparts by $\{neg_i \in B | neg_i \notin \{s_i, t_i\}\}$, where B is a minibatch containing (s_i, t_i). For each counterpart, we form an input token sequence by concatenating the original sentence, `[SEP]` and the POS tag sequence of the sentence. By doing this, we can not only make the input length of the counterparts conform with TS_{s_i}, but also keep both the syntactic and semantic information of the counterpart sentences. As such, the encoding of s_i could learn more discriminative features pertaining to the keywords and their relations. The token sequences

---

[1] The semantic feature of non-keywords is captured in the generation task.

of t_i and neg_i are denoted by TS_{t_i} and TS_{neg_i}, respectively, as depicted in the middle part of Figure 2. We apply average pooling over the token encodings and obtain the encoded TS_{s_i}, TS_{t_i} and TS_{neg_i}. Note that we don't perform perturbation to the counterpart sentences because the average pooling layer would eliminate the effect of perturbation. Denote by e_{s_i}, e_{t_i} and e_{neg_i} the corresponding encodings, the contrastive loss function $\mathcal{L}^i_{con}$ for s_i is computed as follows,

$$\mathcal{L}^i_{con} = -\log \frac{exp(\frac{e_{s_i} \cdot e_{t_i}}{\tau})}{exp(\frac{e_{s_i} \cdot e_{t_i}}{\tau}) + \sum\limits_{neg_i \in B}^{neg_i \notin \{s_i, t_i\}} exp(\frac{e_{s_i} \cdot e_{neg_i}}{\tau})}, \tag{3}$$

where $\cdot$ denotes the dot product and τ is the temperature parameter.

4.3 Task 3: Paraphrase Generation

The last learning task is to generate the paraphrase sentence on the decoder side, which is depicted on the right part of Figure 2. All the token encodings output by the encoder participate into the computation of the encoder-decoder attention layer, so that the decoder can retrieve the information pertaining to both the key semantics of the source sentence via the encodings of the keywords and the relations between the keywords via the encodings of the POS tags. Denote by t^i_j the j^{th} word in the target sentence t_i, the generation loss function $\mathcal{L}^i_{gen}$ for s_i is computed using the sum of negative log-likelihood as follows,

$$\mathcal{L}^i_{gen} = -\sum_{j=1}^{l_t} \log p(t^i_j \mid s_i, \{t^i_0, t^i_1, \ldots, t^i_{j-1}\}), \tag{4}$$

where l_t is the length of the target sentence.

4.4 The Objective Function

The final objective function of PGKPR is the linear combination of the loss functions in the three learning tasks, which is computed as follows,

$$\mathcal{L}^i = \lambda_1 \mathcal{L}^i_{rec} + \lambda_2 \mathcal{L}^i_{con} + \mathcal{L}^i_{gen}, \tag{5}$$

where λ_1 and λ_2 are the two hyperparameters.

5 Performance Evaluation

We implement all the models using Pytorch 1.4 and run all experiments on a Centos machine installed with Tesla V100.

5.1 The DataSets and Evaluation Metrics

We conduct the experiments on two benchmark datasets for paraphrase generation, which are Quora[2] and MSCOCO (Lin et al., 2014). The Quora dataset contains duplicated questions raised by real users, in which each data point consists of a source question and a target question with the similar meaning. The MSCOCO dataset contains images and the corresponding captions annotated by humans. Since each image has five captions, we randomly choose one of them as the source sentence and use the other four as the targets. As such each image brings four pairs of paraphrases.

Following (Gupta et al., 2018; Fu et al., 2019), we split the pre-processed datasets into the training and testing set. For the Quora dataset, there are 100K training paraphrase pairs and 20K testing pairs. The sentences are truncated or zero-padded to the same length 17 to facilitate batch training. For the MSCOCO dataset, there are 93K training pairs and 20K testing pairs. The sentence length is set to 16.

For the main results, we use the commonly-adopted metrics BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) to evaluate the models, as they are proved to correlate with human judgement well (Li et al., 2018; Fu et al., 2019). We report the metrics of 1-4 grams in BLEU, 1-2 grams in ROUGE and ROUGE-L.

5.2 The Comparative Models

Although paragraph generation draws lots of attention, few studies have tried to explicitly preserve the keywords as well as their relations in the source sentence. Among the existing studies, we identified two models that are closely related to ours.

The first model is IANet (Su et al., 2021), which proposes the Primary/Secondary Identification (PSI) algorithm to separate the primary and secondary content of a source sentence. We implemented the two variants mentioned in the paper[3], IANet+X and IANet+S, which use the rule-based method and the pre-training method to identify the primary content. Both variants rely on a manually-determined threshold to separate the primary and secondary content.

The second model is LBOW (Fu et al., 2019), which samples a latent bag of words from the en-

coder to assist the paraphrase generation. The words in the latent bag could be considered to have similar semantics with the keywords in the source sentence, and therefore the model is related to ours. We obtained the code released by the authors[4] and evaluate the two variants LBOW-Topk and LBOW-Gumbel. The former directly chooses the most k probable words from the encoder, and the latter samples randomly from the BOW distribution with gumbel reparameterization.

We include another two models as baselines. The first model is Residual-LSTM (Prakash et al., 2016), which is the very first study that applies deep learning to paraphrase generation. The second model is the original Transformer (Vaswani et al., 2017). We train it directly with the paraphrase pairs in the simple sequence-to-sequence manner.

5.3 The Hyperparameters

Both the encoder and decoder of PGKPR have 6 layers and each layer uses 8 attention heads. The embedding size is set to 512. When training, we set dropout rate to 0.1, learning rate to 0.0001, and use Adam for optimization. The batch size is set to 128. After tuning, we set λ_1 and λ_2 in the objective function to 1 and 0.1 for the Quora dataset, and set to 1 and 1 for the MSCOCO dataset, respectively.

5.4 Main Results

The main results are reported in Table 2. We observe that our PGKPR model outperforms all the comparative models by a notable margin on both datasets.

To further justify the effectiveness of PGKPR, we implemented two additional variants of the model. The first variant is PGKPR-ref, which uses the true paraphrase pairs to identify the keywords in the first stage during inference. Remember that in PGKPR we concatenate a source sentence with itself during inference, since the target sentence is unknown. However, the upper bound of the performance should be achieved when the target sentence is disclosed, i.e., using the true pair of a source sentence and a target sentence to predict the keywords. In Table 2 we observe that PGKPR-ref does not always outperform PGKPR and the overall performance of PGKPR is very close to PGKPR-ref. The reason is that we add the pairs of two source sentences in the training set (see the second paragraph of Section 3), so that PGKPR generalizes well at inference time when the target sentence is unknown.

The second variant is PGKPR-PSI, which uses the PSI algorithm in IANet to identify the keywords. Following (Su et al., 2021), we imple-

mented PGKPR-PSI+X and PGKPR-PSI+S, which are the counterparts of IANet+X and IANet+S. In Table 2 we observe two points. First, the PGKPR-PSI variants perform worse than the original PGKPR. Since the only difference between them is the mechanism for keyword identification, we may conclude that our model-based identification strategy is more suitable for extracting keywords from a source sentence. Second, the PGKPR-PSI variants perform better than the IANet counterparts on almost all metrics. Since both models use PSI to identify the keywords, the results show the effectiveness of multi-task learning in the PGKPR model.

5.5 Ablation Study

We conduct an ablation study to show the effect of the reconstruction loss and the contrastive loss in the multi-task learning. In particular, we remove from the original PGKPR model only the contrastive loss, only the reconstruction loss and both losses, respectively, which results in three ablation models PGKPR w/o $\mathcal{L}_{con}$, PGKPR w/o $\mathcal{L}_{rec}$ and PGKPR w/o $\mathcal{L}_{con}$ and $\mathcal{L}_{rec}$. The results are reported in Table 3. We observe a significant performance drop after removing the losses. Specifically, removing the reconstruction loss results in a larger performance drop than removing the contrastive loss. This justifies the motivation of the current study, i.e., capturing the key semantics and the relations between the keywords in the source sentence should benefit paraphrase generation.

5.6 Comparing with the PSI Algorithm

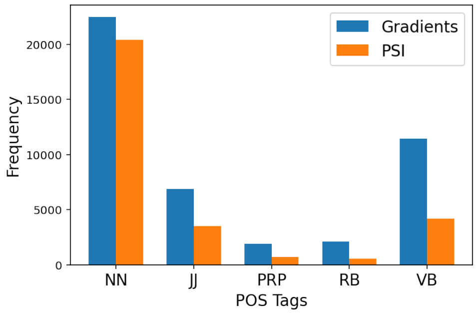

Figure 3: The frequency distribution of the POS tags on Quora.

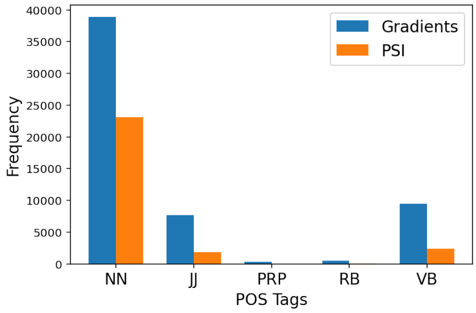

Figure 4: The frequency distribution of the POS tags on MSCOCO.

Only our PGKPR model and the IANet model (Su et al., 2021) explicitly identify the keywords from a source sentence. While IANet uses a rule-based algorithm PSI to identify the keywords, PGKPR adopts the purely data-driven approach based on a prediction attribution technique that computes the gradients. It is thus interesting to compare the keywords identified by the two methods.

To this end, we first extract the keywords from the dataset using the two methods, respectively, and then plot the frequency distribution of the POS tags pertaining to the keywords. For PSI, we set the threshold of the PSI score to separate the primary and secondary content when the IANet-S model achieves the best performance on the testing set. For PGKPR, the keywords are selected with the probabilities calculated from the L2-norms of their gradients (see the first paragraph of Section 4.1).

	Quora	MSCOCO
Source	what are good workouts to lose belly fat ?	a woman with a toothbrush in her mouth
Target	what is the best way to lose belly fat ?	a person standing with a toothbrush in their mouth
Residual-LSTM	what are the best ways to lose belly fat ?	a woman with a toothbrush in her mouth
Transformer	what are some good ways to get rid of belly fat ?	a bunch of food on a table outside
LBOW-Topk	how can i reduce my belly fat ?	a woman is holding a toothbrush in her mouth
IANet+S	what are some workouts to lose weight ?	a woman with a toothbrush in her mouth
PGKPR	what are some good exercises to get rid of belly fat ?	a woman brushing her teeth with a tooth brush

Table 4: Case Study.

The results are shown in Figure 3 and 4, which are the plots on Quora and MSCOCO, respectively. On the X-axis, we use five POS tags, namely, NN, JJ, PRP, RB and VB, which correspond to nouns, adjectives or numerals, pronouns, adverbs and verbs, respectively. It is of the common sense that the words of these POS tags preserve the key semantics of a sentence, and thus we refer to them as the key POS tags. The Y-axis shows the number of each POS tag extracted by the two methods. We observe that on both datasets our gradient-based method extracts more key POS tags than the PSI algorithm does. The results may explain why the original PGKPR model performs better than the PGKPR-PSI variants in Table 2.

5.7 Case Study

In Table 4, we show the generated paraphrases of the five models for two source sentences in the Quora and MSCOCO dataset, respectively. On the left part, we see PGKPR captures the keywords "good workouts" and "lose belly fat", and uses the synonyms "exercises" and "get rid of" in the paraphrase. Other models are generally good, but the paraphrases are not as accuracy and diverse as ours. The sentence produced by IANet+S fails to capture the keyword "belly". On the right part, PGKPR not only captures the key semantics of the source sentence, but also changes the syntax structure. All other models either fail to capture the key semantics or produce a paraphrase syntactically similar to the source sentence. The sentence produced by IANet+S simply repeats the source sentence.

5.8 User Study

We conduct a user study on the quality of the paraphrases generated by the compared models. For LBOW and IANet, we choose the variants with overall better performance in Table 2, namely, LBOW-Topk and IANet+S. As such there are five models for this study. The evaluated metrics are *Fluency*, *Accuracy*, and *Diversity*. Fluency measures whether a sentence is grammatically correct. Accuracy measures whether the semantics of a generated sentence comply with that of the corresponding source sentence. Diversity measures whether a generated sentence differs from the corresponding source sentence in terms of syntax structure.

Models	**Fluency**	**Accuracy**	**Diversity**
Residual-LSTM	1.49	1.14	0.8
Transformer	1.7	1.33	1.11
LBOW-Topk	1.55	1.21	0.85
IANet+S	1.68	1.37	0.97
PGKPR	**1.79**	**1.5**	**1.29**
Target	1.85	1.59	1.47

Table 5: The results of human evaluation. Statistical significance between PGKPR and others is computed with a 2-tailed Student's t-test; $p\text{-}value < 0.05$.

We invite ten Master's students to rate the generated paraphrases. We randomly choose 100 source sentences from the testing sets (50 for Quora and 50 for MSCOCO) and generate the paraphrases for each sentence using the five models. We replicate three times each source sentence and its five paraphrases and obtain 1,500 pairs of paraphrases. We randomly assign the paraphrases to the 10 students, so that each student is assigned with 150 different pairs. We ask the students to rate each generated paraphrase on the three metrics on a scale between 0 to 2, where a higher score means better quality. Then we compute the average scores for each model and the statistical significance between PGKPR and other models. The results are reported in Table 5, where "Target" means the target sentence. We observe that PGKPR performs the best on the three metrics among the models and the difference between PGKPR and each model is statistically significant ($p\text{-}value < 0.05$), verified using a 2-tailed Student's t-test. The results justify the effect of learning simultaneously the keywords and the relations between them and the design of the multiple learning tasks in PGKPR.

6 Conclusion

We propose a new model with multi-task learning for paraphrase generation. The motivation is to simultaneously capture the key semantics of a source sentence and the relations between the keywords. The proposed model, PGKPR, has two stages. In the first stage, PGKPR leverages a data-driven technique to identify the possible keywords in the source sentence. In the second stage, PGKPR adopts the Transformer model and devises three learning tasks, including 1) reconstructing the keywords and the POS tags of all words in the source sentence, 2) contrastive learning for distinguishing the latent features of the paraphrase pair from others, and 3) generating the paraphrase sentence. We conduct extensive experiments to show the superior performance of PGKPR over comparative models, as well as the effect of the keyword identification strategy and the multiple learning tasks. Our future research would focus on how to apply the model in the current study to controllable paraphrase generation and produce more diverse sentences.

Abstract

Chinese Spelling Correction (CSC) is a task to detect and correct misspelled characters in Chinese texts. CSC is challenging since many Chinese characters are visually or phonologically similar but with quite different semantic meanings. Many recent works use BERT-based language models to directly correct each character of the input sentence. However, these methods can be sub-optimal since they correct every character of the sentence only by the context which is easily misled by the misspelled characters. Some other works propose to use an error detector to guide the correction by masking the detected errors. Nevertheless, these methods dampen the visual or phonological features from the misspelled characters which could be critical for correction. In this work, we propose a novel general detector-corrector multi-task framework where the corrector uses BERT to capture the visual and phonological features from each character in the raw sentence and uses a late fusion strategy to fuse the hidden states of the corrector with that of the detector to minimize the misleading impact from the misspelled characters. Comprehensive experiments on benchmarks demonstrate that our proposed method can significantly outperform the state-of-the-art methods in the CSC task.

Table 1: Examples of CSC results, the incorrect and correct characters marked in red and blue respectively.

1 Introduction

Chinese Spelling Correction (CSC) is a fundamental task that aims to automatically detect and correct spelling errors in Chinese texts. These spelling errors are typically caused by human writing, automatic speech recognition (ASR) or optical character recognition (OCR) systems (Afli et al., 2016; Wang et al., 2018). CSC is essential since it is crucial for many downstream tasks like search engine (Martins and Silva, 2004; Gao et al., 2010) and essay scoring (Burstein and Chodorow, 1999).

Despite its recent development, CSC remains a challenging task since many Chinese characters are visually or phonologically similar, but with great different semantic meanings. According to (Liu et al., 2010), around 83% and 48% of errors belong to phonological and visual similarity respectively. Moreover, the Chinese language usually consists of many characters without word deliminators, which makes the CSC system must recognize spelling errors based on contextual information, rather than just relying on individual words or characters.

Many efforts have been put in the CSC task. Early methods are mainly based on the traditional language models (Liu et al., 2010, 2013; Yu and Li, 2014) or sequence-to-sequence models (Wang et al., 2019). Recently, with the emerge of pre-trained BERT model (Devlin et al., 2019), many methods have been proposed and made great progress in CSC. Most of these works like (Cheng et al., 2020; Guo et al., 2021; Wang et al., 2021) use BERT-based language models and confusion set to directly correct each character of the input sentence. However, these methods indistinguishably correct every character of the sentence via the contextual information which is easily misled by the misspelled characters. As shown in the upper case in Table 1, the context is affected by the error

Findings of the Association for Computational Linguistics: ACL 2022, pages 1244 - 1253
May 22-27, 2022

character “以” which makes the correction model mistakenly change the original correct character “关” to “所”. To address the above issues, some other works like (Hong et al., 2019; Zhang et al., 2020; Li et al., 2021) propose to use an error detector to detect the positions of errors which are used as prior knowledge for correction via masking. Nevertheless, these methods in turn would dampen the visual or phonological features from the misspelled characters which could be critical for correction. As illustrated in the lower case in Table 1, despite the model correctly finding the error position, it failed to change the error to correct character “变” since it misses the phonological feature from the misspelled character “遍”. Thus, how to exploit the visual and phonological features of the misspelled characters while expelling their misleading impact on the context still remains to be an open question in the CSC task.

To address the above issues, we propose a novel general multi-task detector-corrector CSC framework (MDCSpell) which can both employ the visual and phonological features of the misspelled characters while eliminating their misleading impact on the context. Specifically, the correction and detection tasks are executed simultaneously where the corrector uses BERT to capture the visual and phonological features of all characters directly from the raw sentence and the detector uses a light-weight transformer to detect the positions of misspelled characters. A late-fusion strategy is employed to fuse the hidden states of the corrector with that of the detector and enable the elimination of the misleading impact from the misspelled characters with an end-to-end joint training. This framework is simple to implement and any BERT-based CSC model can be easily adapted in this framework. Experimental results on three open benchmarks demonstrate that MDCSpell can significantly outperform the competitors.

In summary, our contributions are concluded as follows:

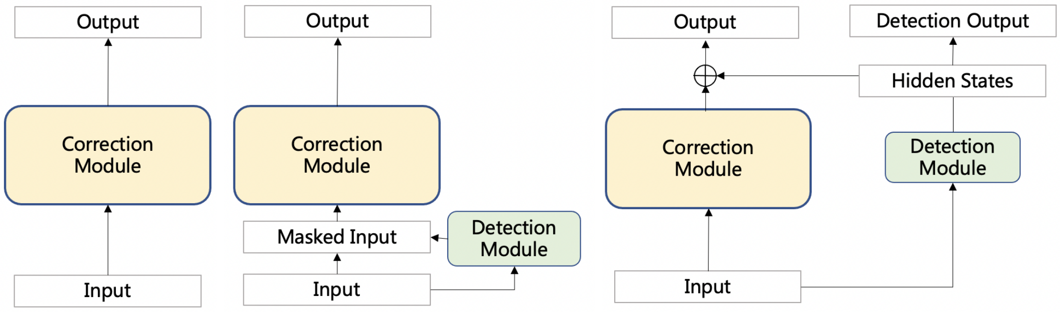
- We propose a novel general multi-task detector-corrector CSC framework MDCSpell which can both make use of the visual and phonological features of the misspelled characters which are critical for correction while minimizing their misleading impact on the context. The proposed framework is simple to implement and any BERT-based CSC models can be easily adapted in this framework.
- We investigate the performance of MDCSpell both quantitatively and qualitatively. The experimental results show the superiority of our method on three open benchmarks.

2 Related Work

Chinese spelling correction (CSC) is an important and challenging task. It mainly needs to detect the wrong characters based on the judgment of the semantics and correct these wrong characters with a full understanding of the context. Most of the early work used unsupervised language models and rules for detection and correction, and used the perplexity of language model for determination (Yeh et al., 2013; Yu and Li, 2014; Xie et al., 2015; Tseng et al., 2015). Recently a lot of works tend to transform CSC into a sequence tagging task, modeling each character in the sentence to determine the position of error and correct it into the right character(Wang et al., 2019; Ji et al., 2017; Chollampatt et al., 2016; Ge et al., 2018).

With the development of large-scale pretraining in NLP, an increasing number of works follow the way of solving sequence labeling problems, i.e., using the BERT-like model to directly map every character in the sentence to the correct ones. (Cheng et al., 2020) proposed a model named SpellGCN which incorporates phonological and visual similarity knowledge into BERT via a specialized graph convolutional network. (Huang et al., 2021) utilized phonological and morphological knowledge to model the similarities of the characters for correction. (Guo et al., 2021) proposed a global attention decoder that learns the global relationship of the potential correct input characters and the candidates of potential error characters. (Wang et al., 2021) proposed a dynamic connected network to model the dependencies between two adjacent Chinese characters to improve the corrector.

Some other works use an error detector as the preliminary for correction which turns the CSC into a two-stage pipeline. (Hong et al., 2019) proposed the FASpell model to predict candidate characters based on the BERT model and exploit the phonological and visual similarity information to select candidate characters. (Zhang et al., 2020) use a two-stage detection and correction method named Soft-Masked BERT, which masked the detected error characters with error probability and then turn the masked input into the BERT model for error correction. (Li et al., 2021) proposed a two-stage



(a) Direct correction (b) Correction with detected masks (c) The proposed scheme

Figure 1: A comparison between three schemes of CSC models. (a) Direct correction scheme directly correct each character of the input sentence without any error positions information. This scheme is vulnerable to the misleading impact on the context from the misspelled characters since the correction mainly relies on the context. (b) This scheme masks the input with detected error positions and predict the correct characters in the masked positions. This scheme can minimize the misleading impact from the misspelled characters, but dampen the useful visual and phonological features from them. (c) Our proposed scheme directly use the raw sentence as the input to the correction module to keep the visual and phonological features of the misspelled characters, and enabling the minimization of the misleading impact from them via the late fusion of hidden states from correction module and detection module.

cloze-style detector-corrector framework for correction.

Although the above methods have achieved good results on CSC tasks, they either suffer from the misleading effect on the context of the misspelled characters or miss the critical visual and phonological features of the spelling errors. In order to solve the above problems, we propose a multi-task learning architecture via late fusion to effectively use detection information for correction decision-making and improve the precision of the model.

3 Methodology

3.1 Problem Formulation

The Chinese Spelling Correction(CSC) task can be formalized as the following task. Given a text sequence of n Chinese characters $X = (x_1, x_1, \ldots, x_n)$, the goal is to output $Y = (y_1, y_2, \ldots, y_n)$, where X represents the original text containing some error characters, and Y represents the correct text after correction. The X and Y have the same length. Therefore, CSC task can be regarded as a sequence tagging task. Usually, no or only a small fraction of misspelled characters is in a sentence and all or most of the characters should be copied.

3.2 Motivations

Our motivation can be shown in the Figure 1. Most of the existing state-of-the-art CSC methods treat the correction as a sequence tagging task like Figure 1(a), that is to use the correction module to classify which character the corresponding token should be converted to. The disadvantage of this type of method is that they lack the awareness of the position of the misspelled characters and correct each characters merely by the context, which is easily misled by the misspelled characters.

In order to solve the problem, some methods (Hong et al., 2019; Zhang et al., 2020), as shown in Figure 1(b), add a detection module before the correction module to mask the positions where errors may occur and predict the correct characters in the masked positions. Although this scheme weakens the misleading impact of the spelling errors to a certain extent, it also leads to a new problem: the correction performance can still be sub-optimal since the phonological and visual information of the misspelled characters, which could be highly similar to the correct characters and helpful for correction, are dampened by the mask.

Therefore, the above issues inspire us to find a new scheme of utilizing the error detection information. Specifically, as shown in Figure 1(c), the raw sentence is directly used as the input of the correction module to keep the visual and phonological features of the misspelled characters, while the hidden states of the correction module are lately fused with those of the detection module. The misleading impact from the misspelled characters is minimized via the end-to-end joint training. In the following sections, we will illustrate how to implement the multi-task framework based on this scheme.

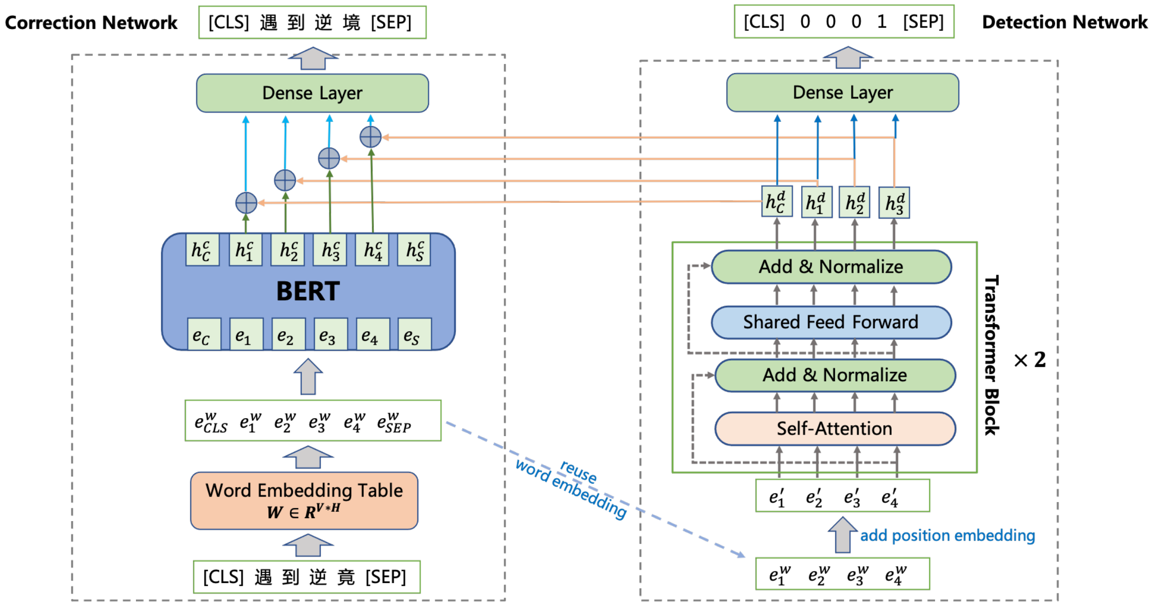


Figure 2: The overall structure of the MDCSpell. The MDCSpell uses a transformer structure as the detection network and a BERT structure as the correction network. These two networks share the same word embedding as input. At the end of the correction network, the hidden states from both the correction and detection networks are fused as input to the classification dense layer which generates the correction results. These two tasks can be trained simultaneously in an end-to-end manner.

3.3 Structure of MDCSpell

We implement the proposed correction scheme as the MDCSpell, which is depicted in Figure 2. MDCSpell consists of a transformer-based detection network and a BERT-based correction network. These two networks use the same word embedding as input. At the end of the correction network, the hidden states from the correction and detection networks are fused into the classification dense layer as input to generate the correction results. These two tasks can be trained simultaneously in an end-to-end manner.

More specifically, we first generate the embedding required by BERT for each character, which is the sum of word embedding, position embedding, and segment embedding. Then we input the embedding sequence of the input text into the detection network and the correction network to obtain the encoded vector respectively. The detection network is a structure based on a multi-layer transformer, which needs to fit whether the characters in each position are misspelled. Therefore, the output encoded vector of the detection network contains the information of the possible error probability of the position. The correction network is a structure based on BERT, which needs to detect what characters need to be output in each position. Next, we fuse the information of the two encoded vectors to generate the final encoded vector. Lastly, a dense layer initialized by the transpose of the word embedding table takes the final encoded vector as input and generates the prediction result.

3.4 Detection Network

The detection network is a binary classification task based on the transformer structure, which is used to determine the error probability of characters in each position. For input text of length n, the input of detection network is the embedding sequence $E = (e_1, e_2, ..., e_n)$ of characters, which is the sum of word embedding, position embedding, and segment embedding. Then a context encoder is used to get the detection encoding vector. Finally, a projection layer is used to project the encoding vector into two-dimensional space, which represents the probability of correctness and error of the position character respectively.

Specifically, in order to capture better context semantics, we use a multi-layer transformer for encoding, where each layer uses the same block structure. The definition of each transformer block is as follows:

$$MultiHead = Concat(head_1, ..., head_n)W^O \tag{1}$$

$$head_i = Attention(QW_i^Q, KW_i^K, VW_i^V) \tag{2}$$

$$FFN(X) = max(0, XW_1 + b_1)W_2 + b_2 \tag{3}$$

Where Q, K, and V represent the representation of the current input sequence, which could be the embedding of characters or the output of the previous transformer block. $MultiHead$ and FFN represent multi-head self-attention and feed-forward network respectively, which are the basic components of the transformer. We denote the sequence of hidden states at the last layer of transformer blocks as $H^d = (h_1^d, h_2^d, ..., h_n^d)$.

The hidden state H^d is both used to predict the positions of the misspelled characters and deliver the position information to the correction network. Specifically, we use a dense layer as the output layer and the softmax function 4 to determine if an error happens. For each character of the raw input, the probability of error detection is defined as

$$P^d(g_i = 1|X) = \sigma(W h_i^d + b) \tag{4}$$

where $P^d(g_i = 1|X)$ is the conditional probability which represents how likely the character corresponding to h_i^d is misspelled, σ represents the nonlinear function which we used sigmoid function, h_i^d denotes the final layer of the transformer-based detection network, W and b are the parameters of the dense layer.

3.5 Correction Network

Correction network is a multi-class classification task based on BERT-base, which is used to find the correct characters to replace the misspelled characters. BERT-base is composed of a stack of 12 identical transformer blocks. We denote the sequence of hidden states at the final layer of transformer blocks as $H^c = \{h_1^c, h_2^c, ..., h_n^c\}$.

Then we fuse the hidden states from the detection network and the correction network. In this work, we specially set the dimensions of the last hidden layer of the two networks to be the same, so we directly add them to get the fused representation

$$H = H^d + H^c \tag{5}$$

where H^d is the hidden states from the final layer of the transformer-based detection network and H^c is the hidden states from the final layer of the BERT-based correction network.

Lastly, we reviewed the correction task and we do not regard the correction task as a classification task through a random initialization projection layer, but as a similarity task, i.e., if the character of one position is correct, then through the encoding of detection and correction network, the final encoded vector should be very similar to the word embedding of the input character. On the contrary, if the character of one position is wrong, then the final encoded vector should be similar to the word embedding of the corrected character. The formula for the classification task is as follows.

$$P(y_i|X) = softmax(W h_i) \tag{6}$$

Specifically, we use the transpose of the word embedding table to initialize the weight of projection layer W instead of random initialization. The result is that the large number of randomly initialized parameters of the projection matrix, could lead to slow convergence, and finally lead to poor performance. Instead, we use the transpose of the word embedding table to initialize the weights of the projection layer considering their similarity. By doing so, the training of the correction network converges much faster and steadily achieves desired performance.

3.6 Training

We define the detection task as the classification task of whether the character should be modified, and the correction task as the classification task of what the correct character is and formalize their loss functions as

$$L^d = -\sum_{i=1}^{n} log P^d(g_i|X) \tag{7}$$

$$L^c = -\sum_{i=1}^{n} log P^c(y_i|X) \tag{8}$$

where L^d and L^c are the loss functions for the training of the detection network and correction network respectively. Finally, we linearly combine the two functions as the overall loss function,

$$L = \lambda L^c + (1 - \lambda) L^d \tag{9}$$

where $\lambda \in [0, 1]$ is the coefficient to balance the detection loss and correction loss. We then simultaneously train the whole network by minimizing the L.

4 Experimental Results

4.1 Datasets

The training data is composed of three training datasets (Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015), which has 10K data samples in total. Following (Wang et al., 2019), we also include

Training Data	#Line	Avg.Length	#Errors
(Wang et al., 2019)	271,329	44.4	382,704
SIGHAN 2013	350	49.2	350
SIGHAN 2014	6,526	49.7	10,087
SIGHAN 2015	3,174	30.0	4,237
Test Data	**#Line**	**Avg.Length**	**#Errors**
SIGHAN 2013	1,000	74.1	996
SIGHAN 2014	1,062	50.1	529
SIGHAN 2015	1,100	30.5	550

Table 2: Statistics information of the used data resources. The number in the bracket in #Line column denotes the number of sentences with errors.

additional 271K samples as the training data, which are generated by an automatic method (Wang et al., 2018).

To evaluate the performance of the proposed method, we used three test datasets from the SIGHAN 2013, SIGHAN 2014, SIGHAN 2015 benchmarks(Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015) as in (Wang et al., 2019). We also follow the same data pre-processing procedure, i.e., the characters in these datasets are converted to simplified Chinese using OpenCC. The statistic of the data is listed in Table 2.

4.2 Baselines

We compare our method with the following typical baselines.

- Hybrid (Wang et al., 2018): This method uses a BiLSTM-based model trained on a generated dataset.

- FASpell (Hong et al., 2019): This method utilizes a specialized candidate selection method based on the similarity metric. This metric is measured using some empirical methods, e.g., edit distance, rather than a pre-defined confusion set.

- BERT (Devlin et al., 2019):The word embedding is used as the softmax layer on the top of BERT for the CSC task. We trained this model using the same setting as our baseline model.

- Soft-Masked BERT (Zhang et al., 2020): This method uses a two-stage detection and correction pipeline method, it masked the detected error character and then turn the input into the BERT model for error correction.

- SpellGCN (Cheng et al., 2020): This method incorporates phonological and visual similarity knowledge into BERT via a specialized graph convolutional network.

- GAD (Guo et al., 2021): This method learns the global relationship of the potential correct input characters and the candidates of potential error characters.

- DCN (Wang et al., 2021): This method uses a dynamic connected network to model the dependencies between two adjacent Chinese characters.

4.3 Evaluation Metrics

The sentence-level precision, recall, and F1 score are reported as the evaluation metrics as in most of the previous work. These metrics are provided for the detection and correction sub-tasks. We consider a sentence to be correctly annotated only if all errors in the sentence are corrected as in (Hong et al., 2019).

4.4 Training Details

We use the pretrained BERT as the correction network. For the sake of faster convergence, we initialize the weights of the transformer in the detection module with the first two layers and the embedding layer of BERT. The overall training process is divided into two stages for training. The first stage is to use nearly all 3 million training data to fine-tune the model, where the batch size is 32 and the learning rate is 2e-5. The second stage is to fine-tune the model on the SIGHAN training data, where the batch size is 32 and the learning rate is 1e-5.

4.5 Main Results

The main results can be found in Table 3. According to this table, our proposed MDCSpell framework consistently achieves the best F1 score, both for the detection task and the correction task, on all of the three datasets. The MDCSpell with the best model setup achieves 0.2%, 0.8%, 2.0% absolute gains on the three datasets compared to the best CSC method, indicating the effectiveness of our method. Also note compared with the BERT baseline (which is the correction part of our MDCSpell), our methods significantly improves the correction F1 score by 7.2%, 4.0%, 5.3% respectively, which illustrates the effectiveness of the detection network in the proposed multi-task architecture.

We can also find that the precision results significantly outperforms the competitors. Compared

Table 3: Experimental results of sentence-level precision, recall, and F1 score (%).

with the best competitor, our method has increased the precision by 2.8%, 3.2%, 3.9% on three datasets respectively. This improvement mainly benefits from the better usage of the detection information which aims to avoid the errors caused by the misleading impact on the context from the misspelled characters as well as make use of the visual and phonological features from them.

It is worth noting that although our method has achieved overall optimal results on precision and F1 score, the recall has a certain gap compared to some methods on these datasets. The reason might be that we did not use any external knowledge like confusion set compared to GAD and DCN. The competitive results achieved by us without using the external knowledge also illustrate the effectiveness of our method.

4.6 Ablation Study

In this subsection, we analyze the effect of the hyperparameters, including the number of detection layers and the value of λ. We evaluate their influence on the SIGHAN15 dataset.

Figure 3 shows the effect on the number of transformer layers in detection network and with or without BERT weights initialization. We compared the effect of the number of transformer layers from 0 to 4 based on the detection F1 score. From the figure we can find that, 1) the results of using BERT weights initialization greatly outperforms that of random initialization no matter how many transformer layers (> 0) are used, 2) as for the number of transformer layers, the best trade-off between performance and number of parameters can be achieved when the number of layers is 2 when using BERT weights initialization. In the main experiment, we used two transformer layers as the detection network with the BERT weights initialization.

In the multi-task learning, the impact of the selection of the scale parameter λ in the loss function on the result is shown in Figure 4. From this result, we can find that setting λ as 0.85 achieves the overall best correction F1 score. This is reasonable since the convergence of the correction task is harder than that of the detection task so that it demands a higher weight during learning. Meanwhile, an excessive high λ would diminish the learning

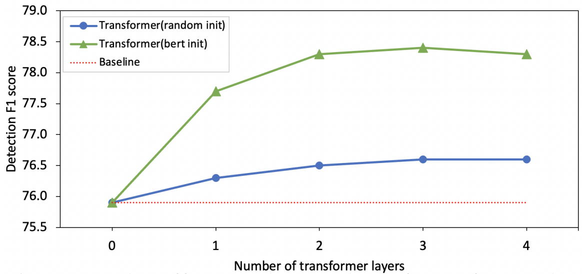

Figure 3: The effect on the number of transformer layers in detection network and with or without BERT weights initialization.

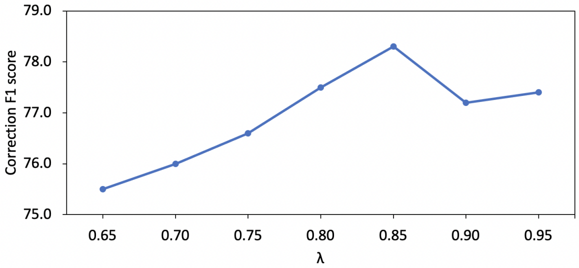

Figure 4: The impact of the selection of the scale parameter λ in the loss function.

of detection which might reduce the contribution from the detection network. Thus a relative higher λ achieves the overall best balance between the learning of these two tasks.

4.7 Case Study

To further analyze our approach, we show several correction results in Table 4 to demonstrate the properties of MDCSpell. It can be seen from the examples that MDCSpell can well capture the context and make judgments without being disturbed by the context of the wrong characters, and correct the wrong characters to its corrected counterparts. In the first case, that MDCSpell does not mistakenly change the correct token “哪里” in the context to the wrong token “那里” that often appears in the corpus like the baseline. In the second case, when there are multiple words that need to be corrected, MDCSpell successfully avoids the misleading affect from the context of the wrong characters, and correct multiple consecutive wrong characters “纳福境” into the correct characters “那附近” to maintain the fluent semantics. Also, it can be seen from the third case that the baseline mistakenly changes the character “高” into “寒” which is apparently affected by the original wrong character “心” since “寒心” is a meaningful word compared to “高心” in Chinese. On the contrary, MDCSpell can avoid this negative impact and successfully change the wrong characters into the correct ones. The success in solving these cases also proves the effectiveness of the MDCSpell.

Input	哪里(nǎ lǐ)有上大学，不想念书的道理?
baseline	那里(nà lǐ)有上大学，不想念书的道理?
MDCSpell	哪里(nǎ lǐ)有上大学，不想念书的道理?
Translation	What is the reason to go to university and not want to study?
Input	从那里，我们可以走到纳福境(nà fú jìng)的新光三钺百货公司逛一逛
baseline	从那里，我们可以走到纳福境(nà fú jìng)的新光三钺百货公司逛一逛
MDCSpell	从那里，我们可以走到那附近(nà fù jìn)的新光三钺百货公司逛一逛
Translation	From there, we can walk to the Shinkong Sanyue Department Store nearby.
Input	他主动拉了姑娘的手，心里很高心(gāo xīn)，嘴上故作生气
baseline	他主动拉了姑娘的手，心里很寒心(hán xīn)，嘴上故作生气
MDCSpell	他主动拉了姑娘的手，心里很高兴(gāo xìng)，嘴上故作生气
Translation	He took the girl’s hand on his own initiative, very happy in his heart, pretending to be angry.

Table 4: Examples of CSC results, the incorrect and correct characters marked in red and blue respectively.

5 Conclusions

Spelling errors have two sides to the CSC task. Specifically, their visual and phonological features are critical for substitution for the correct characters, but their misleading impact on the context can mislead the correction model in turn. In this paper, we proposed a general detector-corrector multi-task framework MDCSpell which exploits the visual and phonological features of the misspelled characters and meanwhile minimizes their misleading impact on the context. The experiments demonstrate the effectiveness of our method. For future work, we will explore how to make better use of external knowledge to strengthen our model and other ways of using the detection information and extend the proposed framework to other problems like grammatical error correction.

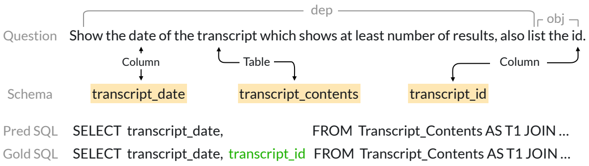
Abstract

The task of converting a natural language question into an executable SQL query, known as text-to-SQL, is an important branch of semantic parsing. The state-of-the-art graph-based encoder has been successfully used in this task but does not model the question syntax well. In this paper, we propose **S^2SQL**, injecting **S**yntax to question-**S**chema graph encoder for Text-to-**SQL** parsers, which effectively leverages the syntactic dependency information of questions in text-to-SQL to improve the performance. We also employ the decoupling constraint to induce diverse relational edge embedding, which further improves the network's performance. Experiments on the Spider and robustness setting Spider-Syn demonstrate that the proposed approach outperforms all existing methods when pre-training models are used, resulting in a performance ranks first on the Spider leaderboard.

1 Introduction

Relational databases are ubiquitous and store a great amount of structured information. The interaction with databases often requires expertise on writing structured code like SQL, which is not friendly for users who are not proficient in query languages. Text-to-SQL aims to automatically translate natural language questions into executable SQL statements (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Zettlemoyer and Collins, 2007; Berant et al., 2013; Li and Jagadish, 2014; Yaghmazadeh et al., 2017; Iyer et al., 2017).

Recently, a large-scale, multi-table, realistic text-to-SQL benchmark, Spider (Yu et al., 2018), has been released. The most effective and popular encoder architecture on Spider is the question-schema interaction graph (Wang et al., 2020). Built on that, many state-of-the-art models have been further developed (Chen et al., 2021; Cao et al., 2021). It jointly models natural language question and structured database schema information, and uses some pre-defined relationships to carve out the interaction between them. However, we observed that the current graph-based model yet has two major limitations.



Show the date of the transcript which shows at least number of results, also list the id.

Pred SQL SELECT transcript_date, FROM Transcript_Contents AS T1 JOIN ...
Gold SQL SELECT transcript_date, transcript_id FROM Transcript_Contents AS T1 JOIN ...

Figure 1: A typical bad case of the current graph-based methods. If the structure of question (dependencies) are not considered, the wrong SQL will be generated even if the linking is correct.

Syntactic Modelling. Jointly modeling syntax and semantics is a core problem in NLP. In the paradigm of deep learning, the role of syntax should be better understood for tasks in which syntax is a central feature (Ge and Mooney, 2005; Michalon et al., 2016; Zhang et al., 2019b; Zanzotto et al., 2020), including the text-to-SQL task. For example, Figure 1 shows that the baseline model can learn the correct linking among `date`, `id` and `transcript` between the question and schema, but fail to identify that `id` should also be included in the `SELECT` clause. On the other hand, with the help of the dependency tree, `date` and `id` are close to each other and thus should appear in the `SELECT` clause simultaneously. However, almost all available approaches treat the language question as a sequence, and syntactic information is ignored in neural network-based text-to-SQL models.

Entangled Edge Embedding. The question-schema interaction graph pre-defines a series of edges, and models them as learnable embeddings. These embeddings should be diverse by nature be-

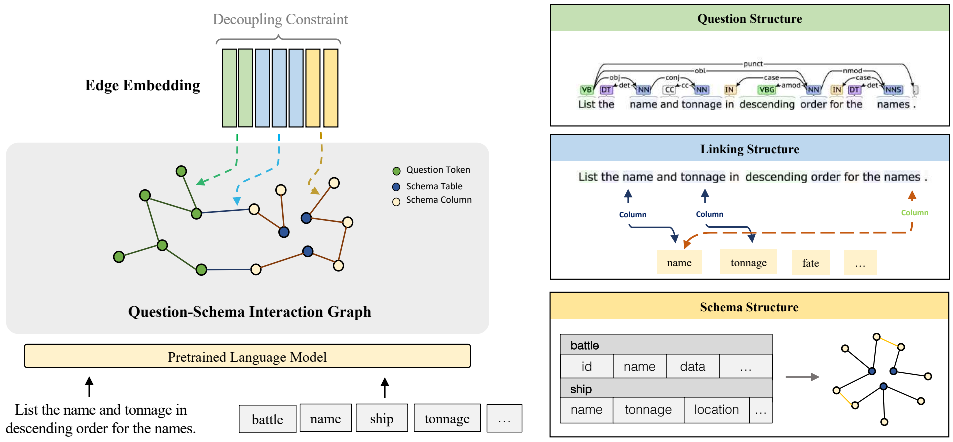

Figure 2: An overview of S^{2}SQL framework. The S^{2}SQL has three relation types to represent the known syntactic information, linking structure and schema information. There structure are integrated into the question-schema interaction graph by learnable edge embedding with decoupling constraints.

cause each of them represents a different type of relations and has a different meaning. Previous work (Brock et al., 2019; Zhang et al., 2020) has proved that the learnable embeddings are easy to be entangled and do not satisfy the diversity objective.

In this paper, we propose **S^{2}SQL**, injecting **S**yntax to question-**S**chema graph encoder for Text-to-**SQL** parsers. S^{2}SQL models the syntactic labels from a syntactic dependency tree as additional edge embeddings. Motivated by the belief that if the structure of input can be reliably obtained and is a central feature of a task, models that explicitly exploit the structure can benefit. In this paper, we investigate and prove that properly introducing syntactic information into text-to-SQL can further improve the performance, and we provide a detailed analysis on why and how the proposed model works. Built on that, we propose a decoupling constraint to encourage the model to learn a diverse set of relation embeddings, which further enhances the network's performance. We evaluate our proposed model on the challenging text-to-SQL benchmark Spider (Yu et al., 2018) and robustness setting Spider-Syn (Gan et al., 2021), and demonstrate that S^{2}SQL outperforms other graph-based models consistently when augmented with different pre-training models. In brief, the contributions of our work are three-fold:

- We investigate the importance of syntax in text-to-SQL and propose a novel and strong encoder for cross-domain text-to-SQL, namely S^{2}SQL.
- To induce the diverse edge embedding learning, we introduce the decoupling constraint, which further improves the performance.
- The empirical results show that our approach outperforms all the existing models on the challenging Spider and Spider-Syn benchmark.

2 The Proposed Method

2.1 Problem Definition

Given a natural language question $\mathcal{Q} = \{q_i\}_{i=1}^{|\mathcal{Q}|}$ and a schema $\mathcal{S} = \langle \mathcal{C}, \mathcal{T} \rangle$ consisting of columns $\mathcal{C} = \left\{c_1^{t_1}, c_2^{t_1}, \cdots, c_1^{t_2}, c_2^{t_2}, \cdots\right\}$ and tables $\mathcal{T} = \{t_i\}_{i=1}^{|\mathcal{T}|}$, text-to-SQL aims to generate the SQL query y for the question sentence. The *de facto* method for text-to-SQL employs an encoder-decoder architecture. In this paper we focus on improving the encoder part. For a detailed description of the decoder, please refer to the work of (Wang et al., 2020; Cao et al., 2021).

2.2 Question-Schema Interaction Graph

The joint input questions and schema items can be viewed as a graph $\mathcal{G} = (\mathcal{V}, \mathcal{R})$, where $\mathcal{V} = \mathcal{Q} \cup \mathcal{T} \cup \mathcal{C}$ are nodes of three types $\{\mathcal{Q}, \mathcal{T}, \mathcal{C}\}$. The initial node embeddings matrix $\mathbf{X} \in \mathbb{R}^{|\mathcal{V}^{|\mathcal{Q}|+|\mathcal{T}|+|\mathcal{C}|}| \times d}$ is obtained by flattening all question tokens and schema items into a sequence: `[CLS]` $q_1 q_2 \cdots q_{|Q|}$ `[SEP]` $t_{10} t_1 c_{10}^{t_1} c_1^{t_1} c_{20}^{t_1} c_2^{t_1} \cdots t_{20} t_2 c_{10}^{t_2} c_1^{t_2} c_{20}^{t_2} c_2^{t_2} \cdots$ `[SEP]`. The type information t_{i0} or $c_{j0}^{t_i}$ is inserted before each schema item. The edge $\mathcal{R} = \{R\}_{i=1,j=1}^{|X|,|X|}$ represents the known relation between two elements in the input nodes.

The RGAT (relational graph attention transformers) (Shaw et al., 2018; Wang et al., 2020; Cao et al., 2021) models the graph $\mathcal{G}$ and computes the output representation $\mathbf{z}$ by:

$$\begin{aligned} e_{ij}^{(h)} &= \frac{\mathbf{x}_i \mathbf{W}_q^{(h)} \left(\mathbf{x}_j \mathbf{W}_k^{(h)} + \mathbf{r}_{ij}^K\right)^\top}{\sqrt{d_z/H}}, \\ \alpha_{ij}^{(h)} &= \operatorname{softmax}\left\{e_{ij}^{(h)}\right\}, \\ \mathbf{z}_i^{(h)} &= \sum_{v_j^n \in \mathcal{N}_i^n} \alpha_{ij}^{(h)} \left(\mathbf{x}_j \mathbf{W}_v^{(h)} + \mathbf{r}_{ij}^V\right), \end{aligned} \quad (1)$$

where matrices $\mathbf{W}_q, \mathbf{W}_k, \mathbf{W}_v$ are trainable parameters in self-attention, and $\mathcal{N}_i^n$ is the receptive field of node v_i^n.

Injecting Syntax The previous work mainly focuses on using linking structure and schema structure in the encoder (Wang et al., 2020), in which the structure of the question is ignored. We proposed an effective approach to integrate syntactic dependency information[1] into the graph. A straightforward idea is to treat all dependent types directly as a new edge type. However, the dependency parser will return 55 different dependency types. Such a large number of edge types will significantly increase the number of relational embedding parameters in S^{2}SQL, leading to over-fitting. In order to address this, similar to (Vashishth et al., 2018), we induct dependency types into three abstract relations, `Forward`, `Backward` and `NONE`. In addition, in order to ensure the simplicity of edge embedding, we only consider the first-order relationship. By stacking multi-layer transformers, the model implicitly captures the multi-order relationship without deliberate construction. Specifically, we compute the distance $\boldsymbol{D}(v_i, v_j)$ between any two tokens v_i and v_j from the question. This distance is set to the first-order distance between v_i and v_j if they have the aforementioned dependency types, and 0 otherwise. Based on this first-order distance $\boldsymbol{D}$, we model the syntactic relation R_{ij}^{question} between tokens v_i and v_j by one of the three previously defined abstract types:

$$\mathcal{R}_{ij}^{\text{question}} = \begin{cases} \texttt{Forward}, & \text{if } \boldsymbol{D}(v_i, v_j) = 1 \\ \texttt{Backward}, & \text{if } \boldsymbol{D}(v_j, v_i) = 1 \\ \texttt{NONE}, & \text{otherwise.} \end{cases} \quad (2)$$

Overall, as shown in Figure 2, S^{2}SQL models three structures in the graph $\mathcal{G}$:

- **Question Structure** $\mathcal{R}^{\text{question}}$: relations that represent syntactic dependency between two question tokens.
- **Linking Structure** $\mathcal{R}^{\text{linking}}$: relations that align entity in question to the corresponding schema columns or tables. (Wang et al., 2020)
- **Schema Structure** $\mathcal{R}^{\text{schema}}$: relations within a database schema, *e.g.*, *foreign key*.

The detailed structure construction could be found in Appendix A.1.

Decoupling Constraint. There are k known edges in $\mathcal{R}$ and each is represented as a relation embedding. Intuitively, these edge embedding $\mathbf{r} = [\mathbf{r}_1, \mathbf{r}_2, ..., \mathbf{r}_k]$ should be diverse because they have different semantic meanings. To avoid the potential risk of coupling edge embedding $\mathbf{r}$ during optimization, we introduce the orthogonality condition (Brock et al., 2019) to $\mathbf{r}$:

$$\mathcal{L}(\mathbf{r}) = \left\|\mathbf{r}^\top \mathbf{r} \odot (\mathbf{1} - I)\right\|_{\text{F}}^2, \quad (3)$$

where $\mathbf{1}$ denotes a matrix with all elements being set to 1 and I is the identity matrix.

3 Experiments

3.1 Experiment Setup

Datasets and Evaluation Metrics. We conduct experiments on Spider (Yu et al., 2018) and Spider-Syn (Gan et al., 2021). Spider is a large-scale, complex, and cross-domain text-to-SQL benchmark. Spider-Syn is derived from Spider, by replacing their schema-related words with manually selected synonyms that reflect real-world question paraphrases. For evaluation, we followed the official evaluation to report exact match accuracy.

3.2 Implementation Details.

We utilize PyTorch (Paszke et al., 2019) to implement our proposed model. During pre-processing, the input of questions, column names, and table names are tokenized and lemmatized with the Standford Nature Language Processing toolkit. For a fair comparison with baselines, we configure it with the same set of hyper-parameters, *e.g.*, stacking 8 self-attention layers, setting dropout to 0.1. The position-wise feed-forward network has an inner layer dimension of 1024. Inside the decoder, we use rule embeddings of size 128, node type embeddings of size 64, and a hidden size of 512 inside the LSTM with a dropout of 0.21.

Table 3: The accuracy on the Spider-Syn dataset.

3.3 Baseline Models.

We conduct experiments on Spider and Spider-Syn and compare our method with several baselines including:

- **RYANSQL** (Choi et al., 2020) is a sketch-based slot filling approach which is proposed to synthesize each SELECT statement for its corresponding position.
- **RATSQL** (Wang et al., 2020) is a relation aware schema encoding model in whuich the question-schema interaction graph is built by n-gram patterns.
- **ShadowGNN** (Chen et al., 2021) processes schemas at abstract and semantic levels with domain-independent representations.
- **BRIDGE** (Lin et al., 2020) represents the question and schema in a tagged sequence where a subset of the fields are augmented with cell values mentioned in the question.
- **LGESQL** (Cao et al., 2021) a line graph enhanced Text-to-SQL model to mine the underlying relational features without constructing metapaths. It was the SOTA model in the Spider leaderboard before ours.

3.4 Results and Analyses

Overall Performance. We first compare S^{2}SQL with other state-of-the-art models on Spider. As shown in Table1, we can see that S^{2}SQL outperforms all existing models. Remarkably, the accuracy of S^{2}SQL + RoBERTa on the hidden test set is 67.1%, which is 2.8% higher than the strong baseline RAT + RoBERTa. Similarity, the accuracy of the SOTA model LGESQL + ELECTRA is 72.0% on the hidden test set, and 75.1% on the development set, while S^{2}SQL + ELECTRA can reach 72.1% test and 76.4 development accuracy. Table 2 shows results on the development set for RAT and S^{2}SQL with Table-based pre-training models. We can see that S^{2}SQL outperforms RAT consistently when augmented with different pre-training models, including RoBERTa (Liu et al., 2019), GraPPa (Yu et al., 2021) and GAP (Shi et al., 2021). In addition, as shown in Table 3, S^{2}SQL demonstrates improvement on the robustness dataset.

Ablation Study. The last row of Table 1 shows that removing the decoupling constraint causes a 0.5% performance drop on the development set. This implies that decoupling entangled embeddings helps to improve the performance. To examine the impact of the decoupling constraint, we visualize the cosine similarity between any two relation em-

Question	*List the name and tonnage in alphabetical descending order for the names.*
Baseline	SELECT name, tonnage FROM ship ORDER BY **tonnage** DESC
S^2SQL	SELECT name, tonnage FROM ship ORDER BY **name** DESC
Gold	SELECT name, tonnage FROM ship ORDER BY name DESC
Syntax	(name, tonnage, CONJ), (order, names, NMOD)
Question	*What is the total population and average area of countries in the continent of North America whose area is bigger than 3000 ?*
Baseline	SELECT sum(population) , avg(surface_area) FROM country where **surface_area** = "North America" and surface_area > 3000
S^2SQL	SELECT sum(population) , avg(surface_area) FROM country where **continent** = "North America" and surface_area > 3000
Gold	SELECT sum(population) , avg(surface_area) FROM country where continent = "North America" and surface_area > 3000
Syntax	(continent, America, NMOD)
Question	*Show the date of the transcript which shows the least number of results, also list the id.*
Baseline	SELECT transcript_date FROM Transcript_Contexts AS T1 JOIN . . .
S^2SQL	SELECT transcript_date, **transcript_id** FROM Transcript_Contexts AS T1 JOIN . . .
Gold	SELECT transcript_date, transcript_id FROM Transcript_Contexts AS T1 JOIN . . .
Syntax	(show, list, DEP) (show, date, OBJ) (list, id, OBJ)

Table 4: Case study: some comparisons with baseline (LGESQL) show that S^2SQL can generate more accurate SQL, where syntax column represents useful syntactic information in the generation of S^2SQL.

beddings. As shown in Figure 3, we observe that the decoupling constraint eliminates the entangling phenomenon (darker colors) and produces a more diverse set of embeddings.

3.5 Qualitative Analysis.

In Table 4, we compare the SQL queries generated by our S^2SQL model with those created by the baseline model LGESQL. We notice that S^2SQL performs better than the baseline system, especially in the case of question understanding that depends on syntax structure. For example, in the first case where the `order` and `name` have `NMOD` relation, baseline fails to For example, in the first example, both `name` and `tonnage` can be linked correctly, but the baseline fails to capture the structure present in `name` and `order`, resulting in a generation error, while S^2SQL predicts the result well.

3.6 About Syntactic Parser.

In our experiments, we use the SpaCy tool as a syntactic parser. It is important to emphasize that the quality of the SpaCy syntactic parsing has marginal impact on the performance of S2SQL. The following three main reasons are given.

- SpaCy is the current SOTA parser tool (95%+ accuracy on the OntoNotes 5.0 corpus) and has been widely used in various papers introducing syntax, which proves its reliability.
- The question in Spider are not extremely complex and can be handled very well.
- Even though syntactic parser errors may introduce noise into S2SQL, our proposed inductive syntactic injection method (instead of independent injection) can mitigate the impact of syntactic type errors.

4 Related Work

Extensive work has been conducted on improving the encoder and decoder (Yin and Neubig, 2017; Wang et al., 2019; Guo et al., 2019; Choi et al., 2020; Kelkar et al., 2020; Rubin and Berant, 2021; Hui et al., 2021b) as well as table-based pretraining (Yin et al., 2020; Yu et al., 2021; Deng et al., 2020; Shi et al., 2021; Wang et al., 2021b). Besides, Wang et al. (2021a) proposed a meta-learning based training objective to boost generalization. Scholak et al. (2021) proposed PICARD, a method for constraining auto-regressive decoders of T5. Among the encoder-related work, Guo et al. (2019) introduced the schema linking module, which aimed to recognize the columns and the tables mentioned in a question. Lin et al. (2020) leveraged the database content to augment the schema representation. Bogin et al. (2019) employed GNN to derive the representation of the schema structure. Then, Chen et al. (2021) proposed ShadowGNN to abstract the representation of question and schema with attention. Besides, Hui et al. (2021a) present a dynamic graph framework that can model contextual information for context-dependent setting. The most recent approaches (Wang et al., 2020; Cao et al., 2021) achieved the best performance through relation-aware transformer. Unlike these works, we investigated the impact of the syntactic structures during the encoding stage.

5 Conclusion

We present syntax-enhanced question-schema graph encoder (S^2SQL) that can effectively model syntactic information for text-to-SQL and introduce the decoupling constraint to induce the diverse relation embedding. The proposed model achieves new state-of-the-art performance on the widely used benchmark, Spider and Spider-Syn.

A Appendix

A.1 Details of Relation Structure.

All structures have been shown in Table 5. a structure (edge) exists from source node $x \in S$ to target node $y \in S$ if the pair fulfills one of the descriptions listed in the Table 5, with the corresponding label.

Source x	Target y	Type	Description
Question	Question	`Forward-Syntax`	y is the target word of x under syntax dependency.
Question	Question	`Backward-Syntax`	y is the source word of x under syntax dependency.
Question	Question	`None-Syntax`	x and y have no syntactic dependency.
Column	Column	`Foreign-Key`	y is the foreign key of x.
Table	Column	`Has`	The column y belongs to the table x.
Table	Column	`Primary-Key`	The column y is the primary key of the table x.
Question	Table	`None-Linking`	No linking between x and y.
Question	Table	`Partial-Linking`	x is part of y, but the entire question does not contain y.
Question	Table	`Exact-Linking`	x is part of y, and y is a span of the entire question.
Question	Column	`None-Linking`	No linking between x and y.
Question	Column	`Partial-Linking`	x is part of y, but the entire question does not contain y.
Question	Column	`Exact-Linking`	x is part of y, and y is a span of the entire question.
Question	Column	`Value-Linking`	x is part of the candidate cell values of column y.

Table 5: The checklist of all relations structure used in S^{2}SQL. All relations above are asymmetric.

Constructing Open Cloze Tests Using Generation and Discrimination Capabilities of Transformers

Mariano Felice, Shiva Taslimipoor and Paula Buttery
ALTA Institute, Computer Laboratory, University of Cambridge
Cambridge, UK
`{mf501,st797,pjb48}@cam.ac.uk`

Abstract

This paper presents the first multi-objective transformer model for constructing open cloze tests that exploits generation and discrimination capabilities to improve performance. Our model is further enhanced by tweaking its loss function and applying a post-processing re-ranking algorithm that improves overall test structure. Experiments using automatic and human evaluation show that our approach can achieve up to 82% accuracy according to experts, outperforming previous work and baselines. We also release a collection of high-quality open cloze tests along with sample system output and human annotations that can serve as a future benchmark.

1 Introduction

Open cloze (Taylor, 1953) tests are a common type of exercise where words are removed from a piece of text and must then be filled in by the students without any options to choose from. They are often used in language learning environments as a quick and effective way to test vocabulary, grammar and reading comprehension (Tremblay, 2011; Trace, 2020). However, designing high-quality cloze tests for language learning is a laborious process that involves finding an optimal distribution of gaps based on aspects such as function, distance, number of answers, etc. (ALTE, 2005; 2011).

In this paper, we propose a strategy to construct open cloze exercises using transformer models (Vaswani et al., 2017). Our transformer-based architecture employs two objectives to predict the words that should be gapped in a text passage. Our main objective is standard token classification, where we aim to minimise the error of classifying a token as a gap or not. The second and auxiliary objective is a language-model-based objective whereby we attempt to minimise the language model error when predicting the right answer for each gap. Our solution is based on a pre-trained ELECTRA (Clark et al., 2020) model that is fine-tuned on the two described objectives in a multi-task scenario.

Our output aims to mimic the style of open cloze tests in the First Certificate in English (FCE) exam[1], which is targeted at learners of English at the B2 proficiency level of the Common European Framework of Reference (CEFR) for languages (Council of Europe, 2001). Unlike other tests, the FCE open cloze task aims to simultaneously test many aspects of grammar and vocabulary that students are expected to know at this level. Since the tests are created from a text passage, they must be skilfully designed in order to ensure an optimal distribution of gaps that adheres to guidelines. A shortened example is shown in Figure 1.

Our system is evaluated under two settings: 1) automatic evaluation, where the generated gaps are compared to gold-standard gaps proposed by test experts, and 2) human evaluation, where the quality of the generated gaps is judged by test experts.

The main contributions of our work are as follows: 1) we are the first to employ transformer models for open cloze test generation, 2) unlike previous studies, we work at the paragraph level, which is a much more challenging task, 3) we propose a multi-task learning approach with two objectives: one is to classify tokens into gaps/non-gaps and the other to minimise the error of re-generating the gapped word, 4) we report state-of-the-art results, outperforming previous work and a strong baseline, 5) we propose additional components to control the structure of the final cloze tests as human experts do, 6) we perform both automatic and human evaluation and 7) we make our test data, system output and human annotations available to the research community[2].

Motorbike stunt rider

I work (1) ______ a motorbike stunt rider — that is, I do tricks on my motorbike at shows. The Le Mans race track in France was (2) ______ I first saw some guys doing motorbike stunts. I'd never seen anyone riding a motorbike using just the back wheel before and I was (3) ______ impressed I went straight home and taught (4) ______ to do the same.

Figure 1: Sample FCE open cloze test (shortened).

2 Related Work

While research into automatic cloze test generation is vast (Mostow et al., 2017; Kurdi et al., 2020; Yang et al., 2021), work on open cloze tests for language learning is scarce. Pino et al. (2008) generate open cloze questions using sample sentences from a learners' dictionary based on four linguistic criteria: (grammatical) complexity, well-defined context (collocations), grammaticality and length. A later version of their system adds hints for gapped words (Pino and Eskenazi, 2009). Exercise Maker (Malafeev, 2014) is a rule-based open source system that attempts to emulate exercises in Cambridge English examinations based on the most frequently tested words. Most of the gaps it proposes were found to be useful and the automated exercises were hard to differentiate from authentic tests.

Chinkina et al. (2017) generate open cloze exercises for phrasal verbs by extracting sentences from news articles and generating a pair of questions and answers where the identified particle verbs are gapped. Similarly, Soonklang et al. (2017) gap words in sentences according to their part of speech in order to practise articles, prepositions, etc. Finally, Marrese-Taylor et al. (2018) use LSTMs to build sequence labelling and classification models that decide where to insert a single gap in a single sentence. Automatic evaluation against gold-standard gaps showed the method was effective.

Other work has focused on creating automated cloze tests by controlling aspects of the proposed gaps so that they correlate with a target proficiency level. Lee et al. (2019), for example, manipulate the difficulty of C-tests (open cloze tests with hints, Grotjahn et al. (2002)) by varying the position and word length of the gaps. A similar concept is presented by Settles et al. (2020) and McCarthy et al. (2021), although difficulty is predicted using a machine-learning model that correlates with CEFR levels. In these cases, tests are dynamically adapted to the examinee's proficiency level during the test session. From a different perspective, Felice and Buttery (2019) show that controlling gap entropy can be useful for designing open cloze tests at different CEFR levels. The work we present in this paper, however, aims to model the more complex task of predicting a full set of gaps at the paragraph level that comply with design and testing principles and is, to the best of our knowledge, the first to employ and adapt transformer-based models for this task.

System evaluation is also challenging, since there is usually more than one potential word in the text that could constitute a good gap. While previous work often made a choice between automatic (Marrese-Taylor et al., 2018) or human evaluation (Malafeev, 2014; Das and Majumder, 2017) for their experiments, we perform both: automatic evaluation to identify the best models during development and human evaluation to measure test quality in the final output.

3 Model

We define open cloze generation as the task of predicting a set of tokens that should be gapped in the text. Unlike previous approaches that work at the sentence level, our models work at the paragraph level (i.e. take the full text as input), since we believe the interactions between gaps can only be optimally captured when the text is processed as a whole rather than sentence by sentence.

Given a text passage, we aim to predict the words that should be gapped in order to create a cloze test that would reliably assess student ability. The task is modelled as a supervised sequence tagging problem where each token is classified as being a good potential gap or not. We employ ELECTRA (Clark et al., 2020), one of the state-of-the-art pre-trained transformer-based language representation models (Wolf et al., 2020). ELECTRA is an extension of BERT (Devlin et al., 2019) with a different pre-training task which is a discriminator (rather than a generator) and aims to detect replaced tokens (rather than generating words for the masks). We believe that this discrimination objective makes it more suitable for our token classification task. Moreover, we also exploit ELECTRA's generation capabilities as a language model for estimating the answers to the proposed gaps as an auxiliary task. Hence, to make the most of this pre-trained model, we fine-tune it using two training objectives, as depicted in Figure 2:

① A *token classification objective* which aims to minimise the error of classifying each token as a potential gap or not.

② A *language modelling objective* that aims to minimise the negative log-likelihood of regenerating the words that have been gapped.

The first objective is typical of any standard token classification model and constitutes our key task. In particular, we use ELECTRA's discriminator head with softmax to tag each word in the input sequence as a 'good' gap or not. All the gaps in our training data are replaced with the first intended target answer and labelled positive, while the remaining tokens are labelled negative (Ⓐ).

The second and auxiliary objective attempts to model our preference for gaps with a restricted number of answers while also ensuring that the original word can be guessed from the context. This is to avoid generating gaps that are too 'open' and therefore ineffective, such as a gap that accepts any noun or adjective. Specifically, we mask the words in the positions that are predicted as gaps by the discriminator and use ELECTRA's generative head to generate the expected words in the blanks (Ⓑ).

While the input layers are shared between the discriminator and the generator model, the two branches of the system leading to the two objectives are fine-tuned in parallel in a multi-task setting.

4 Extensions

Our neural transformer-based sequence tagging model can be very effective at proposing potentially good gaps, but the task becomes more challenging when we expect the output to meet additional requirements such as no repetitions, no gap interdependence, a minimum distance between gaps and a varied selection of lexico-grammatical items. We address these issues using two complementary strategies: a manipulation of the loss function and a post-processing module.

4.1 Loss manipulation

In order to spread gaps evenly throughout the text, we modify the token-level loss function of our tagging model by imposing a higher penalty on tokens that are in close proximity to a gap. Let g be the position of a gap in the sequence, then for each token in position i in the proximity of g, i.e. $|g-i| < D$, the loss function $l_i{}'$ for the token in position i is defined as:

$$l_i{}' = l_i * \frac{W}{|g-i|} \tag{1}$$

where W represents the penalty and D is the maximum distance scope for penalisation.[3] Equation 1 thus gives more weight to tokens closer to gaps, which results in higher penalisation of their cost functions whenever they are misclassified.

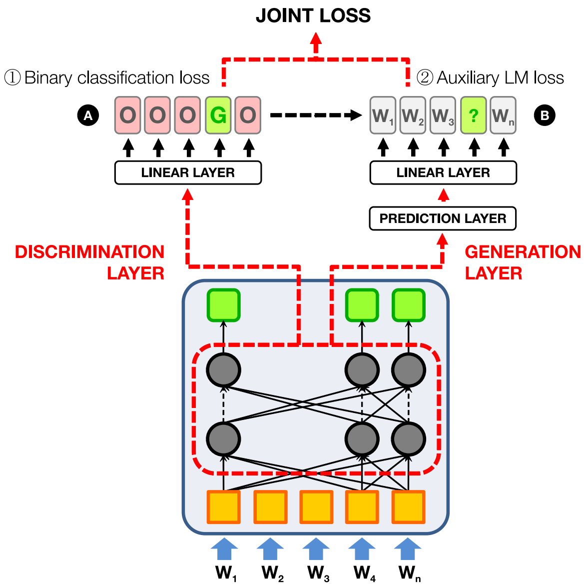

Figure 2: Architecture of our multi-objective ELECTRA-based system. The model is simultaneously trained on two objectives: 1) token classification and 2) LM prediction of gapped words.

4.2 Post-processing

We also employ a post-processing strategy where we replace the gaps that are repeated in the text with better options. We optimise the choice of these alternative gaps by considering the distance between them and the resulting distribution of gaps with different part-of-speech (PoS) tags.

Our post-processing step can be seen as a reranking function. The gap candidates that are originally ranked based on the model's confidence scores change their ranking to match other desirable requirements of a well-structured cloze test. If the selected *n*-best gaps include repetitions, our post-processing algorithm randomly chooses one of them at a time and attempts to replace it with

---

[3] We empirically set the values of constants D and W to 3 and 3.0 respectively.

a better alternative. An alternative gap is deemed better if 1) its answer is not a repetition of another gapped word, 2) its distance to other selected gaps meets the minimum required distance or is higher than the pairwise distances of the originally selected gaps, and 3) it improves the PoS distribution of the gapped words. The PoS distribution of each new selection of gaps is compared to the average gapped PoS distribution of the cloze tests in the training data using Kullback-Leibler (KL) divergence. A combination of gaps that yields lower KL divergence is assumed to be a better solution.

These extensions to the base model bring our final cloze tests closer to those created by human experts by automatically controlling variables that would otherwise need to be adjusted manually. This makes our solution a fully-automated system that can produce ready-to-use cloze tests from an input text passage.

5 Data

To the best of our knowledge, there are no public datasets of full-text open cloze tests that could be used for our task. The CLOTH dataset (Xie et al., 2018), for example, contains gapped passages designed for language learners, but it is primarily focused on reasoning and reading comprehension and uses multiple choice questions where distractors play a major role, making it substantially different to the task we aim to model.

For this reason, we use a collection of expertly created open cloze tests at the B2 CEFR level that was kindly provided by Cambridge University Press & Assessment (CUP&A) for research purposes. Each task consists of a text passage of no more than 300 tokens, a variable number of gaps (between 8 and 16) and a list of valid answers for each gap (between 1 and 7). During the design process, the tasks undergo extensive quality control and pretesting, so their gaps are guaranteed to be very effective at assessing student ability.

For training, we reconstruct the texts by replacing each gap with its first answer and we split the whole collection into train, dev and test. Details of our dataset are shown in Table 1.

Given the lack of publicly available data, we make our test set available with this paper so as to provide a common benchmark for the task and to encourage further research in this area. All the texts were tokenised and parsed using spaCy v2.3[4].

	Train	**Dev**	**Test**
Tasks	356	58	36
Tokens	79,863	12,797	6,621
Gaps	4,565	787	360

Table 1: Number of tasks, tokens and gaps in each section of the data.

6 Experiments

6.1 Setup

We use the pre-trained ELECTRA base discriminator model[5] with 12 attention heads and 12 hidden layers. Along with all the tokens in the sequences, we also input dependency parsing information to the system. More specifically, we concatenate the ELECTRA representation of each token with the representation of its head in the dependency graph.[6] On top of the encoding layers, we have two branches that are being learned simultaneously (Figure 2).

The first branch is a simple linear layer that aims to classify each token as a gap or non-gap. For the second branch, we add ELECTRA's generation layer plus a linear layer which aims to predict the best word from the whole vocabulary as an auxiliary task. We are only interested in predicting the answer words for the gaps. Therefore, we change the input to the second branch by masking the words that are predicted as gaps by the first branch at each step of training. We employ cross-entropy loss on each branch and ignore the loss values for the tokens that are not masked in the second branch. The whole architecture is updated based on the sum of the two losses. Fine-tuning parameters are specified in Appendix B.

6.2 Baselines

We compare our multi-objective ELECTRA model to other systems, namely:

Random baseline Generates a random set of gaps for each task based on the average probability distribution of gapped PoS in the training data.

Exercise Maker Generates gaps using rules and a pre-compiled list of commonly gapped words from a variety of Cambridge English main suite exams (Malafeev, 2014). Set to FCE mode for our experiments.

---

[4] `https://spacy.io/`

[5] `https://github.com/huggingface/transformers`.

[6] If the token is the head, then its representation is repeated.

Class	Label	Description
Good	Good	The gap is appropriate, i.e. it is expected to be effective during testing.
Bad	Too close to other gaps	The gap is in close proximity to another gap.
Bad	Too many possible answers	The gap allows too many answers (often more than 5).
Bad	Too many gaps of this type	There are many gaps with the same part-of-speech or testing focus in the text.
Bad	Answers can change meaning	The gap can be filled by answers that would change the meaning of the text, e.g. 'and' or 'but'.
Bad	Answers can have different PoS	The gap can be filled by answers that have a different grammatical function, e.g. 'which' or 'and'.
Bad	Gap depends on another	There is some dependency between this gap and another in the text.
Bad	Repeated gap	There is already another gap testing the same word in the text.
Bad	Phantom gap	The gap does not require an answer for the text to make sense.
Bad	Unacceptable outlier	The gap does not fit in the text for multiple reasons (e.g. inappropriate difficulty).
Bad	Other (please specify)	Any other reason why the gap is considered unsuitable.

Table 2: Labels used in human annotation.

BERT Predicts potentially good gaps using BERT (Devlin et al., 2019) for token classification. We use the pre-trained base model with standard parameters and fine-tune the weights of the whole architecture.

Standard ELECTRA Similar to BERT, it predicts potentially good gaps using a standard pre-trained ELECTRA-base model. This is a single-objective model that is fine-tuned on token classification only.

Both **random** and **Exercise Maker** attempt to generate the same number of gaps per task as defined in the gold standard, although this is not always possible since the required conditions (such as specific words or PoS) are not always met.

6.3 Evaluation

We report precision (P), recall (R) and F_1 scores based on a strict matching between the gaps predicted by our models and those in the gold standard. While this evaluation strategy might seem strict, it has the advantage of being fully automatic, thus avoiding the subjectivity and time required by human evaluation, so we adopt it during development.

In addition to letting the models decide the optimal number of gaps, we also evaluate system performance when we fix the number of predicted gaps for each task to the number of gaps they have in the gold standard. The n-best predicted gaps are chosen based on their confidence scores. In this scenario, P, R and F_1 become the same.

We also report human evaluation by three test experts from CUP&A who volunteered for the task. The experts were asked to label each proposed gap in each task of our test set (a total of 360 gaps) as either good or bad and provide a reason and optional comments for their choice. The list of labels available to our annotators is shown in Table 2.

Model	P	R	F_1
Random baseline	15.29	14.87	15.08
Exercise Maker	23.33	25.79	24.50
BERT	51.16	47.65	49.34
Standard ELECTRA	55.61	46.00	50.35
Multi-objective ELECTRA	57.41	46.25	**51.23**

Table 3: Models' performance on the development set.

7 Results and Discussion

7.1 Automatic evaluation

We carry out automatic evaluation by computing P, R and F_1 on our development set. Table 3 reports the results of our multi-objective ELECTRA model (enhanced with dependency information) as well as the random baseline, Exercise Maker, BERT, and the standard single-task ELECTRA. This is our base model, which does not include any loss manipulation or post-processing. In this setting, the number of predicted gaps was decided by each model based on the confidence scores (> 0.5 for the positive class).

Overall, we observe that performance increases with more sophisticated models. Exercise Maker relies on previously seen gaps and so outperforms the random baseline by a large margin. However, it can only create gaps for the 139 words in its predefined FCE word list, missing gaps that are not on that list. Neural transformer-based models are the best, with improvements over Exercise Maker of at least 25 F_1 on our development set. Although the improvement of our multi-objective ELECTRA model over BERT does not seem to be very significant based simply on P, R and F_1, a closer look at the results reveals that BERT produces a much higher number of repeated gaps (25 compared to 9 by multi-objective ELECTRA) as well as more cases of gaps in close proximity, as shown in Figure 3.

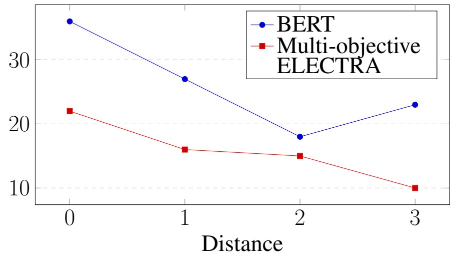

Figure 3: Frequency of pairs of gaps with distance ranging from 0 to 3. Distance is measured by the number of words in between two gapped words. The minimum acceptable number of words between two gaps is 4.

We also perform an ablation study in Table 3 where we compare our multi-objective ELECTRA model to a standard one that does not include our auxiliary language model objective. Results show that the former outperforms the latter on all metrics, confirming that the addition of the LM objective is clearly beneficial.

Table 4 shows the performance of our multi-objective ELECTRA model as we increase the *n*-best list of gaps according to their confidence score. The first row indicates the results of the system when it is forced to predict the exact same number of gaps per task as in the gold standard.[7] This causes P and R to be the same. As we expect, the results show that the number of gaps in the gold data is actually the optimal number to achieve the best F_1 score.

Although our multi-objective model shows good performance based on automatic evaluation, a closer look at the output reveals that the structure of the cloze tests is far from ideal as they often contain repetitions and gaps that are too close to each other, aspects that are carefully controlled in the gold standard. Table 5 shows that system performance effectively improves as we add the extensions proposed in Section 4, indicating that global aspects of the task are not properly captured by our initial model and require further manipulation.

In order to make the structure of our output as similar as possible to our target tasks, we fix the number of predicted gaps for each task to the number of gaps they have in the gold standard. Note that P and R are the same in this setting so we only report F_1. The effect of this decision is shown is Table 6. We can see that adding loss manipulation to our model decreases the number of adjacent gaps from 40 to 23, but increases the number of repeated gapped words from 18 to 33. The decline in the restricted F_1 based on automatic evaluation is not favourable, but we make this sacrifice at the price of achieving a better-structured final test.

# of predicted gaps	P	R	F_1
As-in-gold	54.26	54.26	**54.26**
10	56.72	42.80	48.14
15	51.49	56.93	54.07
20	44.83	66.07	53.42
30	35.63	78.78	49.07

Table 4: Results of multi-objective ELECTRA when we predefine the number of predicted gaps.

	P	R	F_1
Multi-objective ELECTRA	57.41	46.25	51.23
+ loss manipulation	47.87	59.85	**53.19**
+ post-processing	48.42	60.23	**53.68**

Table 5: Effect of loss manipulation and post-processing on our multi-objective ELECTRA model.

After adding post-processing for repeated gaps, we observe that, although overall F_1 performance drops slightly, the number of repeated gapped words decreases favourably from 33 to 9 (Table 6). It also creates a better spread of gaps, as shown by a lower KL-divergence between the average PoS distribution of the output and that of the gold standard (0.55 with post-processing as opposed to 0.59 without it). Post-processing also removes two cases in the development set where the gaps do not meet the minimum 4-word distance.

It is worth recalling that these extensions are highly effective when we do not restrict the number of predicted gaps. Table 5 shows that they significantly improve R, which results in higher overall F_1.

As a result of these experiments, we stick with our post-processing approach for the rest of our experiments and use it to produce the output submitted for human annotation.

7.2 Human evaluation

Following our intuition that test experts could find more value in our system than initially shown by our automatic evaluation, we asked a panel of three test experts to judge the quality of the gaps produced by our extended model on the test set. Inter-annotator agreement on gap classification (good/bad) was found to be moderate (percent agreement is 75.93%, Randolph's free-marginal kappa is 0.52 (Randolph, 2005)).

---

[7] The number of gaps can vary per passage (see Appendix A).

	Restricted F$_1$	Repeated gaps	Adjacent gaps
Multi-objective ELECTRA	54.26	18	40
+ loss manipulation	51.59	33	23
+ post-processing	51.33	**9**	**23**

Table 6: Analysis of our model after adding extensions: loss manipulation and post-processing.

Auto	Ann. 1	Ann. 2	Ann. 3
53.89	82.50	75.83	77.50

Table 7: Accuracy of our extended multi-objective ELECTRA model based on automatic and human evaluation on the test set.

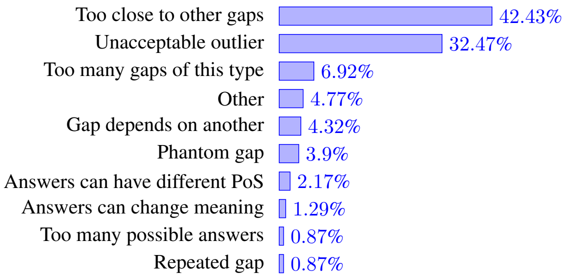

Figure 4: Average frequency of the reasons given by the annotators for rejecting a gap.

Unlike in automatic evaluation, we only report accuracy for our human experiment. System performance using automatic and human evaluation is compared in Table 7 (reported individually for each annotator). These results show that performance increases dramatically when the output is judged by human experts, confirming our suspicion that performance is underestimated by automatic evaluation and that there are many other words in the texts that could constitute equally useful gaps apart from those in the gold standard. With system accuracy ranging between $75\% - 82\%$ for human judgements, we can conclude that at least 7 out of 10 gaps proposed by our system are considered good by our experts.

We observed that differences between annotators' judgements and the gold-standard can occur for many reasons, e.g.:

- non-gaps in the gold standard are not necessarily bad gaps,
- gold standard gaps are derived from pilot testing while annotators' gaps are derived from their expertise,
- previous judgements by the annotators can affect the judgement of new gaps (e.g. choosing the best of two close gaps), etc.

Annotator accuracy against the gold standard ranges between $50\% - 60\%$.

Following our classification in Table 2, we analysed the reasons why some gaps were not considered good by the annotators. Figure 4 shows the average frequency of the different reasons given by the annotators for rejecting a gap proposed by our system. Examples are included in Appendix C.

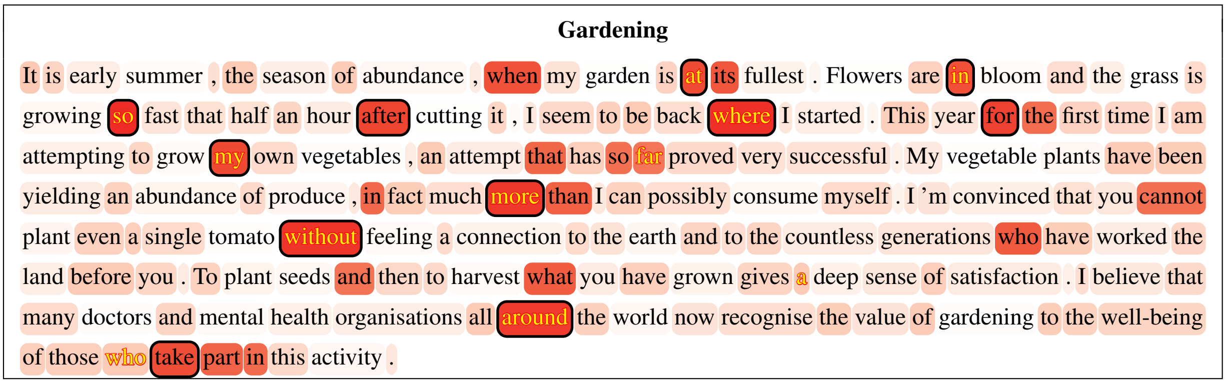
The most frequent reason is the violation of the minimum required distance between two gaps (42.43%). Although our loss-manipulation approach was successful in reducing these cases, we did not attempt to eradicate them completely since there are many factors at play when choosing more appropriate gaps than just distance. In many cases, gaps in close proximity test different words in the same phrase (e.g. *take part in*, *in addition to*, etc.) so we preferred to keep these cases and encourage annotators to comment on their preferences. Repetitions, on the contrary, are much better handled, accounting for only 0.87% of all bad gaps.

The second most frequent reason is 'unacceptable outlier' (32.47%), which normally accounts for cases where the difficulty of the gap is considered inappropriate for the target proficiency level (B2 in this case). This is an interesting phenomenon, since the fact that the text as a whole pertains to a given CEFR level does not guarantee that the gaps created will always be appropriate for the level. The remaining reasons are substantially less frequent than the first two and mostly related to aspects that were not explicitly controlled in our models, except for the third topmost reason ('Too many gaps of this type') which we did control by comparing PoS distributions. These results show that our system is able to capture many aspects of the task that were not explicitly modelled.

Finally, we compared system accuracy per task computed from annotators' judgements vs. the gold standard. Average correlation across all annotators was found to be very weak (Pearson's $r = 0.0558$, Spearman's $\rho = 0.1474$). This suggests that automatic scores are not a good proxy for human perception, with experts being much more positive about our model's output (as shown in Table 7).

7.3 Predictions by Gapped Word Frequency

We found that our model does not overfit to words that are most frequently gapped in the training data, with correlation between gapped word frequency



Gardening

It is early summer , the season of abundance , when my garden is at its fullest . Flowers are in bloom and the grass is growing so fast that half an hour after cutting it , I seem to be back where I started . This year for the first time I am attempting to grow my own vegetables , an attempt that has so far proved very successful . My vegetable plants have been yielding an abundance of produce , in fact much more than I can possibly consume myself . I 'm convinced that you cannot plant even a single tomato without feeling a connection to the earth and to the countless generations who have worked the land before you . To plant seeds and then to harvest what you have grown gives a deep sense of satisfaction . I believe that many doctors and mental health organisations all around the world now recognise the value of gardening to the well-being of those who take part in this activity .

Figure 5: Sample output of our extended ELECTRA model. Darker shades of red indicate higher confidence in inserting a gap. Predicted gaps are framed in black while gold standard gaps are in yellow font.

PoS	**Proportion in TEST**	**P**	**R**	**F_1**
ADP	20.59%	50.00	43.24	46.38
ADV	14.17%	57.69	58.82	58.25
DET	13.89%	56.41	44.00	49.44
SCONJ	13.89%	59.09	78.00	67.24
AUX	10.83%	45.83	28.21	34.92
PRON	9.44%	47.92	67.65	56.10
ADJ	4.44%	60.00	75.00	66.67
NOUN	3.33%	77.78	58.33	66.67
NUM	2.78%	61.54	80.00	69.57
CCONJ	2.50%	55.56	55.56	55.56
VERB	2.22%	50.00	50.00	50.00
PART	1.67%	0.00	0.00	0.00
INTJ	0.28%	50.00	100.00	66.67

Table 8: Performance by PoS on the test set based on automatic evaluation.

and F_1 scores in the test set being negligible (Pearson's $r = 0.0108$, Spearman's $\rho = 0.0915$).

Interestingly, while our model was unable to predict gaps not previously seen in the training data (*turned*, *amount*, *pushed* and *started*), it did predict a (previously unseen) gap for the word *fewer*, which did not match the gold standard but was unanimously deemed good by our annotators.

7.4 Predictions by PoS

We also classified predictions based on their PoS tags[8] and report performance in Table 8. The most frequently gapped PoS tags in our datasets correspond to closed word classes (such as ADP, DET, SCONJ, AUX, etc.), which is expected given that our open cloze tests are mostly focused on testing grammar rather than vocabulary. The best predicted classes, however, are NUM, SCONJ, NOUN, ADJ and INTJ which on closer inspection turn out to be very restricted classes: NUM includes only the word *one*, INTJ only the word *like*, SCONJ only a few subordinating conjunctions while NOUN and ADJ, despite being open classes, are limited to words used in common constructions such as *order* (*in order to*) or *same* (*the same*).

The two worst performing classes are PART (the particles *to* and *not*) and AUX (auxiliary verbs) and, once again, we conjecture that these words are so common in the language and in non-gapped positions that the model is unable to get them right most of the time. The remaining PoS classes vary in performance but we found only very weak correlation between PoS gap frequency in the test set and F_1 scores (Pearson's $r = 0.1932$, Spearman's $\rho = 0.1350$).

When we look at human annotations on the test set, however, performance by PoS is consistently higher and more even across the board. If we require that gaps are rated 'good' by at least two annotators, accuracy values range between 75% and 100% for all PoS, with a mean of 85%.

Under these conditions, the best performing classes are NOUN (100%), INTJ (100%) and ADJ (95%), which agree with automatic evaluation. Out of these, only NOUN achieves perfect accuracy across all annotators. The worst performing classes are PRON (77%), NUM (77%) and VERB (75%) as opposed to the previous AUX and PART counterparts (now 79% and 83% respectively). When we require agreement by all annotators, the worst overall class is CCONJ with 44%.

7.5 Qualitative Analysis

Figure 5 shows the output of our model for a sample text passage, where darker red indicates higher confidence in inserting a gap. The final model's

---

[8] Using the Universal Dependencies tagset: `https://universaldependencies.org/u/pos/`

predictions have a black frame (*at*, *in*, *so*, *after*, etc.) while the gold standard gaps are in yellow font (*at*, *in*, *so*, etc.). There are 8 matched gaps out of 11 in this example, yielding 72.73% accuracy.

As can be seen in the figure, our model is able to identify appropriate gap candidates, even if they do not match the gold standard. In fact, annotators considered all the unmatched gaps in this example (*after*, *for* and *take*) to be good and the second matched gap (*in*) to be inappropriate. It is also interesting to see how the model prioritises function words and content words that are highly restricted in context (such as *take* or *part*), skilfully avoiding general gaps that could accept multiple answers and would be less effective for testing purposes.

8 Conclusion and Future Work

We described the first transformer-based approach to open cloze test generation. Our ELECTRA-based model is trained on two objectives: token classification (gap/non-gap) and language modelling (for predicting the expected answer). The model is further improved by manipulating the loss function and post-processing the results.

System accuracy using automatic evaluation is 53.89% while human evaluation ranges between $75\% - 82\%$, showing that at least 7 out of 10 gaps predicted are considered useful by experts. A detailed analysis of results reveals a few structural problems such as gaps in close proximity and inappropriate difficulty, which we plan to address in future work. Our test data and human annotations are released with this paper.

Abstract

We introduce a method for unsupervised parsing that relies on bootstrapping classifiers to identify if a node dominates a specific span in a sentence. There are two types of classifiers, an inside classifier that acts on a span, and an outside classifier that acts on everything outside of a given span. Through self-training and co-training with the two classifiers, we show that the interplay between them helps improve the accuracy of both, and as a result, effectively parse. A seed bootstrapping technique prepares the data to train these classifiers. Our analyses further validate that such an approach in conjunction with weak supervision using prior branching knowledge of a known language (left/right-branching) and minimal heuristics injects strong inductive bias into the parser, achieving 63.1 F_1 on the English (PTB) test set. In addition, we show the effectiveness of our architecture by evaluating on treebanks for Chinese (CTB) and Japanese (KTB) and achieve new state-of-the-art results.[1]

1 Introduction

Pre-trained language models (PLMs) have become a standard tool in the Natural Language Processing (NLP) toolkit, offering the benefits of learning from large amounts of unlabeled data while providing modular function in many NLP tasks that require supervision. Recent work has shown that PLMs capture different types of linguistic regularities and information, for instance, the lower layers capture phrase-level information which becomes less prominent in the upper layers (Jawahar et al., 2019), span representations constructed from these models can encode rich syntactic phenomena, like the ability to track subject-verb agreement (Goldberg, 2019), dependency trees can be embedded within the geometry of BERT's hidden states (Hewitt and Manning, 2019), and most relevantly to this paper, syntactic information via self-attention mechanisms (Wang et al., 2019; Kim et al., 2020).

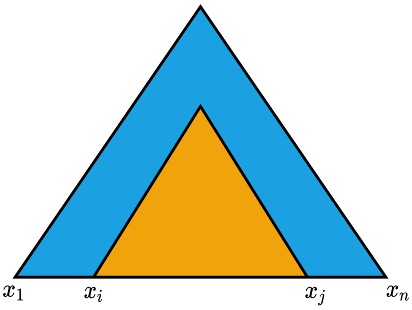

Figure 1: A depiction of a syntax tree, with the inside string as depicted by the sequence $x_i \cdots x_j$ and the outside string as depicted by the sequence $(x_1 \cdots x_{i-1}, x_{j+1} \cdots x_n)$ that provides external context for the inside representations.

We offer another perspective on the way PLMs represent syntactic information. We demonstrate the usability of PLMs to capture syntactic information by developing an unsupervised parsing model that makes heavy use of PLMs. The learning algorithm is light in the injection of hard bias to parse text, emphasizing the role of PLMs in capturing syntactic information.

Our approach to unsupervised parsing is inspired by recent work in the area of spectral learning for parsing (Cohen et al., 2014, 2013) and unsupervised estimation of probabilistic context-free grammars (PCFGs; Clark and Fijalkow, 2020). At its core, our learning algorithm views the presence or absence of a node dominating a substring in the final parse tree as a latent variable, where patterns of co-occurrence of the string that the node dominates (the "inside" string) and the rest of the sentence (the "outside" string) dictate whether the node is present or not. With spectral learning for latent-variable PCFGs (L-PCFGs; Cohen et al., 2014; Cohen and Collins, 2014) the notion of inside *trees* versus out-

side *trees* is important, but in our case, given that the trees are not present during learning, we have to further specialize it to extract information only from the strings.

Consider the diagram of a syntax tree in Figure 1, decomposed into two parts. Following the main notion in spectral learning, each of these parts (the orange part and the blue part) is a “view” of the whole tree that provides information on the identity of the node that spans the words $x_i \cdots x_j$. In the case of the tree being unobserved during training, we have to rely only on the substrings that are spanned by the blue part or the orange part, to hypothesize whether indeed a node exists there.

To represent the inside and outside views, we make use of PLMs. We encode these substrings, and then bootstrap a classifier that determines whether a given span is a constituent or not. The bootstrapping process alternates between the two views, and at each point adds predictions on the training set that it is confident about to train a new classifier. This can be thought of as a form of co-training (Yarowsky, 1995; Blum and Mitchell, 1998), a training technique that relies on multiple views of training instances. We formulate the task of identifying constituents and distituents (referring to spans that are not constituents) in a sentence as a binary classification task by devising a strategy to convert the unlabeled data into a classification task. Firstly, we build a sequence classification model by fine-tuning a Transformer-based PLM on the unlabeled training sentences to distinguish between the true and false inside strings of constituents. Secondly, we use the highly-confident inside strings to produce the outside strings. Additionally, through the use of semi-supervised learning techniques, we jointly use both the inside and outside passes to enrich the model's ability to determine the breakpoints in a sentence. Our final model achieves 63.1 sentence F_1 averaged over multiple runs with random seed on the Penn Treebank test set. We also report strong results for the Japanese and Chinese treebanks.

2 Problem Formulation and Inference

We give a treatment to the problem of unsupervised constituency parsing. In that setup, the training algorithm is given an unlabeled corpus (set of sentences) and its goal is to learn a function mapping a sentence x to an unlabeled phrase-structure tree y that indicates the constituents in x. In previous work with models such as the Constituent-Context Model (CCM; Klein and Manning 2002), the Dependency Model with Valence (DMV; Klein and Manning 2005), and Unsupervised Maximum Likelihood estimator for Data-Oriented Parsing (UML-DOP; Bod 2006), the parts of speech (POS) of the words in x are also given as input both during inference and during training, but we do not make use of such POS tags.

Inference While our learning algorithm is grammarless, for inference we make use of a dynamic programming algorithm, akin to CYK, to predict the parse tree. Inference assumes that each possible span in the tree was scored with a score function $s(i, j)$ where i and j are endpoints in the sentence. The score function is learned through our algorithm. We then proceed by finding the tree t^* such that:

$$t^* = \arg\max_{t \in \mathcal{T}} \sum_{(i,j) \in t} s(i, j),$$

where $\mathcal{T}$ is the set of possible binary trees over the sentence and $(i, j) \in t$, with a slight abuse of notation, denotes that the span (i, j) appears in t.

When $s(i, j)$ is the probability of a span (i, j) being in the correct tree, this formulation gives the tree with the highest expected number of correct constituents (Goodman, 1996). This formulation has been used recently by several unsupervised constituency parsing algorithms (Kim et al., 2019b,a; Cao et al., 2020; Li et al., 2020a).

3 Training Algorithm

At the core of our approach lies the notion of *inside* and *outside* strings. For a given sentence $x = x_1 \cdots x_n$ and a span (i, j), the inside string of span (i, j) is the sequence $x_i \cdots x_j$ while the outside string is the pair $(x_1 \cdots x_{i-1}, x_{j+1} \cdots x_n)$. We denote by $\boldsymbol{h}_{\text{in}}(i, j)$ representations for inside strings and $\boldsymbol{h}_{\text{out}}(i, j)$ representations for outside strings. Both are vectors derived from a PLM (RoBERTa; Liu et al. 2019, as we see later).

These two types of strings provide two views of a given possible splitting point in the syntax tree. We offer three ways, with increasing complexity, to bootstrap a score function that helps identify whether a node should dominate a given span. The main idea behind this bootstrapping is to start with a small seed set of training examples (x, i, j, b) where (i, j) is a span in a sentence x and $b \in \{0, 1\}$, depending on whether the span (i, j)

is dominated by a node in the syntactic tree or not. Bootstrapping the seed set is dependent only on either the inside string or the outside string, and the corresponding classifier built from this bootstrapped seed set returns a probability $p(b \mid x, i, j)$. Once a classifier is learned using the bootstrapping seed set, the classifier is applied on the training set, and the seed set is added to more examples where the classifier is confident of the label b. This is also known as self-training (McClosky et al., 2006, 2008).

In the next three sections, we present three learning algorithms of increasing complexity in their use of inside and outside strings.

3.1 Modeling Using Inside Strings

The inside model m_{in} which is modeled at a sentence level, computes an inside score $s_{\text{in}}(i, j)$ from the inside vector representation $\boldsymbol{h}_{\text{in}}(i, j)$ of each span in the unlabeled input training sentence $\mathbf{U}$. To compute $\boldsymbol{h}_{\text{in}}(i, j)$, we fine-tune the sequence classification model that encodes a fixed-vector representation for each token in the dataset. This captures the phrase information of the inner content in the span. In order to prepare the features for the inside model, we make use of a seed bootstrapping technique (Section 4.2.1). Once we build the inside model m_{in}, we get the most confidently-classified inside strings from $\mathbf{U}$ based on a set threshold $\tau = (\tau_{\text{min}}, \tau_{\text{max}})$. Here, τ_{min} and τ_{max}, form the confidence bounds to select distituents and constituents respectively. We select a random sample of c constituents and d distituents with appropriate labels from these most confident inside strings comprising the labeled inside set $\mathbf{I}$.

3.2 Modeling Using Inside and Outside Strings

To perform the iterative self-training procedure, we follow the steps as detailed in Figure 2. While building the outside model, we extract the tokens at the span boundaries of the pair of outside strings, which is of the form consisting of the triple (x_{i-1}, `[MASK]`, x_{j+1}). The outside model computes an outside score $s_{\text{out}}(i, j)$ from the outside vector representation $\boldsymbol{h}_{\text{out}}(i, j)$ of each span, which models the contextual information of the span. To compute $\boldsymbol{h}_{\text{out}}(i, j)$, we extract the triple for every span (i, j) in the dataset and fine-tune another sequence classification model that encodes a fixed-vector representation for each triple.

```
Inputs: I represents the labeled inside set; U is a set of unlabeled training sentences;

Algorithm:
  • Loop for $K$ iterations:
      1. Learn the inside classifier $m_{\text{in}}$ based on $\boldsymbol{h}_{\text{in}}(i, j)$ derived from I
      2. Use $m_{\text{in}}$ to label U to get the predicted inside strings $\hat{y}_{\text{in}}$
      3. If $\hat{y}_{\text{in}} > \tau_{\text{max}}$, extract $c$ constituents randomly and add it to the set of pseudo-constituents $\mathcal{X}_c$
      4. If $\hat{y}_{\text{in}} < \tau_{\text{min}}$, extract $d$ distituents randomly and add it to the set of pseudo-distituents $\mathcal{X}_d$
      5. $\mathbf{I} = \mathcal{X}_c \cup \mathcal{X}_d$
  • Get outside strings for each I; Assign to the set of labeled output sentences O
  • Learn outside model $m_{\text{out}}$ based on $\boldsymbol{h}_{\text{out}}(i, j)$ derived from O

Output: inside model $m_{\text{in}}$, outside model $m_{\text{out}}$
```

Figure 2: Our self-training algorithm.

3.3 An Iterative Co-training Algorithm

Co-training (Blum and Mitchell, 1998) is a classic multi-view training method, which trains a classifier by exploiting two (or more) views of the training instances. Our final learning algorithm is indeed inspired by it, where we consider the inside and the outside strings to be the two views. Once we have the inside m_{in} and the outside classifiers m_{out} that are trained on their respective conditionally independent inside $\boldsymbol{h}_{\text{in}}(i, j)$ and outside $\boldsymbol{h}_{\text{out}}(i, j)$ feature sets, we can make use of an iterative approach. At each iteration, only the inside strings $\hat{\mathbf{I}}$ that are confident to be likely the insides of constituents and distituents according to the outside model are moved to the labeled training set of the inside model $\mathbf{I}$. Thus, the outside model (teacher) provides the labels to the inside strings on which the inside model (student) is uncertain. Similarly, only the outside strings $\hat{\mathbf{O}}$ that are confident to be the likely outsides of constituents and distituents according to the inside model are moved to the labeled training set of the outside model $\mathbf{O}$. Thus, the inside model provides the labels to the outside strings on which the outside model is uncertain. We describe the steps in Figure 3. Finally, we combine the scores obtained by the inside and the outside model to get the score $s(i, j)$ for each span:

$$s(i, j) = s_{\text{in}}(i, j) \cdot s_{\text{out}}(i, j).$$

Co-training requires the two views to be independent of each other conditioned on the label of the

```
Inputs: $\mathbf{I}$ is the set of labeled inside sentences; $\mathbf{O}$ is the set of labeled outside sentences; $\mathbf{U}$ is a set of unlabeled sentences.

Algorithm: Loop for $K$ iterations:
    • Choose $c$ pseudo-constituents and $d$ pseudo-distituents from the most confidently predicted outside strings $\hat{y}_{\text{out}}$ from $\mathbf{U}$ based on $\tau$
    • Extract the inside strings $\hat{\mathbf{I}}$ corresponding to the $c$ pseudo-constituents and $d$ pseudo-distituents of outside
    • $\mathbf{I} = \mathbf{I} \cup \hat{\mathbf{I}}$
    • Train the inside model $m_{\text{in}}$ based on $\boldsymbol{h}_{\text{in}}(i, j)$ derived from $\mathbf{I}$
    • Choose $c$ pseudo-constituents and $d$ pseudo-distituents from the most confidently predicted inside strings $\hat{y}_{\text{in}}$ from $\mathbf{U}$ based on $\tau$
    • Extract the outside strings $\hat{\mathbf{O}}$ corresponding to the $c$ pseudo-constituents and $d$ pseudo-distituents of inside
    • $\mathbf{O} = \mathbf{O} \cup \hat{\mathbf{O}}$
    • Train the outside model $m_{\text{out}}$ based on $\boldsymbol{h}_{\text{out}}(i, j)$ derived from $\mathbf{O}$

Output: Two models $m_{\text{in}}$, $m_{\text{out}}$, that predict the inside and outside scores for unlabeled sentences. We combine these predictions by multiplying together and optionally re-normalizing their class probability scores.
```

Figure 3: Our co-training algorithm.

training instance. This is the type of assumption that, for example, PCFGs satisfy, when breaking a tree into an outside and inside tree: the two trees are conditionally independent given the nonterminal that connects them. In our case, we satisfy this assumption by creating inside and outside string representations separately, as we see later in Section 4.

Figure 4 illustrates the underlying pipeline of our weakly supervised parsing framework in an end-to-end fashion.

4 Experimental Setup

In this section, we describe our experimental setup: the data we use, the exact details of the experimental use of our approach to unsupervised parsing, and our evaluation methodology.

4.1 Data

We evaluate our methodology on the Penn Treebank (PTB; Marcus et al. 1993) with the standard splits (2-21 for training, 22 for validation, 23 for test). For preprocessing, we keep all punctuation and remove any trailing punctuation. To maintain the unsupervised nature of our experiments, we avoid the common practice of using gold parses of the validation set for either early stopping (Shen et al., 2018, 2019; Drozdov et al., 2019) or hyperparameter tuning (Kim et al., 2019a). Additionally, we experiment on Chinese with version 5.1 of the Chinese Penn Treebank (CTB; Xue et al. 2005) with the same splits as in Chen and Manning (2014), and the Japanese Keyaki Treebank (KTB; Butler et al. 2012). For KTB, we shuffle the corpus and use 80% of the sentences for training, 10% for validation, and 10% for testing.

4.2 Multi-view Learning

In this section, we devise the task of identifying constituents in a sentence by training two models with different views of the data. Ideally, these views complement each other and help each model improve the performance of the other.

4.2.1 Seed Bootstrapping

We treat identifying constituents from unlabeled sentences as a sequence classification task. To generate the *constituent* class, we take the complete sentence `(start:end)`, as a sentence in itself is a constituent, and also the largest among all of its other constituents. To generate the *distituent* class, we take `(start:end-1)`, $\cdots$, `(start:end-6)` slices, where `start` and `end` denote the 0^{th} and N^{th} position (sentence length) respectively. We select the distituents in this manner because the longer the sentence, there would be a significantly unlikely chance that the span of the constituents extends till the very end of the sentence. Additionally, we make use of casing-specific information by adding contiguous title-case words while allowing only the apostrophe mark. Since all of the sentences for the constituent class start with capital letters, we identify the most common first word and generate lower-case equivalents of contiguous title-case words, which starts with it to account for bias due to the casing of spans. While we do use a fixed template to perform the seed bootstrapping process, this is part of the inductive bias of the algorithm, and is relatively easy to acquire. In our analysis, we assume the language is already known before and thereby its *structure* (left/right-branching), a form of weak supervision.

For CTB, we follow the exact same process as PTB for preparing the input data for the first-level sequence classifier, but we do not rely on case-specific information and perform no post-processing. Meanwhile, since KTB is a treebank of a strongly left-branching language, we design our modeling approach slightly differently compared to before, although along the same style. To prepare the data for the sequence classifier, we choose

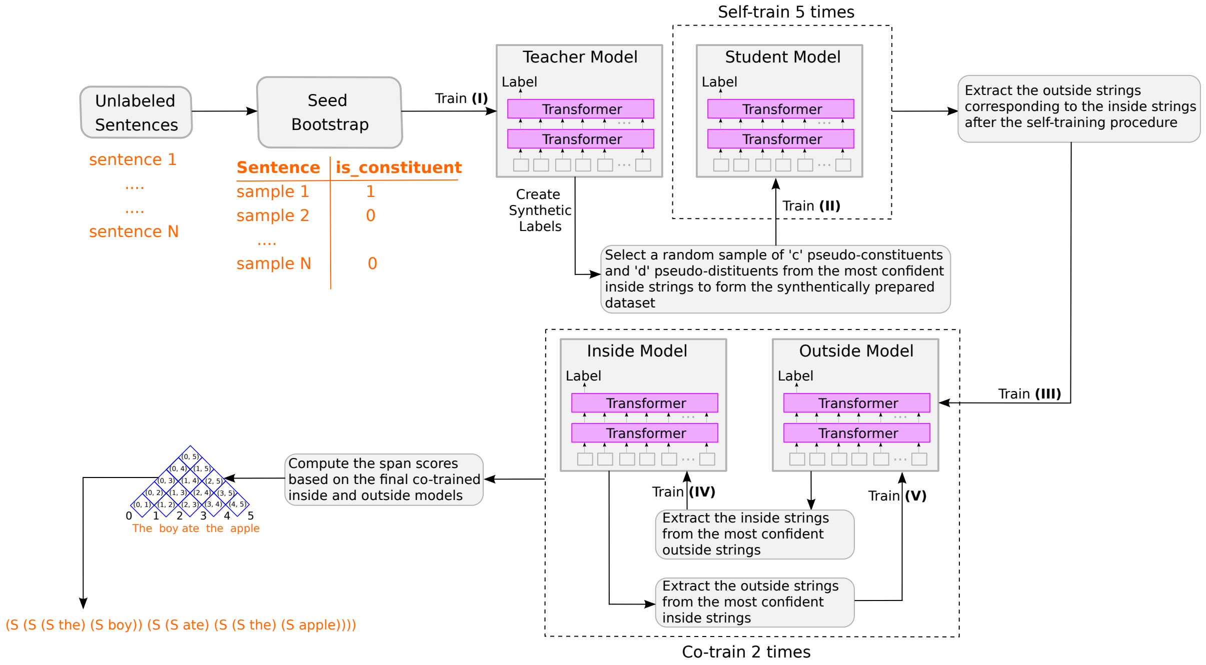

Figure 4: Block diagram detailing our approach. We perform the self-training procedure for five iterations which follow multiple steps; **(I)**: Fine-tune a RoBERTa$_{\text{BASE}}$ model (teacher) on a downstream task using a cross-entropy loss after seed bootstrapping; **(II)**: Synthetically annotate this data using the teacher model and select top K samples corresponding to each class to form the final synthetic dataset; We fine-tune a RoBERTa$_{\text{BASE}}$ model (student) on this dataset using hard labels and retrieve the outside strings from the most confident insides; **(III)**: Train the outside classifier on these outside strings; We perform the co-training procedure for two iterations which follow a two-fold optimizing step; **(IV)**: Retrieve the inside strings from the most confident outsides and train the inside classifier; **(V)**: Retrieve the outside strings from the most confident insides and train the outside classifier.

the slice `(start:end)` in the sentence to label the *constituent* class, whereas, `(start+1:end)`, $\cdots$, `(start+4:end)` slices are chosen to label the *distituent* class. We also split the sentences on "$\star$" mark and treat the resulting fragmented parts as constituents too. Our training does not depend on the development set with the gold-standard annotated trees since we base the necessary string slicing decision on the feedback from the validation split after the bootstrapping procedure in an iterative fashion (increment/decrement the value of slice counter by 1) until we see a degradation in performance (measured using F_1 score) on the synthetic set of seed constituents and distituents.

4.2.2 Inside Model

We fine-tune the RoBERTa model with a sequence classification layer on top using a cross-entropy loss (see Section A.1 in Appendix for training and hyperparameter details). As we supply input data, the entire pre-trained RoBERTa$_{\text{BASE}}$ model and the additional untrained classification layer is trained on our specific downstream task. To compute $\boldsymbol{h}_{\text{in}}(i,j)$, we run the RoBERTa$_{\text{BASE}}$ model and retrieve the `[CLS]` token representation for the span enclosed between the i^{th} and the j^{th} element. The inside model is evaluated on MCC (Matthews Correlation Coefficient) as well as F_1 because the classes are imbalanced. After fine-tuning, our best inside model achieves 0.62 MCC and 0.91 F_1 on the internal validation set. Finally, we fine-tune the inside model on the unlabeled training sentences that generates an inside score $s_{\text{in}}(i,j)$ for every span. Since our major focus was on PTB, we have listed a few *heuristics* that inject further bias into the algorithm acting as the another form of weak supervision. Moreover, incorporating such rules was not necessary for CTB and KTB as our models showed superior performance without them.

Once we compute the inside score, $s_{\text{in}}(i,j)$, we use the following refinement strategies to prune out false constituents: We delete any constituent if it starts or ends with the most common word succeeding the comma punctuation. Additionally, we take the most common starting word and check if its accompanying word does not belong to the NLTK stop words list. We assign the scores of these corresponding spans in the CYK chart cell to the maximum value. Intuitively, from the linguistic definition of constituents, we refrain from bracketing if we identify a contiguous group of rare title-case or uppercase words (tokens not in the top 100 most frequent list in the PTB training sentences). These heuristics only contribute to a certain extent in making the parser strong, and should be considered as a standard post-processing step. Overall, we observe 3.8 F_1 improvements in the case of the inside model. We further note that the contribution due to additional heuristics is much less than the combined self-training and co-training gains since their effect becomes insignificant after multiple iterations of the self-training process due to the predictions approximately following the template rules. As described in Figure 2, we perform self-training on the inside model for five iterations.[2]

4.2.3 Outside Model

We extract the outside strings of spans having the inside score satisfying a pre-determined cut-off value. The Constituent-Context Model (Klein and Manning, 2002) use a smoothing ratio of 1:5 (constituents to distituents) for the WSJ-10 section to take into account the skewness of random spans more likely to represent distituents. In the same vein, the values of lower and upper bounds of the threshold are chosen to ensure the distribution of class labels is about 1:10 (with the distituent class being the majority) which is a crude estimate considering much larger sentence lengths in the WSJ-Full section. Moreover, from a linguistic standpoint, we can be certain that the distituents must necessarily outnumber the constituents. For the self-training experiments, we set the thresholds, τ_{min} as 0.0005 and τ_{max} as 0.995. We treat the outside strings satisfying the upper and lower bounds of the threshold as *gold-standard outside* of constituents and distituents respectively. To compute $\boldsymbol{h}_{\text{out}}(i, j)$, we run the RoBERTa$_{\text{BASE}}$ model on left-outside, i.e., $(i-1)^{\text{th}}$ element and right-outside, i.e., $(j+1)^{\text{th}}$ element, along with a `[MASK]` placeholder token separating the two, and extract the `[CLS]` token representation. As done previously, we fine-tune the outside model on the unlabeled training sentences that generates an outside score $s_{\text{out}}(i, j)$ for every span.

Table 1: Unlabeled sentence-level F_1 on the full as well as sentences of length ≤ 10 of the PTB test set without punctuation or unary chains. We evaluate each model using the evaluation script provided by Kim et al. (2019a) and take the baseline numbers of certain models from (Kim et al., 2019a; Cao et al., 2020). † denotes models trained without punctuation and ⋆ denotes models trained on additional data.

4.2.4 Jointly Learning with Inside and Outside Models

Once we have the outside model, we run it on the training sentences and choose the outside string that the classifier is highly confident about. We extract their inside strings again using the same bounds of the threshold as done previously and retrain the inside model on the *old highly confident inside strings* along with the *new inside strings obtained from the highly confident outside strings*. Similarly, the same technique can be applied to the outside model to augment its input data too. We repeat this process twice (Figure 3).

4.3 Evaluation

We report the F_1 score with reference to gold trees in the PTB test set (section 23). Following prior work (Kim et al., 2019a; Shen et al., 2018, 2019; Cao et al., 2020), we remove punctuation and collapse unary chains before evaluation, and calculate F_1 ignoring trivial spans, i.e., single-word spans and whole-sentence spans, and we perform the averaging at sentence-level (macro average) rather than span-level (micro average), which means that we compute F_1 for each sentence and later average over all sentences. We also mention the oracle upper bound, which is the highest possible score with binarized trees since we compare them against

---

[2] We only use the top 5K inside strings for self-training to cover maximum possible iterations as it is representative of the whole training set in terms of the average sentence length and punctuation marks.

Table 3: Evalb F_1 on the full (F_1-all) and length ≤ 10 (F_1-10) sentences of the KTB test set discarding punctuation corresponding to KTB-40 and KTB-10, respectively. We take the baseline numbers of models from Li et al. (2020b). See Table 7 to view the hyperparameters used for `evalb`.

non-binarized gold trees according to the convention, as most unsupervised parsing methods output fully binary trees. We additionally use the standard PARSEVAL metric computed by the `evalb` program.[3] Although `evalb` calculates the micro average F_1 score, it differs from our micro average metric in the sense that it counts the whole sentence spans, and calculates duplicated spans instead of removing them. Following the recommendations put forth by previous work that has done a comprehensive empirical evaluation on this topic (Li et al., 2020b), we report results on both length ≤ 10 as well as all-length test data.

5 Results and Discussion

Table 1 shows the unlabeled F_1 scores for our model compared to existing unsupervised parsers on PTB. The vanilla inside model is in itself competitive and is already in the range of previous best models like DIORA (Drozdov et al., 2019), Compound PCFG (Kim et al., 2019a).[4] See Appendix A.5 to assess our model's performance on unsupervised labeled parsing.

We further evaluate how our method works for languages with different branching types – Chinese (right-branching) and Japanese (left-branching). We use Transformer models for the representations of the spans for both Chinese and Japanese. See Section A.1 in the Appendix for training details. Tables 2 and 3 shows the results for CTB and KTB respectively. Moreover, we do not include a few models chosen previously for PTB during our analysis, as extending those models for CTB or KTB is non-trivial due to several reasons: such as lack of domain-related datasets (as DIORA uses SNLI and MultiNLI for training), and lack of linguistic knowledge expertise (not easily cross-lingual transferable notion for designing constituency tests).

Figure 8 in the Appendix shows step-wise qualitative analysis for a sample sentence taken from the PTB training set. See Figures 9 and 10 in Appendix to see the visualization for an example tree at every stage of the pipeline for CTB and KTB respectively. As we can observe from all the example tree outputs, the parser using the inside and outside models after the co-training stage produces fewer crossing brackets than the vanilla inside model.

5.1 Effect of Self-training

PLMs that possess rich contextualized textual representations can assist parsing when we have a large volume of unlabeled data. For this reason, we might expect that self-training in combination with pre-training adds no extra information to the fine-tuned parser. However, we find that self-training improves the performance of the parser by about 9.8%, demonstrating that self-training provides advantages complementary to the pre-trained contextualized embeddings (see Table 5 in Appendix for

---

[3] `https://nlp.cs.nyu.edu/evalb`

[4] We do not include the results of Shi et al. (2021) in our analysis because their boost in the performance is contingent on the nature of the supervision data (especially the QA-SRL dataset) rather than on the actual learning process itself. Furthermore, the authors mention that a vast amount of hyperlinks match syntactic constituents, hence restricting the scope for the actual algorithm to derive meaningful trees.

	PRPN	ON	URNNG	Compound PCFG	S-DIORA	Constituency Test	Our Best Parser
SBAR	50.0	51.2	74.8	56.1	59.2	66.1	**81.7**

a more detailed analysis at different stages).

5.2 Effect of Co-training

The question of how to integrate multi-view information is important. One of the options would be to concatenate both the inside and outside vectors while performing training and inference. With this experiment setting, we see negligible improvement as it only scores 13.2 F_1 on the PTB test (without self-training). The whole idea of separating the two models for co-training is to learn constituent boundaries to identify the splitting points in a sentence through independent views of data. This corroborates the effectiveness of co-training compared with concatenation: the simple concatenation strategy cannot fully harvest the information corresponding to each view and indeed render the optimization intractable. After co-training, the parser achieves 63.1 F_1 averaged over four runs, outperforming the previous best-published result (see Table 6 in Appendix to view the improvement at each step). Figure 6 in Appendix compares the performance of different models over varying sentence length (see Figure 5 in Appendix to understand the extent to which bootstrapping helps compared to the vanilla inside model).

5.3 Effect of Distituent Selection

To understand the extent to which the type of the disitituent selection impacts the performance, we assess two settings on the PTB – random and left-branching bias. In the random setting, we select distituents from the slice `(start:`r`)`, where r is a random number generated between `start+1` and `end-1`, both inclusive. This produces 19.3 F_1 for the inside model. Whereas, in the left-branching bias setting, we prepare the seed bootstrapping process as explained in the Section 4.2.1 similar to KTB (a left-branching treebank). This results in 11.2 F_1 score for the inside model. Hence, the manner in which we perform the initial classification has a strong impact on the final tree structures.

5.4 Linguistic Error Analysis

Table 4 shows that our model achieves strong accuracy while predicting all the phrase types except for the Adjective Phrase (ADJP). We list some of the most common mistakes our parse makes and suggest likely explanations for each:

Bracketing inner NP of a definite Noun Phrase. When a definite article is linked with a singular noun, the inner spans need to be shelved, accommodating the larger span with the definite article. E.g.: *the* [*stock market*]

Grouping NP too early overlooking broader context. Due to the way it is trained, the parser aggressively groups rare words in the corpus. Building a better outside model can fix this type of error to a considerable extent. E.g.: *Shearson* [*Lehman Hutton*] *Inc.*

Omitting conjunction joining two phrases. It shows poor signs of understanding co-ordination cases in which conjunction is an adjacent sibling of the nodes being shifted, or is the leftmost or rightmost node being shifted. E.g.: *Notable* [*& Quotable*]

Confusing contractions with Possessives. Due to the presence of a lot of contraction phrases like (*they're*, *it's*), the parser confuses it with that of the Possessive NPs, causing unnecessary splitting. Expanding the contractions can be a good way to correct these systematic errors. E.g.: *the company* [*'s $ 488 million in 1988*]

In the future, we would like to develop error analysis protocols for both CTB and KTB using human-in-the-loop process (leveraging feedback from the respective language experts) and provide an in-depth statistical analysis.

6 Related Work

Recently, neural network-based approaches have shown promising results on inducing parse trees directly from words. Our weakly-supervised parser is comparable in behavior to a fully unsupervised parser as it does not rely on syntactic annotations. We highlight some themes most relevant to our method.

Learning from distant supervision. A related work to ours (Shi et al., 2021) uses answer fragments and webpage hyperlinks to mine syntactic constituents for parsing. Many previous studies depend on punctuation as a strong signal to detect constituent boundaries (Spitkovsky et al., 2013; Parikh et al., 2014).

Incorporating bootstrapping techniques. Co-training (Yarowsky, 1995; Blum and Mitchell, 1998; Abney, 2007) and self-training (Steedman et al., 2003; McClosky et al., 2006; Cohen and Smith, 2010) are bootstrapping methods that attempt to convert a fully unsupervised learning problem to a semi-supervised learning form. More recently, Mohananey et al. (2020); Shi et al. (2020); Steedman et al. (2003) have shown the benefits of using self-training as a standard post-hoc processing step for unsupervised parsing models.

Using inside-outside representations constructed with a latent tree chart parser. Drawing inspiration from the inside-outside algorithm (Baker, 1979), DIORA (Drozdov et al., 2019) optimizes an autoencoder objective and computes a vector representation for each node in a tree by combining child representations recursively. To recover from errors and make DIORA more robust to local errors when computing the best parse in the bottom-up chart parsing, an improved variant of DIORA, S-DIORA (Drozdov et al., 2020) achieves it.

Inducing tree structure by introducing an inductive bias to RNNs. PRPN (Shen et al., 2018) introduces a neural parsing network that has the ability to make differentiable parsing decisions using structured attention mechanism to regulate skip connections in an RNN. ON-LSTM (Shen et al., 2019) enables hidden neurons to learn information by a combination of gating mechanism as well as activation function. In URNNG, Kim et al. (2019b) employs parameterized function over latent trees to handle intractable marginalization and inject strong inductive biases for the unsupervised learning of the recurrent neural network grammar (RNNG; Dyer et al. 2016). Peng et al. (2019) introduces PaLM that acts as an attention component on top of RNN.

Enhancing PCFGs. Compound PCFG (Kim et al., 2019a) which consists of a Variational Autoencoder (VAE) with a PCFG decoder, found the original PCFG is fully capable of inducing trees if it uses a neural parameterization. Jin et al. (2019) show that the flow-based PCFG induction model is capable of using morphological and semantic information in context embeddings for grammar induction. Zhu et al. (2020) proposes neural L-PCFGs to simultaneously induce both constituents and dependencies.

Concerning PLMs. Tree Transformer (Wang et al., 2019) adds locality constraints to the Transformer encoder's self-attention such that the attention heads resemble a tree structure. Kim et al. (2020) extract trees from pre-trained transformers.

Refining based on constituency tests. With the help of transformations and RoBERTa model to make grammaticality decisions, (Cao et al., 2020) were able to achieve strong performance for unsupervised parsing.

7 Conclusion

We propose a simple yet effective method of inducing constituency trees which is the first of its kind in achieving performance comparable to the supervised binary tree RNNG model and setting a new state-of-the-art result for unsupervised parsing using weak supervision. Our model generalizes to multiple languages of known treebanks. We have done comprehensive linguistic error analysis showing a step-by-step breakdown of the F_1 performance for the inside model, inside model with self-training, and the inside-outside model with a co-training-based approach. The effectiveness of our multi-view learning strategy is evident in our experiments. Future work could aim to augment the parser's capabilities to investigate cross-domain generalization and efficient cross-lingual transfer.

A Further Details

A.1 Training Details

We use the Adam optimizer and, on the bootstrapped dataset, fine-tune `roberta-base` consisting of default 125M trainable parameters with a learning rate $3e-5$, batch size 32, maximum epochs 10, maximum sequence length 256, and gradient checkpointing for all our models. The values were chosen as default based on sequence classification tasks on the GLUE benchmark[5] as mentioned in HuggingFace Transformers.[6] We use a train/validation random split of 80/20 on the bootstrapped dataset which contains 100,000 sentences (50,152 for the distituent class and 49,848 for the constituent class) to monitor the validation loss and perform early stopping. The average sentence length is about 22 tokens. Note that the development set of PTB is kept untouched. We set the patience value at 2. Model checkpointing, as well as logging, is carried out after every 100 steps.

We use a p3.8xlarge AWS instance with a single GPU having 64 GB memory to conduct all our experiments. The estimated training time for the inside model is about 0.2h, inside model with self-training (3 iterations) is about 12h, and inside-outside model with co-training (2 iterations) is about 18h. While the inference time for all the models is roughly 1h.

For the Chinese monolingual experiment, we use `bert-base-chinese` which is trained on cased Chinese Simplified and Traditional text, and for Japanese monolingual experiment, we use `cl-tohoku/bert-base-japanese` which is trained on Japanese Wikipedia available at https://huggingface.co/models.

Training Data We tried several strategies to augment the *distituent* class for our models, but without concrete gains. Some of those include word deletion (randomly selects tokens in the sentence and replace them by a special token), span deletion (Same as word deletion, but puts more focus on deleting consecutive words), reordering (randomly sample several pairs of span and switch them pairwise) and substitution (sample some words and replace them with synonyms).

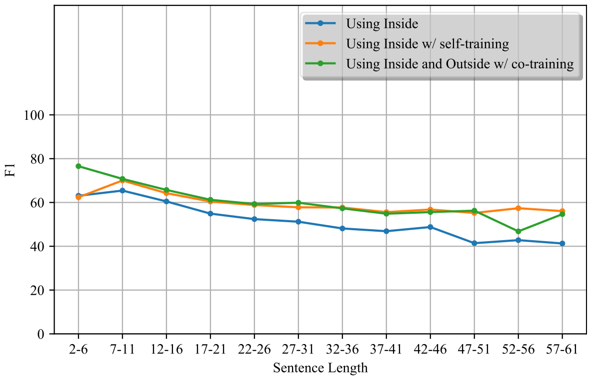

Figure 5: F_1 grouped by sentence length on the PTB test set for different strategies.

Model	#ST-steps			
	0	1	2	3
Inside	55.9	57.7	59.5	61.4

Table 5: Unlabeled sentence-level F_1 on the full PTB test set after applying the iterative Self-training algorithm on the Inside model.

A.2 Effect of Bootstrapping

As shown in Figure 5, the final model with co-training identifies constituents from shorter sentences (WSJ-10) much more precisely compared to the rest of the models. There is a lower performance in F_1 around sentence length of 50-55 zone, but that improves for longer sentences.[7]

A.3 Stages of Self-training

Self-training boosts the performance of the inside model by 5.5 F_1 points as shown in Table 5. As can be seen, the effect of the initial set of candidate constituents and distituents on the final performance is 55.9 F_1 which is not insignificant.[8]

A.4 Stages of Co-training

After co-training, the performance of the inside-outside joint model increases by 1.7 F_1 points as shown in Table 6. Compared to using self-training, one of the reasons the benefit is not significant may be attributed to the fact that the inside vectors (built upon Transformer architecture) inher-

ently possesses contextual knowledge due to being trained on a large corpus.

A.5 Unsupervised Labeled Parsing

We explore unsupervised labeled constituency parsing to identify meaningful constituent spans such as Noun Phrases (NP) and Verb Phrases (VP) to see if the parser can extract such labels. Labeled parsing is usually evaluated on whether a span has the correct label. We can effectively induce span labels using the clustering of the learned phrase vectors from the inside and outside strings. When labeling a gold bracket, our method achieves 61.2 F_1 on the full PTB test set and is comparable with the current best model, DIORA. See Figure 7 to view the visualization of induced and linguistic alignment. RoBERTa does not strictly output word-level vectors. Rather, the output are subword vectors which we aggregate with mean-pooling to achieve a word-level representation using `SentenceTransformers`.[9] We use 600 codes while doing the clustering initially, such that we are left with about 25 clusters after the most common label assignment process, i.e., the number of distinct phrase types. The phrase clusters are assigned to {'NP': 7, 'PP': 5, 'WHPP': 3, 'ADVP': 3, 'ADJP': 2, 'S': 2, 'WHADVP': 1, 'UCP': 1, 'VP': 1, 'PRN': 1, 'QP': 1, 'SBAR': 1, 'WHNP': 1, 'CONJP': 1} according to the majority gold labels in that cluster. These 14 assigned phrase types correspond with the 14 most frequent labels. Table 8 lists the induced non-terminal grouped across different clusters and also their correctness in identifying the gold labels. The further course of action would be to have a joint single model that is capable of achieving both bracketing and labeling. Further, these induced labels can function as features for the inside and outside models to achieve even better predictive ability. It also warrants a multi-lingual exploration in this area.

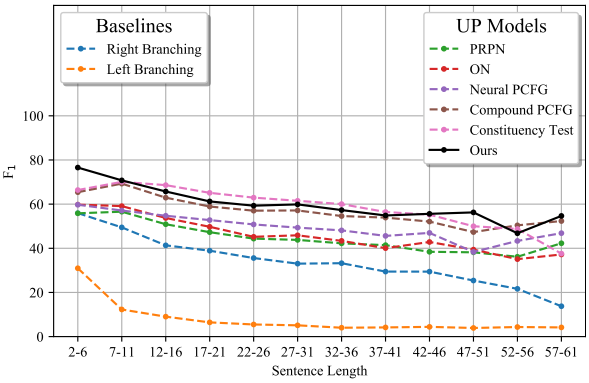

Figure 6: F_1 of different models grouped by sentence length on PTB test set.

A.6 Non-Terminal Label Alignment

Figure 7 shows the alignment between gold and induced labels. We observe that some of the induced non-terminals clearly align to linguistic non-terminals. For instance, S-2 non-terminal has a high resemblance with NP. Similarly, S-8 has a high resemblance with ADVP.

Abstract

Transformer-based language models usually treat texts as linear sequences. However, most texts also have an inherent hierarchical structure, i. e., parts of a text can be identified using their position in this hierarchy. In addition, section titles usually indicate the common topic of their respective sentences. We propose a novel approach to formulate, extract, encode and inject hierarchical structure information explicitly into an extractive summarization model based on a pre-trained, encoder-only Transformer language model (HiStruct+ model), which improves SOTA ROUGEs for extractive summarization on PubMed and arXiv substantially. Using various experimental settings on three datasets (i. e., CNN/DailyMail, PubMed and arXiv), our HiStruct+ model outperforms a strong baseline collectively, which differs from our model only in that the hierarchical structure information is not injected. It is also observed that the more conspicuous hierarchical structure the dataset has, the larger improvements our method gains. The ablation study demonstrates that the hierarchical position information is the main contributor to our model's SOTA performance.

1 Introduction

Texts, especially long documents, contain internal hierarchical structure like sections, paragraphs, sentences, and tokens. When we manually summarize a text, the hierarchical text structure usually plays a key role. Taking a scientific paper as an example, we might focus more on the sections with the titles of "methodology", "discussion", and "conclusion" while paying less attention to the sections like "background". Furthermore, the sentences within one section could have closer relationship with each other, than the ones outside this section. Understanding not only the sequential relations between the sentences but also the internal hierarchical text structure helps us better determine the important sentences within a document. Similarly, a neural summarization model could benefit from these hierarchical structure information.

In this paper, we focus on extractive text summarization of single documents, which is the task of binary sentence classification with labels indicating whether a sentence should be included in a summary. Recently, pre-trained language models based on Transformer (Vaswani et al., 2017), such as BERT (Devlin et al., 2019), have been widely used to extract contextual representations from texts. The pre-trained Transformer language models (TLMs) can be easily reused for fine-tuning on the downstream tasks, so that the representations already learned from the large pre-training corpora are preserved. Liu and Lapata (2019) have achieved the state-of-the-art (SOTA) performance by fine-tuning BERT for extractive summarization on short document datasets including CNN/DailyMail. However, the TLMs consider merely the sequential-context-dependency by adding a linear positional encoding to each input token embeddings. The hierarchical text structure information is not taken into account explicitly.

We propose a novel approach to formulate, extract, encode and inject the hierarchical structure (HiStruct) information explicitly into an extractive summarization model (HiStruct+ model), which consists of a TLM for sentence encoding and two stacked inter-sentence Transformer layers for hierarchical learning and extractive summarization (see Figure 1). We experiment with BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and Longformer (Beltagy et al., 2020) as underlying TLMs. The HiStruct information utilized in our work includes the section titles and the hierarchical positions of sentences, which are encoded using our proposed novel methods. The resulting embeddings can be injected into the TLM sentence representations to provide the HiStruct information for the summarization task.

Findings of the Association for Computational Linguistics: ACL 2022, pages 1292 - 1308
May 22-27, 2022

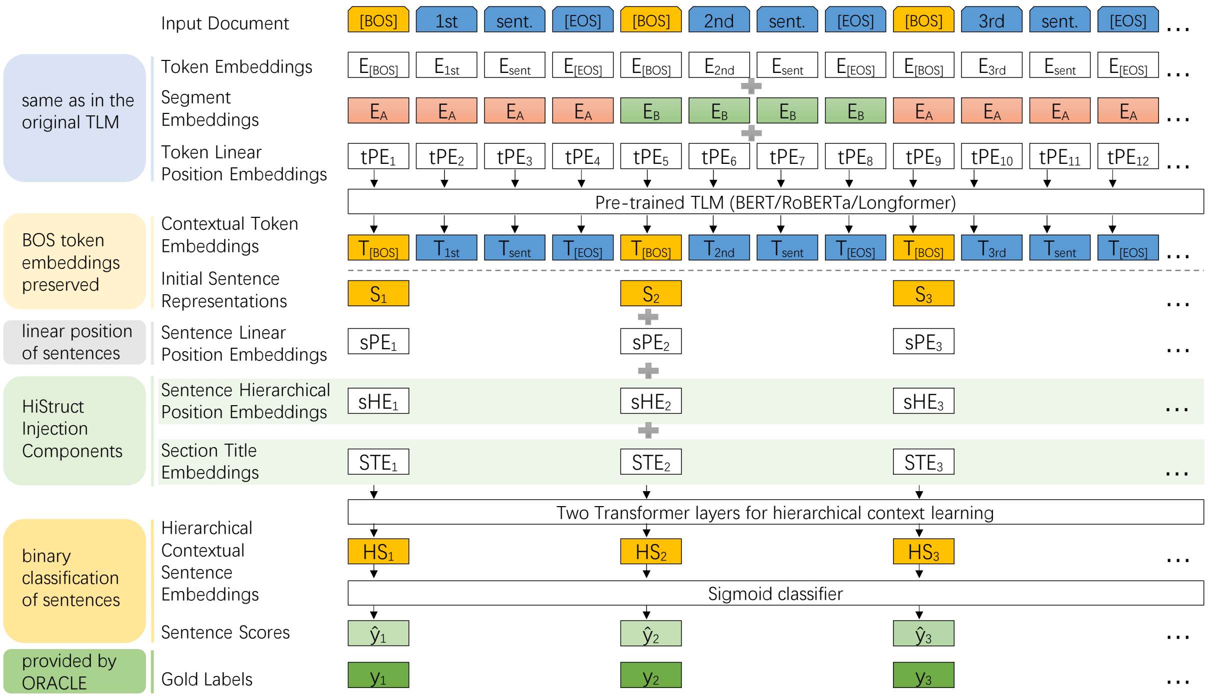

Figure 1: Architecture of the HiStruct+ model. The model consists of a base TLM for sentence encoding and two stacked inter-sentence Transformer layers for hierarchical contextual learning with a sigmoid classifier for extractive summarization. The two blocks shaded in light-green are the HiStruct injection components.

The HiStruct+ models are evaluated on short documents (i. e., CNN/DailyMail (See et al., 2017)) and long documents (i. e., PubMed and arXiv (Cohan et al., 2018)) with various hierarchical characteristics. Our models produce competitive results on CNN/DailyMail and set the SOTA ROUGEs for extractive summarization on PubMed and arXiv to a new level. We also compare the HiStruct+ models with the corresponding strong baselines, which differ from our models only in that the HiStruct information is not injected. Using various experimental settings, our models collectively outperform the baselines on the three datasets, indicating the effectiveness of the proposed HiStruct encoding methods. The improvements are especially substantial on PubMed and arXiv, which contain longer scientific papers with conspicuous hierarchical structures. Ablation studies suggest that the performance gains are mainly contributed by the hierarchical position information of sentences.

Our contributions in this work are four-folds: (1) We conceptualize novel measures to compare the internal hierarchical structure of the datasets. (2) We propose novel methods to formulate the HiStruct information and implement data preprocessing to extract them from the raw datasets. (3) We propose novel methods to encode and inject the HiStruct information into an extractive summarization model explicitly. The effects of different encoding settings and injection settings are systematically investigated. (4) The data containing the extracted HiStruct information, the best HiStruct+ models, as well as the scripts for preprocessing, training and evaluation are available on GitHub[1].

2 Related Work

2.1 Text Summarization

Extractive Text Summarization (ETS) is to classify sentences within a document with labels indicating whether a sentence should be included in the summary. Liu and Lapata (2019) fine-tune BERT with stacked Transformer layers and a sigmoid classifier (BERTSUMEXT). Instead of directly utilizing the existing Transformer encoder for document encoding, Zhang et al. (2019) pre-train a hierarchical Transformer encoder consisting of a sentence encoder and a document encoder (HIBERT) and fine-tune it for ETS. For long documents, Xiao and Carenini (2019) propose a RNN-based ETS model incorporating both the global and the local context (ExtSum-LG). To address the problem of redundancy in extractive summaries, the authors fur-

---

[1] https://github.com/QianRuan/histruct

ther improve their work by introducing redundancy reduction (Xiao and Carenini, 2020). They systematically explore and compare different methods including Trigram Blocking (Paulus et al., 2018), RdLoss, MMR-Select and MMR-Select+ (Xiao and Carenini, 2020). Trigram Blocking is a traditional redundancy reduction method that avoids adding a candidate sentence to the summary if it has trigram overlap with the previously selected sentences. Their previous model combined with the redundancy reduction methods produce SOTA performance for ETS on PubMed and arXiv (Xiao and Carenini, 2020).

Previous works on extractive summarization model hierarchical structure of documents by introducing a hierarchical attention, where they first learn contextual token representations based on the linear dependencies between tokens and then add additional CNN (Cheng and Lapata, 2016) or RNN (Nallapati et al., 2017) or Transformer (Zhang et al., 2019; Liu and Lapata, 2019) layer(s) to learn document-level representations for each sentence based on the linear dependencies between sentences. However, they learn hierarchical representations of sentences in an implicit way. The models are like black boxes, lacking interpretability. In contrast, our proposed approach enriches sentence representations in an explicit way by using section titles and hierarchical positions of sentences as additional HiStruct information, which is more intuitive and interpretable.

Abstractive text summarization (ATS) is to generate summaries with new sentences which are not present in the source text. BERTSUMABS (Liu and Lapata, 2019) uses the pre-trained BERT as the encoder in its encoder-decoder architecture. Instead of simply using the pre-trained BERT, recent works, including T5 (Raffel et al., 2020), BART (Lewis et al., 2020) and PEGAUSUS (Zhang et al., 2020) pre-train encoder-decoder models specifically for seq2seq tasks. The first attempt at addressing neural abstractive summarization of long documents is undertaken by Cohan et al. (2018). Aksenov et al. (2020) overcome the length limitations of BERT by a new method of BERT-windowing, allowing it to deal with longer documents. Gidiotis and Tsoumakas (2020) propose a divide-and-conquer approach to train a model to summarize each part of the document separately. To address the essential issue of the quadratic full attention operation of TLMs, Zaheer et al. (2020) propose BigBird with a sparse attention mechanism.

Hybrid text summarization combines extractive summarization, abstractive summarization, or other techniques as a two-stage hybrid system. MatchSum (Zhong et al., 2020) is a recent work that first selects sentences from a document using an extractive model and builds a set of candidate summaries based on them. The summarization task is then formulated as a semantic text matching problem between the source document and the candidate summaries. Pilault et al. (2020) presents a hybrid system that consists of an extractive model and a Transformer language model. The Transformer language model employs an encoder-decoder architecture for abstractive summarization, conditioned on the sentences extracted by the extractive model.

2.2 Injection of Additional Information

The idea of injecting additional information to TLM is inspired by two former works, LAMBERT (Garncarek et al., 2020) and LayoutLM (Xu et al., 2020), where the visual layout information is injected into BERT by adjusting its input embeddings. These models were not proposed for text summarization and they cannot be applied to plain texts since the layout positions have to be obtained from scanned document images. In contrast, our approach makes use of the internal HiStruct information, which can be found in most types of textual data. Moreover, we enrich the output representations from the TLM instead of adjusting the input embeddings. This saves compute resources since TLM pre-training is not required.

3 Methodology

3.1 Hierarchical Structure Information

Hierarchical position of a sentence is represented in the proposed method as a vector of its positions at each hierarchy-level.

$$SSV_s = (a_s, b_s) \tag{1}$$

Given the s-th sentence within a document, its hierarchical position is formulated as a 2-dimensional vector (a_s, b_s), denoted as the sentence structure vector SSV_s, where a_s represents the linear position of the section containing the sentence and b_s is the linear position of the sentence within the section. All sentences within the same section have the same value in the first dimension of the SSV, indicating the close relationships between them. The second dimension indicates more precisely their linear relations within the section. By this very simple numerical formulation, hierarchical relations between sentences are clearly identified.

Section titles exist in particular in long documents like scientific papers. They usually imply the section content and describe the common topic for its sub-sentences (Ostendorff et al., 2020). In our work, we propose to utilize the corresponding section title as an additional HiStruct information when encoding its sub-sentences. There exist typical section titles in scientific papers. Similar section titles like "Conclusion", "Conclusions" and "Concluding remarks" have the same semantic meaning and can be grouped into one typical section title class of "Conclusions". This is also taken into consideration when encoding the section titles.

3.2 Hierarchical Structure Encoding

Hierarchical position embedding is based on the existing linear position encoding methods (PE), including the sinusoidal method (sin) used by Transformer (Vaswani et al., 2017) and the learnable method (la) used by BERT (Devlin et al., 2019). We use one of the PEs to encode the two dimensions of a SSV respectively, resulting in two embeddings. Using the la PE, the embeddings are initialized randomly and trained with the entire summarization model. Using the sin PE, the two embeddings are calculated simply by Equations 2 and 3 as described by Vaswani et al. (2017).

$$PE_{(pos,2i)} = sin(pos/10000^{2i/d_{model}}) \tag{2}$$

$$PE_{(pos,2i+1)} = cos(pos/10000^{2i/d_{model}}) \tag{3}$$

where pos is the value in one dimension of the SSV and i is the i-th dimension of the resulting embedding.

Given the s-th sentence with the hierarchical position of (a_s, b_s), and the desired size of the output embeddings d, the Sentence Hierarchical Position Embedding (sHE) can be generated by Equations 4, 5, 6, using different combination modes.

$$sHE_{\text{sum}}(s,d) = PE(a_s,d) + PE(b_s,d) \tag{4}$$

$$sHE_{\text{mean}}(s,d) = \frac{PE(a_s,d) + PE(b_s,d)}{2} \tag{5}$$

$$sHE_{\text{concat}}(s,d) = PE(a_s,\frac{d}{2})|PE(b_s,\frac{d}{2}) \tag{6}$$

where the symbol | denotes vector concatenation.

Using one of the PEs (i. e., sin or la) associated with one of the combination modes (i. e., sum, mean or concat), it totals six different settings of the hierarchical position encoding method: sin-sum, sin-mean, sin-concat, la-sum, la-mean and la-concat.

(Classified) section title embedding is generated by the same pre-trained TLM, which is involved in the summarization model. We have two options to encode section titles: section title embedding (STE) and classified section title embedding (classified STE). A section title embedding is generated by feeding the tokenized section title into the TLM and summing up the last hidden states at each token position as a single embedding. Similar section titles consisting of similar tokens lead to embeddings that are already similar to each other in some way. We also manually pre-define typical section title classes and the corresponding intra-class section titles depending on the datasets and the domains. Using the classified STE, all intra-class STEs are replaced with the embedding of its corresponding class. In the case that a section title does not belong to any class or it falls into more than one class, the original STE is used.

3.3 Model Architecture

Figure 1 illustrates the overview architecture of the proposed HiStruct+ model. The model consists of a base TLM for sentence encoding and two stacked inter-sentence Transformer layers for hierarchical learning and extractive summarization. The sequence on top is the input document, tokenized by the corresponding tokenizer of the involved TLM. The input embeddings to the TLM are the same as in the original TLM. In order to represent individual sentences, we insert a BOS token at the start of every sentence. Only the BOS token embeddings are preserved as the initial sentence representations (S_s). Each sentence representation is first enriched with a Sentence Linear Position Embedding, which encodes its linear position within the whole document. An additional Sentence Hierarchical Position Embedding (sHE_s) can be added, which is generated by encoding the hierarchical position of the sentence using the proposed hierarchical position encoding method. If section titles are available, we can further enrich the sentence representation by adding a STE or classified STE (STE_s). The sentence representations with the injected HiStruct information are fed to the two stacked Transformer encoder layers to learn inter-sentence document-level hierarchical contextual features. The result is a set of Hierarchical Contextual Sentence Embeddings (HS_s). The final output layer is a sigmoid classifier, which calculates the confidence score $\hat{y}_s$ of including the s-th sentence in the extractive summary based on the HS_s. The loss of the summarization model is the binary classification entropy of the prediction $\hat{y}_s$ against the gold label y_s.

The two HiStruct injection components shaded in light-green are optional. Removing these from the HiStruct+ model based on BERT, the architecture is identical to BERTSUMEXT (Liu and Lapata, 2019), which is a strong baseline against our models on CNN/DailyMail. When using RoBERTa and Longformer as the base TLM, we also construct a baseline model without the two components. The comparison baselines are named as TransformerETS in this paper. The effectiveness of injecting HiStruct information using the proposed methods can be systematically investigated by comparing our HiStruct+ model to the corresponding TransformerETS baseline which uses the same base TLM and the same input length, but is unaware of the HiStruct information.

4 Experimental Setup

4.1 Datasets

Our models are evaluated on three benchmark datasets for single document summarization, including CNN/DailyMail (See et al., 2017), PubMed and arXiv (Cohan et al., 2018). Table 4 presents detailed statistics of the datasets.

The three datasets represent different document types ranging from short news articles to long scientific papers. To emphasize the difference in the hierarchical structure among different datasets, we define the concepts of hierarchical depth (hi-depth) and hierarchical width (hi-width). The hi-depth refers to the number of the hierarchy-levels within the document. Scientific papers have a deeper hierarchy consisting of sections, paragraphs, sentences and tokens (i. e., hi-depth = 4). In news articles, paragraphs are not further grouped into sections (i. e., hi-depth = 3). In this case, we use paragraphs instead of sections as the highest hierarchy level when representing the hierarchical position of sentences (i. e., the first dimension of the SSVs). The hierarchical width, hi-width $= \dfrac{N_s}{N_{hsh}}$, is the ratio of total number of sentences N_s and the number of the text-units regarding the highest structure hierarchy N_{hsh}. It indicates how many sentences are there on average in every paragraph/section. The more sentences are there, the second dimension of the SSVs has a more wide range of values, and the values in the first dimension of the SSVs differ a lot from the linear sentence positions. Larger hi-depth and larger hi-width indicate that the hierarchical structure of the dataset is more conspicuous.

We hypothesize that the proposed method works better on datasets with more conspicuous hierarchical structures, where hi-depth and hi-width are larger. This will be proved by comparing the performance improvements on the three datasets with different hierarchical characteristics.

CNN/DailyMail is included as an exemplary dataset with less conspicuous hierarchical structure compared to PubMed and arXiv. The average hi-width over all documents is 1.33, which is much smaller than those in PubMed and arXiv. The dataset contains more than 310k news articles. We use the standard splits given by See et al. (2017) for training, validation, and testing.

During data preprocessing, we first split documents into sentences and paragraphs respectively with the Stanford CoreNLP toolkit (Manning et al., 2014). The sentences and paragraphs are tokenized, resulting in the lists of sentence tokens and the lists of paragraph tokens. SSVs corresponding to each sentence can be obtained by comparing those lists side by side. For all three datasets, we use a greedy selection algorithm similar to Nallapati et al. (2017) and Liu and Lapata (2019) to select sentences from documents as the gold extractive summaries (ORACLE). Sentences in the ORACLE summaries are assigned with the gold label 1.

PubMed and arXiv contain longer scientific papers. PubMed contains papers in the bio-medical domain, while arXiv contains papers in various domains. The average hi-width over all PubMed documents is 15.79, in arXiv it is 37.33. We use the original splits given by Cohan et al. (2018) for training, validation, and testing. SSVs are obtained by tokenizing the sentences and sections of every document respectively. The details on the generation of section title embeddings and classified section title embeddings can be found in Appendix A.2.

4.2 Implementation Details

We implement our model based on BERTSUMEXT (Liu and Lapata, 2019) and use HuggingFace Transformers (Wolf et al., 2020) to make use of the pretrained instances of BERT, RoBERTa and Longformer. On CNN/DailyMail, we select 3 sentences with Trigram Blocking. On PubMed and arXiv, 7 sentences are extracted while Trigram Blocking is not applied (see more details with regard to implementation in Appendix A.3 and A.4).

5 Results and Discussion

We evaluate the performance of our summarization models automatically using ROUGE metrics (Lin, 2004) including F1 ROUGE-1 (R1), ROUGE-2 (R2) and ROUGE-L (RL). Tables 1, 2 and 3 summarize the performance of our models in comparison to the baselines and the previously reported SOTA results on CNN/DailyMail, PubMed and arXiv respectively. On all three datasets, ablation studies are systematically conducted to investigate the contributions of different experimental settings. To analyze the output summaries from an overall perspective, we plot the distribution of the extracted sentences on each dataset and compare it to the ORACLE summaries and those outputted by the comparison baseline (see Figure 2). Appendix A.6 demonstrates human evaluation of extracted summaries for a more intuitive understanding about the superiority of the proposed system.

5.1 Results on CNN/DailyMail

ROUGE results on CNN/DailyMail are summarized in Table 1. The first three blocks highlight the results reported by the corresponding papers of abstractive, extractive, and hybrid summarization systems. The best results regarding the respective type of the summarization system are underlined. In the baselines block, the first two lines highlight the ORACLE results that build the upper bounds for extractive systems taking the same number of input tokens. The LEAD-n baselines simply select the first n sentences in a document as its extractive summary. Despite its simplicity, the LEAD-3 baseline already achieves relatively competitive performance. The three TransformerETS models are the corresponding comparison baselines that use the same model architecture and experimental settings as our models but without injected HiStruct information. The following block presents the results of our HiStruct+ models based on different TLMs with various input lengths. To make the evaluation results comparable to the SOTA extractive model BERTSUMEXT, we follow their approach and report the averaged results of three best checkpoints.

Table 1: F1 ROUGE results on CNN/DailyMail. Bold are the scores of the HiStruct+ models that are better than the corresponding TransformerETS baseline. The symbol * indicates an improvement over the corresponding SOTA ROUGE for extractive summarization.

Regardless the base TLM and input length, our HiStruct+ models collectively outperform the corresponding TransformerETS baselines by merely injecting the hierarchical position information of sentences. However, the performance improvements gained by our models on CNN/DailyMail are small. One of the reasons might be that we merely inject the hierarchical position information of sentences, section titles are not available. Furthermore, as discussed in Section 4, the hierarchical structure of the CNN/DailyMail documents is not so obvious as those in PubMed and arXiv.

Compared to the SOTA extractive model, our best HiStruct+ model produces competitive results. The R2 and RL scores are improved slightly. The model can be reused in many hybrid approaches. When we apply MatchSum based on our best

model, the ROUGE results are further increased.

Ablation studies on CNN/DailyMail (see the results and detailed discussions in Appendix A.5) suggest that the setting la-sum works best for hierarchical position encoding. Two stacked Transformer layers in the summarization model perform better than one or three Transformer layers. When taking longer inputs than the length limit of the TLM, substantial improvements are achieved by using the copied token position embeddings for initialization instead of random initialization.

The extracted summaries are analyzed in more detail by plotting the proportions of the extracted sentences at each linear position within the whole document as shown in Figure 2a. The model in green is our best-performed HiStruct+ model on CNN/DailyMail. The model in orange is the corresponding comparison baseline without injected HiStruct information. The model in blue is the ORACLE system, which produces the gold extractive summaries. We can observe that the ORACLE summary sentences are distributed across documents more smoothly, while our HiStruct+ model and the baseline model tend to select the first sentences and fail to select sentences that appear at later positions within the documents. Compared to the baseline, the HiStruct+ model leads to more similar proportions as the ORACLE summaries at the most sentence indices.

Table 2: F1 ROUGE results on PubMed. Bold are the scores of the HiStruct+ models that are better than the corresponding TransformerETS baseline. The symbol * indicates that the corresponding SOTA ROUGE for extractive summarization is improved by our model. The symbol ’ indicates that the SOTA ROUGEs (incl. all types of summarization approaches) are outperformed.

ROUGE results on PubMed are summarized in Table 2. As shown in the baselines block, the ORACLE upper bounds for extractive summarization are increased significantly by increasing the input length, which makes it possible to exploit potential gains from modeling longer input. The

LEAD-n baselines do not produce competitive results on PubMed. It indicates that the first sentences in PubMed are not so informative as those in CNN/DailyMail. The last two TransformerETS models in the block are the comparison baselines that are unaware of HiStruct.

The last block in Table 2 presents the results of two groups of HiStruct+ models, grouped by the base TLM used in the summarization model. In PubMed, we can choose to inject the sentence hierarchical position embeddings (sHEs) with or without the section title embeddings (STEs). STEs can be replaced by classified STEs. This can result in three different injection settings for a model group, namely sHE, sHE+STE, and sHE+STE(classified). For each model setting, we report the results of the best-performed checkpoint.

Our best HiStruct+ model on PubMed is a model based on Longformer-base taking 15,000 input tokens, which injects the sHEs and the classified STEs into the extractive model. It achieves ROUGE results of 46.59/20.39/42.11, which beat the SOTA extractive model ExtSum-LG+MMR-Select+ collectively on all three ROUGE metrics with improvements of 1.2/0.02/1.12. Taking the SOTA abstractive and hybrid approaches into account, our results are still very competitive.

All HiStruct+ models produce the competitive results that are better than or very close to the former SOTA results for extractive summarization. They also collectively outperform the TransformerETS baselines by a large margin on all evaluation metrics. The overperformance is much more substantial than that on CNN/DailyMail, even if only the hierarchical position information is injected. This supports our hypothesis that the proposed model works better on datasets with more conspicuous hierarchical structures.

Ablation studies on PubMed suggest that the largest improvement of our models against the baseline is contributed by the hierarchical position information of sentences. This is observed when we compare the three models in the first group of HiStruct+ models with the first TransformerETS baseline. Injecting merely sHE, the results are already increased by 4.07/3.88/3.86. When the section title embedding (STE) is included additionally, the results are further increased by 0.73/0.65/0.68. When using classified STE instead, the ROUGEs are increased by a small margin of 0.1/0.1/0.09. Comparing the second group of HiStruct+ models to the second TransformerETS baseline, it is also observed that injecting the sHE leads to the largest performance gain.

The extracted summaries analysis on PubMed test set is demonstrated in Figure 2b. The model in green is our best-performed HiStruct+ model on PubMed, the model in orange is the corresponding TransformerETS baseline, the model in blue is the ORACLE system. The ORACLE summaries are distributed across documents evenly. The TransformerETS baseline favors the first 5 sentences and ignores the sentences appearing at later positions. In contrast, our HiStruct+ model overcomes the problem of focusing merely on the first sentences. The outputs of the HiStruct+ model are close to the ORACLE summaries. It indicates that by injecting HiStruct information explicitly using our method, the model successfully learns the deeper internal hierarchical structure of the PubMed documents and relies less on the linear sentence positions.

5.3 Results on arXiv

ROUGE results on arXiv are summarized in Table 3. The results of the HiStruct+ models are presented in two groups. The first group takes 15k input tokens, while the second group increases the input length to 28k. In the groups, different injection settings are compared.

Our best-performed HiStruct+ model on arXiv is an extractive model based on Longformer-base with 28k input tokens, injecting the sHEs with the original STEs. This model beats the results achieved by ExtSum-LG+RLoss and sets the new SOTA ROUGEs for extractive summarization on arXiv to 45.22/17.67/40.16.

All HiStruct+ models collectively outperform the corresponding TransformerETS baselines (i. e., the last two models in the baselines block) by a large margin on all ROUGE scores. On this dataset, the HiStruct+ improvement is much more significant than those on both CNN/DailyMail and PubMed. The arXiv dataset has the largest hi-width among the three datasets and the hierarchical structure is most conspicuous, which might be the reason why the HiStruct+ models yield the largest performance improvements on arXiv.

Ablation studies in the first HiStruct+ group also suggest that the largest improvement of our HiStruct+ model against the TransformerETS baseline is contributed by injecting the sentence hierarchical position information, which is encoded as

sHEs. The effect of using the classified STE on arXiv is opposite to that on PubMed. The summarization performance declines slightly when we replace the STE with the classified STE. This outcome occurs in the second group of HiStruct+ models as well. We notice the fact that there are 500k unique section titles in arXiv, while PubMed contains 164k unique section titles. Accordingly, it becomes much more difficult to group a large number of section titles correctly into several section classes. Furthermore, the PubMed dataset contains papers mostly in the bio-medical domain. The structure of those papers tends to follow specific writing conventions in the bio-medical sciences. The arXiv dataset, in contrast, contains scientific papers that are not limited to a specific domain. As consequence, the document structure and the writing styles are more diverse.

The extracted summaries analysis on arXiv is demonstrated in Figure 2c. The baseline (in orange) tends to select the first sentence and the sentences indexed between 10 and 20, while it excludes sentences at later positions. It is clearly observed that the summary sentences extracted by the HiStruct+ model are evenly distributed, the informative sentences appearing at later positions are not ignored.

6 Conclusions

This work addresses hierarchical modeling for extractive text summarization by explicitly leveraging hierarchical structure information, including section titles, as well as hierarchical position information of the sentences. We propose an intuitive and interpretable approach to formulate, extract, encode and inject the hierarchical structure information into an extractive summarization model.

The proposed HiStruct+ models are systematically evaluated on CNN/DailyMail, PubMed, and arXiv. On PubMed, our model increases the former SOTA ROUGEs for extractive summarization by 1.2/0.02/1.12. On arXiv, the new SOTA results for extractive summarization are set to 45.22/17.67/40.16. Our ablation studies suggest that the SOTA performance are mostly gained by providing the hierarchical position information of sentences to the summarization model. When comparing the HiStruct+ models with the baselines that are unaware of the HiStruct information, improvements are consistently observed on all three datasets under various experimental settings, indicating the effectiveness of the proposed method. Moreover, our experiments show that the more conspicuous hierarchical structure the dataset has, the larger the improvements of our method are. The proposed metrics of hi-depth and hi-width determine whether it is worth using our method by comparing the metrics of any dataset to those of the three involved datasets.

Utilizing the HiStruct information also for abstractive summarization is subject of future work. Similarly, we see great potential in an encoder-decoder architecture with the proposed HiStruct injection components.

Table 4: Statistics of the datasets. * avg. #paragraphs in CNN/DailyMail.

The CNN/DailyMail[2], PubMed and arXiv[3] datasets are used in experiments. We use the original splits provided by See et al. (2017) and Cohan et al. (2018) for training, validation and testing.

A.2 Pre-defined Section Title Classes

The pre-defined dictionaries of the typical section title classes and the corresponding in-class section titles are released in our GitHub project (see Section 1). There are 164,195 unique section titles in PubMed, and 500,015 in arXiv, which are encoded as section title embeddings (STE) respectively using the proposed encoding method.

For PubMed, we define 8 section title classes: introduction, background (i. e., background, review and related work), case (i. e., case reports), method, result, discussion, conclusion and additional information (i. e., additional information such as conflicts of interest, financial support and acknowledgments). For arXiv, we define 10 classes: introduction, background, case, theory (i. e., problem formulation and proof of theorem), method, result, discussion, conclusion, reference and additional information. Classified STEs are prepared accordingly by replacing the original STEs of the intra-class section titles with the encoding of the section title class.

A.3 Implementation Details

The learning rate schedule follows Liu and Lapata (2019) with warm-up. On CNN/DailyMail, we train the HiStruct+ models and the TransformerETS baselines 50,000 steps with 10,000 warm-up steps. On PubMed and arXiv, the models are trained 70,000 steps with 10,000 warm-up steps when taking 15,000 tokens as input. When training models on arXiv with 28,000 input tokens, we train 100,000 steps with 10,000 warm-up steps.

The number of the extracted sentences depends on the dataset. On CNN/DailyMail, we follow Liu and Lapata (2019) to select 3 sentences for each document as its extractive summary and apply Trigram Blocking (Paulus et al., 2018) to reduce the redundancy of the selected sentences. On PubMed and arXiv, 7 sentences are extracted without Trigram Blocking.

The length limit of the original TLM is overcome by adding extra token linear position embeddings (tPE) to cover the desired length. The additional tPE are then trained with the whole summarization model. Instead of initializing them randomly, we copy the original tPE of the TLM multiple times until the desired length is covered.

The HiStruct+ models and the TransformerETS baselines are trained on 3 GPUs (NVIDIA® Quadro RTX™ 6000 GPUs with 24GB memory) with gradient accumulation every two steps. Checkpoints are saved and evaluated on the validation set every 1,000 steps. The top-3 checkpoints based on the validation loss are kept. The batch size varies with the base TLM and the input length. On CNN/DailyMail, the base TLM is fine-tuned with the whole summarization model. Due to resource limitation, the TLM (i. e., Longformer) is not fine-tuned when training the summarization model on PubMed and arXiv with longer inputs.

A.4 Model Architectures and Experimental Settings

The detailed model architectures and experimental settings for the models trained on CNN/DailyMail, PubMed and arXiv are summarized in Table 5, Table 6 and Table 7 respectively. The detailed model architectures and experimental settings include:

---

[2] https://cs.nyu.edu/~kcho/DMQA/

[3] https://github.com/armancohan/long-summarization

Base TLM: the Transformer language model used for sentence encoding in the summarization system.
Input length: how many tokens are taken as input.
Extra tPE: how to initialize the extra input token linear position embeddings when taking longer input. We can choose to randomly initialize them or copy the original ones.
FT: whether the base TLM is fine-tuned with the entire summarization model.
TL: the number of the Transformer layers stacked upon the base TLM for extractive summarization.
WS: warmup steps, how many steps are used for warming-up of the learning rate.
TS: the total training steps.
BS: batch size, how many documents are used as one batch during training.
AC: accumulation count, gradient accumulation every k steps.
GPU: the number of GPUs used for training, we use NVIDIA® Quadro RTX™ 6000 GPUs with 24GB memory.
HiStruct: the injection setting. Hierarchical structure information that can be injected into the summarization model are: sHE (i. e., sentence hierarchical position embeddings), STE (i. e., section title embeddings), or STE(classified) (i. e., classified section title embeddings)
HPE: the hierarchical position encoding method used in the model. The method is based on the sinusoidal (sin) or the learnable (la) linear position encoding method associated with a combination mode (i. e., sum/mean/concat)
#PE: the numbers of the learned position embeddings for each hierarchy-level of the hierarchical positions and the linear sentence positions, when using the learnable position encoding method. We set them to a same value during training.
SS: saving steps, save checkpoints every k steps.
n: select n sentences as the extractive summary for each document.
TB: trigram blocking, whether to apply Trigram Blocking during sentence selection

A.5 Ablation Studies on CNN/DailyMail

The effect of token-level hierarchical position embeddings is investigated in experiments. The hierarchical position embeddings of tokens are generated as followings:

Given the t-th token within the document, its hierarchical position is represented by Equation 7:

$$TSV_t = (a_t, b_t, c_t) \tag{7}$$

where a_t represents the linear position of the section which contains the token, b_t is the sentence's position within the section and c_t is the linear position of the token within the sentence.

Given the t-th token and the desired size of the output embeddings d, its token hierarchical position embeddings (tHE) is encoded by Equations 8, 9, 10, using different combination modes.

$$tHE_{\text{sum}}(t, d) = PE(a_t, d) + PE(b_t, d) + PE(c_t, d) \tag{8}$$

$$tHE_{\text{mean}}(t, d) = \frac{PE(a_t, d) + PE(b_t, d) + PE(c_t, d)}{3} \tag{9}$$

$$tHE_{\text{concat}}(t, d) = PE(a_t, \frac{d}{3})|PE(b_t, \frac{d}{3})|PE(c_t, \frac{d}{3}) \tag{10}$$

Initial experiments are conducted to assess the summarization performance of the HiStruct+ models with or without the tHE. For this purpose, we compare a HiStruct+ model merely injecting sentence hierarchical position embeddings (i. e., sHE) with a HiStruct+ model with both sentence and token hierarchical position embeddings (i. e., sHE& tHE). That is, it adds the corresponding tHEs to the input embeddings at each input position, which are fed into the TLM. It also injects sHEs into the output sentence representations.

Table 8 summarizes the evaluation results of three groups of HiStruct+ models based on different TLM with various input lengths. In each group, all experimental settings and parameters are the same, except for the injection setting of tHE. The experimental results suggest that the HiStruct+ models with merely sHE consistently outperform the HiStruct+ models with both sHE & tHE under various circumstances. The reason might be that we directly fine-tune the TLM on the extractive summarization task. When adding extra tHE to the input embeddings to the TLM, we do not pre-train the TLM with the adjusted inputs. It is reasonable that the TLM has difficulties in understanding of the new inputs based on the knowledge learned from the original format of encoding. Previous works, such as LayoutLM (Xu et al., 2020), LamBERT (Garncarek et al., 2020) and HIBERT (Zhang et al., 2019), which adjust the input embeddings or the encoder architecture of the pre-trained TLM, continue to pre-train the TLM on their own data. Continuing pre-training of the language models is a core part of these works and leads to significant improvements on downstream tasks. Due to lack of computing resources, we are not able to pre-train the language models. Furthermore, the key goal of our work is

to experiment with various methods to make use of the internal hierarchical text structure information for extractive summarization. In this work, we conduct further experiments without token-level hierarchical position information and leave for future work the pre-training of language models with the adjusted input embeddings.

The effect of different settings for hierarchical position encoding is investigated. As explained previously, based on different position encoding (PE) methods (i. e., sin or la) associated with various combination modes (i. e., sum, mean or concat), we have totally six different settings for hierarchical position encoding: sin-sum, sin-mean, sin-concat, la-sum, la-mean and la-concat. We investigate the effect of those 6 encoding settings systematically in experiments while keeping the rest settings and parameters the same, so that the evaluation results are comparable.

Table 9 summarizes the evaluation results of six HiStruct+ models using the six encoding settings respectively, which are all trained on CNN/DailyMail based on BERT-base with 1,024 input tokens, injecting merely sHE. We observe that when using the la method, the combination mode sum leads to better results compared to the other modes (see the first three columns in Table 9). When using the sin method, the various combination modes do not make a conspicuous difference in summarization performance. The sum and concat modes perform slightly better. When using the sum mode, the la and the sin methods produce similar results (see the first row in Table 9).

The effect of the encoding settings la-sum vs. sin-sum is further investigated in experiments. As discussed above, the encoding settings la-sum and sin-sum lead to similar results. We conduct experiments to further investigate the effect of using these methods. We also compare our HiStruct+ models with the corresponding TransformerETS baseline which differs from our models only in that it does not take into account extra HiStruct information.

Underlined are the best ROUGEs in each block.

Table 10 includes the ROUGEs of three set of comparison models, which use different TLM with various input lengths. In each group, the first model is the baseline without HiStruct injection. The second model and the third model differ from each other only with regard to the encoding setting. The experimental results suggest that both of the settings improve the summarization performance of the baseline model. It is also observed that the la-sum method outperforms the sin-sum method slightly on CNN/DailyMail. The differences are not substantial.

The effect of the number of the stacked Transformer layers is investigated in our experiments. We fine-tune an extended BERT-base model with 1,024 input tokens for extractive summarization. We construct the HiStruct+ models with 1, 2, 3 stacked Transformer layers respectively, while keeping all other settings the same. The results of those three HiStruct+ models are reported in the first block in Table 11. It is suggested that two stacked Transformer layers perform best in our HiStruct+ models for extractive summarization.

The effect of different initialization strategies for the additional input Token Linear Position Embeddings is also investigated in experiments. When taking input texts longer than the original input length of the base TLM, we need to add extra Token Linear Position Embeddings (tPE) for each extended position. We can choose to randomly initialize the extra tPE or copy the original ones to cover the extended input length. To investigate the effect of different initialization strategies, we use the basic settings of the HiStruct+ model with two summarization layers, namely the second model in the first block in Table 11. To build the comparison model, only the initialization strategy is changed to random. As shown in the second block in Table

Table 11: Ablation study on CNN/DailyMail (d). The first block deals with the variation of the numbers of inter-sentence Transformer layers stacked on top of the TLM. The second block deals with the different methods to initialize extra input Token Linear Position Embeddings when taking longer input. The third block deals with the effect of Sentence Linear Position Embeddings. Underlined are the best ROUGEs in each block.

11, substantial improvements are achieved by using the copied tPEs for initialization instead of random initialization. ROUGE-1, ROUGE-2 and ROUGE-L are increased by 2.84, 2.51 and 2.95 respectively.

The effect of the Sentence Linear Position Embeddings is also investigated in experiments. As shown in Figure 1, besides the hierarchical positions of each sentence, we also take the linear position of each sentence within the whole document into account by adding a Sentence Linear Position Embedding (sPE) to each sentence representation. We assess the effect of the sPE by comparing two HiStruct+ models with or without the sPE. The second model in the first block in Table 11 is compared to a model that differs from it only in the injection of sPE. The results are shown in the third block in Table 11. The HiStruct+ model with sPE outperforms the HiStruct+ model without sPE by a small margin regarding all ROUGE metrics.

A.6 Human Evaluation of Extracted Summaries

To have a more intuitive understanding about the superiority of the proposed system, we showcase two samples in Figure 3 for human evaluation and case analysis. The extractive summaries predicted by the HiStruct+ model and the baseline model are demonstrated respectively, in comparison with the gold summary (i.e., the abstract of the paper). To construct a final summary, top-7 sentences with the highest scores predicted by the model are extracted, and then combined in their original order.

The first arXiv sample shows that the baseline simply selects the first sentences. The predicted summary focuses on detailed background knowledge and lacks an overview of the proposed work. In contrast, our HiStruct+ model selects sentences at later positions. The first five sentences introduce the main content and the entire proceeding of the work from an overall perspective. The last two sentences draw conclusions and give an outlook to future work, which is indicated by the phrases highlighted in green.

The PubMed sample also indicates that the baseline favors the first sentences, which is consistent with our observations in Figure 2. Although the last two sentences highlight the same conclusion as in the gold summary that locally informed diagnosis and treatment strategies are needed, too much background information is unnecessarily included in the first five sentences. Our HiStruct+ model selects more informative sentences at later positions. The predicted summary covers all key parts of the gold summary: 1). the statistics are reported (i.e., 26% of primary tuberculosis (tb) was multidrug resistant (mdr)); 2). the novel strain s256 is mentioned; 3). the conclusion is highlighted. The overall topic of the work is especially highlighted by the sentence with the green-colored phrase.

An Isotropy Analysis in the Multilingual BERT Embedding Space

Sara Rajaee★ and **Mohammad Taher Pilehvar**☆

`mp792@cam.ac.uk`

Abstract

Several studies have explored various advantages of multilingual pre-trained models (such as multilingual BERT) in capturing shared linguistic knowledge. However, less attention has been paid to their limitations. In this paper, we investigate the multilingual BERT for two known issues of the monolingual models: anisotropic embedding space and outlier dimensions. We show that, unlike its monolingual counterpart, the multilingual BERT model exhibits no outlier dimension in its representations while it has a highly anisotropic space. There are a few dimensions in the monolingual BERT with high contributions to the anisotropic distribution. However, we observe no such dimensions in the multilingual BERT. Furthermore, our experimental results demonstrate that increasing the isotropy of multilingual space can significantly improve its representation power and performance, similarly to what had been observed for monolingual CWRs on semantic similarity tasks. Our analysis indicates that, despite having different degenerated directions, the embedding spaces in various languages tend to be partially similar with respect to their structures.[1].

1 Introduction

The multilingual BERT model (Devlin et al., 2019, mBERT), pre-trained on 104 languages with no supervision, has shown impressive ability in capturing linguistic knowledge across different languages (Pires et al., 2019). Many studies have explored the encoded knowledge in multilingual CWRs using probing tasks and under zero-shot setting (Wu and Dredze, 2019; K et al., 2020; Chi et al., 2020). Following the probing studies, in this paper, we investigate the multilingual embedding space of BERT, focusing on its geometry in terms of isotropy. Previous research has shown that many pre-trained models, such as GPT-2 (Radford et al., 2019), BERT, and RoBERTa (Liu et al., 2019), have degenerated embedding spaces that downgrade their semantic expressiveness (Ethayarajh, 2019; Cai et al., 2021; Rajaee and Pilehvar, 2021). Several proposals have been put forward to overcome this challenge (Gao et al., 2019; Zhang et al., 2020). However, to our knowledge, no study has so far been conducted on the degeneration problem in multilingual embedding spaces.

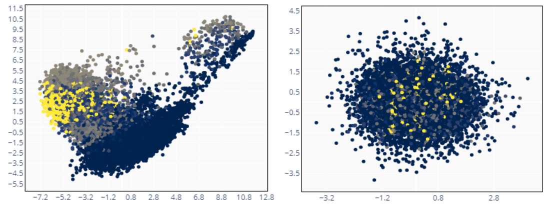

Figure 1: Degenerated (left) and isotropic (right) embedding spaces for Spanish plotted using PCA. Frequency-based distribution can be easily detected in the space (lighter colors indicate higher frequency). See Appendix C for more languages.

Using two well-known metrics, we evaluate isotropy in the mBERT embedding space for six different languages (including two low resources): English, Spanish, Arabic, Turkish, Sundanese, and Swahili. We find that the representation spaces are massively anisotropic in all these languages. However, unlike monolingual CWRs, where a few dimensions dominate the cosine similarity metric and have a high contribution to the anisotropic distribution (Timkey and van Schijndel, 2021), there is no dominant dimension that defines anisotropy in the multilingual representations. Extending our study to other structural properties of the multilingual space, we also investigate outliers, i.e., specific dimensions with consistently high values (Kovaleva et al., 2021). Our findings reveal that, as opposed to English BERT, the multilingual BERT space does not involve any major outliers. This indicates that the suggestion of Luo et al. (2021) on the role of

---

Findings of the Association for Computational Linguistics: ACL 2022, pages 1309 - 1316
May 22-27, 2022

positional embeddings in the emergence of outliers may not be valid. Moreover, our analysis reveals that word frequency plays an important role in the distribution of the multilingual embedding space: words with similar frequencies create distinct local regions in the embedding space.

In analyzing multilingual space, we take a further step toward making the space isotropic. By applying a cluster-based isotropy enhancement method (Rajaee and Pilehvar, 2021), we demonstrate that increasing isotropy of multilingual embedding space can result in significant performance improvements on semantic textual similarity tasks. Our frequency analysis and the remarkable performance improvement in the zero-shot setting denote that the feature space of mBERT has encoded a common linguistic knowledge into its dominant directions to some extent across different languages.

2 Background

The representation degeneration problem in LMs has attracted lots of attention in recent years. Several regularizer-based methods have been proposed to make the space isotropic by adding an extra constraint to the loss function during pre-training (Gao et al., 2019; Zhang et al., 2020; Wang et al., 2020). Because of the re-training cost, other light approaches have been presented as a post-processing step (Li et al., 2020; Rajaee and Pilehvar, 2021). While analyzing the isotropy of embedding space is a well-studied area in English space, there are limited related studies on the multilingual embedding space. In this line, Vulić et al. (2020) investigated the structural similarity of different language embedding spaces by evaluating their isomorphism. Xu and Koehn (2021) showed the positive effect of isotropic space on the degree of isomorphism, which in turn results in improved performance in cross-lingual alignment algorithms. However, a focused study on the isotropy of multilingual embedding space has not been conducted. In this work, we provide more insights on the anisotropic distribution of multilingual embeddings and their notable differences from their English counterpart.

2.1 Isotropy

Geometrically, in an anisotropic space, embeddings occupy a narrow cone. This brings about an overestimation of the similarity between embeddings (Gao et al., 2019). To quantify isotropy, we utilize two well-known metrics based on cosine similarity and principal components (PCs).

	BERT	**mBERT**					
	En	En	Es	Ar	Tr	Su	Sw
$I_{Cos}(\mathcal{W})$	0.34	0.24	0.27	0.27	0.25	0.25	0.27
$I_{PC}(\mathcal{W})$	2.4E-5	6.4E-5	5.0E-5	1.6E-5	2.5E-4	1.2E-4	7.8E-5

Table 1: The isotropy of BERT and mBERT on a sub-set of Wikipedia, reporting based on $I_{Cos}(\mathcal{W})$ and $I_{PC}(\mathcal{W})$.

Cosine Similarity. Ethayarajh (2019) used cosine similarity between random embeddings as an approximation of isotropy in the space. As mentioned before, random embeddings with an isotropic distribution have near-zero cosine similarities. The metric can be formulated as follows:

$$I_{Cos}(\mathcal{W}) = \frac{1}{N} \sum_{i=1, x_i \neq y_i}^{N} Cos(x_i, y_i) \qquad (1)$$

where $x_i \in X, y_i \in Y$, X and Y are the sets of randomly sampled embeddings, and $\mathcal{W}$ is the embedding matrix. N is the number of sampled pairs that is set to 1000 in our experiments. Lower $I_{Cos}(\mathcal{W})$ values indicate higher isotropy.

Principal Components. Mu and Viswanath (2018) proposed a metric based on principal components (PCs), approximated as follows:

$$I_{PC}(\mathcal{W}) \approx \frac{\min_{u \in U} F(u)}{\max_{u \in U} F(u)}, F(u) = \sum_{i=1}^{M} \exp(u^T w_i) \quad (2)$$

where w_i is the i^{th} word embedding, M is the number of all representations in the space, U is the set of eigenvectors of the embedding matrix, and $F(u)$ is the partition function described in Equation 2. Arora et al. (2016) proved that $F(u)$ could be approximated using a constant for isotropic embedding spaces. Therefore, $I_{PC}(\mathcal{W})$ would be close to one in an isotropic embedding space.

3 Analysis

For all experiments, we opted for the multilingual BERT model (mBERT), which has a 12-layer transformer-based architecture similar to English BERT-base, and the representations are obtained from the last layer[2]. We selected English, Spanish,

---

[2] To broaden our insights on the geometry of multilingual space, we expand our analyses to XLM-R model. The related results are reported in Appendix A.

	$I_{Cos}(\mathcal{W})$	**First**	**Second**	**Third**
BERT	0.34	0.385	0.005	0.005
English	0.24	0.041	0.029	0.020
Spanish	0.27	0.033	0.029	0.018
Arabic	0.27	0.033	0.025	0.022
Turkish	0.25	0.036	0.024	0.024
Sundanese	0.25	0.036	0.016	0.016
Swahili	0.27	0.025	0.018	0.014

Table 2: The contribution of top-three dimensions to the expected cosine similarity ($I_{Cos}(\mathcal{W})$) in BERT and mBERT models.

Arabic, Turkish, Sundanese, and Swahili. Our selection of these languages was to ensure that our analysis covers both high and low-resource languages. As our evaluation benchmark, we chose a subset of Wikipedia articles in the selected languages. The analysis experiments in Sections 3.1 to 3.3 have been conducted on the same dataset.

In what follows, we first assess isotropy as a desirable property in the multilingual space and evaluate the contribution of individual dimensions to this property. We also expand our study to the outliers and word-frequency bias in CWRs. The former is a weak point of language models, and the latter is a well-known bias in the monolingual embedding space. Lastly, we assess the effect of isotropy enhancement on the quality of the multilingual embeddings in the semantic similarity task.

3.1 Probing isotropy

As the first step, we quantify the isotropy of the mBERT and BERT embedding spaces using the two metrics. For mBERT, we separately assess the isotropy of each language in the embedding space.

Based on the presented results in Table 1, the average cosine similarity between random embeddings ($I_{Cos}(\mathcal{W})$) is much higher than zero, denoting anisotropic distribution in all considered languages. Measuring isotropy using $I_{PC}(\mathcal{W})$ also confirms the anisotropy issue in mBERT's space as well as the monolingual BERT model.

Aligned with the numerical results, the illustration of multilingual CWRs in the left column of Figure 1 gives us a clear perspective of the degenerated distribution in space.

3.2 Sensitivity to Rogue Dimensions

As we discussed before, cosine similarity is a widely used metric to measure the degree of isotropy in embedding space where a near-zero similarity demonstrates isotropic distribution. In this section, we evaluate the contribution of individual dimensions to the cosine similarity of two randomly chosen embeddings. Evaluating dimension-wise contribution sheds more light on the sensitivity of similarity-based metrics to individual dimensions and their role in (an)isotropic distribution.

The dimension-based cosine similarity between x and y vectors with d dimensions can be defined as follows (Timkey and van Schijndel, 2021):

$$Cos(x, y) = \sum_{i=1}^{d} \frac{x_i y_i}{\|x\| \|y\|} \tag{3}$$

where $CC_i = x_i y_i / \|x\| \|y\|$ is the contribution of i^{th} dimension to the cosine similarity.

We compute the average cosine similarity, $I_{Cos}(\mathcal{W})$, by randomly sampling 1000 token pairs and report the average contribution of the top-three dimensions to the average cosine similarity.

The results are reported in Table 2. Aligned with the findings of Timkey and van Schijndel (2021), we observe that only one dimension has a considerable contribution to the cosine similarity metric in the BERT embedding space. Therefore, the anisotropic distribution is dominated by the mentioned dimension and is not a global property of the whole space. Unlike the monolingual BERT, multilingual BERT has no rogue dimensions. Hence, the anisotropic structure of the multilingual space cannot be attributed to certain dimensions.

3.3 Outlier Dimensions

Pre-trained LMs exhibit consistent outliers, peculiar dimensions with large values, in their LayerNorms' weights and consequently, in their contextual representations across all layers. Through several experiments, Kovaleva et al. (2021) have demonstrated that disabling these outliers can notably impair the performance of pre-trained and fine-tuned LMs. Trying to find the root cause of outliers, Luo et al. (2021) have shown that removing positional embeddings makes the outliers disappear, concluding that the positional information is responsible for the emergence of outliers.

In this part, we investigate rogue dimensions in the multilingual embedding space of BERT. We check outliers by averaging over 10000 randomly selected representations and calculate the mean and standard deviation (σ) of dimensions' distribution. Following the Kovaleva et al. (2021)'s suggestion, we consider a dimension as an outlier if its value

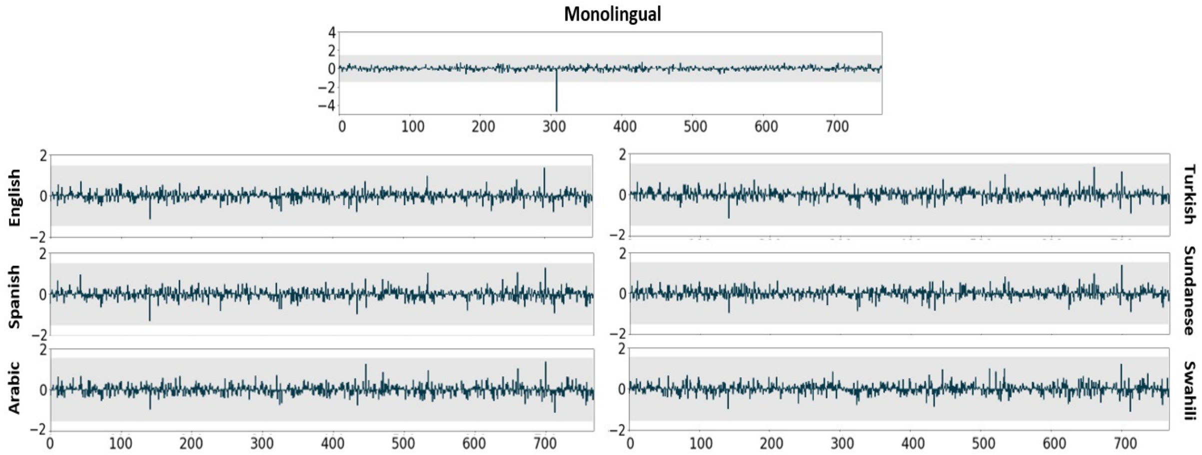

Figure 2: The average representation in English BERT (top) and mBERT (bottom). The shaded area denotes 3σ. While an outlier has emerged in the former, we do not see any major outliers in the multilingual space.

is at least 3σ larger/smaller than the mean of the distribution.

Results are shown in Figure 2. On top, the outlier dimension of the mean representation can be easily detected in the English BERT. However, interestingly, multilingual BERT exhibits no major outliers in its embedding space across different languages. It can be concluded that, contrary to the suggestion of Luo et al. (2021), positional embeddings cannot be responsible for outliers, given that both multi- and monolingual spaces are constructed using the same training procedure involving positional encodings. We leave further investigation of outliers in contextual embedding spaces to future work.

Putting together the results of the previous sections, we observe that the mBERT embedding space is highly anisotropic, despite not having any outliers or dominant dimensions in the cosine similarity metric.

3.4 Word frequency Bias

It has been shown that frequency plays an important role in the distribution of CWRs. Frequency-similar words make distinct local regions in the embedding space (Gao et al., 2019), with high-frequency and rare words being around the center and far from the origin, respectively (Li et al., 2020). Frequency-based distribution is a factor that hampers the expressiveness of the embedding space. So, it is essential to investigate frequency bias in the multilingual embedding space.

In this experiment, we analyze English, Spanish, and Arabic since there are enough resources to properly define word frequency in these languages. We randomly sample 500 sentences from the corresponding Wikipedia datasets and obtain a word representation by averaging over all its sub-token representations.

Figure 1 shows the distribution of word representations per word frequency[3]. Every point represents a word embedding dyed based on its frequency. As can be observed on the left, multilingual CWRs are biased toward their frequency, where words with similar frequencies create clustered regions. A similar pattern can be observed for the English BERT CWRs (Rajaee and Pilehvar, 2021), with the only difference that in mBERT, low-frequency words are distributed near the origin and frequent words are far from it.

3.5 Isotropy Enhancement

Making the embedding space isotropic has theoretical and empirical benefits (Gao et al., 2019). Several approaches have been proposed to improve isotropy in monolingual CWRs. Some require a retraining of the model with additional objectives to address the degeneration problem (Gao et al., 2019; Zhang et al., 2020), whereas others are applied as a light post-processing (Mu and Viswanath, 2018). To investigate the effect of isotropy enhancement for the multilingual embedding space, we opted for our cluster-based approach (Rajaee and Pilehvar, 2021), which is a recent example from the latter category. The proposed method splits the space into several clusters and discards dominant directions for each cluster. The approach also allows us to investigate the similarity of the clustered structure of the embedding space across different

Applying the cluster-based method can improve the performance on the multi- and cross-lingual datasets in both Individual and Zero-shot settings.

languages under a zero-shot setting. More details on this method can be found in Appendix E.

We consider the multilingual and cross-lingual Semantic Textual Similarity (Cer et al., 2017, STS) that involves instances from Arabic, English, Spanish, and Turkish (Appendix D). We run our experiments in **Individual** and **Zero-shot** settings. In the former, we perform experiments individually on each language by clustering the corresponding space and applying the isotropy enhancement approach. The goal is to see whether increasing isotropy leads to performance improvement in the multilingual space and to compare the extent of improvements in cross- and multilingual tracks. In the zero-shot scenario, we are interested in evaluating the shared structural properties among languages, specifically, the similarity of the encoded linguistic knowledge in the dominant directions of different languages. To this end, we obtain clusters, their means, and dominant directions on the English dataset and leverage these for isotropy enhancement in other languages.

The reported results in Table 3 show that increasing the isotropy in the multilingual embedding space can enhance the performance in all tracks (multi- and cross-lingual). The improvement could be attributed to the potential of the applied method in discarding frequency bias from the embedding space. The visualization of the embedding space after isotropy enhancement, Figure 1 (right), clearly reveals that the frequency bias is faded after this process. Moreover, the results of the zero-shot setting suggest that the encoded information in dominant directions is similar across the languages because the improvement is compatible with the setting in which the dominant directions are obtained in each track individually.

4 Conclusion

In this paper, we provide several analyses on the geometry of multilingual embedding space from the viewpoint of isotropy. We show that, similarly to its monolingual English counterpart, the multilingual BERT has a highly anisotropic embedding space. However, interestingly, the two spaces differ in their distribution of dimensions. The English BERT has a few high-contribution outlier dimensions, whereas the multilingual space does not possess any such disruptive rouge features. We also investigate the structure of multilingual embeddings from the perspective of frequency-based distribution and show that they have a biased structure towards word frequency and that the distribution is similar across different languages. As the last step, we evaluate the impact of isotropy improvement on the quality of multilingual embeddings. We observe that increasing isotropy can improve multilingual CWRs' performance on STS and address their frequency bias.

A XLM-R

XLM-R is a Transformer-based language model trained on 100 languages (Conneau et al., 2020). In comparison to mBERT, it has seen much more data during its pre-training, leading to higher performance on several downstream tasks. For our analysis, we follow the settings used for mBERT and take RoBERTa (Liu et al., 2019) as its monolingual counterpart.

A.1 Results

Probing Isotropy. Table 4 summarizes the isotropy evaluation for RoBERTa and XLM-R models. As we expected, both models have an extremely anisotropic distribution. However, the degree of anisotropy is much higher in the multilingual model.

Sensitivity to Rouge Dimensions. To find out the contribution of individual dimensions to the high cosine similarity between random embeddings and anisotropic distribution, we report the contribution of top-three dimensions in Table 5.

In contrast to mBERT, a few dimensions have a significant role in the anisotropic distribution in the XLM-R model and RoBERTa. Furthermore, the results demonstrate that the contribution of rouge dimensions notably increases in the multilingual model.

Outliers. Following our settings in the BERT analysis (Section 3.3), we plot the average representations of the RoBERTa and XLM-R models to investigate the existence of outliers. The visualization of the mean representations across different languages and the monolingual model can be found in Figure 3. As we expected from the results of the previous part, outliers can easily be detected in the mono and multilingual models. The number of outliers is the same in both models. However, the absolute value of the outliers increases significantly in the multilingual models.

Conclusion. Our investigations on the geometry of embedding space in the RoBERTa and XLM-R models demonstrate a clear distinction to the BERT counterpart. We show that although all the mentioned models have anisotropic embedding spaces, they possess different geometrical structures from the perspective of isotropy and rouge dimensions. Working on the reasons behind such discrepancies is an interesting future direction that can enhance our knowledge of how language models shape their underlying representation space.

B Wordfreq

We have employed the Wordfreq library to investigate word frequency bias in our experiments. This library obtains word frequency from the corpus containing eight different domains in 36 languages. Our target languages are in the *large* category, which means their word lists cover rare words appearing at least once per 100 million words. As a result, the wordfreq could be a suitable tool for our purpose.

C Frequency-based Distribution

Frequency-based distribution can negatively affect the expressiveness of space. Though it is a well-known bias in pre-trained LMs (e.g., BERT and GPT-2), it is not studied in a multilingual setting. As discussed in Section 3.4, we have studied frequency bias in mBERT and demonstrated that, similarly to its monolingual counterparts, mBERT suffers from frequency-based distribution in its space. The illustration of this bias and the impact of the cluster-based approach on mitigating the issue can be found in Figure 4.

D Multilingual STS Task

Multi and cross-lingual Semantic Textual Similarity (STS) is the main task in our experiments. STS is a paired sentence task in which samples have been labeled by a score in the continuous range of 0 (irrelevant) to 5 (most semantic similarity). In the multilingual tracks, in a pair, both sentences are in the same language, while sentences have different languages in the cross-lingual tracks. The reason behind choosing STS as the target task for our experiments is that Multilingual BERT has a pretty low performance on it.

In our experiments, we take the average of all tokens in a sentence as the sentence representation and consider the cosine similarity of the sentence representations in a sample as the semantic similarity score.

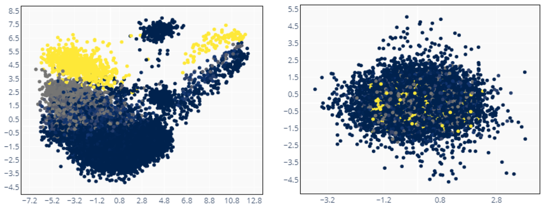
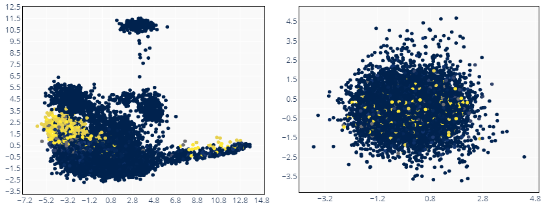
Table 5: The contribution of top-three dimensions to the expected cosine similarity ($I_{Cos}(\mathcal{W})$) in the RoBERTa and XLM-R embedding spaces.

E Cluster-based Isotropy Enhancement

We pick the cluster-based approach (Rajaee and Pilehvar, 2021) to improve the isotropy in multilingual embedding space. In this method, the embeddings are clustered using the k-means clustering algorithm, and then dominant directions of every cluster are nulled out independently. Dominant directions have been calculated using Principal Component Analysis (PCA). The primary key in this method is obtaining dominant principal components (PCs) of clustered areas in the embedding space separately, which makes this approach suitable for exploring the clustered structure of the multilingual CWRs. We apply the cluster-based approach to multi and cross-lingual CWRs with two different settings, Individual and Zero-shot. The number of clusters and discarded dominant directions are 7 and 12, respectively.



(a) English



(b) Arabic

Figure 4: Degenerated (left) and isotropic (right) embedding spaces for the two languages. Frequency-based distribution can be easily detected using two top PCs in the space (lighter colors indicate higher frequency). Eliminating top dominant directions not only makes the embedding space isotropic, but also removes frequency bias in multilingual CWRs.

Multi-Stage Prompting for Knowledgeable Dialogue Generation

Abstract

Existing knowledge-grounded dialogue systems typically use finetuned versions of a pretrained language model (LM) and large-scale knowledge bases. These models typically fail to generalize on topics outside of the knowledge base, and require maintaining separate potentially large checkpoints each time finetuning is needed. In this paper, we aim to address these limitations by leveraging the inherent knowledge stored in the pretrained LM as well as its powerful generation ability. We propose a multi-stage prompting approach to generate knowledgeable responses from a single pretrained LM. We first prompt the LM to generate knowledge based on the dialogue context. Then, we further prompt it to generate responses based on the dialogue context and the previously generated knowledge. Results show that our knowledge generator outperforms the state-of-the-art retrieval-based model by 5.8% when combining knowledge relevance and correctness. In addition, our multi-stage prompting outperforms the finetuning-based dialogue model in terms of response knowledgeability and engagement by up to 10% and 5%, respectively. Furthermore, we scale our model up to 530 billion parameters and show that larger LMs improve the generation correctness score by up to 10%, and response relevance, knowledgeability and engagement by up to 10%. Our code is available at: `https://github.com/NVIDIA/Megatron-LM`.

1 Introduction

Dialogue systems face the problem of producing bland and generic outputs that are devoid of content (Wolf et al., 2019; Holtzman et al., 2019; Ma et al., 2020). Recent efforts have been made to address these concerns by grounding dialogue responses on a source of knowledge (Dinan et al., 2018; Zhou et al., 2018; Zhao et al., 2019; Santhanam et al., 2020; Prabhumoye et al., 2021). Therefore, building a knowledgeable dialogue system has become one of the key milestone tasks in conversational research.

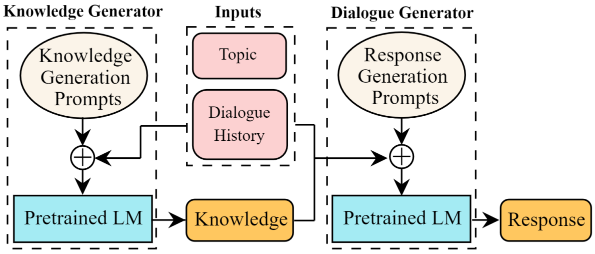

Figure 1: Our proposed framework (MSDP) for the knowledgeable dialogue generation.

Current knowledge-grounded dialogue systems highly rely on a massive external knowledge corpus for a retrieval model to obtain relevant knowledge (Dinan et al., 2018; Kim et al., 2019; Zhao et al., 2020), which inevitably brings several limitations. First, retrieval systems are constrained to the size and domains of the database, and they cannot generalize to out-of-domain topics that are not covered by the database. Second, retrieval from a massive corpus takes substantial resources. Reimers and Gurevych (2021) show that it is more difficult for the state-of-the-art retrieval model (Karpukhin et al., 2020) to retrieve relevant knowledge when the size of the database increases. The larger database increases the chance that an irrelevant document is closer to the query embedding than the relevant document.

We aim to address these limitations by using a relatively small database and a pretrained language model (LM) (Shoeybi et al., 2019; Brown et al., 2020) as an additional source of knowledge to ground a dialogue system. Since the LM inherently stores a variety of knowledge (Petroni et al., 2019), it can help dialogue systems generalize to out-of-domain topics that are not explicitly present in the

database. We propose a prompt-based approach to directly generate the context-relevant knowledge from the LM. Specifically, we select a few dialogue contexts and their associated knowledge from the database to be given as prompts to the LM for the knowledge generation. These samples are chosen such that the dialogue contexts are semantically closer to the current dialogue context.

Moreover, finetuning LMs, which current dialogue systems rely on, could lead to overfitting when the finetuning dataset is relatively small. Also, gigantic LMs like GPT-3 (Brown et al., 2020) and Megatron-Turing NLG 530B (Smith et al., 2022), may only be available through APIs. Hence, finetuning them on the dialogue task might not be a feasible solution. To bypass the finetuning process, we propose to further prompt the LM to generate the response based on the dialogue context and previously generated knowledge. We select a few dialogue contexts and corresponding knowledge and responses to be given as prompts to the LM for the response generation. The samples are chosen such that their responses are knowledgeable and highly conditioned on the corresponding knowledge.

In summary, we present a novel **M**ulti-**S**tage **D**ialogue **P**rompting (MSDP) framework, which consists of a first-stage prompting for the knowledge generation and a second-stage prompting for the response generation. Our framework does not need any finetuning or updates to the pretrained weights of the LM, can generate relevant and factually correct knowledge, and is effective at producing knowledgeable and engaging responses.

Our contributions are summarized as follows:

- We propose a novel multi-stage prompting framework for knowledgeable dialogue generation that only uses a single LM and does not require any finetuning.

- We show that for in-domain dialogue topics, our knowledge generator can outperform the state-of-the-art retrieval model by 5.8% when combining relevance and correctness, and it can also better generalize to out-of-domain topics by a 6.4 F1-score improvement.

- We show that MSDP can outperform the finetuning-based dialogue model for response knowledgeability and engagement by up to 10% and 5%, respectively.

- We scale our technique up to a 530-billion-parameter LM and demonstrate that larger LMs improve the generation correctness score by up to 10%, and response relevance, knowledgeability and engagement by up to 10%.

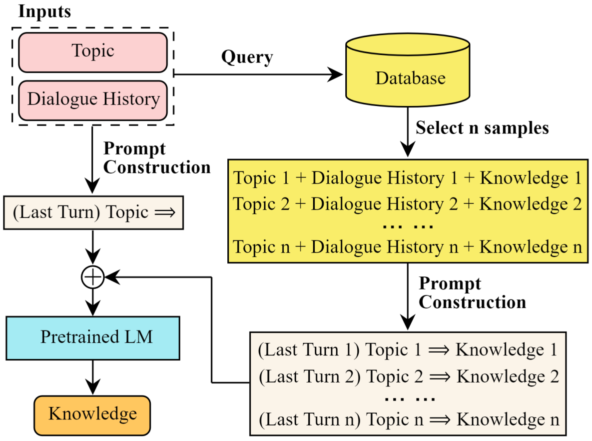

Figure 2: Prompting for the knowledge generation.

2 Framework

Our proposed multi-stage dialogue prompting (MSDP) framework is illustrated in Figure 1. It consists of a knowledge generator and a dialogue generator, both using the same pretrained LM. The knowledge generator produces relevant knowledge to the input topic and dialogue history, while the dialogue generator generates engaging and knowledgeable responses based on the dialogue context and the generated knowledge.

We denote the input topic as t, the input dialogue history as h, the last dialogue turn as h^*, and a database of samples as D. Each data sample in D is denoted by d_i, and consists of a topic t_i, a dialogue history h_i with the last turn as h_i^*, corresponding knowledge k_i, and a response r_i.

2.1 Knowledge Generator

To bypass the dependence on a large-scale knowledge base, we propose a prompt-based knowledge generation approach, which uses a relatively small database (about 70K samples) and a pretrained LM to generate context-relevant knowledge. As shown in Figure 2, the knowledge generation consists of sample selection and knowledge generation.

Sample Selection We hypothesize that selecting appropriate samples as prompts is the key to generating high-quality knowledge sentences. Intuitively, leveraging the knowledge from similar topics or dialogue context can help the LM to generate contextually relevant and factually correct knowledge sentences. Hence, we propose a query-based sample selection method, which aims to search similar samples from D based on the input query (q). To ensure that the selected examples are relevant to the query, we utilize a pretrained sentence encoder (SE) (Devlin et al., 2019; Karpukhin et al., 2020) to obtain the representations for the query and each data sample (d_i) in D. Then, we calculate the similarity between the query and each sample using the dot product of their representations:

$$Sim(q, d_i) = SE(t+h)^{\intercal} \cdot SE(t_i + h_i),$$

where the input of the SE is a concatenation of the topic and dialogue history. Finally, we select n samples that have the highest similarity scores to q. This selection process can be done efficiently since the database is relatively small.

Knowledge Generation Inspired by the few shot approach in Brown et al. (2020), feeding the pretrained LM with suitable and intuitive prompts can allow it to generate relevant content. The template of the constructed prompts is illustrated in Figure 2. Concretely, the prompt for the i^{th} sample ($prompt_i$, $i \in [1, n]$) is "(h_i^*) t_i $\Rightarrow$ k_i"[1], and the prompt for the current dialogue context ($prompt_{curr}$) is "(h^*) t $\Rightarrow$", where we use the symbol "$\Rightarrow$" to guide the LM for knowledge generation. We only use the last dialogue turn to construct prompts because the previous turns are mostly not relevant to the knowledge, and adding redundant information could lead to negative effects for knowledge generation. Given that k_i usually has a closer connection with t_i than h_i^*, we put k_i closer to t_i than h_i^* in the prompts. Finally, we concatenate the constructed prompts using "`\n`" and feed them into the LM to generate the knowledge:

$$k' = \mathcal{LM}(prompt_1 \texttt{\textbackslash n} \dots prompt_n \texttt{\textbackslash n}\; prompt_{curr})$$

where k' denotes the generated knowledge for the input. Since "`\n`" is used to separate the prompts, the model will start generating "`\n`" followed by another random example after finishing the knowledge generation. Hence, we consider the generated sentence before "`\n`" as k'.

2.2 Dialogue Generator

The architecture of our proposed dialogue generator is illustrated in Figure 3. Finetuning a LM could lead to overfitting when the finetuning dataset is relatively small. In addition, since usually one can only access to the gigantic LMs, like GPT-3 (Brown et al., 2020) and Megatron-Turing NLG 530B (Smith et al., 2022) using only APIs, finetuning them might not be a feasible solution. Therefore, we propose to circumvent the finetuning by prompting the pretrained LM for the response generation, which requires only a few dialogue examples. To generate knowledgeable and engaging responses, we focus on how to select samples and how to effectively prompt the LM for the response generation.

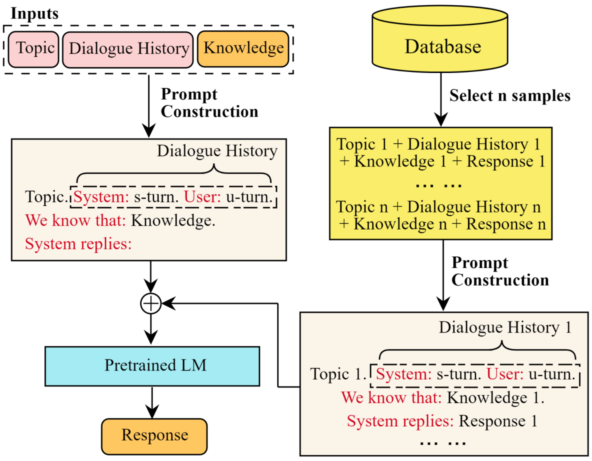

Figure 3: Prompting for the dialogue response generation. We use comprehensive words (denoted in red color) to connect the dialogue history, knowledge and response for the prompt construction.

Sample Selection One of the essential skills for the knowledgeable dialogue model is to effectively leverage the knowledge produced in the first stage, in order to make the generated responses knowledgeable. Considering that we can provide the LM with only a few dialogue samples, it could be difficult for it to learn how to generate a response based on the knowledge unless there are strong connections between the dialogue response and knowledge in the samples that we provide. Hence, we focus on selecting the samples in which the responses are knowledgeable and highly conditioned on the corresponding ground truth knowledge. Concretely, for each example in the database, we calculate how much ground truth knowledge accounts for the dialogue response by using the word overlap ratio. Then, we filter out the examples where the ratio is lower than 0.6 (this number is decided based on a hyper-parameter search among {0.4, 0.5, 0.6, 0.7, 0.8}). Also having responses be too knowledgeable

---

[1] For example, (I love pizza) Pizza ⇒ Pizza is a traditional Italian dish typically topped with tomato sauce and cheese.

could make it less engaging. Therefore, we also filter out the examples where the ratio is higher than 0.9 since we expect the response to contain information other than the knowledge. After the filtering, to ensure that our approach does not depend on the dialogue context, we randomly select n samples from the rest of the dialogue examples. These selected n samples will be later constructed as prompts and used for the response generation.

Response Generation Aside from the ability to leverage the generated knowledge, another essential skill for the dialogue model is to have the ability to chat based on the dialogue context. To equip our model with this skill, we focus on constructing intuitive prompts for the selected examples and feed them into the LM. The constructed prompts for the selected examples and inputs are illustrated in Figure 3. For prompts from the selected examples, we use "System:" and "User:" to connect different turns in the dialogue history, and "We know that:" and "System replies:" are used to introduce the knowledge and response, respectively. For prompts from the current conversation (i.e., inputs), we follow the same template except that we keep the response empty for the pretrained LM to generate.

After the prompt construction, we concatenate the prompts for selected samples and the inputs using "`\n`", and then feed them into the pretrained LM to generate the response. Similar to what we have described in Section 2.1, we consider the generated sentence before "`\n`" as the response.

3 Experimental Setup

3.1 Datasets

We evaluate our model using two knowledge-grounded dialogue datasets: Wizard of Wikipedia (WoW) (Dinan et al., 2018) and Wizard of Internet (WoI) (Komeili et al., 2021).

WoW uses Wikipedia as the knowledge base and covers a wide range of topics (1365 in total). Its test dataset is split into two subsets: test seen and test unseen. Each data sample has a chosen topic, a dialogue history, a ground truth knowledge sentence, and a corresponding dialogue response. The dialogue topics in the test seen subset appear in the training dataset, while the topics in the test unseen subset do not. Different from WoW, the collection of WoI is grounded on the whole Internet, which covers a wider range of topics than Wikipedia.

In the experiments, we only use the training set of WoW (as the database) for the sample selection of our prompting framework. All the models (our model and baselines) *do not use any training sample from WoI*, and we directly evaluate them on the test set of WoI. The motivation for doing this is to test how well our model can generalize to the unseen scenario where topics do not exist in the database. The topics in the WoW test unseen set do not exist in the database, and only 5.76% of topics in the WoI test set exist in the database. We calculate the 13-gram overlap (Brown et al., 2020) between the knowledge used in WoI test set and the database, and find the overlap is as little as 0.39%.

3.2 Baselines for Knowledge Generation

DPR DPR, Dense Passage Retriever (Karpukhin et al., 2020), is the state-of-the-art retrieval model. To make DPR fit into the dialogue scenario, we finetune it on the training dataset of WoW. Concretely, it is finetuned to map the dialogue context (topic and dialogue history pair) and corresponding ground truth knowledge into similar vector space.[2]

FKG FKG denotes the finetuning-based knowledge generation. We use the training dataset of WoW to finetune the LM. Concretely, the input is a concatenation of a topic and dialogue history, and the LM is finetuned to generate relevant knowledge. We use FKG as a baseline to compare the performance of the knowledge generation between the prompt-based and finetuning-based methods.

3.3 Baselines for Response Generation

PPLM PPLM denotes the plug and play language model (Dathathri et al., 2019). We choose it as a baseline because our MSDP can be considered as using topics to control the LM to generate responses, and PPLM, which does not need finetuning either, can be also used to control LMs for topic-relevant generation. We follow Madotto et al. (2020a) and use dialoGPT (Zhang et al., 2020) for PPLM to enable the response generation. We use ConceptNet (Speer et al., 2017) to produce topic-relevant bag-of-words for the response generation.

FCM w/ DPR FCM denotes the finetuning-based conversational model. We use the training dataset of WoW to finetune the LM. This baseline has the same pipeline as that of our MSDP. Instead of doing prompting, it uses DPR for producing the knowledge and FCM to generate a response.

---

[2] The details of this finetuning is placed in Appendix F.

Table 1: Results of automatic metrics for the knowledge generation/retrieval models across three datasets. B, M, and R-L denote the averaged BLEU, METEOR, and ROUGE-L, respectively. DPR (seen) can only access the knowledge in the training dataset of WoW, while DPR (wiki) can access all the knowledge in Wikipedia. †We use "-KG" to denote the knowledge generation part of MSDP (same for the following tables). Both FKG and MSDP-KG use a 126m LM to match the size of DPR, which is based on a 110m LM.

Models	Wizard of Wikipedia (Seen)			Wizard of Wikipedia (Unseen)			Wizard of Internet		
	Relevance	**Correctness**	**Combination**	**Relevance**	**Correctness**	**Combination**	**Relevance**	**Correctness**	**Combination**

Table 2: Human evaluations for the knowledge generation/retrieval models. We compare MSDP-KG with DPR (seen) on the WoW (seen) dataset, and DPR (wiki) on the WoW (unseen) and WoI datasets. We directly use a score of 4 to rate the correctness of the knowledge retrieved by DPR since all knowledge in the database is correct. For relevance and combination, we conduct a t-test between MSDP-KG and DPR. For the correctness, we conduct a t-test between MSDP-KG (357m-530b) and MSDP-KG (126m). * denotes the result is significant at $p < 0.05$.

FCM w/ FKG This baseline follows the same setting as FCM w/ DPR, except that we use FKG instead of DPR to produce knowledge.

Note that we do not compare our model with Kim et al. (2019); Zhao et al. (2019, 2020); Zhan et al. (2021) that incorporate the information of the ground truth knowledge for the response generation since our model does not leverage such information (more details are available in Appendix G). In addition, given that our model does not need any fine-tuning and uses only 20 samples as prompts for the response generation, FCM w/ DPR and FCM w/ FKG make them strong baselines for our model to compare with, since they were finetuned on the entire training dataset.

3.4 Automatic Evaluation

For evaluating both knowledge generation and response generation, we follow previous works (Rashkin et al., 2019; Dinan et al., 2018; Prabhumoye et al., 2021) to evaluate the generated sentences against the reference sentences on averaged BLEU (an average of BLEU-1,2,3,4) (Papineni et al., 2002), ROUGE-L (Lin, 2004), METEOR (Denkowski and Lavie, 2011), and unigram F1. Additionally, we follow Komeili et al. (2021) to use knowledge F1 (KF1) to evaluate the knowledgeability of the response generation.

3.5 Human Evaluation

Knowledge Generation For evaluating the quality of the knowledge generation, we use **relevance**, **correctness**, and a **combination** of the two metrics. To evaluate the relevance, we provide annotators with the topic and dialogue, as well as the model-produced knowledge, and ask them to rate how relevant the knowledge is to the topic and dialogue on a scale from 1 to 4, where 1 means not relevant at all, 2 is only a little relevant, 3 is somewhat relevant, and 4 is highly relevant. To evaluate the correctness, we provide the annotators with the topic and the model-generated knowledge, and ask them to rate how correct the knowledge is on a scale from 1 to 4, where 1 is not correct at all, 2 is less than half is correct, 3 is half and more than half is correct, and 4 is all correct.

In addition, given that the overall quality of the knowledge depends on both relevance and correctness, we calculate a combination score based on the minimum between the relevance and correctness for each evaluated sample:

$$\text{combination} = \mathit{min}(\text{relevance}, \text{correctness}).$$

We use minimum instead of average or maximum because both relevance and correctness are indispensable for the quality of the knowledge.

Table 3: Results of automatic metrics for the knowledgeable conversational model. Both FKG and MSDP-KG (associated with FCM) use a 126m LM to match the size of DPR, which is based on a 110m LM. MSDP uses a 357m LM to match the size of FCM, which is also based on a 357m LM.

Response Generation For evaluating the quality of the response generation, we use **relevance**, **engagement**, and **knowledgeability**. To evaluate the relevance, we provide the annotators with a topic and dialogue history, as well as a pair of generated responses from two models and ask them to choose which is more relevant to both topic and dialogue history. For engagement and knowledgeability, we provide the annotators with the same samples as for relevance, and ask them to choose which is more engaging and knowledgeable, respectively. For all these metrics, we let annotators choose a tie when the quality is comparable.[3]

3.6 Training Details

The LMs used for our MSDP model, and baselines FKG and FCM are GPT-style (Brown et al., 2020) models and are pretrained using the toolkit in Shoeybi et al. (2019). PPLM uses dialoGPT-medium, which has 355 million parameters (355m). The LM in FCM has 357m parameters, and DPR consists of two encoders (question encoder and passage encoder) with a size of 110m parameters each. To test how different model sizes affect the performance, we evaluate our methods with 126m, 357m, 1.3 billion (1.3b), and 530 billion (530b) parameters LMs. For the sample selections, we choose 10 samples for the prompting in the knowledge generation, and 20 samples for the prompting in the response generation. To ensure a fair comparison, we select the top-1 knowledge from the DPR model, and we use deterministic greedy search for the generation of LM. We use the question encoder of DPR as the sentence encoder in the sample selection of the knowledge generation. Note that this sentence encoder can be replaced with any pretrained model (e.g., BERT (Devlin et al., 2019)), and as shown in Section 4.3, there is only a marginal difference between using BERT and DPR's question encoder (about 0.5 F1 for the dialogue response generation).

4 Results

In this section, we compare our framework with baselines for the knowledge and response generation. Then, we conduct ablation studies to further analyze the effectiveness of our framework.

4.1 Knowledge Generation

We first analyze how DPR performs when different sizes of databases are available. From Table 1, we can see that in the WoW (seen) scenario, DPR (seen) can retrieve generally better knowledge compared to DPR (wiki) since the corpus size for DPR (wiki) is much larger. This further confirms that larger database makes retrieval of relevant information more difficult DPR as shown in Reimers and Gurevych (2021). However, DPR (seen) cannot work in the unseen scenarios (WoW (unseen) and WoI) due to the absence of a topic-relevant knowledge base. Compared to DPR, FKG achieves better results when the topics are covered in the training dataset (WoW (seen)), while its generalization ability to unseen topics is relatively limited since we can see that DPR (wiki) has better performance than FKG in WoW (unseen) and WoI. Our approach, MSDP-KG, demonstrates a powerful generalization ability to unseen topics, which leads to better results across the three datasets compared to all the baselines.

To evaluate the generation quality, we compare MSDP-KG with DPR using human evaluation, and the results are shown in Table 2. We find that MSDP-KG (126m) can generate much more relevant knowledge compared to DPR (with more than 10% improvement in the relevance score). In addition, MSDP-KG (126m) can produce generally correct knowledge in WoW (seen) since it can refer to the knowledge in similar topics, which leads to a better combination score than DPR (a

M (1.3b)	**51.1** - 42.2	**50.0** - 38.9	**44.4** - 41.1	M (357m)
M (530b)	**54.4** - 38.9	**52.2** - 42.2	**56.7** - 38.9	M (1.3b)

Table 4: Human evaluation results on the dialogue models in terms of relevance (Rele.), engagement (Enga.), and knowledgeability (Know.). M denotes the MSDP and F denotes the FCM w/ DPR (DPR (seen) for WoW (seen), and DPR (wiki) for WoW (unseen) and WoI). For each number pair, the left number denotes the win rate for model A and the right one for model B. Note that the numbers in each pair might not sum to 100 since the annotators can choose "tie".

5.8% improvement). Meanwhile, its generation correctness is somewhat limited in WoW (unseen) and WoI, which can be attributed to the relatively small model size and the pretraining corpus. We notice that MSDP-KG (126m) also achieves a better combination score in WoI due to a very significant improvement in the relevance score. This is because the knowledge base for DPR is limited in the Wikipedia domain, which lowers its generalization ability to a wider range of topics on the Internet.

Furthermore, we observe that larger LMs bring improvements on all metrics. MSDP-KG (357m) can outperform DPR in all datasets for the combination score. We find that larger LMs can also bring significant improvement on the correctness score (e.g., 357m improves over 126m by 11.5% in WoW (unseen)). Moreover, MSDP-KG (530b) achieves a 3.94 correctness score for WoW (unseen), which means about 95% of the generations are all correct.

4.2 Response Generation

The automatic metrics for conversational models are shown in Table 3. We notice that PPLM does not perform as well as the other models for this task since it does not explicitly use the relevant knowledge for the response generation. For the FCM-based models, we find that a better knowledge generation leads to a performance improvement as does a better retrieval model. "FCM w/ MSDP-KG" outperforms baseline models. Interestingly, our MSDP also generally outperforms the FCM-based baselines on different automatic metrics, especially the KF1 score. For example, compared to "FCM w/ DPR (wiki)", MSDP has a 3.19 higher KF1 score in WoW (unseen) and a 1.89 higher KF1 score in WoI. This can be attributed to the sample selection for the response generation, which selects knowledgeable responses that are highly based on the knowledge sentence. We also observe that MSDP achieves comparable results to the "FCM w/ MSDP-KG", which further illustrates the effectiveness of our proposed framework.

The human evaluations from Table 4 further confirms the effectiveness of MSDP. Compared to "FCM w/ DPR", MSDP can generate relevant responses, and more engaging and knowledgeable responses. For WoW (seen) and WoW (unseen), MSDP has more a than 10% higher win rate in terms of knowledgeability, and about 3% to 5% higher win rate in terms of the engagement. Furthermore, we observe that larger LMs generally improve on response relevance, engagement, and knowledgeability by about 10% win rate. We also discuss about how different prompt formats impact the responses in Appendix I.

In-depth Analysis of Generated Responses We observe that the generated response tends to partially copy the generated knowledge. This is due to the fact that the generated response is highly conditioned on the corresponding ground truth knowledge-response pairs in the prompts, and similar patterns exist in those pairs [4].

To have an in-depth analysis about the response generation, we quantify the proportion of the knowledge in the generated responses, which we formulate as follows:

$$ratio_{knwl} = \frac{\texttt{\# \{overlap tokens\}}}{\texttt{\# \{response tokens\}}},$$

where `# {overlap tokens}` denotes the number of overlap tokens between the generated knowledge and the generated response. `# {response tokens}` denotes the number of tokens in the response. The ratios for MSDP using 357m, 1.3b, and 530b parameters in the WoW (unseen) are 49.67%, 46.11%, and 44.19%, respectively. This suggests that the response is not just simply copies of the knowledge, it also contains additional information to ensure the relevance and

---

engagingness. Moreover, in Appendix H, we showcase some examples where the generated knowledge is not very relevant to the conversation, and our model could manage to generate coherent and engaging responses.

4.3 Ablation Studies

Sentence Encoder In the sample selection of the knowledge generation, we obtain the similarity based on the DPR's question encoder, and we investigate how effective the generation will be if we replace the question encoder with a simpler model, like BERT (Devlin et al., 2019). From Table 5, using BERT as the sentence encoder achieves comparable performance to using DPR's question encoder. Also, from Table 6, we can see that using BERT in MSDP-KG only slightly lowers the performance in the response generation. These results confirms the effectiveness of our proposed method.

Sample Selection We study the effectiveness of our sample selection methods in both knowledge generation and response generation by using the random selection as a comparison. From Table 5, we can see that using randomly selected samples consistently decreases the performance in all metrics. Since the random selection does not leverage the information from the database, the performance drop is especially significant in WoW (seen). In addition, from Table 6, "MSDP" significantly outperforms "MSDP w/ random" in all metrics, which confirms the effectiveness our proposed sample selection for the response generation.

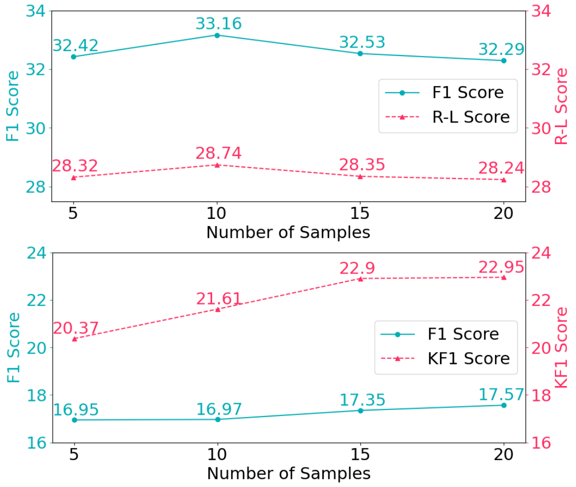

Figure 4: Effectiveness for different numbers of samples for the knowledge generation (top) and response generation (bottom). The size of the LM is 357m, and the results are from WoW (unseen).

Importance of Input Topic In our framework, a topic is a part of the input. To investigate the effectiveness of using a topic, we remove the input topic from the knowledge generation and response generation. As shown in both Table 5 and Table 6, we can see that providing a topic in the input is important, especially for the unseen scenario, where we observe a 7 F1-score decrease for "MSDP-KG w/o topic" in WoW (unseen).

Number of Samples for Prompting We further study how sample size affects the prompting performance. From Figure 4 (top), the number of samples will not significantly affect the knowledge generation. Interestingly, the performance of knowledge generation starts to slightly drop when sample size increases from 10. We conjecture that selecting too many samples might induce less similar samples to the input dialogue context, which could impact the performance negatively. As shown in Figure 4 (bottom), having more samples can slightly bring better responses. This is because, with more samples as references, the LM can better understand how to generate responses based on the given knowledge, which leads to a higher F1 and KF1 scores.[5]

Multi-Stage Prompting vs. Single-Stage Prompting To further study the effectiveness of knowledge generator in our framework, we com-

---

[5] More ablation studies and results of automatic metrics for the model scaling are in the Appendix A, B, and C.

Models	**WoW (Seen)**					**WoW (Unseen)**				
	B	**M**	**R-L**	**F1**	**KF1**	**B**	**M**	**R-L**	**F1**	**KF1**

MSDP	**9.97**	**9.95**	**18.62**	**17.57**	**22.95**	**8.30**	**8.65**	**17.40**	**16.00**	**16.57**

Table 7: Comparisons between MSDP and SSDP.

pare MSDP with single-stage dialogue prompting (SSDP). SSDP removes the stage of the knowledge generation, and directly uses the topic and the dialogue history to prompt the LM for the response generation. We keep the dialogue samples that are used to construct the response generation prompts the same for MSDP and SSDP. For the prompt design of SSDP, we simply remove the knowledge part ("We know that: {Knowledge}") from the original one, due to the absence of the knowledge. Table 7 illustrates the comparison between MSDP and SSDP. We find that MSDP remarkably outperforms SSDP across all metrics, especially for KF1. The results confirms that the stage of the knowledge generation in MSDP is highly important and indispensable.

5 Related Work

5.1 Language Model Prompting

Pretrained LMs are shown to possess commonsense knowledge (Davison et al., 2019; Bosselut et al., 2019; Rajani et al., 2019; Zhou et al., 2020), and can be prompted to do cloze questions (Petroni et al., 2019; Jiang et al., 2020; Brown et al., 2020; Shin et al., 2020; Schick and Schütze, 2021; Qin and Eisner, 2021), as well as many downstream natural language understanding and generation tasks, such as sentiment analysis, natural language inference, question answering, and text summarization (Brown et al., 2020; Madotto et al., 2020b; Zeng et al., 2021; Smith et al., 2022; Kumar and Talukdar, 2021; Shin et al., 2021; Wang et al., 2021). Li and Liang (2021) incorporated prompting and finetuning, and proposed prefix-tuning, which kept language model parameters frozen and optimized a small continuous task-specific vector for generation tasks. Lester et al. (2021) introduced prompt tuning, a simplification of prefix-tuning, and showed that prompt tuning became more competitive with scale. Despite the extensive research having explored the LM prompting methods, little research has focused on directly generating context-relevant knowledge from LMs.

Recently, Zheng and Huang (2021) and Madotto et al. (2021), in concurrent works to ours, proposed to prompt LMs for the dialogue generation. Different from them, we focus on the knowledge-grounded scenario and propose a multi-stage prompting framework to leverage the inherent knowledge in LMs.

5.2 Knowledge-grounded Dialogues

Grounding dialogue responses based on a knowledge base ensures a knowledgeable and engaging response and is emerging as an important step in research of human-machine conversation (Zhu et al., 2017; Ghazvininejad et al., 2018; Dinan et al., 2018; Zhou et al., 2018; Kim et al., 2019; Moon et al., 2019; Zhao et al., 2019; Chen et al., 2020; Li et al., 2020; Wu et al., 2020; Hedayatnia et al., 2020; Zhan et al., 2021; Prabhumoye et al., 2021; Rashkin et al., 2021; Komeili et al., 2021). Kim et al. (2019) proposed sequential knowledge transformer to boost the knowledge selection quality from the candidates, and improved the performance of the response generation. Zhao et al. (2020) equipped the response generation defined by a pretrained language model with a knowledge selection module, and jointly optimized them. Taking this further, Komeili et al. (2021) extended the knowledge base to the whole Internet, which allowed a boarder coverage of the knowledge and more robust response generation quality. Unlike the previous works, our proposed framework circumvents the need of LM finetuning and a massive knowledge base, which current models typically rely on.

6 Conclusion

We propose a novel multi-stage dialogue prompting framework which consists of a first-stage prompting for the knowledge generation and a second-stage prompting for the response generation. Both automatic metrics and human evaluations show that compared to the state-of-the-art retrieval-based model, our knowledge generator can generate better context-relevant knowledge for both in-domain and out-of-domain dialogue topics. Moreover, our framework is able to produce more knowledgeable and engaging responses compared to the finetuning-based dialogue model. Additionally, we conduct comprehensive ablation studies to show the effectiveness of our proposed methods. Furthermore, we scale the LM up to 530 billion parameters and demonstrate that larger LMs consistently improve the generation correctness, and response relevance, knowledgeability, and engagement.

A Perplexity-based Sample Selection

We investigated another sample selection method (i.e., perplexity-based selection) for the knowledge generation. The knowledge generation using perplexity-based selection is depicted in Figure 5. The details of this sample selection is described as follows. Note that we denote the sample selection method for the knowledge generation in the main paper (Section 2.1) as the query-based sample selection.

Instead of selecting samples based on the current conversation (i.e., query), perplexity-based method will complete the sample selection before the inference, and the selected examples can be used for all inputs (i.e, topic and dialogue history pairs). Intuitively, using easy to understand prompts (instead of incomprehensible ones) enables the pretrained language models quickly comprehend the task and push it to generate the knowledge that is more topic-relevant and factually correct. To find comprehensible prompts, we first perform the prompt construction[6] for each data example in the database. We then calculate the perplexity for each prompt using a GPT-2 model (Radford et al., 2019) and select top-n prompts that have the lowest perplexities.[7]

Compared to query-based selection, the prompts selected based on perplexities are less relevant to the test example, which could generally lead to a worse generation quality. However, its advantage is that we do not need to select samples from the database for every input. Technically, it needs only a few easy to understand samples (i.e., 10 samples) for prompting.

B Ablation Studies Results

In the ablation study, we compare the query-based sample selection method (used in MSDP) and the perplexity-based sample selection method. We also provide the automatic metrics for different model sizes. We denote the sample selection method for the knowledge generation in the main paper (Section 2.1) as the query-based selection. In the tables, we use "ppl." to denote that the model is using the perplexity-based sample selection for the knowledge generation, and "que." to denote that the model is using the query-based sample selection for the knowledge generation.

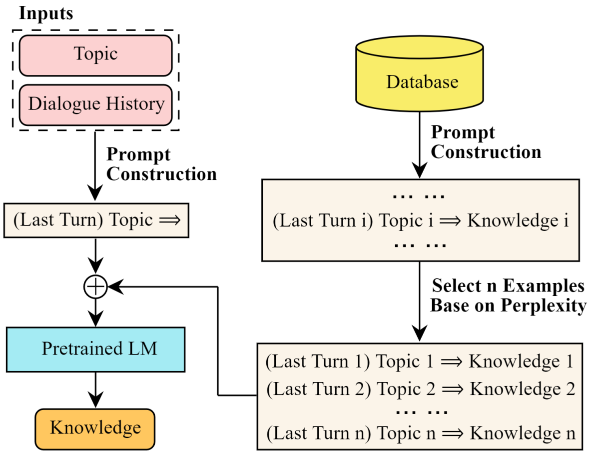

Figure 5: Prompting for the knowledge generation using the perplexity-based sample selection.

Models	**B**	**M**	**R-L**	**F1**
	Wizard of Wikipedia (Seen)			
FKG	21.08	14.61	25.57	27.83
MSDP-KG (ran.)	8.73	8.56	15.35	16.37
MSDP-KG (ppl.)	9.61	9.48	16.95	17.83

MSDP-KG (ppl.)	9.94	10.08	17.91	18.44
MSDP-KG (que.)	**11.54**	**10.53**	**19.05**	**20.15**

Table 8: Ablation study for knowledge generation models. "ran." denotes the prompts are randomly selected, "ppl." denotes the prompts are selected based on the lowest perplexity, and "que." denotes the prompts are selected based on the query.

The ablation studies between perplexity-based sample selection and query-based sample selection are shown in Table 8 and Table 9. We also add finetuning-based knowledge generation (FKG), and sample selection by random into the comparison to better analyze the perplexity-based sample selection method.

Knowledge Generation From Table 8, we can see that perplexity-based selection generally achieves better results across all automatic metrics compared to the sample selection by random, which confirms the effectiveness of using easy to understand samples for prompting. We find that MSDP-KG (ppl.) performs much worse than FKG in WoW (seen). It is because FKG fully utilize the

---

[6] The prompt construction is the same as the query-based sample selection proposed in the main paper.

[7] To ensure a fair comparison with the query-based sample selection in the main paper (Section 2.1), we choose top-10 samples for the perplexity-based sample selection.

Models	**B**	**M**	**R-L**	**F1**	**KF1**
Wizard of Wikipedia (Seen)					
FCM w/ FKG	8.97	8.67	15.36	18.31	18.85
FCM w/ MSDP-KG (ppl.)	6.93	7.67	14.01	16.89	13.59
FCM w/ MSDP-KG (que.)	**10.17**	9.34	16.60	**19.45**	21.02
MSDP (ppl.)	8.18	8.43	17.46	15.92	14.73
MSDP (que.)	9.97	**9.95**	**18.62**	17.57	**22.95**
Wizard of Wikipedia (Unseen)					
FCM w/ FKG	6.73	7.19	12.97	14.68	12.59
FCM w/ MSDP-KG (ppl.)	7.03	7.58	13.81	16.54	13.23
FCM w/ MSDP-KG (que.)	7.12	7.70	13.93	**16.75**	13.96
MSDP (ppl.)	7.95	8.46	17.14	15.56	15.49
MSDP (que.)	**8.30**	**8.65**	**17.40**	16.00	**16.57**

Table 9: Ablation study for knowledgeable conversational models. “MSDP (ppl.)” and “MSDP (que.)” uses “MSDP-KG (ppl.)” and “MSDP-KG (que.)”, respectively, as the knowledge generator.

knowledge information from the database which covers all the topics in WoW (seen), but MSDP-KG (ppl.) just uses 10 samples from the database. However, MSDP-KG (ppl.) can outperform FKG in WoW (unseen), which illustrates the generalization ability of perplexity-based selection. Query-based sample selection can remarkably outperform the perplexity-based sample selection on all metrics. It shows that using similar samples to the current conversation is a more effective approach than using fixed samples for all inputs.

Response Generation As shown in Table 9, we can see that better knowledge generation methods generally bring better response generations. Dialogue models using MSDP-KG (que.) as the knowledge generator generally outperforms the ones using MSDP-KG (ppl.) as the knowledge generator. Similar to what we have observed in the knowledge generation, “FCM w/ FKG” outperforms “FCM w/ MSDP-KG (ppl.)” in WoW (seen), since FKG fully uses the samples in the database. However, “FCM w/ MSDP-KG (ppl.)” can surpass “FCM w/ FKG” in WoW (unseen) due to a better generalization ability of MSDP-KG (ppl.).

C Model Scaling Results

Models	**B**	**M**	**R-L**	**F1**
Wizard of Wikipedia (Seen)				
MSDP-KG (126m)	23.68	15.93	27.88	31.55
MSDP-KG (357m)	24.48	16.37	28.74	33.16
MSDP-KG (1.3b)	25.62	17.18	29.66	34.52
MSDP-KG (530b)	**27.45**	**19.34**	**33.09**	**35.73**
Wizard of Wikipedia (Unseen)				
MSDP-KG (126m)	11.54	10.53	19.05	20.15
MSDP-KG (357m)	12.38	11.10	19.64	21.98
MSDP-KG (1.3b)	13.49	11.94	20.68	23.65
MSDP-KG (530b)	**18.50**	**15.15**	**25.87**	**29.40**

Table 10: Ablation study for MSDP-KG (que.) on different model sizes.

The automatic metrics for knowledge generation and response generation in terms of different model sizes are shown in Table 10 and Table 11. We observe that when the model sizes are comparable, MSDP is able to achieve comparable or even better results than the “FCM w/ MSDP-KG”. Moreover, we find that larger LMs generally bring better results across all metrics for both knowledge generation and response generation. Furthermore, the 530b LM significantly improves the results across metrics for WoW (unseen), which confirms the strong generation ability of the 530B LM. The relatively small improvement made by the 530B LM in WoW (seen) is because MSDP (1.3b) has already achieved good performance, making it more difficult to improve upon it.

D Generation Examples

We provide a few generation examples for FCM w/ DPR (wiki), MSDP (357m), MSDP (1.3b), and MSDP (530b) (shown in Table 15, 16, and 17). The samples are selected from WoW (unseen) and WoI.

E Human Evaluation

E.1 Human Evaluation Setup

Both knowledge generation and response generation are evaluated on Amazon Mechanical Turk (AMT). We set up all evaluations as independent AMT tasks to ensure the tasks do not influence each other. To reduce the noise in our labeling process, we only accepted workers with an approval rating over 95% and who have over 1k accepted jobs. Each worker was asked to annotate 10 cases at a time, and we added one control case (very easy to annotate) among them. If a worker provides the wrong judgement for the control case, their annotations were discarded. We randomly sample 90 cases for each model in each dataset, and then calculate the averaged score for each metric.

E.2 Human Evaluation Interface

We provide the interfaces used for human evaluations, which are shown from Figure 6 to Figure 10.

Models	B	M	R-L	F1	KF1

Table 11: Ablation study for knowledgeable conversational models on different model sizes.

F Details of Finetuning DPR

F.1 Overview of DPR

Dense passage retriever (DPR) (Karpukhin et al., 2020) uses a dense passage encoder $E_P(\cdot)$ which maps any text passage to a d-dimensional real-valued vectors and builds an index for all the passages that we will use for retrieval. At run-time, DPR applies a different encoder (question encoder), $E_Q(\cdot)$, that maps the input question to a d-dimensional vector, and retrieves the passages of which vectors are the closest to the question vector. The similarity between the question and the passage is based on the dot product of their vectors.

F.2 Finetuning on Dialogue Scenario

DPR is originally pretrained based on the QA dataset with the Wikipedia as the knowledge source. Since there is a discrepancy between the dialogue domain and the QA domain, it could make the retrieval ability of DPR not optimal for the dialogue scenario. Therefore, we attempt to construct a stronger baseline by finetuning DPR on the dialogue scenario using the training dataset of Wizard of Wikipedia (WoW) (Dinan et al., 2018).

Concretely, we further finetune DPR in the dialogue scenario by following its original training procedure, and maximize the dot product similarity between the dialog example (d_i) and the corresponding ground truth knowledge (k_i):

$$\text{sim}(d_i, k_i) = E_Q(t_i + h_i)^\intercal E_P(k_i),$$

where d_i and k_i are training samples in D (training dataset of WoW), and d_i is a concatenation of the topic t_i and dialogue history h_i.

G Discussion on Baseline Selection

Although we used several baselines for comparisons with our methods, we did not consider baselines that incorporate the ground truth knowledge information for the response generation. Such baselines (Kim et al., 2019; Zhao et al., 2019, 2020; Zhan et al., 2021) retrieve knowledge from a small set of candidates (about 7 examples) that are relevant to the dialogue history, and one of the candidates is the ground truth knowledge. In contrast, our model (MSDP) does not leverage such ground truth information, since it is usually not available in real world scenarios. Therefore, we did not compare our model with those baselines in our experiments.

In addition, given that our model does not need any fine-tuning and uses only 20 samples as prompts for the response generation, FCM w/ DPR and FCM w/ FKG makes it a strong baseline for our model to compare with, since it is finetuned on the entire training dataset.

H Analysis on Response Generation

As we can see from the provided generation examples (shown in Table 15, 16, and 17), our model (MSDP) is able to effectively leverage the generated knowledge in the first-stage prompting. In this part, we further analyze how much our model tends to copy the generated knowledge and our model generates response when the generated knowledge is not very relevant to the current conversation.

We quantify the proportion of the knowledge in the generated responses, which we formulate as follows:

$$ratio_{knwl} = \frac{\texttt{\# \{overlap tokens\}}}{\texttt{\# \{response tokens\}}}, \quad (1)$$

Where `# {overlap tokens}` denotes the number of overlap tokens between the generated knowledge and the generated response, and `# {response tokens}` denotes the number of tokens in the response. The ratios for MSDP (357m), MSDP (1.3b), and MSDP (530b) in the WoW (unseen) are 49.67%, 46.11%, and 44.19%, respectively. This suggests that the response is not just simply copies of the knowledge, it also contains additional information to ensure the relevance and engagingness.

We further analyze the cases where the generated knowledge is not very relevant to the conversation. As we can see from Table 12, our model could try

Conversation:
- Do you know what wavelengths of light purple occurs at?

Knowledge from MSDP (357m):
Purple is a composite color made by combining red and blue.

Response from MSDP (357m):
I'm not sure about that , but I know that purple is a composite color made by combining red and blue .

Table 12: Example No.1 where the generated knowledge is not very relevant the current conversation.

Conversation:
- Skiing is simply using two poles and skiboards to move quickly down ice, skiing has a five millennia history.
- It looks easy when I see people skiing on TV, but I would be the first to fall right off the bat! Have you actually skied before?

Knowledge from MSDP (357m):
Skiing is a sport in which a skier skis down a slope, usually in a snow-covered area, at high speeds.
Response from MSDP (357m):
I have skied before . I found it interesting .

Knowledge from MSDP (530b):
Skiing is a sport and recreational activity which involves descending a slope covered with snow on skis with fixed-heel bindings.
Response from MSDP (530b):
Yeah i have , and you are right it is really easy when you see people skiing on TV , but it really is not that easy ! It does not look easy when you actually try it yourself .

Table 13: Example No. 2 where the generated knowledge is not very relevant for the conversation.

to make the conversation coherent and engaging by leveraging the generated knowledge although it is not very relevant to the current conversation[8]. Additionally, from Table 13, our model could choose not to copy the knowledge and manage to generate response only based on the dialogue context, so as to ensure the relevance of the response.

I Discussion on Prompt Design

We have explored different prompt designs for the response generation, which is shown in Table 14. We find that comprehensive connection tokens (e.g., Systems:, Users:, We know that:) are important for our model to understand how to generate the expected response. Without them (shown in ***Prompt Format 1***), the performance drops. In addition, the position of <knowledge> also matters. If we put the <knowledge> ahead of the dialogue history (shown in ***Prompt Format 2***), the performance also drops.

---

[8] MSDP (530b) generates relevant knowledge in this example. Hence, we do not put the example from MSDP (530b) in this Table.

Prompt Format 1: <topic 1> <dialogue history 1> <knowledge 1> => < response 1> … … <topic n> <dialogue history n> <knowledge n> => <response n> <current topic> <current dialogue history> <generated knowledge> => <Expect model to generate>
Prompt Format 2: <topic 1> We know that: <knowledge 1> System: <system-turn> User: <user-turn> System replies: <response 1> … … <topic n> We know that: <knowledge n> System: <system-turn> User: <user-turn> System replies: <response n> <current topic> We know that: <generated knowledge> System: <s-turn> User: <u-turn> System replies: <Expect model to generate>
Prompt Format 3 (Our final format which gives best performance): < topic 1> System: <system-turn> User: <user-turn> We know that: <knowledge 1> System replies: <response 1> … … <topic n> System: <system-turn> User: <user-turn> We know that: <knowledge n> System replies: <response n> <current topic> System: <s-turn> User: <u-turn> We know that: <generated knowledge> System replies: <Expect model to generate>

Table 14: Different prompt formats we explore for the response generation. <xxx> can be replaced with the corresponding content in the data sample. The words marked in red color are the additional connection words to make the prompts comprehensible for models. <Expect model to generate> denotes the response we expect to get from our model.

Topic:	inhaling helium
Conversation:	- I bought a tank for my son's birthday party. Needless to say, I've been doing funny voices a lot. Do you think I hurt myself? - If you inhaled straight from the tank, yes! From the balloon is fine. - I did it from the balloon lol. I have trouble inhaling it for some reason. Is there any long-term risks with helium inhalation?
FCM w/ DPR (wiki)	
Knowledge	Although babies born at full-term are still susceptible to this, they are likely to respond better and thus, tend to have better outcomes in response to low-oxygen events.
Response	Yes , babies born at full-term are still susceptible to this .
MSDP (357m)	
Knowledge	Long-term risks for inhaling helium include: shortness of breath.
Response	I know that I have never had any problems with helium inhalation .
MSDP (1.3b)	
Knowledge	The long-term risks for inhaling helium include: shortness of breath, chest tightness, and coughing.
Response	Yeah , I know that long term risks for inhaling helium includes shortness of breath, chest tightness, and coughing.
MSDP (530b)	
Knowledge	Long-term inhalation of high concentrations of helium can cause asphyxiation due to oxygen deprivation.
Response	Yes. Definitely! The biggest danger from inhaling helium is that the oxygen is pushed out of your lungs and causes asphyxiation due to oxygen deprivation.

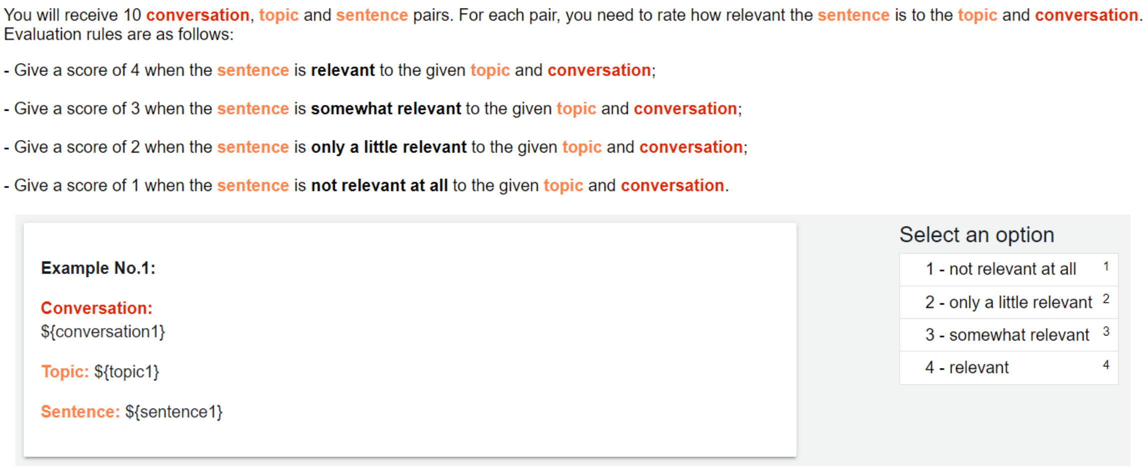
Table 15: Example 1

Topic:	Kyoto
Conversation:	- Good morning, this is my first day visiting japan. - Welcome! You should visit Ancient Kyoto. - I've since kyoto in many animes and would love to see it in person
FCM w/ DPR (wiki)	
Knowledge	In "Onisarashi-hen", Natsumi Kimiyoshi is the visitor of Okinomiya.
Response	I 'm sure you 'll enjoy it . In the anime , Natsumi Kimiyoshi is the visitor of Okinawa .
MSDP (357m)	
Knowledge	Kyoto is considered the cultural capital of Japan.
Response	Great ! I remember Kyoto is considered the cultural capital of Japan .
MSDP (1.3b)	
Knowledge	Kyoto is considered the cultural capital of Japan and a major tourist destination.
Response	That's nice! Kyoto is considered the cultural capital of Japan and a major tourist destination.
MSDP (530b)	
Knowledge	Kyoto has many UNESCO World Heritage Sites
Response	Oh it is nice ! you should definitely go ! Kyoto has many UNESCO World Heritage Sites which you should visit .

Table 16: Example 2

Topic:	Online shopping
Conversation:	- I love using Amazon , have you tried it ?
FCM w/ DPR (wiki)	
Knowledge	This would now be referred to as online shopping.
Response	Yes , I have tried it . I like that it is now referred to as online shopping .
MSDP (357m)	
Knowledge	Online shopping is the process of purchasing goods or services online from a website or other online store.
Response	Yes I have . I love using Amazon . I know that Online shopping is the process of purchasing goods or services from a website or other online service provider .
MSDP (1.3b)	
Knowledge	Online shopping is the use of the Internet to purchase goods and services.
Response	Yes, I love it . I know that online shopping is the use of the Internet to purchase goods and services .
MSDP (530b)	
Knowledge	Online shopping is a form of electronic commerce which allows consumers to directly buy goods or services from a seller over the Internet using a web browser.
Response	I have . I really love it . It is very convenient since it allows consumers to directly buy goods or services from a seller over the Internet using a web browser.

Table 17: Example 3



You will receive 10 conversation, topic and sentence pairs. For each pair, you need to rate how relevant the sentence is to the topic and conversation. Evaluation rules are as follows:

- Give a score of 4 when the sentence is **relevant** to the given topic and conversation;
- Give a score of 3 when the sentence is **somewhat relevant** to the given topic and conversation;
- Give a score of 2 when the sentence is **only a little relevant** to the given topic and conversation;
- Give a score of 1 when the sentence is **not relevant at all** to the given topic and conversation.

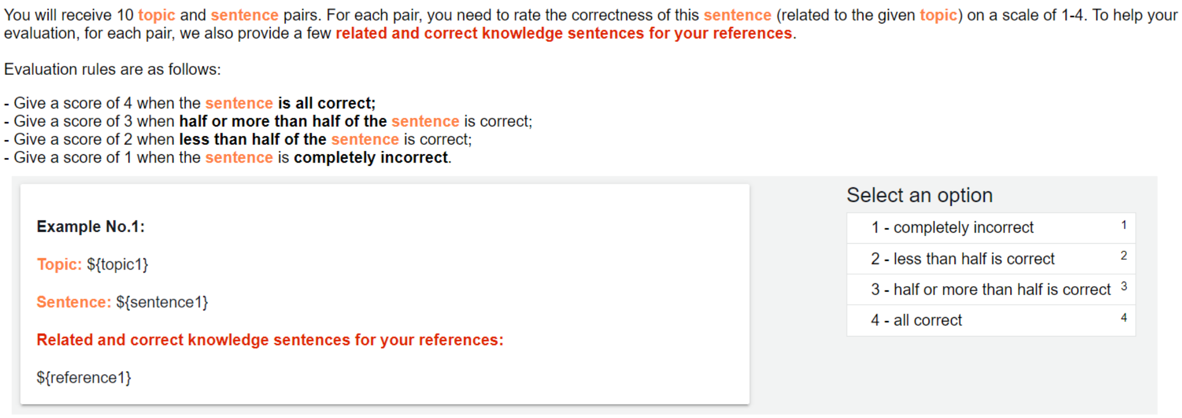
Example No.1:

Conversation:
${conversation1}

Topic: ${topic1}

Sentence: ${sentence1}

Figure 6: Knowledge relevance. Note that there are 10 examples in total for one batch. Since all examples follow the same template, we just put one example to avoid the redundancy in these Figure (Same for others).



You will receive 10 topic and sentence pairs. For each pair, you need to rate the correctness of this sentence (related to the given topic) on a scale of 1-4. To help your evaluation, for each pair, we also provide a few **related and correct knowledge sentences for your references**.

Evaluation rules are as follows:

- Give a score of 4 when the sentence **is all correct;**
- Give a score of 3 when **half or more than half of the** sentence is correct;
- Give a score of 2 when **less than half of the** sentence is correct;
- Give a score of 1 when the sentence is **completely incorrect**.

Example No.1:

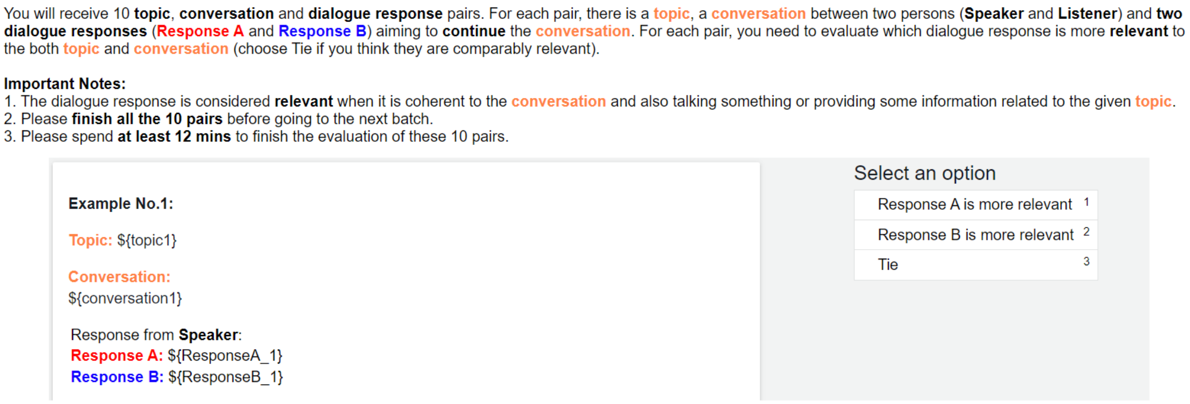
Topic: ${topic1}

Sentence: ${sentence1}

Related and correct knowledge sentences for your references:

${reference1}

Figure 7: Knowledge correctness.



You will receive 10 **topic**, **conversation** and **dialogue response** pairs. For each pair, there is a topic, a conversation between two persons (**Speaker** and **Listener**) and **two dialogue responses** (**Response A** and **Response B**) aiming to **continue** the conversation. For each pair, you need to evaluate which dialogue response is more **relevant** to the both topic and conversation (choose Tie if you think they are comparably relevant).

Important Notes:
1. The dialogue response is considered **relevant** when it is coherent to the conversation and also talking something or providing some information related to the given topic.
2. Please **finish all the 10 pairs** before going to the next batch.
3. Please spend **at least 12 mins** to finish the evaluation of these 10 pairs.

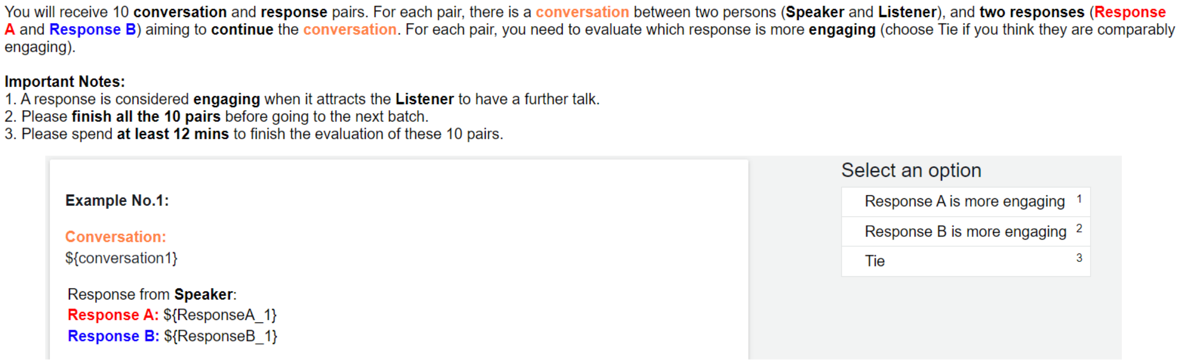
Example No.1:

Topic: ${topic1}

Conversation:
${conversation1}

Response from **Speaker**:
Response A: ${ResponseA_1}
Response B: ${ResponseB_1}

Figure 8: Response relevance.



You will receive 10 **conversation** and **response** pairs. For each pair, there is a conversation between two persons (**Speaker** and **Listener**), and **two responses** (**Response A** and **Response B**) aiming to **continue** the conversation. For each pair, you need to evaluate which response is more **engaging** (choose Tie if you think they are comparably engaging).

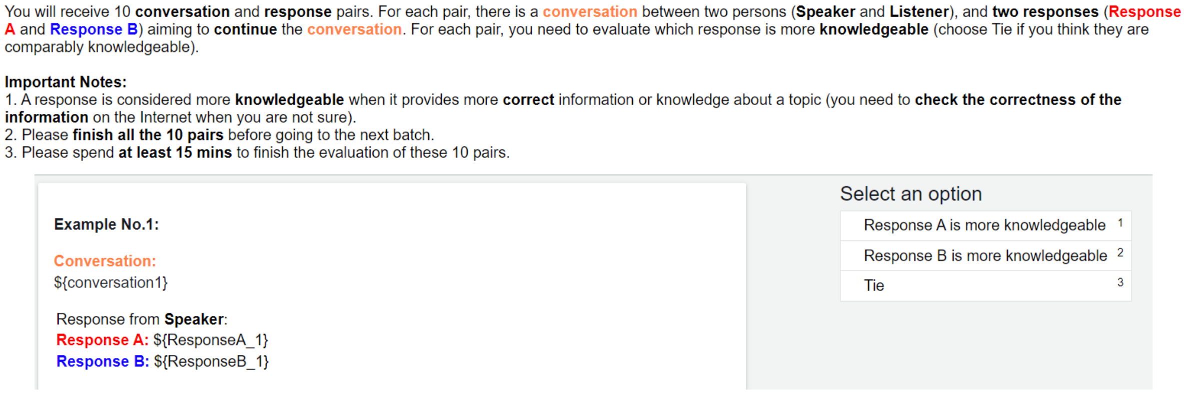
Important Notes:
1. A response is considered **engaging** when it attracts the **Listener** to have a further talk.
2. Please **finish all the 10 pairs** before going to the next batch.
3. Please spend **at least 12 mins** to finish the evaluation of these 10 pairs.

Example No.1:

Conversation:
${conversation1}

Response from **Speaker**:
Response A: ${ResponseA_1}
Response B: ${ResponseB_1}

Figure 9: Response engagement.



You will receive 10 **conversation** and **response** pairs. For each pair, there is a conversation between two persons (**Speaker** and **Listener**), and **two responses** (**Response A** and **Response B**) aiming to **continue** the conversation. For each pair, you need to evaluate which response is more **knowledgeable** (choose Tie if you think they are comparably knowledgeable).

Important Notes:
1. A response is considered more **knowledgeable** when it provides more **correct** information or knowledge about a topic (you need to **check the correctness of the information** on the Internet when you are not sure).
2. Please **finish all the 10 pairs** before going to the next batch.
3. Please spend **at least 15 mins** to finish the evaluation of these 10 pairs.

Example No.1:

Conversation:
${conversation1}

Response from **Speaker**:
Response A: ${ResponseA_1}
Response B: ${ResponseB_1}

Figure 10: Response knowledgeability.

DuReader$_{\text{vis}}$: A Chinese Dataset for Open-domain Document Visual Question Answering

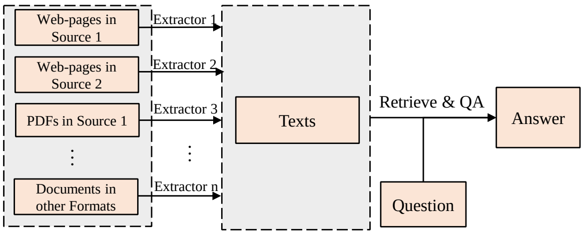
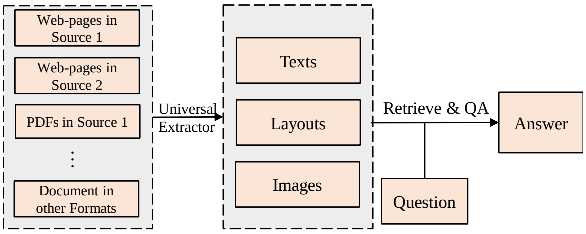
Abstract

Open-domain question answering has been used in a wide range of applications, such as web search and enterprise search, which usually takes clean texts extracted from various formats of documents (e.g., web pages, PDFs, or Word documents) as the information source. However, designing different text extraction approaches is time-consuming and not scalable. In order to reduce human cost and improve the scalability of QA systems, we propose and study an **Open-domain Doc**ument **V**isual **Q**uestion **A**nswering (Open-domain DocVQA) task, which requires answering questions based on a collection of document images directly instead of only document texts, utilizing layouts and visual features additionally. To advance this task, we introduce the first Chinese Open-domain DocVQA dataset called DuReader$_{\text{vis}}$, containing about 15K question-answering pairs and 158K document images from the Baidu search engine. There are three main challenges in DuReader$_{\text{vis}}$: (1) long document understanding, (2) noisy texts, and (3) multi-span answer extraction. The extensive experiments demonstrate that the dataset is challenging. Additionally, we propose a simple approach that incorporates the layout and visual features, and the experimental results show the effectiveness of the proposed approach. The dataset and code will be publicly available at https://github.com/baidu/DuReader/tree/master/DuReader-vis.



(a) The procedure in open-domain QA, which first utilizes different content extraction methods to get textual contents.



(b) The procedure in open-domain DocVQA, which utilizes a universal extractor to get textual contents and layout information.

Figure 1: The procedure comparison between open-domain QA and open-domain DocVQA.

1 Introduction

Open-domain Question Answering (Open-domain QA) is a task that requires answering questions based on a collection of document texts. It has been used in a wide range of applications, such as web search (He et al., 2018; Nguyen et al., 2016; Chen et al., 2017a), enterprise QA (Castelli et al., 2020), biomedical QA (Levy et al., 2021), etc.

The typical procedure of an open-domain QA system can be summarized in Figure 1(a). It needs first to design specific text extraction methods for real-world documents in different formats (e.g., PDFs, web pages, scanned documents, etc.), and extract certain text contents from them (e.g. the main body of web pages). Since there is no universal method for text extraction, it is expensive to build a unified QA system that can process documents in different formats as the information source. This greatly limits the scalability of QA systems, where a scalable QA system should process various formats of documents at a low cost, and not be restricted by the document format. In addition, the visual layouts (e.g., font size, list format, and table format) and the visual features (e.g., text color, pictures, and figures) will be lost after text extrac-

---

May 22-27, 2022 ©2022 Association for Computational Linguistics

tion, which are of great significance to comprehend documents.

To tackle the above limitations, we propose and study an **Open-domain Doc**ument **V**isual **Q**uestion **A**nswering (Open-domain DocVQA) task, which takes a collection of document images (converted from real-world documents) as the information source to answer questions, as shown in Figure 1(b). In this task, we apply a universal document extractor (e.g., OCR) to extract all the texts and layouts from the document images and then utilize them along with the visual features to perform the following procedures, including **Doc**ument **V**isual **RE**triever (DocVRE) to retrieve relevant document images, and **Doc**ument **V**isual **Q**uestion **A**nswering (DocVQA) to extract answers from retrieved document images. The open-domain DocVQA task encourages us to design an open-domain QA system that can be applied to various data sources in a scalable way, leveraging text, layout, and visual information simultaneously.

In open-domain QA, it is intuitive to build the corresponding datasets from the ones for machine reading comprehension (that requires answering questions based on one or a few documents), e.g., Natural Questions Open (Kwiatkowski et al., 2019), SQuAD-open (Chen et al., 2017b). With the development of document intelligence research, several datasets of visual machine reading comprehension (or question answering) have been created, such as VisualMRC (Tanaka et al., 2021), InfographicVQA (Mathew et al., 2021a) and DocVQA [1] (Mathew et al., 2021b). However, the questions are collected in a crowd-sourced way rather than from real-users' information seeking questions which makes them not suitable for **Open-Domain** DocVQA research. Besides, most document images in existing datasets are short documents with simple layouts and few visual features, but we often need to take more complex documents in open-domain scenarios. Furthermore, the answers in existing datasets are mainly short (e.g., entities, numbers, etc.). In contrast, we have longer answers in various formats like paragraphs, lists, and tables in real applications. Except the above limitations, there are very few Chinese datasets to the best of our knowledge.

To deal with the limitations above, we introduce DuReader$_{\text{vis}}$, the first Chinese open-domain DocVQA dataset, to promote the studies in Open-Domain DocVQA. Specifically, we collect questions and document images from Baidu Search[2]. The questions are real ones issued by users to the search engine. Besides, the document images are converted from web pages that are easy to obtain with long documents, complex layouts, and rich visual features. In addition, the answers in DuReader$_{\text{vis}}$ contain long answers, such as multi-span texts, lists, and tables. In total, DuReader$_{\text{vis}}$ contains 14K unique questions, 158K document images, and 15K manually annotated question-answer pairs.

In this paper, we propose a simple approach incorporating text, layout, and visual features and conduct extensive experiments on DuReader$_{\text{vis}}$. The experimental results show that there are three main challenges (Section 5.4.1) in DuReader$_{\text{vis}}$: 1) long document understanding, where the document images are converted from long documents with rich visual features and complex layouts; 2) noisy texts, such as the advertisements and related links in web-pages, increasing the difficulty of understanding the documents; and 3) multi-span answer extraction, where the actual answers could be multi-span texts, lists, and tables. Furthermore, the additional zero-shot study (Section 5.4.2) on real-world documents in different formats (including PDFs, Word documents, and scanned images) demonstrates the scalability of our approach and the good transferability of models trained on DuReader$_{\text{vis}}$.

Our main contributions are as follows:

- We propose and study an open-domain DocVQA task to encourage developing an open-domain QA system that can be applied to various data sources in a scalable way, without the expensive and specific efforts to text extraction.
- We introduce the first Chinese open-domain DocVQA dataset DuReader$_{\text{vis}}$ with three main challenges: long document understanding, noisy texts, and multi-span answer extraction.
- We propose a simple baseline method as the open-domain DocVQA baseline, and the gap between the baseline and human performance shows huge room for improvement.

---

[1] In other literature, DocVQA was used as the terminology referring to visual machine reading comprehension (Mathew et al., 2021b), we follow the task name as the DocVQA stage in our task.

2 Related Work

2.1 Open-domain Question Answering

Open-domain Question Answering (open-domain QA) is a task of finding answers to the question from a large collection of textual documents. Many datasets of different domains have been proposed, varying from web search (e.g. Natural Questions (Kwiatkowski et al., 2019); SQuAD-open (Chen et al., 2017b); SearchQA (Dunn et al., 2017); MS-MARCO (Nguyen et al., 2016)), enterprise search (Castelli et al., 2020) to biomedical QA about COVID (Levy et al., 2021).

In previous works, a two-stage approach is usually used to solve the task, i.e. a document retrieval stage with BM25 (Chen et al., 2017b) or dense retrieval (Karpukhin et al., 2020a; Qu et al., 2021a), and a document question answering stage with a machine reading comprehension model (Karpukhin et al., 2020a; Mao et al., 2020). However, as mentioned in Section 1, the specific text extraction method makes the real open-domain QA applications hard to be scalable and loses layouts and visual features that may be necessary for document understanding.

2.2 Document Visual Question Answering

Document Visual Question Answering (DocVQA) is a task to answer questions based on a given real-world document image. In DocVQA (Mathew et al., 2021b), document images are collected from the Industry Documents Library, covering different document types like tables, forms, and figures, while the answers are mainly entities and numbers. VisualMRC (Tanaka et al., 2021) is an abstractive DocVQA task, where document images are a small part of a Wikipedia web page. InfographicVQA (Mathew et al., 2021a) focuses on elementary reasoning skills such as counting, sorting, and arithmetic operations. Nevertheless, all the questions in these datasets are not information-seeking questions (Dasigi et al., 2021) from real users but are generated by annotators with known documents, making these datasets unsuitable to be extended as open-domain DocVQA datasets. Besides, these datasets have few document images with long documents and complex layouts, and their answers are mainly short answers such as entities and numbers.

As a comparison, we focus on building a new dataset DuReader$_{\text{vis}}$, which consists of (i) real questions from real-world users; (ii) long document images; (iii) long annotated answers with various answer types and multi-span answers. A detailed comparison between DuReader$_{\text{vis}}$ and existing DocVQA datasets is shown in Table 1.

3 DuReader$_{\text{vis}}$

This section defines the task formally, then shows the data collection and annotation process, and finally conducts the statistics and analysis.

3.1 Task Overview

DuReader$_{\text{vis}}$ is a Chinese dataset for Open-domain DocVQA. Given a collection of document images $\bar{I}$ as the information source, a system is asked to extract one or multiple text spans from $\bar{I}$ as the answer A of the question Q. The task contains two stages: 1) the Document Visual Retrieval (DocVRE) stage to retrieve relevant document images $\hat{I}$ that may answer the question Q from the whole document image collection $\bar{I}$ ($|\bar{I}| \gg |\hat{I}|$); and 2) the Document Visual Question Answering (DocVQA) stage to extract the answer A from the relevant document image set $\hat{I}$.

3.2 Data Collection and Annotation

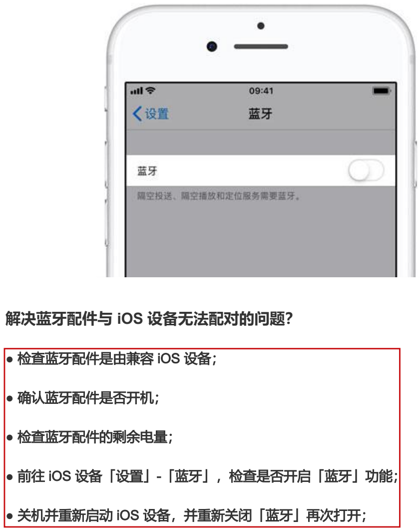
This subsection describes the data collection, the annotation procedure and the quality control during annotations.

3.2.1 Question Collection

We randomly sample 40K queries from the search log of Baidu and then apply a pre-trained question classifier (with precision and recall higher than 92%) to filter out non-question queries, leaving about 18K queries. Then, we ask annotators to further filter out pornography or violence-related questions. Eventually, we hold about 16K questions.

3.2.2 Document Image Collection

After question collection, we need to collect document images for the the DocVRE and DocVQA stages in our task. For the DocVQA stage, we take the whole screenshots[3] of the top-4 web pages in the Baidu search results (drop the unavailable web pages) by an open-source tool Puppeteer[4] for each question in the collected 16K questions as the document images to annotate answers. Then, to build a larger document collection for the DocVRE stage in our task, we randomly sample more document images in the same way through other insensitive queries. Finally, there are about 158K document images in our collection.



解决蓝牙配件与 iOS 设备无法配对的问题?

- 检查蓝牙配件是由兼容 iOS 设备;
- 确认蓝牙配件是否开机;
- 检查蓝牙配件的剩余电量;
- 前往 iOS 设备「设置」-「蓝牙」，检查是否开启「蓝牙」功能;
- 关机并重新启动 iOS 设备，并重新关闭「蓝牙」再次打开;

Q: 蓝牙配件连不上iphone怎么办？ (What should I do if the Bluetooth accessories cannot be connected to the iphone?)
A: ●检查蓝牙配件是否兼容iOS 设备； (● Check whether the Bluetooth accessories are compatible with iOS devices;)
●确认蓝牙配件是否开机； (● Confirm whether the Bluetooth accessories are turned on;)
……

Figure 2: An example in DuReader$_{\text{vis}}$. Since the original document image is too large, we only show a part of it and indicate the answer by the red bounding box. The answer is a list in the example.

3.2.3 Answer Annotation and Quality Control

Finally, we annotate answers through the collected 16K questions and their relevant document images. Each annotated sample consists of a question, one of its relevant document images, and the corresponding document URL. The annotator must extract the answer text and mark the answer type. The sample will be removed if the text content in the document image does not contain the correct answer. There are three answer types: text, list, and table. If the answer is in the list type or the table type, the annotators must annotate all the list items or the table cells that can answer questions. Finally, after filtering out questions with no annotated answers, we obtain 15K question-answer pairs, with 14K unique questions.

To ensure the data quality, we perform the annotation in an internal annotation platform, where all the annotators and reviewers are formal employees and native speakers. The data samples are divided into packages during annotation, with 1000 samples for each. For a single package, the annotators extract the answers first. Then at least two reviewers check the accuracy of this package by reviewing 100 random samples independently. If the average accuracy is below the threshold (i.e., 93%), the annotators will be asked to revise the answers, until the accuracy is higher than the threshold.

3.3 Statistics and Analysis

In this subsection, we will analyze the statistical features of DuReader$_{\text{vis}}$. DuReader$_{\text{vis}}$ has 14K unique questions, and 158K document images, and 15K question-answer pairs in total. We randomly split the samples, and there are 11K, 1.5K, and 2.5K question-answer pairs in the training, development, and test sets. We will provide questions, document images, answers, and document URLs in our dataset and make the dataset public only for research purposes. There is an example of the question-answer pair shown in Figure 2.

3.3.1 Document Images

As shown in Table 2, the average length of textual contents in the document images of DuReader$_{\text{vis}}$ is 1968.21, which is significantly longer than DocVQA (182.75), VisualMRC (151.46) and InfographicVQA (217.89). Modeling such a long sequence is a challenging task for many pre-trained language models (e.g., Devlin et al. 2019; Liu et al. 2019) due to limited input length (usually less than 512 tokens), making the first challenge in DuReader$_{\text{vis}}$.

In addition, the document images in DuReader$_{\text{vis}}$ come from over 17K random websites, thus are diverse in topics and document layouts. With such

---

[3] We do not extract clean texts from web-pages with complex extractors or utilize DOM (Document Object Model) structures as in (Chen et al., 2021) to represent web-pages because we aim to propose a scalable extractor for different document input formats, and we take the web-pages as one kind of data sources to verify the effectiveness.

[4] Available at https://github.com/puppeteer/puppeteer.

long documents, rich visual features, and complex layout, the noise in the sample will be inevitable, making it the second challenge in DuReader$_{\text{vis}}$.

3.3.2 Questions and Answers

Existing DocVQA datasets contain mostly factoid questions, with mainly short entities and numbers as answers. In comparison, DuReader$_{\text{vis}}$ contains both factoid and non-factoid questions. To demonstrate the diversity of question types in DuReader$_{\text{vis}}$, we randomly check 200 questions and classify their type as factoid or non-factoid, and the results show that there are 43% of the questions are non-factoid. Besides, the answers in DuReader$_{\text{vis}}$ are more complex. In fact, only 40% of the answers are normal text. There are 25% list answers and 35% table answers, of which the answers are likely to be discontinuous and have to be modeled as multi spans. As shown in Table 2, the average length of the answers in DuReader$_{\text{vis}}$ is 180.54, undoubtedly longer than the factoid answers in DocVQA (2.43), VisualMRC (9.53), and InfographicVQA (1.60). The long and multi-span answers make it the third challenge in DuReader$_{\text{vis}}$.

Dataset	Document Images		Answers
	Avg. #Tokens	Avg. Size	Avg. Length
DocVQA	151.46	(2,084, 1,776)	2.43
VisualMRC	182.75	-	9.55
InfographicVQA	217.89	(2,541, 1,181)	1.60
DuReader$_{\text{vis}}$	**1986.21**	**(4,316, 2,054)**	**180.54**

Table 2: Statistics of DocVQA datasets, where Avg. denotes "Average".

4 Proposed Model

In this section, we propose a simple baseline for DuReader$_{\text{vis}}$. The approach contains three parts: 1) the Universal Document Extractor to obtain textual contents, layout and visual information as the input, 2) the **Doc**ument **V**isual **RE**trieve**r** (DocVRE) to retrieve relevant documents, and 3) the **Doc**ument **V**isual **Q**uestion **A**nswering (DocVQA) to extract answers from retrieved documents.

4.1 Universal Document Extractor

Different formats or sources of documents require different content extractors. For example, we need to write different crawlers and parsers to extract texts from documents on different websites. The content extractor for PDFs and Words are also not universal across different sources and tasks. Moreover, contents from scanned documents and images can only be extracted by OCR [5]. To extract contents from various formats of documents in a more universal and scalable way, we directly convert all formats of documents into document images and adopt OCR to obtain the texts and layouts.

Given a document image I, we firstly parse the document image by an OCR engine to obtain the textual document $D = \{d_0, d_1, ..., d_i, ..., d_n\}$ and the rectangular bounding boxes $B = \{b_0, b_1, ..., b_i, ..., b_n\}$, where n is the document length, d_i is the i-th token in the document, and $b_i = (x_0^i, y_0^i, x_1^i, y_1^i)$ denoting the left, top, right, and bottom position of the i-th token boundary.

4.2 Document Visual Retriever

DocVRE aims to retrieve relevant documents from an extensive collection of documents. In this paper, we adopt the text contents in document images to build the retrieval library and use BM25 (Robertson and Zaragoza, 2009) to retrieve relevant documents.

4.3 Document Visual Question Answering

DocVQA aims to extract answers in the documents returned by DocVRE, that contains two challenges: long document understanding and multi-span answer extraction. For the long document understanding, we utilize a Hierarchical LayoutXLM (Xu et al., 2021) (Hi-LayoutXLM) to model the interaction within the documents by using text, layout, and visual information. Then, we extract multi-span answers by a sequence labeling method based on CRF (Conditional Random Fields). The model of DocVQA includes three stages: the paragraph encoder, the document encoder, and the answer extractor, as shown in Figure 3.

Paragraph Encoders: We take LayoutXLM as the paragraph encoder, which accepts text, layout, and visual features as inputs. Due to the input length limitation of LayoutXLM, we split the document and the bounding box (D, B) into m groups from $(\bar{D_1}, \bar{B_1})$ to $(\bar{D_m}, \bar{B_m})$. Then, for each group $(\bar{D_j}, \bar{B_j})$, we feed them along with the question Q and the whole document image I into the same LayoutXLM to get the hidden representations H_j of each token in the $\bar{D_j}$. Initially, the LayoutXLM encodes the concatenation of the question Q and

---

[5] OCR has been well-studied and been widely applied in many applications, which is not the bottleneck of our method.

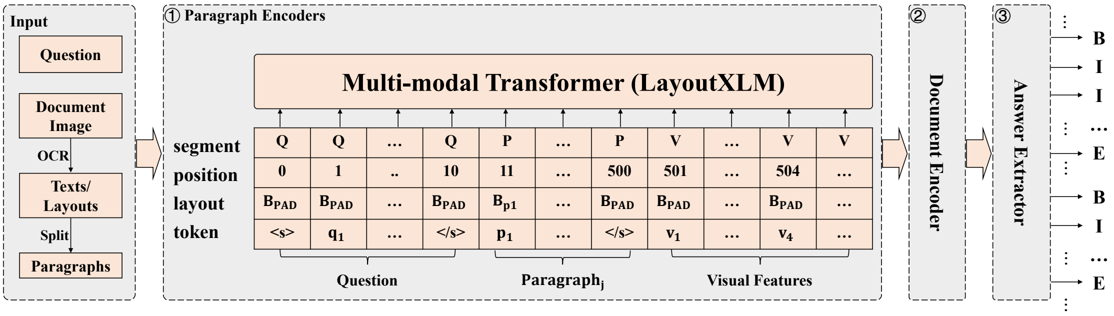


Figure 3: The stages of DocVQA. Taking a question and a document image, we utilize OCR to extract texts and layouts from the document image and split them into m paragraphs with an average length of 512. DocVQA contains three stages: 1) Paragraph encoders using LayoutXLM to encode the input texts, layouts, and visual features, where the visual features are extracted by Mask-RCNN. All paragraph encoders share the same parameters; 2) Document encoder to further encode documents by combining all paragraph encodings in document images together; 3) Answer extractor applies a CRF layer to label multi-span answers with the BIOES label format.

the paragraph $\bar{D}_j$ as the **text embedding** E_{T_j}, encodes the whole document image I by a visual encoder (Mask-RCNN (He et al., 2017)) as the **image embedding** E_I, encodes the sequence position of the text inputs as the **position embedding** E_{P_j}, and encodes the bounding boxes $\bar{B}_j$ as the **layout embedding** E_{B_j}. All the embeddings are as the inputs of LayoutXLM, as shown in Figure 3.

Document Encoder: We combine the hidden representations H_j of each paragraph $\bar{D}_j$ together to get the document hidden representation H_D and then take one layer of the multi-modal Transformer as the document encoder to further encode the document for labeling answers.

Answer Extractor: Finally, we apply a CRF layer to label all the answer spans with the “BIOES” label format in the answer extractor. Similar to Named Entity Recognition (NER), “B” denotes the first token of the answer span, “I” denotes the subsequent tokens inside the answer span, “E” denotes the end of the answer span, and “O” denotes tokens outside answer spans. Besides, if there is only one token in the answer span, it will be labeled as “S”. A Viterbi algorithm (Viterbi, 1967) is adopted to decode the tag sequence with the highest probability. There is an example of the multi-span answer shown in Appendix A.2 in Figure 5.

5 Experiment

In this section, we firstly describe the experiments we conduct on DuReader$_{\text{vis}}$ dataset and then conduct further analysis and discussion. Case studies are shown in Appendix A.2.

5.1 Experimental Setup

In this subsection, we describe the experimental baselines and evaluation metrics.

5.1.1 Baselines

For DocVRE, we use BM25 to retrieve relevant document images as the baseline. For DocVQA, we apply two text-based pre-trained models (containing RobertaXLM-base (Liu et al., 2019) and BERT-base-Chinese (Devlin et al., 2019)) into our proposed framework as the baseline, where we only use the textual contents as the input and replace the LayoutXLM with text-based pre-trained models.

5.1.2 Evaluation Metrics

For DocVRE, we evaluate the retrieval results by Recall@5, Recall@10, and MRR. For DocVQA and Open-domain DocVQA, we concatenate all answer spans together and use Rouge-L and F1 to evaluate the answer extraction performance. The details are shown in Appendix A.1.

5.2 Implementation Details

We utilize Paddle-OCR[6] to parse document images. The OCR results containing texts and bounding boxes are sorted by line. We evaluate PaddleOCR on our dataset and get F1 above 90, which shows that OCR is not the bottleneck of our task. For DocVQA baselines, we set the max paragraph number to 8, meaning the max document token length is about 4000. We truncate documents with more tokens. The Hi-LayoutXLM has about 200M parameters. We train 10 epochs using the AdamW

(Loshchilov and Hutter, 2017) optimizer with a 3e-5 learning-rate.

5.3 Main Results

The results of DocVRE, DocVQA and Open-domain DocVQA (DocVRE+DocVQA) are shown in Table 4, Table 3, Table 5 respectively.

DocVRE: From Table 4, we can see that BM25 obtains decent performance for retrieval, and the top 1 document will be used for DocVQA in the Open-domain QA setting.

DocVQA: As shown in Table 3, Hi-LayoutXLM performs best overall baselines, which denotes that the layout and visual features provide benefits for understanding document images. The results also show that there is still a performance gap between baseline models and human performance. Except for the overall performance, we also report the performance of the baselines on each answer type. All the models obtain better results on the list type since list items commonly have indicators like numbers and have similar layouts in the document, assisting models to gain further improvements (also shown in Figure 2). The performance gap between Hi-RoBERTaXLM and Hi-LayoutXLM in the table-type and list-type answers are bigger since lists and tables have rich layout and visual information, which is conducive to the list and table understanding. In comparison, the text-type answers focus more on understanding the text content, where the layout and visual information cannot provide too many benefits, thereby the performance gap is smaller.

Open-domain DocVQA: The experimental results of Open-domain DocVQA are shown in Table 5. Since DocVRE can not perform perfectly, the performance of our model on the open-domain DocVQA has decreased compared to that on the DocVQA. Compared to “BM25+Hi-BERT” and “BM25+Hi-RoBERTaXLM”, our method also performs better, with the same observations as DocVQA results.

Table 5: Experimental results on the Open-domain DocVQA task in DuReader$_{\text{vis}}$ (dev/test).

	Rouge-L	F1
BM25+Hi-BERT	29.19/33.21	29.44/33.53
BM25+Hi-RoBERTaXLM	29.52/33.01	30.40/33.69
BM25+Hi-LayoutXLM	**33.04/33.89**	**36.61/37.47**

5.4 Analysis and Discussion

In this subsection, we will perform more analysis to demonstrate the three challenges in DuReader$_{\text{vis}}$, the scalability of our approach, and the performance gap between our approach and open-domain QA. Finally, we will show the error case study and give some promising future directions.

5.4.1 Challenges in DuReader$_{\text{vis}}$

As mentioned above, our dataset has three main challenges: 1) long document understanding, 2) noisy texts, and 3) multi-span answer extraction. In this subsection, we will analyze their influence on DocVQA respectively.

Long Document Understanding: We conduct a statistical analysis of the relationship between the model performance and the document length on the development set of DuReader$_{\text{vis}}$ using Hi-LayoutXLM. As shown in Figure 4, documents in DuReader$_{\text{vis}}$ mainly have 500 to 3000 tokens. As the length of the document increases, the model performance gradually decreases. The increased document length makes documents harder to understand and makes models harder to extract valuable information to answer questions.

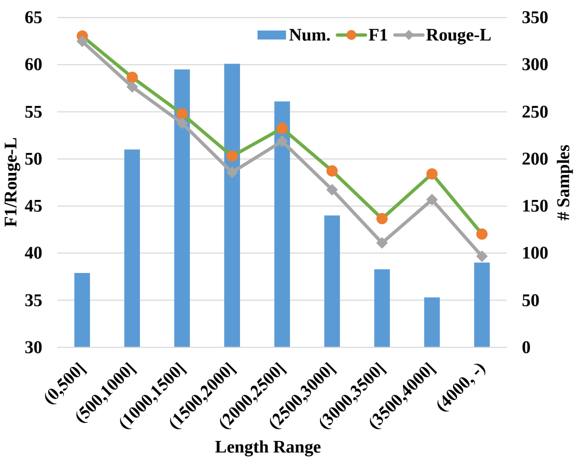

Figure 4: Length analysis on the development set of DuReader$_{\mathrm{vis}}$. #Samples: the number of samples.

Noisy Texts: Documents from web pages commonly contain much noise, such as advertisements, relevant recommendations, etc. It is hard to distinguish between main contents and noise accurately, so we roughly remove noise through a heuristic algorithm. Then, we conduct a comparison experiment between whether denoising or not. After removing noise, there is a performance improvement (F1: 53.10 → 57.24 (+4.14), and Rouge-L: 50.94 → 54.83 (+3.89)). We attribute it to the fact that noisy texts increase the total amount of information in the document, and it is easier for models to focus more on the valuable information after removing noise.

Multi-span Answer Extraction: In this part, we perform experiments to verify that the task of the multi-span answer extraction is more challenging than that of the single-span answer extraction. We convert the multi-span extraction task to the single-span extraction task by concatenating all answer spans together and inserting the concatenated answers to the position of the first answer span. And then we make a comparison between the above two tasks. Compared with the multi-span answer extraction, the single-span answer extraction performs better (F1: 53.10 → 59.38 (+6.28), and Rouge-L: 50.94 → 58.08 (+7.14)), which indicates that the task format of the multi-span answer extraction is harder to model. If there is no multi-span answers, our task will be easier.

5.4.2 Zero Shot Study

In this subsection, we randomly select 100 questions (do not occur in DuReader$_{\mathrm{vis}}$) from Baidu and obtain the most relevant documents from a large Chinese document collection website. Documents contain PDFs, Word documents, and scanned documents. We use Hi-LayoutXLM trained on DuReader$_{\mathrm{vis}}$ to test the performance on the selected 100 questions directly. The model gets decent performance (40.53 F1 and 36.71 Rouge-L) compared to that on the test dataset in DuReader$_{\mathrm{vis}}$. The test procedure on the selected queries proves the scalability of our approach, and the results show the good transferable ability of the model trained on DuReader$_{\mathrm{vis}}$.

Table 6: Comparisons between Open-domain QA and Open-domain DocVQA (dev/test). The metric for retrieval is MRR. The metric for reader is Rouge-L.

	Retrieval	Reader	Retrieval + Reader
Open-domain QA	67.67/68.82	62.45/63.49	40.28/42.40
Open-domain DocVQA	65.08/63.98	50.94/53.10	33.04/36.61

5.4.3 Open-domain DocVQA v.s. Open-domain QA

The goal of the open-domain DocVQA is to develop a more scalable QA system that can be applied to diverse domains and document formats. In section 5.4.2, we have shown that our approach can be applied to various formats and achieve decent performance. In the future, we aim to achieve competitive (even better) performance compared to well-designed format-specific or task-specific QA systems.

In this subsection, we design an experiment to see the performance gap between our scalable open-domain DocVQA system (as shown in Figure 1(b)) and the well-designed format-specific open-domain QA system which extracts text contents from web pages with well-designed text extractors (Figure 1(a)). The results on DuReader$_{\mathrm{vis}}$ are shown in Table 6. Open-domain QA performs better for two reasons: 1) The textual contents are clean with little web-page noise. 2) The extracted contents only contain clean text, making the whole input shorter. The results show that there still leaves room for open-domain DocVQA to improve. It is of great value for researchers to push open-domain DocVQA to obtain competitive results with task-specific or format-specific methods to reduce task-specific or format-specific efforts.

5.4.4 Error Case Study and Future Directions

We randomly sample and manually analyze 100 error cases with Rouge-L lower than 0.5 from the prediction results. There are 55% wrong samples in the retrieval stage, caused by the lousy string matching in the BM25 without understanding the semantics. In addition, about 15% of samples have multi-span answers, about 15% of samples make almost complete wrong predictions, and about 5% of samples output no answer. Furthermore, about 10% of samples have noisy texts.

From the results, we can give some promising directions to improve: 1) Utilize multi-modal information to model the long document images and reduce the impact of noises automatically; 2) Utilize dense retrieval methods (Karpukhin et al., 2020b; Qu et al., 2021b; Ren et al., 2021) to improve the document retrieval; 3) Pre-train multi-modal language models for long document images; and 4) Advanced methods to extract multi-span answers.

6 Conclusion

We propose an open-domain document visual question answering task to encourage scalable QA applications. We introduce DuReader$_{\text{vis}}$ to move toward the open-domain DocVQA research. There are three challenges: long document understanding, noisy text, and multi-span answer extraction. We propose a baseline and the results show that there is still a huge gap compared to human performance. We show the scalability of our approach by a zero-shot study. Finally, we give error cases and future directions.

Ethic Consideration

This dataset should be ONLY used for NLP research purposes. All the instances in DuReader$_{\text{vis}}$ are collected from public data and have been desensitized. All annotators and reviewers are formal employees and native speakers, thus we make sure that all workers are fairly compensated. Experienced reviewers have reviewed our dataset and the data collection process.

There are no copyright issues in our dataset. Firstly, the document images are crawled from the public data following the crawler protocol. Secondly, we strictly restrict the use of our dataset to academic research. If the websites think it needs to be removed, we will respond to removal at any time.

A Appendix

A.1 Evaluation Metrics

We describe the metrics used in our experiments in details.

Recall@K: Recall@K is calculated as the proportion of questions where the top-k retrieved document images contain the answers.

MRR: Mean Reciprocal Rank (MRR) is the average of all question's reciprocal of the rank at the first retrieved relevant document image.

Rouge-L: Rouge-L uses LCS-based (Longest Common Subsequence-based) F-measure to estimate the similarity between the reference X of length m and the predication Y of length n.

F1: F1 measures the average overlap between the prediction and the reference, where we treat them as bags of tokens and compute their F1. We report the average over the F1 values of all questions.

A.2 Case Study

Here we give some results and show the performance of our proposed baseline, as shown in Figure 5, 6, 7.

In Figure 5, the answers are multi table cells which are not continuous. We can see that our model can predict the right answer by utilizing the layout information, while Hi-RoBERTaXLM cannot predict any answers since the information in the pages are difficult to model for Hi-RoBERTaXLM.

In Figure 6, the answer has highlight layout and visual information (the font is big and the color is red). It is easy to be captured by our model, while it is hard for Hi-RoBERTaXLM to predict the right answer.

In Figure 7, the answer is a single-span text, and the question is highlighted in the document image. Hi-RoBERTaXLM also predicts an answer, but the answer is not complete compared with the ground truth. The answer predicted by Hi-LayoutXLM is better. We can see that the layout can help locate the right answers.

From the above three cases, we can see that our approach can utilize layout and visual information to model multi-span answers much better than the baseline Hi-RoBERTaXLM.

Coloring the Blank Slate: Pre-training Imparts a Hierarchical Inductive Bias to Sequence-to-sequence Models

Aaron Mueller[ȼ] **Robert Frank**[ϒ] **Tal Linzen**[Ʒ]

Abstract

Relations between words are governed by hierarchical structure rather than linear ordering. Sequence-to-sequence (seq2seq) models, despite their success in downstream NLP applications, often fail to generalize in a hierarchy-sensitive manner when performing syntactic transformations—for example, transforming declarative sentences into questions. However, syntactic evaluations of seq2seq models have only observed models that were *not* pre-trained on natural language data before being trained to perform syntactic transformations, in spite of the fact that pre-training has been found to induce hierarchical linguistic generalizations in language models; in other words, the syntactic capabilities of seq2seq models may have been greatly understated. We address this gap using the pre-trained seq2seq models T5 and BART, as well as their multilingual variants mT5 and mBART. We evaluate whether they generalize hierarchically on two transformations in two languages: question formation and passivization in English and German. We find that pre-trained seq2seq models generalize hierarchically when performing syntactic transformations, whereas models trained from scratch on syntactic transformations do not. This result presents evidence for the learnability of hierarchical syntactic information from non-annotated natural language text while also demonstrating that seq2seq models are capable of syntactic generalization, though only after exposure to much more language data than human learners receive.

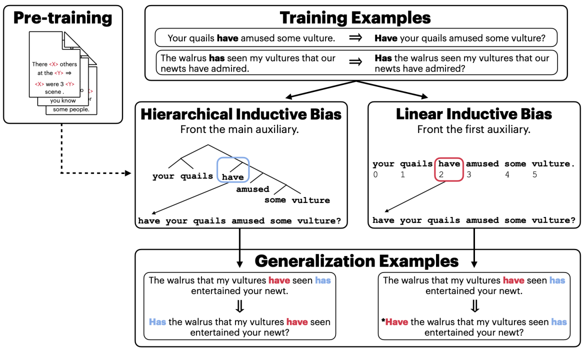

Figure 1: The poverty of the stimulus experimental design. We fine-tune pre-trained seq2seq models and train small seq2seq models from scratch to perform syntactic transformations. The training set contains ambiguous examples consistent with hierarchical and linear transformation rules. The generalization set contains examples where only the hierarchical rule results in the correct output. Pre-trained models generalize using the hierarchical rule, while models trained from scratch generalize using the linear rule.

1 Introduction

Human language is structured hierarchically. In NLP tasks like natural language inference, syntactic competence is a prerequisite for robust generalization (e.g., McCoy et al., 2019). Probing studies have found that masked language models (MLMs) contain hierarchical representations (Tenney et al., 2019; Hewitt and Manning, 2019; Clark et al., 2019), while behavioral studies of recurrent neural language models (Linzen et al., 2016; Marvin and Linzen, 2018; Wilcox et al., 2018; van Schijndel et al., 2019) and MLMs (Goldberg, 2019; Hu et al., 2020) have found that models are largely able to capture long-range syntactic dependencies that require hierarchical representations of sentences.

Recent evidence suggests that MLMs like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) can learn to make hierarchical linguistic generalizations through exposure to text (Warstadt and Bowman, 2020), though acquiring many of these linguistic generalizations requires large amounts of data (Warstadt et al., 2020). However, this evidence comes from binary acceptability judgment tasks, where a classifier head is attached to an MLM and the model is fine-tuned to classify which sentence in a given minimal pair is consistent with a hierarchical linguistic generalization, rather than a positional surface heuristic. Consider the following

Findings of the Association for Computational Linguistics: ACL 2022, pages 1352 - 1368
May 22-27, 2022

two transformations of Example (1):

(1) The yak that your unicorns **have** amused **hasn't** entertained a newt.
   a. **Hasn't** the yak that your unicorns **have** amused entertained a newt?
   b. ***Have** the yak that your unicorns amused hasn't entertained a newt?

Example (1a) correctly forms the question by moving the main auxiliary verb to the front of the sentence, while (1b) relies on the incorrect positional heuristic that the first auxiliary in the declarative sentence should be moved to the front of the sentence. When differentiating grammatical and ungrammatical auxiliary movements, a model could rely on distributional information (Lewis and Elman, 2001) such as bigram heuristics (Reali and Christiansen, 2005; Kam et al., 2008) to make correct judgments in many cases, so high performance on binary classification tasks may overstate the syntactic competence of a model.

By contrast, *performing* a syntactic transformation—e.g., given a declarative sentence like Example (1) as input, transforming it into a polar question like (1a)—is more difficult. It requires multiple complex but systematic operations that rely on hierarchical structure, including movement, number agreement, and—in languages that have grammatical case, such as German—case reinflection. Evaluations of syntactic transformational abilities can therefore act as more targeted behavioral indicators of syntactic structural representations in neural models. McCoy et al. (2018) evaluate non-pre-trained recurrent sequence-to-sequence (seq2seq) models (Sutskever et al., 2014) on the question formation task, finding that they rely on linear/positional surface heuristics rather than hierarchical structure to perform this syntactic transformation. More recent studies have also exclusively considered recurrent seq2seq models and Transformer models (Petty and Frank, 2021) trained from scratch on other transformations like tense reinflection (McCoy et al., 2020) and passivization (Mulligan et al., 2021), finding similar results. These studies were designed to understand the inductive biases of various seq2seq architectures, which is why they do not pre-train the models on non-annotated natural language data before training them to perform syntactic transformations.

In this study, we create German datasets and modify English datasets for evaluating the inductive biases of pre-trained models. We use these datasets to analyze performance in monolingual and zero-shot cross-lingual settings. Further, we analyze *how* pre-trained models perform syntactic transformations. Our findings indicate that pre-trained models generally perform syntactic transformations in a hierarchy-sensitive manner, while non-pre-trained models (including randomized-weight versions of pre-trained models) rely primarily on linear/positional heuristics to perform the transformations. This finding presents additional evidence to Warstadt et al. (2020) and Warstadt and Bowman (2020) for the learnability of hierarchical syntactic information from natural language text input. Our code and data are publicly available.[1]

2 Syntactic Transformations

2.1 Languages

We evaluate on syntactic transformations in English and German. We choose English to allow for comparisons to previous results (McCoy et al., 2018; Mulligan et al., 2021). We further extend our evaluations to German because it exhibits explicit case marking on determiners and nouns; this typological feature has been found to increase the sensitivity of language models to syntactic structure (Ravfogel et al., 2019). This allows us to compare transformational abilities for languages with different levels of surface cues for hierarchy.

2.2 Tasks

We employ a *poverty of the stimulus* experimental design (Wilson, 2006), where we train the model on examples of a linguistic transformation that are compatible with either a hierarchical rule or a linear/positional rule, and then evaluate the model on sentences where only the hierarchical rule leads to the generalization pattern that is consistent with the grammar of the language (Figure 1).[2] In other words, we are interested in whether T5 and mT5 (henceforth, (m)T5), as well as BART and mBART (henceforth, (m)BART), demonstrate a **hierarchical inductive bias**,[3] unlike the linear inductive bias displayed in prior work by non-pre-trained models.

---

[1] `https://github.com/sebschu/multilingual-transformations`

[2] There are other rules that could properly transform the stimuli we use, but we find that the models we test do learn one of these rules or the other.

[3] When multiple generalizations are consistent with the training data, "inductive bias" refers to a model's choice of one generalization over others.

☐ Train, dev, test ▨ Generalization

Structure	Question Formation	Passivization
No RC/PP	quest: some xylophones have remembered my yak. → have some xylophones remembered my yak?	passiv: your quails amused some vulture. → some vulture was amused by your quails.
RC/PP on object	quest: my zebras have amused some walrus who has waited. → have my zebras amused some walrus who has waited?	passiv: some tyrannosaurus entertained your quail behind your newt. → your quail behind your newt was entertained by some tyrannosaurus.
RC/PP on subject	quest: my vultures that our peacock hasn't applauded haven't read. → haven't my vultures that our peacock hasn't applauded read?	passiv: the zebra upon the yak confused your orangutans. → your orangutans were confused by the zebra upon the yak.

Table 1: The distribution of syntactic structures in the train, test, and generalization sets. To expose the model to all structures during training and fine-tuning, we also include identity transformations for all structures using the "decl:" prefix, where the input and output sequences are the same declarative or active sentence (see §3.1). We use the test set to evaluate whether models have learned the task on in-distribution examples, and the generalization set to evaluate whether models generalize hierarchically. See Appendix A for example sentences in German.

We focus on two syntactic transformation tasks: **question formation** and **passivization**. See Table 1 for a breakdown of which structures we present to the model during training and which we hold out to evaluate hierarchical generalization. See Table 2 for examples of hierarchical and linear generalizations for each transformation.

Question formation. In this task, a declarative sentence is transformed into a polar question by moving the main (matrix) auxiliary verb to the start of the sentence; this hierarchical rule is called MOVE-MAIN. The linear rule, MOVE-FIRST, entails moving the linearly first auxiliary verb to the front of the sentence. Examples of both rules are provided in Figure 1 and Example (1). We train the model on sentences with no relative clauses (RCs) or with RCs on the object, where the first auxiliary verb is always the matrix verb. Disambiguating examples are those which place RCs on the subject, where the matrix auxiliary verb is the linearly second auxiliary in the sentence.

In English, we use the auxiliaries "has", "hasn't", "have", and "haven't", with past participle main verbs (e.g., "have *entertained*", "has *amused*"). We use affirmative and negative forms to distinguish between the multiple auxiliaries: exactly one of the auxiliaries in such sentences is negative and the other is positive (counterbalanced across examples). As a result, we can determine whether the induced mapping is linear or hierarchical. In German, negation is realized as a separate word that is not fronted with the auxiliary. To distinguish the multiple auxiliaries, we therefore use the modal "können" (*can*) along with the auxiliary "haben" (*have*), together with infinitival or past participle main verbs as appropriate. This allows us to distinguish models with a hierarchical bias from those with a linear bias on the basis of the fronted auxiliary.

Passivization. In this task, an active sentence is transformed into a passive sentence by moving the object noun phrase (NP) to the front of the sentence (MOVE-OBJECT). Our training examples are also compatible with a linear rule, MOVE-SECOND, in which the linearly second NP moves to the front of the sentence. We train on sentences with no prepositional phrases (PPs) or with PPs modifying the object, where the second NP is always the object. Disambiguating examples are those which place prepositional phrases (PPs) on the subject, where the object is the linearly third NP in the sentence.

Passivization additionally requires other movements, insertions, tense reinflection, and (for German) case reinflection. In Examples (2) and (3) below, the object (in blue) is fronted; 'be'/'werden' (in red) is inserted and inflected to agree with the fronted NP; the original subject NP (in brown) is moved to a 'by'/'von' phrase after the inserted verb; and the main verb (in orange) is reinflected to be a past participle or infinitive. In German, the case of the NPs (reflected largely in the determiners) must be reinflected, and the main verb needs to be moved to the end of the sentence.

(2) *English Passivization*:

a. Your quails amused some vulture.
b. Some vulture was amused by your quails.

(3) *German Passivization*:

a. Ihr Esel unterhielt meinen Salamander.
Your.NOM donkey entertained my.ACC salamander.

b. Mein Salamander wurde von ihrem Esel unterhalten.
My.NOM salamander was from your.DAT donkey entertained.

Input	Output (hierarchical)	Output (linear)
quest: My unicorn that **hasn't** amused the yaks **has** eaten.	**Has** my unicorn that hasn't amused the yaks eaten?	**Hasn't** my unicorn that amused the yaks has eaten?
quest: Die Hunde, die deine Löwen bewundern **können**, **haben** gewartet.	**Haben** die Hunde, die deine Löwen bewundern können, gewartet?	**Können** die Hunde, die deine Löwen bewundern, haben gewartet?
passiv: Her walruses above **my unicorns** annoyed **her quail**.	**Her quail** was annoyed by her walruses above my unicorns.	**My unicorns** were annoyed by her walruses.
passiv: Unsere Papageie bei **meinen Dinosauriern** bedauerten **unsere Esel**.	**Unsere Esel** wurden von unseren Papageien bei meinen Dinosauriern bedauert.	**Meine Dinosaurier** wurden von unseren Papageien bedauert.

Table 2: Examples from the generalization set with hierarchical- and linear-rule transformations. Glossed German examples are provided in Appendix A.

3 Experimental Setup

3.1 Data

We modify and supplement the context-free grammar of McCoy et al. (2020) to generate our training and evaluation data.[4] For each transformation, our training data consists of 100,000 examples with an approximately 50/50 split between identity examples (where the input and output sequences are the same) and transformed examples. The identity examples include the full range of declarative or active structures (including sentences with RCs/PPs on subjects), thereby exposing the network to the full range of input structures we test. For the transformed examples, however, training data includes only examples with no RCs/PPs or RCs/PPs on the object NP—i.e., cases that are compatible with both the hierarchical and linear rules. We also generate development and test sets consisting of 1,000 and 10,000 examples, respectively, containing sentences with structures like those used in training; these are for evaluating in-distribution transformations on unseen sentences.

For each transformation, we also generate a generalization set consisting of 10,000 transformed examples with RCs/PPs on the subject NP. For such examples, models relying on the linear rules will not generalize correctly.

3.2 Models

We experiment with T5 (Raffel et al., 2020) and BART (Liu et al., 2020), two English pre-trained sequence-to-sequence models. We also experiment with their multilingual variants mT5 (Xue et al., 2021) and mBART (Liu et al., 2020).[5] These are 12-layer Transformer-based (Vaswani et al., 2017) architectures with bidirectional encoders and autoregressive decoders. While we use the base sizes of (m)T5, we use the large sizes of (m)BART to keep the sizes of the models similar.

When fine-tuning (m)T5 and (m)BART, we use task prefixes in the source sequence. We use "quest:" for question formation and "passiv:" for passivization. As in previous work, we also include identity transformation examples (prefixed with "decl:"), i.e., examples for which the model has to output the unchanged declarative or active sentence. When training seq2seq baselines from scratch, we follow McCoy et al. (2020) and append the task markers to the end of the input sequence.

For fine-tuning on syntactic transformations, we use batch size 128 and initial learning rate 5×10^{-5}. We fine-tune for 10 epochs and evaluate every 500 iterations. We find that the validation loss generally converges within 1–2 epochs.

To confirm the finding of McCoy et al. (2020) and Petty and Frank (2021) that non-pre-trained models fail to generalize hierarchically, we also train baseline seq2seq models similar to the models used in those studies. We implement 1- and 2-layer LSTM-based seq2seq models, as well as 1- and 2-layer Transformer-based seq2seq models where the Transformers have 4 attention heads.[6] We find that the 1-layer models consistently achieve higher sequence accuracies on the dev sets, so we focus on the 1-layer baselines. We re-use all hyperparameters from McCoy et al. (2020). All baseline scores are averaged over 10 runs.

3.3 Metrics

For all transformations, we are primarily interested in *sequence accuracy*: is each token in the tar-

---

[4] We generate our evaluation set such that it consists of grammatical but semantically improbable sentences which are unlikely to occur in a natural language corpus. This is to alleviate the confound of token collocations in the pre-training corpus.

[5] We use HuggingFace implementations (Wolf et al., 2020).

[6] Our implementations are based on the syntactic-transformation-focused `transductions` repository: `https://github.com/clay-lab/transductions`

	Question Formation		Passivization	
Model	English	German	English	German
LSTM	0.95	0.94	0.97	0.97
Transformer	0.95	0.93	0.98	0.98
T5	1.00	–	1.00	–
mT5	1.00	1.00	1.00	1.00
BART	0.96	–	0.95	–
mBART	1.00	1.00	1.00	1.00

Table 3: Sequence accuracies on the (in-distribution) test sets for English and German syntactic transformations. All models learn the in-distribution transformations.

	Question Formation		Passivization	
Model	English	German	English	German
LSTM	0.11	0.33	0.05	0.44
Transformer	0.07	0.05	0.04	0.07
T5	0.87	–	1.00	–
mT5	0.99	1.00	1.00	1.00
BART	0.96	–	1.00	–
mBART	0.59	0.82	0.80	0.98

Table 4: Main auxiliary accuracies (for question formation) or object noun accuracies (for passivization) on the generalization sets for English and German syntactic transformations. Only pre-trained models generalize hierarchically.

get sequence present in the proper order in the predicted sequence? However, it is possible that models could generalize hierarchically while making some other mistake, so we also use two more relaxed metrics. For question formation, we use *main auxiliary accuracy*, which evaluates whether the correct auxiliary was moved to the front of the sentence. The first word in the target sequence is always the main auxiliary verb, so we calculate main auxiliary accuracy by checking if the first word is the same in the predicted and target sequences. For passivization, we use *object noun accuracy*, which measures whether the correct object noun was moved to the subject position. The second word in the target sequence is always the original object noun, so we calculate object noun accuracy by checking if the second word is the same in the predicted and target sequences.

4 Results

All models learn the in-distribution transformations. We first present results on unseen sentences whose structures were seen in training, where both the hierarchical and the linear rules result in correct generalization (Table 3). All models perform well in this setting, including the LSTM- and Transformer-based models trained from scratch. However, (m)T5 converges to higher sequence accuracies than the non-pre-trained models. Additionally, while the non-pre-trained models require about 15–20 epochs of training to converge to a high score, (m)T5 and (m)BART converge to near-perfect sequence accuracy after only a fraction of an epoch of fine-tuning.

Only pre-trained models generalize hierarchically. Evaluations on the generalization-set examples (where the linear rule leads to incorrect generalization) reveal that none of the trained-from-scratch models have learned the hierarchical rule. These models consistently stay at or near 0% sequence accuracy on the generalization set throughout training, so we present main auxiliary/object noun accuracies (Table 4). Accuracy remains low even on these more forgiving metrics, indicating that the non-pre-trained models have not acquired the hierarchical rules.

Low accuracies do not necessarily indicate reliance on the linear MOVE-FIRST or MOVE-SECOND rules. To test whether the non-pre-trained models have learned the linear rules, we implement metrics which calculate the proportion of generalization-set examples for which the MOVE-FIRST rule (for question formation) or MOVE-SECOND rule (for passivization) were used; we refer to these as the move-first frequency and move-second frequency, respectively. For each model and language, the sum of the main auxiliary accuracy and move-first frequency for question formation is ≈ 1.0; the sum of the object noun accuracy and move-second frequency for passivization is also ≈ 1.0. Thus, where the model did not move the main auxiliary or object noun, it generally used the linear rule. In other words, **the non-pre-trained models demonstrate *linear* inductive biases.** This finding is in line with prior evaluations of non-pre-trained seq2seq models (McCoy et al., 2020; Mulligan et al., 2021; Petty and Frank, 2021).[7]

By contrast, (m)T5 and (m)BART achieve very high main auxiliary/object noun accuracies on the generalization sets. mBART struggles with En-

---

[7] Nonetheless, higher accuracies on German transformations support the hypothesis that more explicit cues to syntactic structure (here, case-marked articles and nouns) allow models to learn hierarchical syntactic generalizations more easily. This agrees with the findings of Ravfogel et al. (2019) and Mueller et al. (2020).

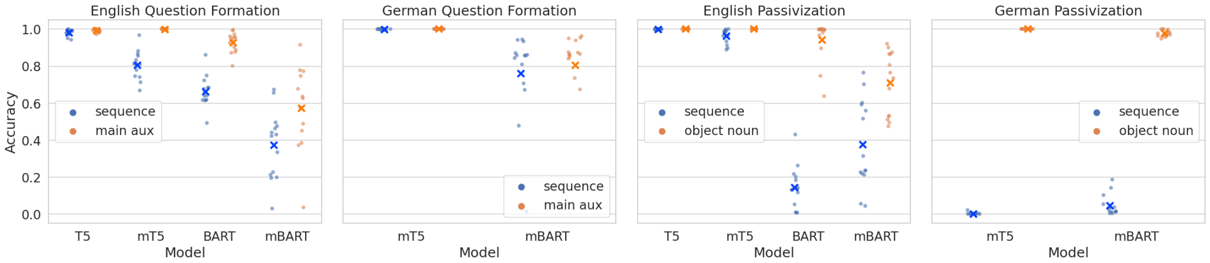

Figure 2: Accuracies at every 500 fine-tuning iterations across 10 epochs of fine-tuning on each syntactic transformation. Xs indicate mean accuracies across epochs. T5 models are generally better at performing syntactic transformations than BART models. Monolingual models tend to achieve higher accuracies than multilingual models. We present full learning curves in Appendix B.

glish question formation, achieving an average 59% main auxiliary accuracy throughout fine-tuning. However, it does achieve a maximum accuracy >90%, indicating that it is capable of hierarchical generalization after observing certain training examples. These accuracies are still well above the ≈0% accuracies of the non-pre-trained models.

Because sequence accuracy on the generalization set is often unstable for all pre-trained models, we present plots showing the distribution of accuracies sampled at every 500 fine-tuning iterations throughout 10 epochs of fine-tuning (Figure 2). Each pre-trained model learns the in-distribution transformation before the first 500 iterations of fine-tuning, so each plotted accuracy can be taken as indicative of model preferences after they have learned the transformations. (m)T5's sequence accuracies are generally close to 100% for all transformations except German passivization; this is far better than the non-pre-trained models' 0% sequence accuracies. (m)BART struggles more with syntactic transformations as indicated by its lower average accuracies, though it is still capable of detecting the correct auxiliaries and objects to move as indicated by the high *maximum* main auxiliary and object noun accuracies in Figure 2. This indicates that **pre-trained seq2seq models demonstrate a hierarchical inductive bias**, and that they can quickly learn syntactic transformations.

There are two main differences between the two classes of models we test: (m)T5 and (m)BART are not only pre-trained, but are also much deeper and much more parameterized than our non-pre-trained models. Are hierarchical inductive biases a feature of deep architectures, then, or are they acquired during pre-training? To control for pre-training while keeping the model size consistent, we randomize the weights of mT5 (the better-performing model) and fine-tune for up to 500 epochs using an initial LR[8] of 5×10^{-4}. For all of the transformations, the maximum accuracies of the randomized models are much lower than the average accuracies of the pre-trained models (Table 5), which suggests that the deeper architecture on its own does not lead to structure-sensitive generalizations. This in return indicates that **pre-trained models do not start with a hierarchical inductive bias; they *acquire* it through pre-training**, extending the findings of Warstadt and Bowman (2020) to generative sequence-to-sequence models. However, as indicated by the non-zero main auxiliary/object noun accuracies, the randomly initialized mT5 models do not exhibit a consistent linear generalization either—unlike the 1-layer non-pre-trained models. This may be due to the large number of parameters compared to the size of the transformations training corpus. A randomly initialized model of this size would likely need orders of magnitude more training data to learn stable generalizations.

	Question Formation		**Passivization**

T5	0.48	–	0.25	–
mT5	0.50	0.44	0.25	0.50
BART	0.40	–	0.30	–
mBART	0.48	0.38	0.29	0.44

Table 5: *Maximum* main auxiliary and object noun accuracies through 500 epochs of fine-tuning *after randomizing the weights* of each pre-trained model. Sequence accuracies remain near 0 throughout fine-tuning.

Each pre-trained model almost always chooses the correct auxiliary/object to move; what errors

---

[8] We tune over learning rates $\in 5 \times 10^{\{-2,-3,-4,-5\}}$ for the randomized models, finding that 5×10^{-4} yields the best main auxiliary and object noun accuracies on in-domain evaluations.

account for their sub-perfect sequence accuracies, then? We perform a detailed error analysis, finding that pre-trained models drop PPs from the second noun phrase but otherwise perform many complex hierarchy-sensitive transformations properly. See Appendix C for details.

5 Transformation Strategies

Our results indicate that pre-trained seq2seq models can consistently perform hierarchy-sensitive transformations. What strategy do they follow to do this? Because pre-training corpora include actives, passives, declaratives, and questions, model representations could encode these high-level sentence features.[9] Thus, one strategy could be to learn a mapping between abstract representations of different sentence structures (REPRESENTATION strategy). Alternatively, models could learn to correctly identify the relevant syntactic units in the input, and then learn a "recipe" of steps leading to the correct transformations (RECIPE strategy).

To distinguish which strategy models use to perform syntactic transformations, we observe cross-lingual zero-shot transfer on syntactic transformations. We exploit that English and German use the same operations for question formation, whereas passivization in German involves the additional steps of case reinflection and moving the main verb. If structural representations are shared across English and German,[10] we do not expect divergent behaviors for question formation and passivization: if a model employs the REPRESENTATION strategy, then after fine-tuning on only English passivization, it should also correctly perform German passivization, including the additional steps of case reinflection and moving the main verb. Conversely, if it employs the RECIPE strategy, we expect a model trained on English passivization to only perform the steps that are required for English passivization, resulting in incorrect case marking and no main verb movement in German.

We first verify that mT5 and mBART are capable of cross-lingual transfer by training a model on the English question formation task and evaluating on German. In early experiments, we noticed the issue of "spontaneous translation" (Xue et al., 2021); we therefore also include German identity transformations in the training data to train the decoder to also output German sentences.

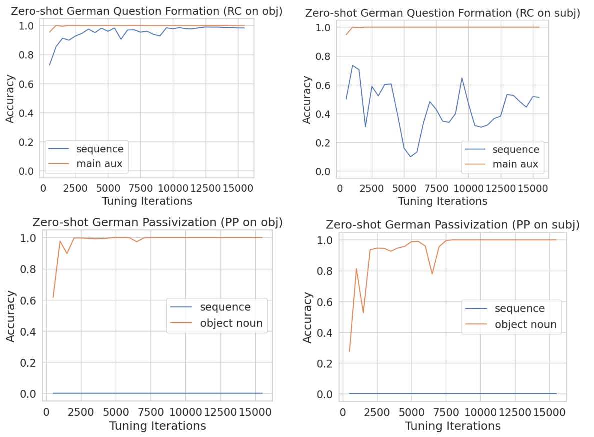

Figure 3: Learning curves for mT5 on German transformations after fine-tuning on English/German identity examples and English transformations. We show accuracies for German question formation with RCs on objects (top left) and RCs on subjects (top right), as well as accuracies for German passivization with PPs on objects (bottom left) and PPs on subjects (bottom right).

As the top two panels of Figure 3 show, mT5 can correctly perform German question formation on in-domain structures (RCs on objects) after being exposed only to English transformations. For out-of-domain structures (RCs on subjects), mT5 almost always moves the main auxiliary but almost never deletes it from its original position, resulting in lower sequence accuracies. Apart from this error, the model is capable of cross-lingual transfer on the question formation task. By contrast, mBART achieves poor results on zero-shot German question formation, so we cannot make conclusive arguments using this approach; see Appendix D.

Given that cross-lingual transfer is possible for mT5, how does the model behave in the passivization task, which differs between English and German? We fine-tune mT5 on English passivization (as well as German identity transformations on active sentences). The results of this experiment (the lower two panels in Figure 3) show that the model is still able to move the main object to the subject position, but also that it never correctly performs German passivization in its entirety. This is because the model performs exactly the same steps for German sentences as for English sentences, resulting in outputs with English syntax:

---

[9] For example, (sets of) neuron activations have been found to encode syntactic features in MLMs (Ravfogel et al., 2021; Finlayson et al., 2021; Hernandez and Andreas, 2021).

[10] Shared cross-lingual structural representations have been found for multilingual MLMs (Chi et al., 2020), and we provide further evidence for shared representations in this section.

(4) Meinen Kater bei ihrem Molch was
My.ACC cat by your.DAT newt was
verwirrten by die Esel.
confused.PAST by the.NOM donkeys.

These behavioral patterns suggest that mT5 employs the RECIPE strategy: it succeeds if a transformation's required operations are the same across languages (as for question formation) but fails if the steps differ (as for passivization). Even in passivization, however, the model still learns to move the correct NPs, which provides additional evidence that mT5 makes use of structural features when performing transformations. Given the similarities between mT5's and mBART's architectures and training setups, one could reasonably presume that mBART may follow a similar strategy to perform syntactic transformations; nonetheless, mBART is less consistent in performing syntactic transformations, so this method cannot present strong evidence for use of the RECIPE strategy for that model.

6 Corpus Analysis

Pre-trained models learn to use hierarchical features for performing syntactic transformations. Is this because there is explicit supervision for the hierarchical rules in the pre-training corpora? In other words, are there *disambiguating examples* in these models' training corpora that helps them memorize hierarchical transformation patterns? Here, we focus on English question formation examples in mT5's training corpus.[11] Disambiguating examples would be rare, as a single pre-training context window must contain a declarative sentence as well as the same sentence transformed into a question; humans would tend to replace at least some of the constituents with pronouns or delete them (e.g., Ariel, 2001). It would also require the MOVE-FIRST rule to not correctly transform the sentence—*and* for at least one of the auxiliaries to be noised in one sentence but not the other, such that the auxiliary has to be recovered from the other sentence. For example:

(5) . . . Has this company which hasn't had any legal violations been reported to the Better Business Bureau? This company which hasn't had any legal violations <X> been reported to the Better Business Bureau. . .

We search for English disambiguating question formation examples. To this end, we sample 5M English documents from mT5's training corpus mC4, segmenting each document into sentences using spaCy.[12] This yields 118.3M sentences. We examine each pair of adjacent sentences in each document, manually inspecting any sentence pair meeting the following criteria: (1) the token Jaccard similarity of the sentences is > 0.7; (2) one sentence begins with an auxiliary verb and the other does not; (3) there are at least two distinct auxiliaries in both sentences. There are 277 sentence pairs in our sample that met all criteria, of which 13 are adjacent declarative/question pairs that are equivalent except for the fronted auxiliary. Thus, the probability of an equivalent declarative/question pair with two auxiliaries in mC4 is $\approx 1.1 \times 10^{-7}$. As T5's and mBART's training corpora consist of data from similar webtext distributions, it is likely that these structures exist in those corpora as well.

Crucially, however, none of the declarative/question pairs were disambiguating examples: each pair was consistent with the linear MOVE-FIRST rule. What is the probability of a disambiguating example, then? If we assume that the probability of a sentence containing an RC on the subject is independent from the probability of a declarative/question sentence pair, we can take the product of both probabilities to obtain an estimate. From the same sample of 118.3M sentences, we use spaCy's dependency parser to extract sentences containing an RC on the subject and where at least one auxiliary verb appears in the sentence. We obtain $526,944$ such sentences, meaning that the probability of an RC on a subject in an auxiliary-containing sentence in mC4's English corpus is $\approx 4.5 \times 10^{-3}$. Thus, the probability of declarative/question pair with an RC on the subject and auxiliary in the RC is $\approx (4.5\times10^{-3})\cdot(1.1\times10^{-7}) = 4.95\times10^{-10}$. mT5 is trained on up to 1T tokens of data, and 5.67% of its documents are English; it therefore observes $\approx$ 56.7B English tokens. If we optimistically assume that English sentences contain an average of 15 tokens, it observes 3.78B English sentences. Then we would expect $3.78\text{B}\times(4.95 \times 10^{-10}) \approx 2$ disambiguating examples. This is not including the auxiliary masking criterion, which would make such examples even less likely.

Thus, while we cannot definitively rule out the

---

[11] mT5 outperforms mBART. If disambiguating contexts in the pre-training data lead to syntactic generalizations, then we expect these examples to be more likely in mT5's training corpus.

[12] `https://spacy.io`

possibility of disambiguating examples in mC4, they are rare if they exist in the corpus at all. Nonetheless, we have found evidence for supervision on question formation in the form of adjacent declarative/question sentence pairs, even if they do not explicitly support the hierarchical rule.

7 Discussion

Our experiments provide evidence that pre-trained seq2seq models acquire a hierarchical inductive bias through exposure to non-annotated natural language text. This extends the findings of Warstadt and Bowman (2020) and Warstadt et al. (2020) to a more challenging generative task, where models cannot rely on n-gram distributional heuristics (Kam et al., 2008). This also provides additional evidence that masking and reconstructing subsets of input sequences is a powerful training objective for inducing linguistic generalizations, whether in masked language models like RoBERTa (Warstadt and Bowman, 2020) or sequence-to-sequence models. Span denoising ((m)T5's objective) appears more effective for learning syntactic transformations than full sequence reconstruction ((m)BART's objective) given that (m)T5 is more consistently able to perform transformations, though there are too many other differences in training data and hyperparameters between (m)T5 and (m)BART for us to be able to directly implicate the training objective. This hypothesis can be tested explicitly in future work by training identical models that differ only in their pre-training objective.

Counter to McCoy et al. (2020), our findings suggest that hierarchical architectural constraints (e.g., tree-structured networks) are not necessary for robust hierarchical generalization as long as the model has been exposed to large amounts of natural language text—possibly far more language than humans would be exposed to. However, one difference between the randomly initialized models employed by McCoy et al. (2020) and pre-trained models is that pre-trained models have likely seen the structures (but not sentences) present in the generalization set; thus, rather than relying on syntactic features, the model could choose the correct transformation because it is more similar to the grammatical examples it has already seen. We found declarative/question pairs in mT5's training corpus, but we did not find any examples that explicitly demonstrated the hierarchical rule for question formation. While we cannot fully rule out the possibility of disambiguating examples, this strategy is still unlikely given that pre-trained models produce ungrammatical transformations, both in monolingual transformations (e.g., not deleting the main auxiliary after copying it to the start of the sentence) and in cross-lingual German passivization. Additionally, because we use greedy decoding, models are not able to take future words into account when predicting the fronted auxiliary: they must select the appropriate auxiliary to move solely based on the encoder's representations.

More broadly, our findings counter the assumption that a hierarchical constraint is necessary in language learners to acquire hierarchical generalization (Chomsky, 1965). While the pre-trained models that we considered observe far more input than a child would receive (Linzen, 2020), Huebner et al. (2021) recently demonstrated high performance on grammaticality judgments for models trained on much smaller child-directed speech corpora, suggesting that our findings may also hold when training models on more human-like input.

8 Conclusions

We have performed an analysis of the syntactic transformational ability of large pre-trained sequence-to-sequence models. We find that pre-trained models acquire a hierarchical inductive bias during pre-training, and that the architecture does not yield this hierarchical bias by itself.

It remains an open question whether such deep and highly parameterized models or such large pre-training datasets are necessary for hierarchical generalization. Future work could ablate over model depth and pre-training corpus size to observe the relative contribution of architecture and the training set to inducing hierarchical inductive biases in seq2seq models.

Acknowledgments

We thank the members of NYU's Computation and Psycholinguistics Lab and the reviewers for their thoughtful feedback. We also thank R. Thomas McCoy for providing sentence generation scripts.

A German Structures

Here, we present examples of the sentences in the training, development, test, and generalization sets for the German question formation and passivization tasks (Table 6). As in English, we train the model on declarative or active sentences, as well as question-formation or passivization examples with no RCs/PPs or with RCs/PPs on subjects (i.e., sentences that are consistent with the hierarchical and linear rules described in §3.1). Then we evaluate its generalization on sentences where the linear rule does not properly transform the sentence.

For further clarity, we present glossed examples of each German structure below for both tasks.

(6) *German Question Formation (no RC)*:

a. Unsere Salamander haben die
Our.NOM salamanders have the.ACC
Pfaue bewundert.
peacocks admired.
"Our salamanders have admired the peacocks."

b. Haben unsere Salamander die
Have our.NOM salamanders the.ACC
Pfaue bewundert?
peacocks admired?
"Have our salamanders admired the peacocks?"

(7) *German Question Formation (RC on object)*:

a. Einige Molche können meinen Papagei,
Some.NOM newts can my.ACC parrot,
der deinen Raben trösten kann,
that.NOM your.ACC ravens comfort can,
nerven.
annoy.
"Some newts can annoy my parrot that can comfort your ravens."

b. Können einige Molche meinen Papagei,
Can some.NOM newts my.ACC parrot,
der deinen Raben trösten kann,
that.NOM your.ACC ravens comfort can,
nerven?
annoy?
"Can some newts annoy my parrot that can comfort your ravens?"

(8) *German Question Formation (RC on subject)*:

a. Ihr Hund, den ihr Geier
Your.NOM dog, that.ACC your.NOM vulture
nerven kann, hat einige Pfauen
annoy can, has some.ACC peacocks
amüsiert.
amused.
"Your dog that can annoy your vulture has amused some peacocks."

b. Hat ihr Hund, den ihr
Has your.NOM dog, that.ACC your.NOM
Geier nerven kann, hat einige
vulture annoy can, some.ACC peacocks
Pfauen amüsiert.
amused?
"Has your dog that can annoy your vulture amused some peacocks?"

Table 6: The distribution of syntactic structures in the German train, test, and generalization sets. We use the test set to evaluate whether models have learned the task on in-distribution examples, and the generalization set to evaluate hierarchical generalization.

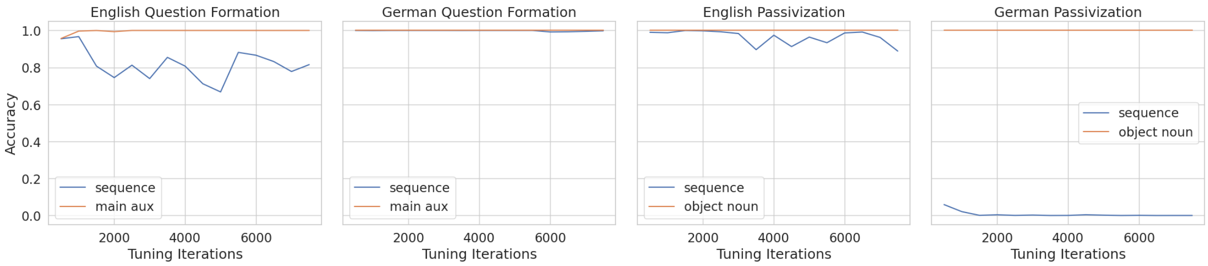

Figure 4: Learning curves over 10 epochs of fine-tuning for mT5 on both syntactic transformation tasks.

.

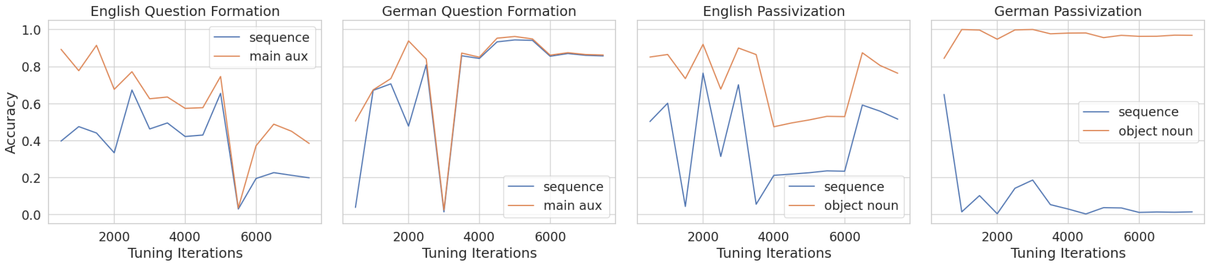

Figure 5: Learning curves over 10 epochs of fine-tuning for mBART on both syntactic transformation tasks.

.

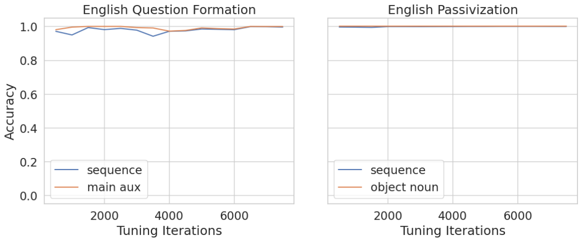

Figure 6: Learning curves over 10 epochs of fine-tuning for T5 on both syntactic transformation tasks.

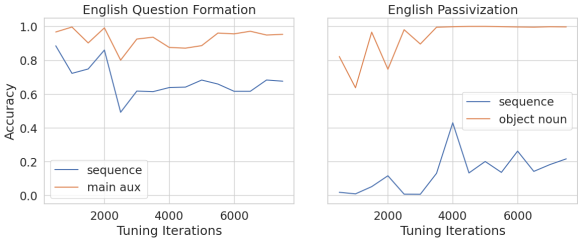

Figure 7: Learning curves over 10 epochs of fine-tuning for BART on both syntactic transformation tasks.

in these curves are the same as those shown in Figure 2, but now associated with their respective fine-tuning iteration.

All models except mBART immediately achieve near-perfect main auxiliary and object noun accuracies. Their loss on the validation sets converges almost immediately, so it's possible that reductions in generalization accuracies throughout fine-tuning are due to overfitting to the training distribution. For mBART, however, main auxiliary and object noun accuracies start high and then begin to vary dramatically throughout fine-tuning. This is perhaps due to quick overfitting on the training distribution. We analyze what errors cause mBART's deficiencies in §C.2.

C Error Analysis

Each pre-trained model almost always chooses the correct auxiliary/object to move; what other errors account for their sub-perfect sequence accuracies? We implement more specific metrics to observe more closely what mistakes (m)T5 and (m)BART are making. We show results for mT5 in §C.1 and mBART in §C.2, but the errors we discuss are generally consistent across models. We also present more detailed metrics for the most complex transformation, German passivization, in §C.3.

C.1 mT5

Figure 8 depicts results for mT5 for German passivization, the transformation on which all models

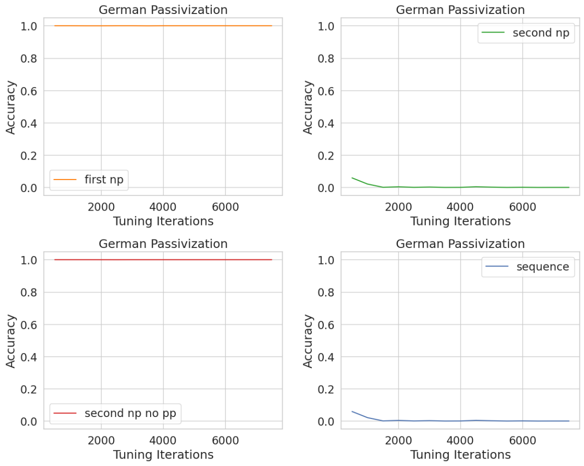

Figure 8: Learning curves displaying alternative accuracy metrics for mT5 on German passivization. We present the accuracy of the model in properly moving the object NP to the start of the sentence (top left), moving the subject NP after the auxiliary verb (top right), moving the subject NP after the auxiliary verb with or without its attached PP (bottom left), and the full sequence accuracy (bottom right).

achieve the lowest sequence accuracy. mT5 is almost always successful at the hierarchical transformation of moving the object NP to subject position (including its attached PP when present), and it correctly moves the original subject noun to a "by" phrase following the auxiliary. However, for both English and German passivization, the main error accounting for sub-perfect sequence accuracies is that the model fails to preserve the PP on the second NP (in the by-phrase):

(12) My yaks below the unicorns comforted the orangutans.
→ The orangutans were comforted by my yaks.

As mT5 has not been fine-tuned on output sequences where PPs appear at the end of the sentence, the decoder could be assigning low probabilities to end-of-sentence PPs while otherwise encoding a hierarchical analysis of sentence structure.

Errors for question formation are more varied. Pre-trained models' sub-perfect main auxiliary accuracies on question formation are mainly due to improper negations on the main auxiliary: when the noun in the relative clause and the main noun agree in number, models will sometimes delete the main auxiliary (as expected) while copying the incorrect auxiliary to the beginning of the sentence. Additionally, the discrepancy between sequence and main auxiliary accuracies is almost always attributable to models not deleting the main auxiliary after moving it to the start of the sentence. These results (as with the passivization results) suggest that **pre-trained seq2seq models are better at performing hierarchy-sensitive transformations than the sequence accuracies initially suggest—but also that they can fail to perform theoretically simpler operations,** such as deletions and moving all parts of a constituent.

We present more detailed error analyses in Appendix C.3. We find that pre-trained models also consistently succeed in case reinflection, tense reinflection, and passive auxiliary insertion.

C.2 mBART

We have shown in §C.1 that mT5 achieves subperfect sequence accuracies on passivization due to its dropping the prepositional phrase on the second NP. Here, we present results for mBART (Figure 9). The takeaways for mBART are similar to mT5's: the model succeeds in moving the proper nouns, but it often drops the prepositional phrase from the second NP during movement.

As the model also fails to perform English question formation consistently, we also observe what errors it makes in that task. We find that deficiencies in main auxiliary accuracy are due to the model copying the incorrect auxiliary to the beginning of the sentence, while gaps between main auxiliary and sequence accuracy are due to the model dropping the relative clause on the second NP.

C.3 More Detailed Metrics

We also present more detailed analyses of other required operations in passivization: namely, are mT5 and mBART capable of tense reinflection, case reinflection, and auxiliary insertions? And are they capable of this in zero-shot settings? Results for mT5 (Figure 10) and mBART (Figure 11) suggest that both models are generally capable of tense reinflection, case reinflection, and auxiliary insertion in supervised contexts.

D Zero-shot mBART Accuracies

Here, we present learning curves for mBART on zero-shot cross-lingual syntactic transformations (Figure 12). While mBART is typically able to select the correct auxiliary verb or object noun to move, it never transforms the sequence fully correctly.

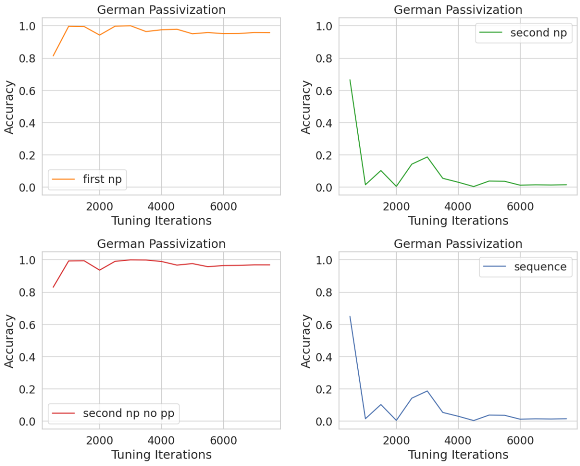

Figure 9: Learning curves displaying alternative accuracy metrics for mBART on German passivization. We present the accuracy of the model in properly moving the object NP to the start of the sentence (top left), moving the subject NP after the auxiliary verb (top right), moving the subject NP after the auxiliary verb with or without its attached PP (bottom left), and the full sequence accuracy (bottom right).

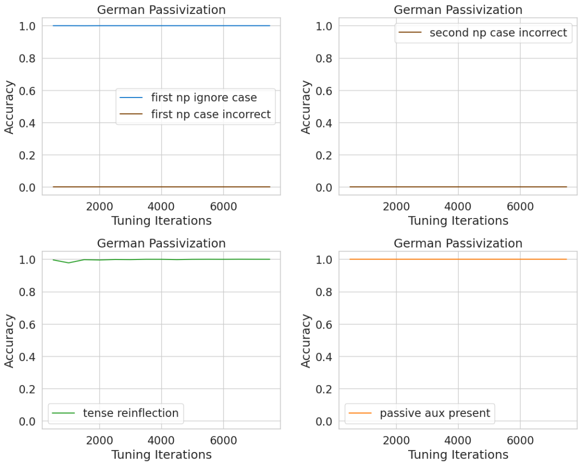

Figure 10: Learning curves displaying alternative accuracy metrics for mT5 on German passivization. We present the proportion of examples for which the model moves the first NP without reinflecting its case (top left), moves the second NP without reinflecting its case (top right), reinflects the tense of the main verb (bottom left), and inserts the passive auxiliary *werden* with the proper inflection.

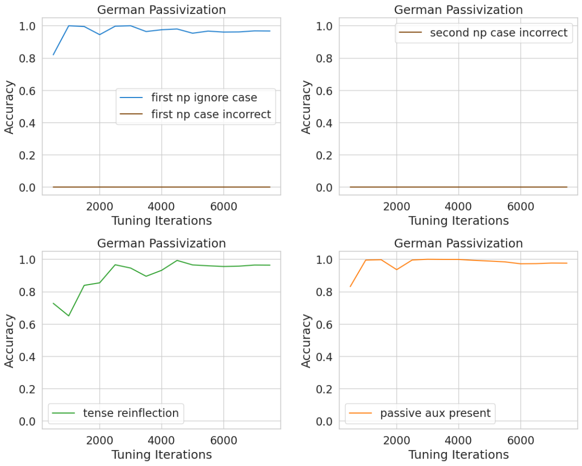

Figure 11: Learning curves displaying alternative accuracy metrics for mBART on German passivization. We present the proportion of examples for which the model moves the first NP without reinflecting its case (top left), moves the second NP without reinflecting its case (top right), reinflects the tense of the main verb (bottom left), and inserts the passive auxiliary *werden* with the proper inflection.

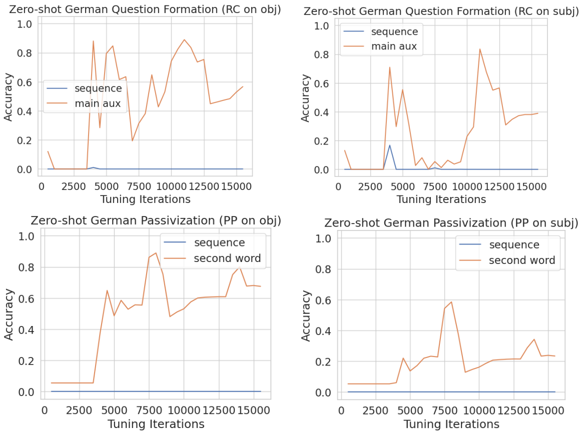

Figure 12: Learning curves for mBART on German transformations after fine-tuning only on English/German identity examples and English transformations. We show accuracies for German question formation with RCs on objects (top left) and RCs on subjects (top right), as well as accuracies for German passivization with PPs on objects (bottom left) and PPs on subjects (bottom right).

C^{3}KG: A Chinese Commonsense Conversation Knowledge Graph

Abstract

Existing commonsense knowledge bases often organize tuples in an isolated manner, which is deficient for commonsense conversational models to plan the next steps. To fill the gap, we curate a large-scale multi-turn human-written conversation corpus, and create the first Chinese commonsense conversation knowledge graph which incorporates both social commonsense knowledge and dialog flow information. To show the potential of our graph, we develop a graph-conversation matching approach, and benchmark two graph-grounded conversational tasks. Our code and data could be found in `https://github.com/XiaoMi/C3KG`.

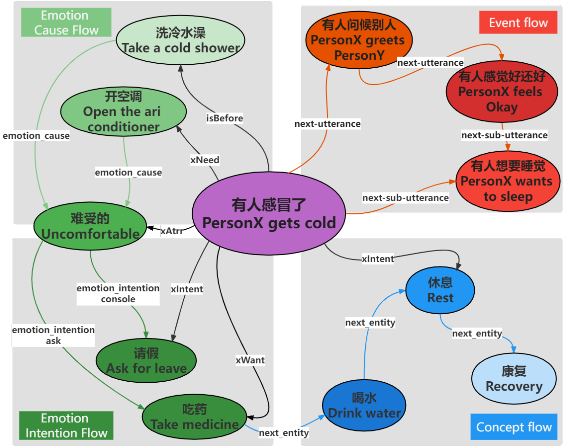

Figure 1: A tiny subset of C^{3}KG, with four unique types of dialog flow relations.

1 Introduction

Commonsense knowledge describes facts and related judgments in our everyday world, which is essential for machine when interacting with humans. These years have witnessed a growing number of literature incorporating commonsense knowledge into various downstream tasks (Bauer et al., 2018; Chen et al., 2019; Lin et al., 2019; Guan et al., 2019; Ji et al., 2020).

Recently, Sap et al. (2019) curate ATOMIC, a large-scale commonsense knowledge base, which covers event-centered social aspects of inferential knowledge tuples. For example, there exist tuples like {*PersonX adopts a cat*, `xEffect`, *feels happy*} and {*PersonX adopts a cat*, `xWant`, *company*}. Here, `xEffect` and `xWant` are two of nine relations defined in ATOMIC to infer people's mental states for a given event, e.g., *PersonX adopts a cat*. As such, it is promising to detect ATOMIC events mentioned in conversations, and utilize the inferred knowledge when developing social chatbots.

In spite of the potential, it has two major difficulties. For instance, when a friend in *distress* tells us that he recently adopted a cat, we humans will easily suspect that he might has allergies to the cat. However, such reasoning is difficult for chatbots. Given the event-relation pair {*PersonX adopts a cat*, `xEffect`, ___}, ATOMIC contains multiple tails like {*finds out he has allergies*} and the tail {*becomes less lonely*}. To this end, the first difficulty comes from the existence of multiple tails, which will confuse the chatbots when inferring the cause behind the negative emotion. Secondly, the knowledge tuples in ATOMIC are isolated. It is thus more difficult for the chatbots to reason which tail(s) of knowledge should be used to produce coherent responses. For example, if the tuple {*PersonX adopts a cat*, `isAfter`, *finds a cat at the animal shelter*} is detected from the dialogue history, then the tuple {*PersonX adopts a cat*, `xNeed`, *go to an animal rescue center*} should not be considered anymore for future conversations. We argue that these issues hamper the application of ATOMIC to multi-turn dialogue modeling where the conversational agents need not only know the current state but also plan the future **dialog flow**.

To remedy these issues, we define 4 novel dialog flow relations, i.e., event flow, concept flow,

---

[*] Corresponding author: yanranli.summer@gmail.com

Findings of the Association for Computational Linguistics: ACL 2022, pages 1369 - 1383

emotion-cause flow, emotion-intent flow, as depicted in Figure 1. To build up the relations, we collect a large-scale multi-turn conversations in everyday scenarios, and manually annotate the conversations with emotional information. Based on the annotations, we are able to extract conversation-related events in ATOMIC and connect them using different dialog flows. In this way, we augment ATOMIC with conversation-specific knowledge, which facilitates chatbots to pick out useful commmonsense knowledge, and relieves their confusion on noisy knowledge that are incoherent with dialog flows. We believe our graph is favorable for commonsense conversation modeling.

To highlight: (1) We curate a new Chinese corpus, containing multi-turn human-written conversations on dailylife topics and rich, high-quality annotations on the level of sub-utterance; (2) We create and will release the first large-scale **C**hinese **c**ommonsense **c**onversation knowledge graph, **C^{3}KG**, which contain 4 types of unique dialog-flow edges to store the distilled conversation knowledge from the multi-turn conversation corpus; (3) We devise a graph-conversation matching approach, and benchmark 2 typical tasks grounded on commonsense conversation graph.

2 Related Work

2.1 Commonsense Knowledge Bases

ConceptNet (Speer et al., 2017a) is a popular commonsense knowledge base (CKB), which has a Chinese version with a relatively small set of knowledge (Kuo et al., 2009). Another large-scale CKB is TransOMCS (Zhang et al., 2020a), which is built automatically by converting syntactic parses of Web sentences into structured knowledge. However, the majority of relations in existing CKBs are taxonomic relations such as `isA` and `Synonym` (Davis and Marcus, 2015), which inevitably limits their capabilities. Differently, we rely on mental CBK ATOMIC (Sap et al., 2019), translate ATOMIC into Chinese and build dialog flow relations on it, with the aim of facilitating Chinese conversational systems.

To construct these CKBs, ATOMIC and ConceptNet rely on crowd-sourcing by which annotators add tail knowledge to a given entity or event based on their own commonsense. To improve efficiency, Bosselut et al. (2019) propose COMET, a pretrained language model which is able to generate diverse tail knowledge given any new event. This automates the collection procedure and results in a scaling of commonsense knowledge. Nevertheless, Zhang et al. (2020a) argues that COMET still suffers from overfitting problem and tends to produce high-frequent and repetitive knowledge. To address, they develop DISCOS (Fang et al., 2021) that learn the extracting patterns from existing CKBs and automatically distill commonsense knowledge from the AESR knowledge graph (Zhang et al., 2020b).

2.2 Connecting Knowledge and Conversation

One line of work attempts to extract structured knowledge from conversations. These works detect named entities from each utterance in conversational datasets (Xu et al., 2020c; Zou et al., 2021a; Ghosal et al., 2021) and build up the relationship based on their sequential order and Pointwise Mutual Information (PMI) (Church and Hanks, 1990). There also exist some works that adopt automatic extraction tools, such as OpenIE, to construct conversational knowledge bases of certain domains (Ahmad et al., 2020). Although plausible, these knowledge graphs are built on the granularities of word or phrase, which makes them hard to match the overall semantics of dialogue sentences. In this paper, we build a Chinese commonsense conversation knowledge graph based on both multi-turn conversational corpus and event-centered knowledge base. At the same time, we propose to use Sentence-BERT (Reimers and Gurevych, 2019a), a transformer-based semantic similarity model, to construct dialog flow edges in our knowledge graph.

There is also another line of growing interests in incorporating commonsense knowledge into conversation modeling. Both Zhou et al. (2018) and Zhang et al. (2019) introduce knowledge triplets from ConceptNet (Speer et al., 2017b) into open-domain response generation. Recently, Li et al. (2021a) and Zhong et al. (2021) exploit ConceptNet to enhance emotion reasoning for response generation, and others design graph reasoning methods to plan the topic transition in the responses (Moon et al., 2019; Tang et al., 2019; Xu et al., 2020a; Li et al., 2021c). One distinct work is Ghosal et al. (2020), which utilizes ATOMIC (Hwang et al., 2020) in emotional dialogue modeling for emotion identification. In this paper, we connect the heads and tails in ATOMIC according to four types of dialog flows. Because the resulted graph C^{3}KG contains both social knowledge from ATOMIC and dialogue knowledge from our corpus, it is thus more suitable for empathetic conversation modeling.

3 A Scenario-based Multi-turn Conversation Corpus

Our aim is to extract common dialog flow information from real conversations. In this way, it is crucial to ensure the quality of the conversation corpus and the reliability of the extraction method. In the following, we firstly introduce the conversation corpus **CConv** we depend on.

Instead of using the noisy Internet data, we collect a multi-turn human-written Chinese conversation corpus based on crowdsourcing. Initially, 100 workers are hired, and they are randomly paired to talk in text under a given scenario. Each scenario is one sentence describing the suggested conversation context which often involves certain everyday events. Besides, the workers are also required to follow certain rules like "each utterance should longer than 6 Chinese characters", which are critical to help ensure the quality of the collected conversation. At the beginning of the crowdsourcing, we check each collected conversation and re-train the workers. To ensure the quality, we keep only 62 well-trained workers and let them finish our task. Note that the workers are paid with 1 CNY per utterance (nearly 0.2 dollar per utterance). Finally, we obtain 32k sessions of high-quality two-party conversations (650k utterances in total) on 200 scenarios of 15 daily topics.

To facilitate future research, we then hire another 3 well-trained assistants to manually annotate the conversations with fine-grained emotional labels including speaker's emotion type, emotion cause, and response intention type. Following Rashkin et al. (2019), we define emotion type with 5 general classes {joy, angry, sad, surprising, other}. Emotion cause span is a continuous text spans implying the reason of certain emotion (Li et al., 2021b). Response intention type is essential for building empathetic chatbots, and we define 6 commonly-adopted intent classes of {ask, advise, describe, opinion, console, other} following Welivita and Pu (2020). A snippet of a conversation example is given in Figure 2. In Appendix, we present more information of the constructed corpus.

By utilizing the annotations, we are able to distill dialogue knowledge to enhance the conversation graph and graph-grounded conversation modeling.

4 Overview and Processing of ATOMIC

Because our conversation corpus is Chinese, we want to build a Chinese conversation knowledge graph. It is well known that to build a knowledge graph from scratch is laborious and time-consuming. Instead, we base on ATOMIC and design a pipeline method to translate it into Chinese, meanwhile ensuring the resulted knowledge graph is reliable and suitable for conversation grounding.

4.1 Brief Introduction of ATOMIC

We firstly give a brief description of ATOMIC (Sap et al., 2019). ATOMIC organizes commonsense knowledge in the form of triplet <head, relation, tail>, where head often describes a daily event.

There are two unique properties making ATOMIC suitable and attractive for building empathic chatbots. Firstly, ATOMIC collects knowledge about how people will react to a given event. This kind of knowledge is related to people's mental states, which is beneficial for understanding implicit emotions. For example, given a head event *PersonX makes PersonY's coffee*, ATOMIC contains knowledge that PersonY will be *grateful* along the relation `oReact`. Secondly, ATOMIC organizes knowledge using several inferential relations and naturally supports *if-then* reasoning, which is crucial generating coherent responses. Totally, there are 9 relations defined in ATOMIC. The details can be found in Appendix.

In the terms of translating ATOMIC to Chinese, we apply **Regular Replacement** and **Joint Translation** method to improve the quality of translation. We give more details of our translation methods in the Appendix. we denote the translated ATOMIC as **ATOMIC-zh**.

5 Conversation Knowledge Graph Construction

5.1 Overview of C^{3}KG

To supply dialog flow information for commonsense reasoning, we create a **C**hinese **C**ommonsense **C**onversation **K**nowledge **G**raph, **C^{3}KG**, whose statistics are summarized in below.

We then introduce our method of constructing a conversational knowledge graph based on ATOMIC-zh and our multi-turn conversation corpus. In general, we extract events from each conversations and match with the head in ATOMIC-zh.

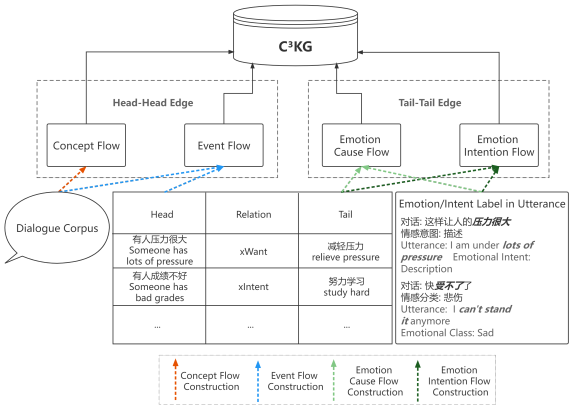

Figure 2: Construction Process of C^{3}KG.

#Relations	ATOMIC Relations	636,636
	Event Flows	571,196
	Concept Flows	77,587
	Emotion-Cause Flows	269
	Emotion-Intent Flows	553
#Triplets	1,286,241	

Table 1: Statistics of C^{3}KG.

The core is how to build new dialog flow relations, which is depicted in Figure 2, and will be detailed present in the following section.

5.2 Event Extraction

Knowledge in ATOMIC-zh is event-based and most of them are declarative sentences with some entities omitted. However, utterances in the open-domain dialogue dataset contain a lot of colloquial expressions and sub-sentences with more complex structures. To address, we develop a dependency parsing-based event detection pipeline to extract salient events in each utterance. The overview of our algorithm is described in Algorithm 1.

Pre-processing. We first split each utterance with punctuation, and operate on the level of sub-utterances. To reduce noise, we then filter short sub-utterances with transitive and dumb semantics like “好的” (OK), “就是这样” (That’s it). After that, we perform Dependency Syntactic Parsing and POS tagging using ltp4[1], and extract event mentions based on two kinds of structural patterns, verb-driven and adjective-driven clauses.

Verb-driven. Verb-driven clauses have a verb connecting to the root node in the dependency tree. After filtering some noisy words, we obtain verb-driven event mentions. For example, we extract the

Algorithm 1 Event Extraction from Utterance

```
Input: An utterance $U$
Output: A set of event mentions $M$
Split $U$ with punctuation, and get a series of sub-utterance $SU$, filter $SU$ based on length
for each $su \in SU$ do
    Obtain the dependency tree $dep$ and POS tagging result $pos$ of $su$
    Find the $had$ node which connects directly to the $ROOT$ node in the dependency tree
    if POS tag of the $had$ node $\in [v, a]$ then
        Append $had$ to $HAD$
    end if
    if The number of verbs connected directly to $had$ more than 1 then
        Recursively search verbs in the sub-tree of $had$ and replace $had$ in $HAD$ with the founded verbs
    end if
    for $had \in HAD$ do
        if POS of node $had$ is $v$ then
            Keep words in $su$ that appear after $had$ and words connect directly to $had$ and relation is ‘ADV’, connect them and append to $M$
        else
            Remain words in $su$ that connect directly to $had$ and relation is ‘SBV’, connect them and append to $M$
        end if
    end for
end for
Return $M$
```

mention “催促提供物资的商家” (urged the merchants who provide supplies) from utterance “我和上司已经在催促提供物资的商家了” (My boss and I have already urged the merchants who provide supplies). In this utterance, we filter subject of utterance“我和上司” (My boss and I), adverbial“已经” (have already) and modal particle“了” (yet) at the end of the utterance.

Adjective-driven. Besides, adjective-driven clauses often have meaningful entities in sub-utterances. Similarly, we extract adjective-driven event mentions based on the adjective-driven clauses by keeping the modifier of its key adjective and filtering out other words. For example, we extract the mention “学习节奏快” (The pace of learning is fast) from the utterance “但学习节奏

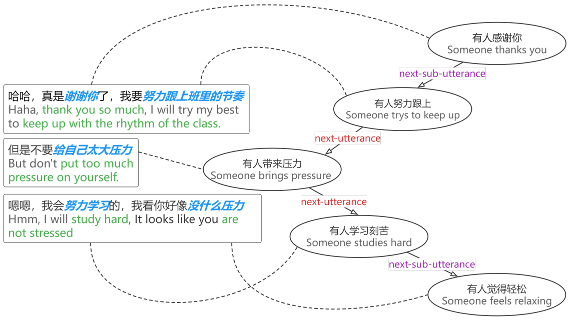
---

[1] https://github.com/HIT-SCIR/ltp

也太快了吧” (But the pace of learning is too fast). In this utterance, we filter the initial conjunction “但是” (but), adverbial “也” (no meaning) and “太” (too) and modal particle “了” (yet) and “吧” (no meaning) at the end of the utterance.

Recursive Applying. The resulted event mentions may still contain multiple verbs and several semantic units. In this case, we apply a secondary decomposition. For example, we will split the event mention “以为进了大学就可以放松放松” (could relax after entering university) into two events “进了大学” (entering university) and “就可以放松放松” (could relax). To do so, we count the number of verbs connected to the root word in the mention as well as the depth of the sub-trees led by those verbs. Based on the results, we determine whether the mention needs a secondary decomposition using a threshold. If needed, we recursively search verbs in the original dependency tree and replace the key verb with the verbs we found.

5.3 Event Linking as Matching



哈哈，真是谢谢你了，我要努力跟上班里的节奏
Haha, thank you so much, I will try my best to keep up with the rhythm of the class.

但是不要给自己太大压力
But don't put too much pressure on yourself.

嗯嗯，我会努力学习的，我看你好像没什么压力
Hmm, I will study hard, It looks like you are not stressed

Figure 3: An Example of Head-Head Edge Construction for Event Flows.

In order to discover common dialog flows among the knowledge base, the event mentions in the conversations are then linked to ATOMIC heads using matching techniques.

Typically, we adopt Sentence-BERT, a powerful semantic matching model, which is based on Siamese and Triplet Network and pre-trained on sentence pairs in different relationships (Reimers and Gurevych, 2019b). It encodes two given sentences separately and calculates the similarity between their representations, and thus performing efficiently in large-scale many-to-many matching.

To enhance the matching performance, we fine-tune Sentence-BERT on our corpus. Specifically, we randomly select 8,000 <m, h> mention-head pairs matched by pre-trained Sentence-BERT, and manually label a matching score in {0,1} for fine-tuning. Note the reason why we adopt discrete 0,1 instead of continuous $[0, 1]$ scores is that using the former effectively mitigates the domain gap. It will induce the matching model to label 0 for those <m, h> share similar characters in surface but different meanings in semantics. After fine-tuning, we calculate the cosine similarity scores and choose the head with the highest score as the matching result given an event mention.

5.4 Edge Construction

Now we have 32k sessions of multi-turn conversations and link their event mentions to ATOMIC heads. The remaining is how to utilize them and build commonsense conversation knowledge graph. In this work, we propose three kinds of edges to reflect different types of dialog flows.

5.4.1 Head-Head Edge Construction

Event Flow. Naturally, a dialogue is hierarchical in that it consists of a sequence of utterances produced by two interlocutors, where each utterance is composed of one or several sub-utterances. If two event mentions are detected together within in a conversation, the co-occurrence can be regarded as a dialog flow example. Following the flow, it is then intuitive to connect the ATOMIC heads linked by the mentions, as illustrated in Figure 3. By connecting intra-utterance and inter- utterance mentions, we acquire the event flows of `next-sub-utterance` and `next-utterance`.

Concept Flow. ATOMIC also has entity-level heads in addition to the phrase-level events. To utilize them, we perform entity linking by detecting word entities with POS tag belonging to {verb, noun, adjective} in the original conversations, and match them with the entity-level ATOMIC heads to construct concept flow edges similarly. These concept flows are helpful for planning and transiting the contents in topic-aware conversation (Yao et al., 2018; Moon et al., 2019; Xu et al., 2020b; Zou et al., 2021b).

Because we are interested in the most common dialog flows, we only keep those highly-frequent connections, and create a head-to-head dialog flow between the ATOMIC head entities and events.

5.4.2 Tail-Tail Edge Construction

Besides, we also consider another essential type of dialog flow, i.e., emotion-based empathy flow.

Tail$_{emotion}$	xAttr,xReact
Tail$_{before}$	isAfter, xNeed
Tail$_{after}$	isBefore, xWant, xIntent, xEffect, oEffect

Table 2: Relation Categories For Emotion-based Edge Construction.

In this paper, we utilize the emotional labels on our corpus (in Section 3) to construct two kinds of emotion-based edges connecting tails in our knowledge graph. Intuitively, `emotion-cause` dialog flow reflects the reasons for a specific emotion, which is useful for fine-grained emotion understanding. And `emotion-intent` empathy flow indicates what response intentions are proper to use when the other one is in a specific emotion, which is critical for response empathy.

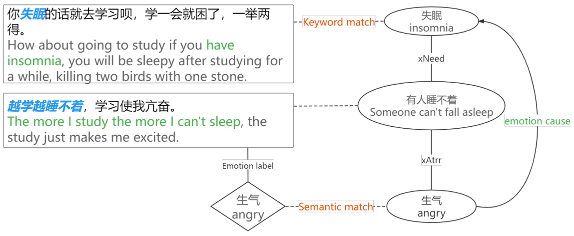
Pre-processing. To construct emotion-based edges, we category the tails into 3 classes according to their connecting relations, as listed in Table 2. The first class of tails are linked by relations $xAttr$ or $xReact$, which reflects people's psychological reaction towards a certain event (head). For instance, {*PersonX runs out of steam*, `xAttr`, *tired*} indicates that someone is lacking energy. We denote the first class as Tail$_{emotion}$. The second class Tail$_{before}$ states the events commonly happen before the heads, e.g., {*PersonX runs out of steam*, `isAfter`, *PersonX exercises in gym*}. On the contrary, the last class Tail$_{after}$ contain the events following the head events like {*PersonX runs out of steam*, `xWant`, *to get some energy*}.

By analyzing these relations and tails, we find heuristics to build emotion-based dialog flows. By connecting the head and tails in class Tail$_{emotion}$, we are able to create causal emotional inference like {*PersonX exercises in gym*, `emotion-cause`, *tired*}. Through cross linking the tails in class Tail$_{emotion}$ and Tail$_{after}$, we are able to develop the inferential edges like {*tired*, `emotion-intent`, *to get some energy*}.

Filtering. Based on the heuristics, we apply SentiLARE[2] to match each tail in class Tail$_{emotion}$ to one of 4 emotion labels defined in our dataset, i.e., {joy, sad, angry, others}. For label 'surprising' (which is not contained in the labels of SentiLARE), we use Sentence-BERT[3] and set a threshold of 0.7 to label 'surprising' in the tails whose label is 'others' according to SentiLARE. The tails sharing the same emotion class with the original utterance are kept to build emotion-based dialog flows.

Emotion Cause Flow. Then, we apply keyword-based exact matching between the tails in Tail$_{before}$ with dialogue context. For Tail$_{before}$, if there is an keyword exactly matched with some keywords in the previous utterances, we create an $emotion-cause$ edge flowed from the tail of Tail$_{before}$ to those filtered tails in Tail$_{emotion}$, indicating that the event of Tail$_{before}$ may cause person to feel the emotion of the tail in Tail$_{emotion}$.

Figure 4 depicts the process of constructing the labeled `emotion-cause` edge. Firstly, we match the tail *angry* in Tail$_{emotion}$ to the utterance emotion label "angry". Then, we detect that the tail *insomnia* in Tail$_{before}$ shows up in the previous utterance. So we build a `emotion_cause` edge from the tail *angry* to tail *insomnia*. This kind of tail-tail `emotion_cause` flows is supportive for chatbots to have a better understanding of users' emotional mood by reasoning its cause.



你失眠的话就去学习呗，学一会就困了，一举两得。
How about going to study if you have insomnia, you will be sleepy after studying for a while, killing two birds with one stone.

越学越睡不着，学习使我亢奋。
The more I study the more I can't sleep, the study just makes me excited.

Figure 4: An Example of Tail-Tail Edge Construction for Emotional Cause Flows.

Emotion Intent Flow. For tails in class Tail$_{after}$, we create an `emotion_intent` flow from those filtered tails in Tail$_{emotion}$ to the tails in Tail$_{after}$. Notably, we also assign one of five intent labels to each `emotion_intent` edge, i.e., {ask, advise, describe, opinion, console} (Section 3).

Figure 5 depicts the process of constructing the labeled `emotion-intent` edge. We start by matching the tail *Uncomfortable* in Tail$_{emotion}$ to the utterance emotion label "sad". Then, we detect that the tail *Take medicine* in Tail$_{after}$ shows up in the next utterance. As such, we build a `emotion_intent` edge from the tail *Uncomfortable* to tail *Take medicine*, and add the intent label of the second utterance "ask" on to the edge. This kind of tail-tail `emotion_intent` flows is supportive for chatbots to choose proper response strategy under a certain situation.

Expertise Label. Considering that both emotion

---

[2] https://github.com/thu-coai/SentiLARE

[3] This model is not fine-tuned on our dataset.

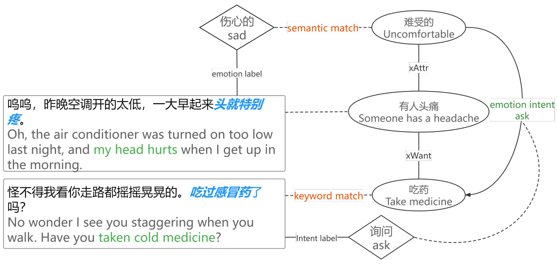


Figure 5: An Example of Tail-Tail Edge Construction for Emotional Intent Flows.

and intent within each utterance is latent and subtle, it is very hard to make the emotion flow results of automatically extraction behave well in the terms of number. In that case, we also hire 2 expertise with rich experience in psychology, and hire them to label both emotion cause and intent in high-frequency scenarios for emotion expression, like sleeplessness and academic pressure.

For expertise convenience, we also build an interactive annotation tool for more easily annotating and exploring in our C^{3}KG. The system integrates functions like revising and adding tails, which would be a good supplement and cleaning tool for our C^{3}KG. There are more details of our tool in the Appendix.

6 Evaluation

6.1 Matching Evaluation

Manual Assessment. We randomly choose 100 utterances to evaluate our event extraction (Section 5.2) and matching methods (Section 5.3). We denote our proposed method as $Parsing$. To compare with it, we use another two methods to process utterances: POS employs POS tagging-based templates to extract events, and $Simple$ only splits and filters utterances according to punctuation before matching. We report matching results using both Sentence-BERT and Sentence-BERT-finetune.

In Table 3, Similarity stands for the averaged matching degree, and Number for the average number of matched ATOMIC heads of the chosen utterances, which can be seen as an indicator for matching recall. Although the three methods have similar average similarity without finetuning, our Parsing method gets an obvious similarity improvement after finetuning as compared with Simple and POS without loss of knowledge recall, which is also significantly better than POS-based method.

Method	SBERT		SBERT-finetune	
	Similarity	Number	Similarity	Number
Simple	51.3%	**1.57**	53.2%	**1.57**
POS	**51.4%**	0.75	54.1%	0.75
Parsing	51.3%	1.53	**55.3%**	1.53

Table 3: Comparison of Matching Approaches.

Method	Fluency	Logic
Separate translation	0.825	0.71
Joint translation	**0.92**	**0.88**

Table 4: Evaluation of Translation Quality.

Scenario Graph Visualization. We also build up scenario graphs based on matching results and the scenario descriptions. By visualizing the matched result for each topic of scenarios, we are able to better understand the matching quality.

Specifically, we use sub-sentence to match heads in ATOMIC-zh, and use the top 0.5% heads we match in each scenario to build scenario-based graphs. Each of them can be seen as a sampled sub-graph from ATOMIC-zh, with higher topic coherence with its scenario. After annotation, the matching accuracy based on 3 annotators reaches 0.71, which indicate a fair quality of scenario graph. To depict, we visualize a snippet of the scenario graph "sickness" in Figure 6. Please kindly note that for clarity, we only visualize a small set of relation and tails in Figure 6. In fact, every scenario graphs contain the full set of C^{3}KG relations. For more scenario graphs, please check Appendix.

6.2 Graph Evaluation

Node Evaluation. Since our C^{3}KG is built upon the translated ATOMIC-zh. We firstly evaluate the quality of our graph in terms of translation accuracy. In specific, we randomly sample 200 triplets from C^{3}KG, and ask annotators to label each Chinese triplet in terms of fluency and logic correctness with {0,1} scores. To validate our joint translation method, we also compare with the results using separate translation.

As shown in Table 4, the significant increases on both Fluency and Logic aspects clearly demonstrate the superiority of joint translation method. In terms of logical coherence, we find many sample cases are labeled with 0 logical score due to the incompleteness of their heads, which somehow confuses the semantics and obstacles logical connection to the tails. For example, {有人把他父亲, `xAttr`, 告密者} ({*PersonX gets PersonX's father*, `xAttr`, *a tattletale*}) seems ridiculous. However,

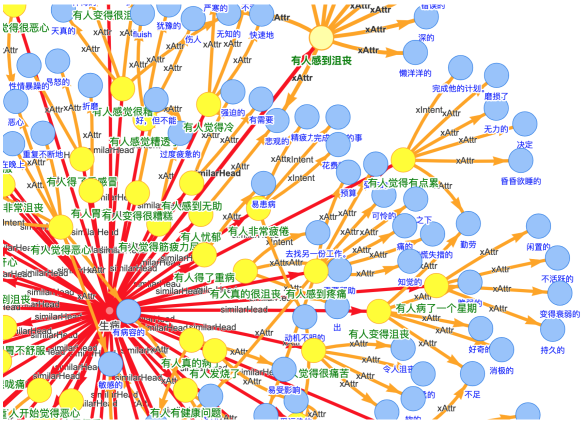

Figure 6: Scenario Graph of “Sickness”.

if we add 叫来 (*came*) in the end of the heads, then we could imagine a scenario where a child threatens another child by summoning parents. Nonetheless, such seemingly illogical knowledge might still be informative for downstream tasks with fuzzy matching techniques. Hence, we retain this kind of incomplete heads.

Edge Evaluation. At the heart of C^{3}KG is the novel dialog flow relations we develop in this work. To validate the quality and robustness of these relations, we utilize another open-domain multi-turn Chinese dialogue dataset, MOD (Fei et al., 2021)[4]. In specific, we extract event mentions from MOD utterances and match them to our graph using the methods as in Section 5.2. Then we evaluate the connectivity and average distance of the matched results, w.r.t. both `next_utterance` and `next_sub_utterance` relations. This aims to assess the aggregation degree of related content in our knowledge graph.

KG	next_utterance		next_sub_utterance	
	Con.	AVG_Dist.	Con.	AVG_Dist.
C^{3}KG	**96.68%**	**1.86**	**96.51%**	**1.90**
ATOMIC-zh	6.90%	7.52	5.21%	10.81

Table 5: Edge Evaluation Result on MOD dataset.

Table 5 shows our edge evaluation result on MOD. For comparison, we add the test result of ATOMIC-zh, considering their similarity in size. The comparing result shows the effectiveness of our event flow, which leads the matching of context within a dialogue has higher connectivity and shorter distance.

Method	Emotion (acc.)	Intent (acc.)
Base	90.7%	65.3%
Knowledge	**93.6%**	**71.3%**
History	90.5%	64.7%
Knowledge+History	91.2%	67.4%

Table 6: Baselines for Graph-grounded Tasks.

7 Proposed Tasks

To show the potential, we propose two graph-grounded conversational tasks, i.e., emotion classification and intent prediction, and train benchmark models using our labeled corpus CConv.

Task 1: Emotion Classification requires to produce an emotion label conditions on the conversations. Following common practice, we choose the BERT model, and sample the `xAttr`, `xReact` tails from our matching head as extra input.

Task 2: Intent Prediction requires to predict a proper type of response intent for the conversations. We choose BERT model, and sample the `oReact`, `oEffect` tails from our matching heads. As simple baselines, we introduce history and graph knowledge through concatenation with an input format as U_{i-2} [SEP] U_{i-1} [SEP] U_i [SEP] `OReact` tail [SEP] `oEffect` tail.

Both of the above sampling steps use a threshold of 0.7 between processed sub-utterances and matched heads, to reduce noise introducing of our sampled knowledge. The accuracies of baseline methods are reported in Table 6. $Base$ denotes only using the utterance to do prediction. $Knowledge$ and $History$ denote whether to add knowledge we sampled and dialogue history to the model. While adding knowledge improves the model performances, it seems problematic to directly concatenating history dialogues, which may bring noises. The moderate scores also indicate that there is still a room to improve for graph-grounded conversation understanding.

8 Discussions of Future Work

In this work, we provide a systematic approach from event mention detection, event linking to conversation graph construction which consists of 4 distinguished types of dialog flows. For each step, there exist possible refinements. For example, we plan to include other event-based resources to improve graph-conversation matching accuracy as well as the graph knowledge coverage.

We also plan to continue the annotations to supply more dialog flow information especially those

---

[4] `https://github.com/lizekang/DSTC10-MOD`

empathy ones, and evaluate more dialog flow relations on other datasets.

Acknowledgements and Ethical Considerations

We would like to thank the anonymous reviewers for their constructive comments. This work was approved by XiaoAI team. All personally identifiable information in our dataset was removed.

At last, we discuss the potential ethic impacts of this work. (1) **Transparency**: We will release the newly introduced corpus and the built conversation knowledge graph, as well as the benchmark approaches to facilitate future research. Similar datasets and knowledge bases include EmpatheticDialogues (Rashkin et al., 2019) and ATOMIC (Sap et al., 2019), which are often public available and have been used extensively. (2) **Privacy**: The corpus is crowdsourced under a set of specific rules to forbid the workers disclosure sensitive and personal identifiable information. (3) **Politeness**: Because our conversations are human-written and are related to healthy dailylife scenarios, they are expected to be clean, legal, and polite. The crowdsourcing rules are designed to avoid emotionally triggering words as much as possible.

A Corpus: CConv

A.1 Example & Statistics

In our corpus CConv, conversations are conducted based on a scenario between two parties. Table 8 gives an example conversation. The statistics of CConv is also present in Table 7. Since there are 200 scenarios in total, and hence we have 160 diverse multi-turn conversations in average.

# sessions of dialogues	32,612
# utterances	650,147
# unique scenarios	200
# conversation topics	15
Avg. # words per utterance	7.8
Avg. # turns per dialogue	19.9

Table 7: The Statistics of the Corpus CConv.

A.2 Topics and Scenarios

To ensure the diversity of the conversations, we select 15 everyday topics. For each topic, we manually write tens of one-sentence scenario to guide the conversation context.

In total, we have 15 topics and 200 scenarios. To better understand, we show some example topics and scenarios in Table 9.

A.3 Annotation Criteria

To facilitate future research, we hire another 3 well-trained assistants to manually annotate the conversations with fine-grained emotional labels including speaker's emotion type, emotion cause, and response intention type. The annotation example in given along with the example in Table 8.

Emotion Class. Following Rashkin et al. (2019), we define emotion type with 5 general classes {joy, angry, sad, surprising, other}.

Emotion Cause Span. Emotion cause span is a continuous text spans implying the reason of certain emotion (Li et al., 2021b).

Response Intent. Response intention type is essential for building empathetic chatbots, and we define 6 commonly-adopted intent classes of {ask, advise, describe, opinion, console, other} following Welivita and Pu (2020), which are described in Table 10.

B ATOMIC

In this work, we introduce ATOMIC (Sap et al., 2019) as the commonsense knowledge base due to its attractive properties of mental state inferences and *if-then* causal relations, as analyzed before.

ATOMIC (Sap et al., 2019) is a novel event-centered knowledge graph, consisting of 880K tuples of social commonsense knowledge. Distinguished from ConceptNet (Speer et al., 2017a), there are two unique properties making ATOMIC suitable and attractive for building empathic chatbots. Firstly, ATOMIC collects knowledge about how people will feel and react to a given event. This kind of knowledge is related to people's mental states, which is beneficial for understanding implicit emotions. For example, given a head event *PersonX makes PersonY's coffee*, ATOMIC contains knowledge that PersonY will be *grateful* along the relation `oReact`. Secondly, ATOMIC organizes knowledge using several inferential relations and naturally supports *if-then* reasoning, which is crucial generating coherent responses.

Here, we adopt the figures and demonstrations from the original ATOMIC paper (Sap et al., 2019) to present the 9 relations defined in ATOMIC and give some examples in Figure 7 and Table 11.

C Translation Method

C.1 Replacement of Certain Tokens

We begin with translating high-frequency patterns in the original triplets. As compared to the predefined set of relations, it is more difficult to handle the heads and tails. In ATOMIC, for example, there exist **185,046** heads and tails containing tokens like "*PersonX*" and "*PersonY*". These personal pronouns stand for the givers and the receives for a certain event, and can be regarded as the speech parties in a conversation. Also, some ATOMIC heads like {*PersonX gets ____ as a pet*}, have a blank which can be filled with various tokens.

These aforementioned patterns bring ambiguity to the triplet semantics, and will confuse the translation model. To address, we devise a series of replacement rules to keep the original semantics while translation. For example, for the ATOMIC head *PersonX votes for personY*, we convert it to be "Someone votes for someone else" and send it to our translation model.

C.2 Joint Translation of Head and Tail

Nevertheless, the majority of the heads and tails in ATOMIC are short phrases, while machine translation models are often context-based. The multi-sense characteristics of language will further dete-

Situation			
同事之间，一方身体不舒服，另一方表达关心 Acted as colleagues, one person is sick, and the other one cares about his/her health.			
Conversation			
Speaker	Utterance	Emotion	Intent
1	你今天来得比平时晚呀。是身体不舒服吗? (You are later than normal days. Are you OK?)	other	ask
2	呜呜，昨晚空调开的太大，一大早起来头就特别疼。 (Yesterday the air conditioner was too cold that I had a headache this morning.)	sad	description
1	怪不得，那你吃过感冒药了吗? (I know. Have you taken the medicine?)	other	ask
2	吃过了，现在已经好多了，就是有点想睡觉。 (Sure. I feel better now, just feel a little bit sleepy.)	other	description
...	...	...	...
2	今天的工作安排多么? (What are today's arrangements?)	other	other
1	我会帮你做的。你好好休息吧! (I will help finish them. You'd better take a good rest.)	other	advise
2	真是太感谢你了! (I really appreciate a lot for your help!)	joy	other

Table 8: Example Conversation with Annotations. Note that the underlined words stand for the emotion cause span. Words are shorten due to space limit.

Topic	Scenario
Study	两个学生之间，讨论课业压力大，总是做不完作业 (Between two students, discuss the overload homework) 考研失败，向朋友倾诉自己的伤心和烦恼 (Fail the entry exam of graduate study, express the distress to a friend)
Entertainment	讨论自己最喜欢的一部电影，以及为什么喜欢它 (Discuss one of your favorite films and why) 聊一聊自己曾经单曲循环过的歌曲，以及当时自己的感受 (Talk about a music or a song you have put on repeat all the night)
Love	情侣之间，因为生活作息不一致而吵架闹别扭 (Between a couple, quarrel with the lover due to inharmonious habits) 自己订婚了，激动地与好友分享喜讯 (Being engaged, share the good news to the best friend)

Table 9: Example Topics and Scenarios.

Intent Type	Definition	Example
ask	to know further details or clarify	*What happended?*
describe	present more details and explain the reasons	*I'm sad because I failed the exam.*
advise	give explicit solutions	*Try to exercise more.*
opinion	share own thoughts	*I don't like being disturbed after work.*
console	pacify others	*I hope you'd feel better.*
other	-	*Goodbye.*

Table 10: Annotation Criteria for Response Intent.

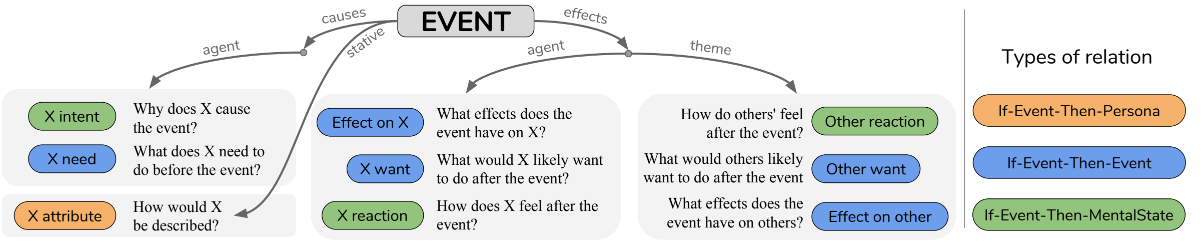

Figure 7: The taxonomy of *if-then* reasoning types. We consider nine *if-then* relations that have overlapping hierarchical structures as visualized above. One way to categorize the types is based on the type of content being predicted: (1) **If-Event-Then-Mental-State**, (2) **If-Event-Then-Event**, and (3) **If-Event-Then-Persona**. Another way is to categorize the types based on their causal relations: (1) **"causes"**, (2) **"effects"**, and (3) **"stative"**. Some of these categories can further divide depending on whether the reasoning focuses on the "agent" (X) or the "theme" (Other) of the event.

Event	Type of relations	Inference examples	Inference dim.
"PersonX pays PersonY a compliment"	If-Event-Then-Mental-State	PersonX wanted to be nice PersonX will feel good PersonY will feel flattered	xIntent xReact oReact
	If-Event-Then-Event	PersonX will want to chat with PersonY PersonY will smile PersonY will compliment PersonX back	xWant oEffect oWant
	If-Event-Then-Persona	PersonX is flattering PersonX is caring	xAttr xAttr
"PersonX makes PersonY's coffee"	If-Event-Then-Mental-State	PersonX wanted to be helpful PersonY will be appreciative PersonY will be grateful	xIntent oReact oReact
	If-Event-Then-Event	PersonX needs to put the coffee in the filter PersonX gets thanked PersonX adds cream and sugar	xNeed xEffect xWant
	If-Event-Then-Persona	PersonX is helpful PersonX is deferential	xAttr xAttr
"PersonX calls the police"	If-Event-Then-Mental-State	PersonX wants to report a crime Others feel worried	xIntent oReact
	If-Event-Then-Event	PersonX needs to dial 911 PersonX wants to explain everything to the police PersonX starts to panic Others want to dispatch some officers	xNeed xWant xEffect oWant
	If-Event-Then-Persona	PersonX is lawful PersonX is responsible	xAttr xAttr

Table 11: Examples of **If-Event-Then-X** commonsense knowledge present in Sap et al. (2019). For inference dimensions, "x" and "o" pertain to PersonX and others, respectively (e.g., "xAttr": attribute of PersonX, "oEffect": effect on others).

riorate the translation quality if we separately feed each single head and tail to a translation model.

To remedy the issues, we instead translate the head and tail in each triplet together. Given a triplet <h, r, t>, we connect the head h with its t using a heuristic connecting word r' w.r.t. the relation r, and obtain one long sentence l. After translating the long text, we split the translation result with the connecting word and turn it into h_{tr} and t_{tr}:

$$\begin{aligned} l &= \mathrm{CONNECT}(h, r', t) \\ l'_{tr} &= \mathrm{TRANSLATION}(l) \qquad (1) \\ h_{tr}, r_{tr}, t_{tr} &= \mathrm{SPLIT}(m'_{tr}, r'_{tr}) \end{aligned}$$

where the resulted <h_{tr}, r_{tr}, t_{tr}> is the translated triplets. And CONNECT, SPLIT denote the corresponding operation. TRANSLATION stands for our translation model. By this means, we expect the connected l provides more contextual information for better semantic translation. The comparison results between separate translation and joint translation will be given in Section 6.2.

Note that auxiliary translation methods can be used. In this work, we use Xiaomi commercial Translation service.[5] For simplicity, we denote the translated ATOMIC as **ATOMIC-zh**.

D Evaluation

D.1 Template-based Event Extraction Methods

To evaluate our matching methods proposed in this work, we randomly choose 100 utterances and compare with several approaches. In specific, we propose a baseline POS matching method, which employs POS tagging-based templates to extract events. The templates are given in Table 12.

D.2 More Examples of Constructed Scenario Graphs and Annotation Tool

In this section, we visualize more snippets of the scenario graphs. They are "insomnia" in Figure 9. We also give examples of revising function in our interactive annotation tool in Figure 10 and Figure 11, with the head "有人睡不着" (someone cannot fall asleep).

Please kindly note that for clarity, we only visualize a small set of relation and tails in each figure, and try to give a comprehensive view of the relations by showing different relations in different scenario graphs. In fact, every scenario graphs contain the full set of C^{3}KG relations.

Abstract

After a period of decrease, interest in word alignments is increasing again for their usefulness in domains such as typological research, cross-lingual annotation projection and machine translation. Generally, alignment algorithms only use bitext and do not make use of the fact that many parallel corpora are multiparallel. Here, we compute high-quality word alignments between multiple language pairs by considering all language pairs together. First, we create a multiparallel word alignment graph, joining all bilingual word alignment pairs in one graph. Next, we use graph neural networks (GNNs) to exploit the graph structure. Our GNN approach (i) utilizes information about the meaning, position and language of the input words, (ii) incorporates information from multiple parallel sentences, (iii) adds and removes edges from the initial alignments, and (iv) yields a prediction model that can generalize beyond the training sentences. We show that community detection provides valuable information for multiparallel word alignment. Our method outperforms previous work on three word alignment datasets and on a downstream task.

1 Introduction

Word alignments are crucial for statistical machine translation (Koehn et al., 2003) and useful for many other multilingual tasks such as neural machine translation (Alkhouli and Ney, 2017; Alkhouli et al., 2016), typological analysis (Lewis and Xia, 2008; Östling, 2015; Asgari and Schütze, 2017) and annotation projection (Yarowsky and Ngai, 2001; Fossum and Abney, 2005; Wisniewski et al., 2014; Huck et al., 2019). The rise of deep learning initially led to a temporary plateau, but interest in word alignments is now increasing, demonstrated by several recent publications (Jalili Sabet et al., 2020; Chen et al., 2020; Dou and Neubig, 2021).

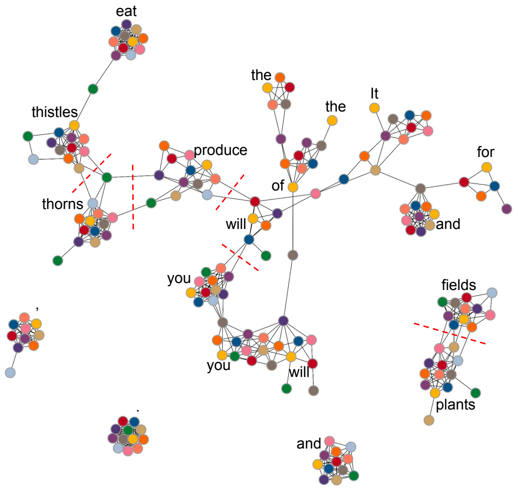

Figure 1: Alignment graph for the verse "It will produce thorns and thistles for you, and you will eat the plants of the field." in a 12-way multiparallel corpus. Colors represent languages. Each English (yellow) node is annotated with its word. Red dashed lines cut links that incorrectly connect distinct concepts. We exploit community detection algorithms to detect distinct concepts. This provides valuable information for our GNN model and improves word alignments.

While word alignment is usually considered for bilingual corpora, our work addresses the problem of *word alignment in multiparallel corpora*, containing sentence level parallel text in more than two languages. Examples of multiparallel corpora are JW300 (Agić and Vulić, 2019), PBC (Mayer and Cysouw, 2014) which covers the highest number of languages (1334), and Tatoeba.[1] While the per-language amount of data provided in such corpora is less than bilingual corpora, they support highly low-resource languages, many of which are not covered by existing language technologies (Joshi et al., 2020). Therefore, these corpora are essential for studying many of the world's low-resource languages.

We consider the task of word alignment for multiparallel sentences. The basic motivation is that the alignment between words in languages U and

---

[1] `https://tatoeba.org`

Findings of the Association for Computational Linguistics: ACL 2022, pages 1384 - 1396
May 22-27, 2022 ©2022 Association for Computational Linguistics

V can benefit from word-level alignments of U and V with a translation in a third language W. Following up on the work of Imani Googhari et al. (2021), we model multilingual word alignments with tools borrowed from graph theory (community detection algorithms) combined with neural network based models, specifically, the graph neural network (GNN) model of Scarselli et al. (2009).

GNNs were proposed to extend the powerful current generation of neural network models to the processing of graph-structured data and they have gained increasing popularity in many domains (Wu et al., 2020; Sanchez-Gonzalez et al., 2018; He et al., 2020). GNNs can incorporate heterogeneous sources of signal in the form of node and edge features. We use this property to take into account properties of the whole alignment graph, notably its tendency to cluster into *communities*, see Figure 1.

With our new proposed methods, we obtain improved results on word alignment for three language pairs: English-French, Finnish-Hebrew and Finnish-Greek. As a demonstration of the importance of high-quality alignments, we use our word alignments to project annotations from high-resource to low-resource languages. We improve a part-of-speech tagger for Yoruba by training it over a high-quality dataset, which is created using annotation projection.

Contributions: i) We propose a graph neural network model to enhance word alignments in a multiparallel corpus. The model incorporates a diverse set of features for word alignments in multiparallel corpora and an elegant way of training it efficiently and effectively. **ii)** We show that community detection improves multiparallel word alignment. **iii)** We show that the improved alignments improve performance on a downstream task for a low resource language. **iv)** We propose a new method to infer alignments from the alignment probability matrix. **v)** We will make our code publicly available.

2 MultiParallel Word Alignment Graphs

2.1 Building MultiParallel Word Alignment Graphs

Our starting point is the work of Imani Googhari et al. (2021), who introduce MPWA (MultiParallel Word Alignment), a framework that utilizes the synergy between multiple language pairs to improve bilingual word alignments for a target language pair. The rationale is that some of the missing alignment edges between a source and a target language can be recovered using their alignments with words in other languages.

An MPWA graph is constructed using the following two steps:

1. create initial bilingual alignments for all language pairs in a multiparallel corpus using a bilingual word aligner;

2. represent the bilingual alignments for each multiparallel sentence in a graph containing one vertex for each token occurring in any language and one edge for each initial bilingual word alignment link.

Potentially missing alignment links are then added based on the graph structure in an inference step, casting the word alignment task as an edge prediction problem. Figure 1 gives an example of a multiparallel word alignment graph for a 12-way multiparallel sentence.

Imani Googhari et al. (2021) use two traditional graph algorithms, Adamic-Adar and non-negative matrix factorization, for predicting new alignment edges from the MPWA graph. However, these graph algorithms are applied to individual multiparallel sentences independently and therefore cannot accumulate knowledge from multiple sentences. Moreover, their edge predictions are solely based on the structure of the graph and do not take advantage of other beneficial signals such as a word's language, relative position and meaning. Another limitation of this work is that it only adds links and does not remove any, which is important to improve precision.

This work addresses these shortcomings by using GNNs to predict alignment edges from MPWA graphs.

2.2 Community Detection in Alignment Graphs

One important advantage of GNNs over traditional graph algorithms is that they can directly incorporate signals from different sources in the form of node and edge features. We utilize this by taking into account the following observation: The nodes in the alignment graph are words in parallel sentences that are translations of each other. If the initial bilingual alignments are of good quality, we expect words that are mutual translations to form densely connected regions or *communities*; see Figure 1. These communities should not be linked to each other, each corresponding to a distinct connected component. In other words, ideally, words representing a concept should be densely connected, but there should be no links between different concepts. While, this intuition will not be true for all concepts between all possible language pairs, we nonetheless hypothesize that identifying distinct concepts in a multiparallel word alignment graph can provide useful information.

To examine to what extent these expectations are met, we count the components in the original Eflomal-generated (Östling and Tiedemann, 2016) graph (see §4.2 for details on the initial alignments). Table 1 shows that the average number of components per sentence is less than three ("Eflomal intersection", columns #CC). But intuitively, the number of components should roughly correspond to sentence length (or, more precisely, the number of content words). This indicates that there are many links that incorrectly connect different concepts. To detect such links, we use community detection (CD) algorithms.

CD algorithms find subnetworks of nodes that form tightly knit groups that are only loosely connected with a small number of links (Girvan and Newman, 2002). One well-known approach to CD attempts to maximize the modularity measure (Newman and Girvan, 2004). Modularity assesses how beneficial a division of a community into two communities is, in the sense that there are many links within communities and only a few between them. Given a graph G with n nodes and m edges and G's adjacency matrix $A \in \mathbb{R}^{n \times n}$, modularity is defined as:

$$mod = \frac{1}{2m} \sum_{ij} \left(A_{ij} - \gamma \frac{d_i d_j}{2m} \right) I(c_i, c_j) \quad (1)$$

where d_i is the degree of node i. $I(c_i, c_j)$ is 1 if nodes i and j are in the same community, 0 otherwise.

As exact modularity maximization is intractable, we experiment with two CD algorithms implementing different heuristic approaches:

- Greedy modularity communities (GMC). This method uses Clauset-Newman-Moore greedy modularity maximization (Clauset et al., 2004). GMC begins with each node in its own community and greedily joins the pair of communities that most increases modularity until no such pair exists.

	FIN-HEB		FIN-GRC		ENG-FRA	
	#CC	F_1	#CC	F_1	#CC	F_1
Eflomal intersection	2.2	0.404	1.6	0.646	2.2	0.678
GMC	13.7	0.396	10.1	0.375	13.5	0.411
LPC	41.5	0.713	37.1	0.754	46.0	0.767
Sentence length	25.7		23.2		27.4	

Table 1: Effect of community detection algorithms (GMC and LPC) on alignment prediction. #CC: average number of connected components. F_1: word alignment performance.

- Label propagation communities (LPC). This method finds communities in a graph using label propagation (Cordasco and Gargano, 2010). It begins by giving a label to each node of the network. Then each node's label is updated by the most frequent label among its neighbors in each iteration. It performs label propagation on a portion of nodes at each step and quickly converges to a stable labeling.

After detecting communities, we link all nodes inside a community and remove all intercommunity links. GMC (LPC) on average removes 3% (7%) of the edges. Table 1 reports the average number of graph components per sentence before and after running GMC and LPC, as well as the corresponding F_1 for word alignment (see §4.1 for details on the evaluation datasets). We see that the number of communities found is lower for GMC than for LPC; therefore, LPC identifies more candidate links for deletion.[2] Comparing the number of communities detected with the average sentence length, GMC seems to have failed to detect enough communities to split different concepts properly. The F_1 scores confirm this observation and show that LPC performs well at detecting the communities we are looking for.

This analysis shows that CD algorithms compute valuable information for word alignments. To exploit this in our GNN model, we add node community information as a node feature; see §3.1.3.

3 Predicting and using MultiParallel Word Alignments (MPWAs)

3.1 GNNs for MPWA

GNNs can be used in transductive or inductive settings. Transductively, the final model can only be

---

[2] LPC may detect more communities than average sentence length because of null words: words that have no translation in the other languages, giving rise to separate communities.

used for inference over the same graph that it is trained on. In an inductive setting, which we use here, nodes are represented as feature vectors, and the final model has the advantage of being applicable to a different graph in inference.

Below is the step-by-step overview of our GNN-based approach for an MPWA graph:

1. run community detection algorithms on the initial graph (§2.2);

2. obtain features for the nodes of the graph (§3.1.3);

3. compute node embeddings from node features and initial alignment links in the GNN encoding step (§3.1.2);

4. learn to distinguish between nodes that are aligned together and that are not aligned together in the GNN decoding step (§3.1.2);

After the GNN model is trained on multiple MPWA graphs, it is used to infer an alignment probability matrix between tokens in a source language and tokens in a target language for a multiparallel sentence, see §3.1.4. Our method predicts new alignment links from this matrix, independently of initial edges. Therefore, given an initial bilingual alignment, it is not limited to adding edges, but it can also remove them.

3.1.1 Model Architecture

Our model is inspired by the Graph Auto Encoder (GAE) model of Kipf and Welling (2016) for link prediction. A GAE model consists of an encoder and a decoder. The encoder creates a hidden representation for each node of the graph and the decoder predicts the links of the graph given the nodes' representations. Using the graph of word alignments, the model will learn the word alignment task. Therefore it will be able to predict word alignments that are missed by the original bilingual word aligner and also detect incorrect alignment edges.

We make changes to this model to improve the model's quality and reduce its computational cost. We use GATConv layers (Veličković et al., 2018) for the encoder instead of GCNConv (Kipf and Welling, 2017) and a more sophisticated decoder instead of simple dot product for a stronger model. We also introduce a more efficient training procedure.

The **encoder** is a graph attention network (GAT) (Veličković et al., 2018) with two GATConv layers followed by a fully connected layer. Layers are connected by RELU non-linearities. A GATConv layer computes its output $\mathbf{x}'_i$ for a node i from its input $\mathbf{x}_i$ as

$$\mathbf{x}'_i = \alpha_{i,i}\mathbf{W}\mathbf{x}_i + \sum_{j \in \mathcal{N}(i)} \alpha_{i,j}\mathbf{W}\mathbf{x}_j, \qquad (2)$$

where $\mathbf{W}$ is a weight matrix, $\mathcal{N}(i)$ is some *neighborhood* of node i in the graph, and $\alpha_{i,j}$ is the attention coefficient indicating the importance of node j's features to node i. $\alpha_{i,j}$ is computed as

$$\alpha_{i,j} = \frac{\exp\left(\mathrm{g}\left(\mathbf{a}^\top[\mathbf{W}\mathbf{x}_i \,\|\, \mathbf{W}\mathbf{x}_j]\right)\right)}{\sum_{k \in \mathcal{N}(i)\cup\{i\}} \exp\left(\mathrm{g}\left(\mathbf{a}^\top[\mathbf{W}\mathbf{x}_i \,\|\, \mathbf{W}\mathbf{x}_k]\right)\right)} \qquad (3)$$

where $\|$ is concatenation, g is LeakyReLU, and $\mathbf{a}$ is a weight vector. Given the features for the nodes and their alignment edges, the encoder creates a contextualized hidden representation for each node.

Based on the hidden representations of two nodes, the **decoder** predicts whether a link connects them. The decoder architecture consists of a fully connected layer, a RELU non-linearity and a sigmoid layer.

3.1.2 Training

By default, GAE models are trained using full batches with random negative samples. This approach requires at least tens of epochs over the training dataset to converge and a lot of GPU memory for graphs as large as ours. We train our model using mini-batches to decrease memory requirements and improve the performance. Using our training approach the model converges after one epoch. We take care to select informative negative samples (as opposed to random selection) as described below.

Figure 2 displays our GNN model and the training process. The training set contains one graph for each sentence. Each graph is divided into multiple batches. Each batch contains a random subset of the graph's edges as positive samples. The negative samples are created as follows. Given a sentence $u_1 u_2 \ldots u_n$ in language U and its translation $v_1 v_2 \ldots v_m$ in language V, for each alignment edge $u_i{:}v_j$ in the current batch, two negative edges $u_i{:}v'_j$ and $u'_i{:}v_j$ ($j' \neq j$, $i' \neq i$) are randomly sampled.

For each training batch, the encoder takes the batch's whole graph (i.e., node features for all

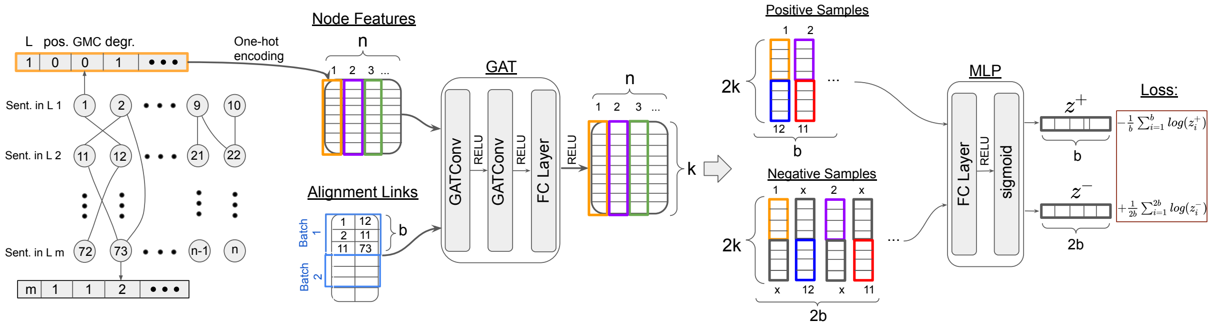

Figure 2: GNN training. At each training step, node features and links of a multiparallel sentence are fed to a graph attention network (GAT) that creates hidden representations for all nodes. On the decoder side, at each step, one batch of alignment links and hidden node representations is used to create positive and negative samples, which are then processed and classified by a multi-layer perceptron (MLP). Parameters of GAT and MLP are updated for each batch. FC = fully connected.

graph nodes and all graph edges) as input and computes hidden representations for the nodes. On the decoder side, for each link between two nodes in the batch, the hidden representations of the two nodes are concatenated to create the decoder's input. The decoder's target is the link class: 1 (resp. 0) for positive (resp. negative) links. We train with a binary classification objective:

$$\mathcal{L} = -\frac{1}{b}\sum_{i=1}^{b}\log(p_i^+) + \frac{1}{2b}\sum_{i=1}^{2b}\log(p_i^-) \qquad (4)$$

where b is the batch size and p_i^+ and p_i^- are the model predictions for the i^{th} positive and negative samples within the batch. Parameters of the encoder and decoder as well as the node-embedding feature layer are updated after each training step.

3.1.3 Node Features

We use three main types of node features: (i) graph structural features, (ii) community-based features and (iii) word content features.

Graph structural features. We use *degree, closeness* (Freeman, 1978) , *betweenness* (Brandes, 2001) , *load* (Newman, 2001) and *harmonic centrality* (Boldi and Vigna, 2014) features as additional information about the graph structure. These features are continuous numbers, providing information about the position and connectivity of the nodes within the graph. We standardize (i.e., z-score) each feature across all nodes, and train an embedding of size four for each feature.[3]

Community-based features. One way to incorporate community information into our model is to train the model based on a refined set of edges after the community detection step. This approach hobbles the GNN model by making decisions about many of the edges before the GNN gets to see them. Our initial experiments also confirmed that training the GNN over CD refined edges does not help. Therefore, we add community information as node features and let the GNN use them to improve its decisions. We use the community detection algorithms GMC and LPC (see §§2.2) to identify communities in the graph. Then we represent the community membership information of the nodes as one-hot vectors and learn an embedding of size 32 for each of the two algorithms.

Word content features. We train embeddings for *word position* (size 32) and *word language* (size 20). We learn 100-dimensional multilingual *word embeddings* using Levy et al. (2017)'s sentence-ID method on the 84 PBC languages selected by Imani Googhari et al. (2021). Word embeddings serve as initialization and are updated during GNN training.

After concatenating these features, each node is represented by a 236 dimensional vector that is then fed to the encoder.

3.1.4 Inducing Bilingual Alignment Edges

Given a source sentence $\hat{x} = x_1, x_2, \ldots, x_m$ in language X and a target sentence $\hat{y} = y_1, y_2, \ldots, y_l$ in language Y, we feed all possible alignment links between source and target to the decoder. This produces a symmetric alignment probability matrix S of size $m \times l$ where S_{ij} is the predicted alignment probability between words x_i and y_j. Using these values directly to infer alignment edges is usually suboptimal; therefore, more sophisticated methods

---

[3] Learning a size-four embedding instead of a single number gives the feature a weight similar to other features – which have a feature vector of about the same size.

have been suggested (Ayan and Dorr, 2006; Liang et al., 2006). Here we propose a new approach: it combines Koehn et al. (2005)'s Grow-Diag-Final-And (GDFA) with Dou and Neubig (2021)'s probability thresholding. We modify the latter to account for the variable size of the probability matrix (i.e., length of source/target sentences). Our method is not limited to adding new edges to some initial bilingual alignments, a limitation of prior work. As we predict each edge independently, some initial links can be discarded from the final alignment.

We start by creating a set of *forward* (source-to-target) alignment edges and a set of *backward* (target-to-source) alignment edges. To this end, first, inspired by probability thresholding (Dou and Neubig, 2021), we apply softmax to S, and zero out probabilities below a threshold to get a source-to-target probability matrix S^{XY}:

$$S^{XY} = S * (\text{softmax}(S) > \frac{\alpha}{l}) \qquad (5)$$

Analogously, we compute the target-to-source probability matrix S^{YX}:

$$S^{YX} = S^{\top} * (\text{softmax}(S^{\top}) > \frac{\alpha}{m}) \qquad (6)$$

where α is a sensitivity hyperparameter, e.g., $\alpha = 1$ means that we pick edges with a probability higher than average. We experimentally set $\alpha = 2$. Next, from each row of S^{XY} (S^{YX}), we pick the cell with the highest value (if any exists) and add this edge to the *forward* (*backward*) set.

We create the final set of alignment edges by applying the GDFA symmetrization method (Koehn et al., 2005) to *forward* and *backward* sets. The gist of GDFA is to use the intersection of *forward* and *backward* as initial alignment edges and add more edges from the union of *forward* and *backward* based on a number of heuristics. We call this method *TGDFA* (Thresholding GDFA).

We also experiment with combining TGDFA with the original bilingual GDFA alignments. We do so by adding bilingual GDFA edges to the union of *forward* and *backward* before performing the GDFA heuristics. We refer to these alignments as *TGDFA+orig*.

We evaluate the resulting alignments using F_1 score and alignment error rate (AER), the standard metrics in the word alignment literature.

3.2 Annotation Projection

Annotation projection automatically creates linguistically annotated corpora for low-resource languages. A model trained on data with "annotation-projected" labels can perform better than a completely unsupervised method. Here, we focus on universal part-of-speech (UPOS) tagging (Petrov et al., 2012) for the low resource target language Yoruba; this language only has a small set of annotated sentences in Universal Dependencies (Nivre et al., 2020) and has poor POS results in unsupervised settings (Kondratyuk and Straka, 2019).

The quality of the target annotated corpus depends on the quality of the annotations in the source languages and the quality of the word alignments between sources and target. We use the Flair (Akbik et al., 2019) POS taggers for three high resource languages, English, German and French (Akbik et al., 2018), to annotate 30K verses whose Yoruba translations are available in PBC. We then transfer the POS tags from source to target using three different approaches: (i) We directly transfer annotations from English to the target. (ii) For each word in the target, we get its Eflomal bilingual alignments in the three source languages and predict the majority POS to annotate the target word. (iii) The same as in (ii), but we use our GNN (TGDFA) alignments (instead of Eflomal alignments) to project from source to target. In all three approaches, we discard any target sentence from the POS tagger training data if more than 50% of its words are annotated with the "X" (other) tag.

We train a Flair SequenceTagger model on the target annotated data using mBERT embeddings (Devlin et al., 2019) and evaluate on Yoruba test from Universal Dependencies.[4]

4 Experimental Setup

4.1 Word Alignment Datasets

Following Imani Googhari et al. (2021), we use PBC, a multiparallel corpus of 1758 sentence-aligned editions of the Bible in 1334 languages.

Evaluation data. For our main evaluation, we use the two word alignment gold datasets for PBC published by Imani Googhari et al. (2021): Blinker (Melamed, 1998) and HELFI (Yli-Jyrä et al., 2020). **The HELFI dataset** contains the Hebrew Bible, Greek New Testament and their translations into Finnish. For HELFI, we use Imani Googhari et al. (2021)'s train/dev/test splits. **The Blinker dataset** provides word level alignments between English and French for 250 Bible verses.

Table 2: Word alignment results on PBC for GNN and baselines. The best result in each column is in bold. GNN outperforms the baselines as well as the graph algorithms WAdAd and NMF on F_1 and AER.

Training data. The graph algorithms used by Imani Googhari et al. (2021) operate on each multiparallel sentence separately. In contrast, our approach allows for an inductive setting where a model is trained on a training set, accumulating knowledge from multiple multiparallel sentences. We combine the verses in the training sets of Finnish-Hebrew and Finnish-Greek for a combined training set size of 24,159.[5]

4.2 Initial Word Alignments

We use the Eflomal statistical word aligner to obtain bilingual alignments. We train it for every language pair in our experiments. We do not consider SimAlign (Jalili Sabet et al., 2020) since it is shown to perform poorly for languages whose representations in the multilingual pretrained language model are of low quality. We use Eflomal asymmetrical alignments post-processed with the intersection heuristic to get high precision bilingual alignments as input to the GNN. We use the same subset of 84 languages as Imani Googhari et al. (2021).

4.3 Training Details

We use PyTorch Geometric[6] to construct and train the GNN. The model's hidden layer size is 512 for both GATConv and Linear layers. We train for one epoch on the training set – a small portion of the training set is enough to learn good embeddings (see §5.1.1). For training, we use a batch size of 400 and learning rate of .001 with AdamW (Loshchilov and Hutter, 2017). The whole training process takes less than 4 hours on a GeForce GTX 1080 Ti and the inference time is on the order of milliseconds per sentence.

5 Experiments and Results

5.1 Multiparallel corpus results

Table 2 shows results on Blinker and HELFI for our GNNs and the baselines: bilingual alignments and two graph-based algorithms WAdAd and NMF from Imani Googhari et al. (2021). Our GNNs yield a better trade-off between precision and recall, most likely thanks to their ability to remove edges, and achieve the best F_1 and AER on all three datasets, outperforming WAdAd and NMF.

GNN (TGDFA) achieves the best results on HELFI (FIN-HEB, FIN-GRC) while GNN (TGDFA+orig) is best on Blinker (ENG-FRA). As argued in Imani Googhari et al. (2021), this is mostly due to the different ways these two datasets were annotated. Most HELFI alignments are one-to-one, while many Blinker alignments are many-to-many: phrase-level alignments where every word in a source phrase is aligned with every word in a target phrase. This suggests that one can choose between GNN (TGDFA) and GNN (TGDFA+orig) based on the desired characteristics of the alignment.

5.1.1 Effect of Training Set Size

To investigate the effect of training set size, we train the GNN on subsets of our training data with increasing sizes. Figure 3 shows results. Performance improves fast until around 2,000 verses; then it stays mostly constant. Using more than 6,400 samples does not change the performance at all. Therefore, in the other experiments we use 6,400 randomly sampled verses from the training set to train GNNs.

---

[5] Note that we do not use any gold alignments for training the GNN. Using the verses from HELFI train split as our training set is for convenience. Our ablation experiment (Figure 3) show that a smaller subset of the training set is sufficient to achieve good performance

[6] `pytorch-geometric.readthedocs.io`

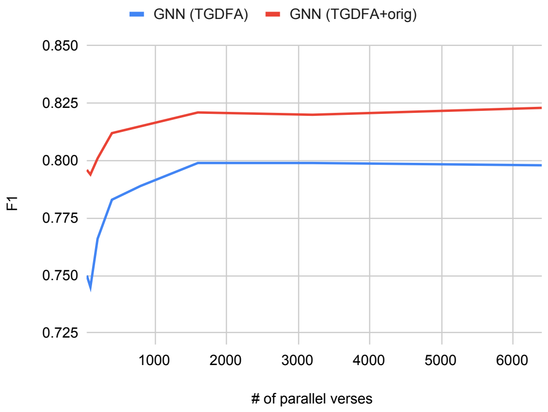

Figure 3: F_1 of GNN (TGDFA) and GNN (TGDFA+orig) on Blinker as a function of train size

5.1.2 Ablation Experiments

To examine the importance of node features, we ablate language, position, centrality, community and word embedding features. Table 3 shows that removal of graph structural features drastically reduces performance. Community features and language information are also important. Removal of word position information and word embeddings – which store semantic information about words – has the least effect. Based on these results, it can be argued that the lexical information contained in the initial alignments and in the community features provides a strong signal regarding word relatedness. The novel information that is crucial is about the overall graph structure which goes beyond the local word associations that are captured by word position and word embeddings.

5.1.3 Effect of Word Frequency

We investigate the effect of word frequency on alignment performance where frequency is calculated based on the source word in the PBC; the first bin has the highest frequency. Figure 4 shows that the performance of Eflomal drops with frequency and it struggles to align very rare words. In contrast, GNN is not affected by word frequency as severely and its performance gains are even greater for rare words. WAdad which is the multilingual baseline from (Imani Googhari et al., 2021) has the same trend as the GNN method, but the GNN method is more robust.

5.2 Annotation Projection

Table 4 presents accuracies for POS tagging in Yoruba. Unsupervised baseline performance is 50.86%. Supervised training using pseudo-labels mostly outperforms the unsupervised baseline. Projecting the majority POS labels to Yoruba improves over projecting English labels. Using the GNN model to project labels works best and outperforms Eflomal-GDFA-majority (resp. the unsupervised baseline) by 5% (resp. 15%) absolute improvement.

6 Related Work

Bilingual Word Aligners. Much work on bilingual word alignment is based on probabilistic models, mostly implementing variants of the IBM models of Brown et al. (1993): e.g., Giza++ (Och and Ney, 2003), fast-align (Dyer et al., 2013) and Eflomal (Östling and Tiedemann, 2016). More recent work, including SimAlign (Jalili Sabet et al., 2020) and SHIFT-ATT/SHIFT-AET (Chen et al., 2020), uses pretrained neural language and machine translation models. Although neural models achieve superior performance compared to statistical aligners, they can only be used for fewer than two hundred high-resource languages that are supported by multilingual language models like BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020). This makes statistical models the only option for the majority of the world's languages.

Model	Yoruba YTB
Unsupervised (Kondratyuk and Straka, 2019)	50.86
Eflomal Inter – eng	43.45
Eflomal GDFA – eng	55.13
Eflomal Inter – majority	54.13
Eflomal GDFA – majority	60.27
GNN (TGDFA) – majority	**65.74**
GNN (TGDFA+orig) – majority	64.55

Table 4: POS tagging with annotation projection for Yoruba. Apart from "Unsupervised", all lines show a sequence tagger trained on pseudo-labels induced by word alignments. GNN-based pseudo-labels outperform prior work by 5% absolute.

Multiparallel Corpora. Prior applications of using multiparallel corpora include reliable translations from small datasets (Cohn and Lapata, 2007), and phrase-based machine translation (PBMT) (Kumar et al., 2007). Multiparallel corpora are also used for language comparison (Mayer and Cysouw, 2012), typological studies (Östling, 2015; Asgari and Schütze, 2017) and PBMT (Nakov and Ng, 2012; Bertoldi et al., 2008; Dyer et al., 2013). ImaniGooghari et al. (2021) provide a tool to browse a word-aligned multiparallel corpus, which can be used for the comparative study of languages and for error analysis in machine translation.

To the best of our knowledge Lardilleux and Lepage (2008) and Östling (2014)[7] are the only word alignment methods designed for multiparallel corpora. However, the latter method is outperformed by Eflomal (Östling and Tiedemann, 2016), a bilingual method from the same author. Recently, Imani Googhari et al. (2021) proposed MPWA, which we use as our baseline.

Graph Neural Networks (GNNs) have been used to address many problems that are inherently graph-like such as traffic networks, social networks, and physical and biological systems (Liu and Zhou, 2020). GNNs achieve impressive performance in many domains, including social networks (Wu et al., 2020) and natural science (Sanchez-Gonzalez et al., 2018) as well as NLP tasks like sentence classification (Huang et al., 2020), question generation (Pan et al., 2020), summarization (Fernandes et al., 2019) and derivational morphology (Hofmann et al., 2020).

7 Conclusion and Future Work

We introduced graph neural networks and community detection algorithms for multiparallel word alignment. By incorporating signals from diverse sources as node features, including community features, our GNN model outperformed the baselines and prior work, establishing new state-of-the-art results on three PBC gold standard datasets. We also showed that our GNN model improves downstream task performance in low-resource languages through annotation projection.

We have only used node features to provide signals to GNNs. In the future, other signals can be added in the form of edge features to further boost the performance.

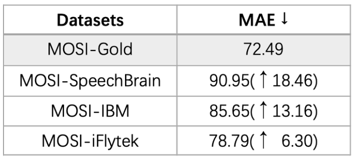
Abstract

Multimodal sentiment analysis has attracted increasing attention and lots of models have been proposed. However, the performance of the state-of-the-art models decreases sharply when they are deployed in the real world. We find that the main reason is that real-world applications can only access the text outputs by the automatic speech recognition (ASR) models, which may be with errors because of the limitation of model capacity. Through further analysis of the ASR outputs, we find that in some cases the sentiment words, the key sentiment elements in the textual modality, are recognized as other words, which makes the sentiment of the text change and hurts the performance of multimodal sentiment analysis models directly. To address this problem, we propose the sentiment word aware multimodal refinement model (SWRM), which can dynamically refine the erroneous sentiment words by leveraging multimodal sentiment clues. Specifically, we first use the sentiment word position detection module to obtain the most possible position of the sentiment word in the text and then utilize the multimodal sentiment word refinement module to dynamically refine the sentiment word embeddings. The refined embeddings are taken as the textual inputs of the multimodal feature fusion module to predict the sentiment labels. We conduct extensive experiments on the real-world datasets including MOSI-Speechbrain, MOSI-IBM, and MOSI-iFlytek and the results demonstrate the effectiveness of our model, which surpasses the current state-of-the-art models on three datasets. Furthermore, our approach can be adapted for other multimodal feature fusion models easily[1].



Datasets	MAE ↓
MOSI-Gold	72.49
MOSI-SpeechBrain	90.95(↑ 18.46)
MOSI-IBM	85.65(↑ 13.16)
MOSI-iFlytek	78.79(↑ 6.30)

1 Introduction

Multimodal sentiment analysis (MSA) has been an emerging research field for its potential applications in human-computer interaction. How to effectively fuse multimodal information including textual, acoustic, and visual to predict the sentiment is a very challenging problem and has been addressed by many previous studies. Some works focus on introducing additional information into the fusing model, such as the alignment information between different modal features (Wu et al., 2021) and unimodal sentiment labels (Yu et al., 2021). And other works consider the semantic gaps between multimodal data and adopt the adversarial learning (Mai et al., 2020) and multi-task learning (Hazarika et al., 2020) to map different modal features into a shared subspace.

Despite the apparent success of the current state-

of-the-art models, their performance decreases sharply, when deployed in the real world. The reason is that the input texts are provided by the ASR models, which usually are with errors because of the limitation of model capacity. To further analyze this problem, we build three real-world multimodal sentiment analysis datasets based on the existing dataset, CMU-MOSI(Zadeh et al., 2016). Specifically, we adopt three widely used ASR APIs including SpeechBrain, IBM, and iFlytek to process the original audios and obtain the recognized texts. Then, we replace the gold texts in CMU-MOSI with the ASR results and get three real-world datasets, namely MOSI-SpeechBrain, MOSI-IBM, and MOSI-iFlytek. We evaluate the current state-of-the-art model, Self-MM(Yu et al., 2021), and report the mean absolute error (MAE) on the multimodal sentiment analysis task. As we can see in Figure 1(a), when the model is deployed in the real world, there is an obvious drop in model performance.

The further in-depth analysis of ASR errors shows that the sentiment word substitution error can hurt the MSA model directly. The reason is that the sentiment words in the text are the most important clues in the textual modality for detecting sentiment and incorrectly recognizing them could change the sentiment conveyed by the text. To have an intuitive understanding of the sentiment word substitution error, we take an example in Figure 1(b). The gold text is “And I was really upset about it", but the ASR model (SpeechBrain) recognizes the sentiment word “upset" wrongly as “set", which results in the change of the sentiment semantics of the text and directly affects the MSA model performance. We list the percentages of the sentiment word substitution error on the MOSI dataset for three ASR APIs in Figure 1(b). The percentage of the sentiment word substitution error on the MOSI-IBM is 17.6%, which means about 17 of 100 utterances have this type of error. To further demonstrate the negative effect of the substitution error on the MSA models, we split the test data of MOSI-IBM into two groups by whether there is a substitution error. We evaluate Self-MM on the test data and observe that the misclassification rate of the group in which the substitution error exists is higher than the other group (29.9% vs 15.8%). This result indicates that the sentiment word substitution error could hurt the state-of-the-art MSA model.

To tackle this problem, we propose the sentiment word aware multimodal refinement model, which can detect the positions of the sentiment words in the text and dynamically refine the word embeddings in the detected positions by incorporating multimodal clues. The basic idea of our approach is shown in Figure 1(c). We consider leveraging the multimodal sentiment information, namely the negative sentiment conveyed by the low voice and sad face, and textual context information to help the model reconstruct the sentiment semantics for the input embeddings. Specifically, we first use the sentiment word location module to detect the positions of sentiment words and meanwhile utilize the strong language model, BERT, to generate the candidate sentiment words. Then we propose the multimodal sentiment word refinement module to refine the word embeddings based on the multimodal context information. The refinement process consists of two parts, filtering and adding. We apply the multimodal gating network to filter out useless information from the input word embeddings in the filtering process and use the multimodal sentiment word attention network to leverage the useful information from candidate sentiment words as the supplement to the filtered word embeddings in the adding process. Finally, the refined sentiment word embeddings are used for multimodal feature fusion.

We conduct extensive experiments on the MOSI-SpeechBrain, MOSI-IBM, and MOSI-iFlytek datasets to demonstrate the effectiveness of our proposed model. The experimental results show that: (1) There is an obvious performance drop for the state-of-the-art MSA model, when the model is deployed in the real world taking the ASR outputs as the input of textual modality; (2) Our proposed model outperforms all baselines, which can dynamically refine the sentiment word embeddings by leveraging multimodal information.

The main contributions of this work are as follows: (1) We propose a novel sentiment word aware multimodal refinement model for multimodal sentiment analysis, which can dynamically reconstruct the sentiment semantics of the ASR texts with errors by utilizing the multimodal sentiment information resulting in more robust sentiment prediction; (2) We validate the negative effect of the sentiment word substitution error on the state-of-the-art MSA model through the in-depth analysis; (3) We evaluate our model on three real-world datasets, and the experimental results demonstrate that our model outperforms all baselines.

2 Related Work

Multimodal sentiment analysis has gained increasing attention from the community recently and some process has been made. In general, there are three findings presented by previous work.

Performing the cross-modal alignment is helpful for multimodal feature fusion. Chen et al. (2017) considered that the holistic features mainly contain global information, which may fail to capture local information. Therefore, they applied the force-alignment to align the visual and acoustic features with the words and further obtained the word-level features. To effectively fuse them, they proposed the GME-LSTM(A) model, which consists of two modules, the gated multimodal embedding and the LSTM with the temporal attention. However, obtaining the word-level features needs to perform the force-alignment, which is time-consuming. To address it, Tsai et al. (2019) proposed the MulT model, which uses the cross-modal attention to align different modal features implicitly. Instead of performing the alignment in the time dimension, some works focusing on semantic alignment. Hazarika et al. (2020) considered that the semantic gaps between heterogeneous data could hurt the model performance and proposed the MISA model, which maps the different modal data into a shared space before multimodal feature fusion. Wu et al. (2021) first utilized the cross-modal prediction task to distinguish the shared and private semantics of non-textual modalities compared to the textual modality and then fuse them. The above works show that performing the cross-modal alignment is helpful for multimodal feature fusion.

Training the MSA models in an end-to-end manner is more effective. Most of the previous studies adopt a two-phase pipeline, first extracting unimodal features and then fusing them. Dai et al. (2021) considered that it may lead to sub-optimal performance since the extracted unimodal features are fixed and cannot be further improved benefiting from the downstream supervisory signals. Therefore, they proposed the multimodal end-to-end sparse model, which can optimize the unimodal feature extraction and multimodal feature fusion jointly. The experimental results on the multimodal emotion detection task show that training the models in an end-to-end manner can obtain better results than the pipeline models.

Leveraging the unimodal sentiment labels to learn more informative unimodal representations is useful for multimodal feature fusion. Yu et al. (2020) considered that introducing the unimodal sentiment labels can help the model capture the unimodal sentiment information and model the difference between modalities. Motivated by it, they built the CH-SIMS dataset, which contains not only the multimodal sentiment labels but also unimodal sentiment labels. And based on it, they proposed a multi-task learning framework to leverage two types of sentiment labels simultaneously. However, this method needs unimodal labels, which is absent for most of the existing datasets. To address it, Yu et al. (2021) proposed the Self-MM model, which first generates the unimodal labels by utilizing the relationship between the unimodal and multimodal labels and then uses the multi-task learning to train the model. These two works both address the usefulness of introducing unimodal labels.

However, even though lots of models are proposed and obtain promising results on the benchmark datasets, there are few works considering the noisy inputs when the MSA models are deployed in the real world. Chen et al. (2017) presented the Gated Multimodal Embedding to filter out the noises from the acoustic and visual data. Pham et al. (2019) considered that visual and acoustic data may be absent and proposed the MCTN model to handle it. Liang et al. (2019) and Mittal et al. (2020) also mainly focused on dealing with the noises introduced by the visual and acoustic data, and their models are based on the word-level features, which are obtained by aligning the audios with the gold texts. There is only one work (Dumpala et al., 2018) considering that the texts are output by the ASR models, which may be erroneous. But this work does not study how do the ASR errors affect the MSA models and does not evaluate the SOTA MSA models on the datasets. Besides, the proposed model needs the gold texts when training, which is time-consuming and labor-consuming.

Comparing to the above works, we evaluate the SOTA MSA models on the real-world datasets and observe that the performance of models decreases sharply because of the erroneous ASR texts. Through in-depth analysis of the ASR outputs, we find the sentiment word substitution error in the ASR texts could hurt the MSA models directly. To address it, we propose the sentiment word aware multimodal refinement model, which only uses the

ASR texts in the training and testing phrases.

3 Approach

In this section, we describe the sentiment word aware multimodal refinement model in detail. An illustration of our proposed model is given in Figure 2. Our model consists of three modules including the sentiment word location module, multimodal sentiment word refinement module, and multimodal feature fusion module. We first use the sentiment word location module to detect the possible positions of sentiment words and then utilize the multimodal sentiment word refinement module to dynamically refine the word embeddings in the detected positions. Finally, the refined word embeddings are fed into the multimodal feature fusion module to predict the final sentiment labels.

3.1 Sentiment Word Position Detection

The core idea of the sentiment word position detection module is to find out the possible positions of sentiment words in the ASR texts. Note that, it is different from locating sentiment words depending on the word semantics, since the ASR models may recognize a sentiment word as a neutral word, which makes it hard to locate correctly. For example, given a gold text “And I was really upset about it", the ASR model recognizes it as “And I was really set about it". It is easy for the model to label the word “set" as a neutral word. Therefore, we choose to detect the position of the sentiment words instead of locating them.

To achieve it, we consider adopting a powerful language model, since the language model can model the context information of the sentiment words such as syntactic and grammatical information and predict the appropriate words for the target position. Specifically, we choose the BERT model (Devlin et al., 2019) as our language model since the masked language modeling pretraining objective meets our needs perfectly. Given the sentence $\{w_1, w_2, ..., w_{n_l}\}$, we first mask each word w_i in the sentence sequentially, and in practice, we replace the word with the special word [MASK]. For example, we mask the first word in the sentence and obtain $\{[\mathrm{MASK}], w_2, ..., w_{n_l}\}$. And then we use the BERT model to predict the possible words in the position of the masked word. We sort the predicted candidate words by the prediction probabilities and get the Top-k candidate words $C_i = \{c_1^i, c_2^i, ..., c_k^i\}$.

Next, we distinguish the sentiment words from the candidates using the sentiment lexicons (Hu and Liu, 2004; Wilson et al., 2005) and k_i is the number of selected sentiment words corresponding to the position i. The larger the number is, the more possible the position is. And we obtain the most possible position of sentiment word, $s = \arg\max(\{k_1, k_2, ..., k_{n_l}\})$. Considering that in some cases there is not a sentiment word in the sentence, we use a sentiment threshold to filter out the impossible ones. In practice, we use the gate mask p to record it, and p is 1 if k_s is larger than $k/2$ and 0 otherwise.

3.2 Multimodal Sentiment Word Refinement

In order to reduce the negative effects of the ASR errors, we propose the multimodal sentiment word refinement module, in which we refine the word embeddings of sentiment words from two aspects. One is that we uses the multimodal gating network to filter out the useless information from the input word embeddings. The other one is that we design the multimodal sentiment attention network to incorporate the useful information from candidate words generated by the BERT model.

Given an utterance, which includes three modal unaligned features, word embeddings, acoustic features, and visual features, we denote them as $\mathbf{x}^i = \{x_t^i : 1 \le t \le n_i, x_t^i \in \mathbb{R}^{d_x^i}\}$, $i \in \{l, v, a\}$. To obtain the multimodal information corresponding to each word, We utilize the pseudo-alignment method to align the features. We split the the acoustic and visual features into non-overlapping feature groups, of which lengths are $\left\lfloor \frac{n_a}{n_l} \right\rfloor$ and $\left\lfloor \frac{n_v}{n_l} \right\rfloor$ respectively, and average the features in each group and obtain the aligned features, $\mathbf{u}^i = \{u_t^i : 1 \le t \le n_l, u_t^i \in \mathbb{R}^{d_x^i}\}$, $i \in \{v, a\}$.

To obtain the context-aware representations, we apply the BERT model and LSTM networks to encode the features, producing $\mathbf{h}^i = \{h_t^i : 1 \le t \le n_l, h_t^i \in \mathbb{R}^{d_h^i}\}$, $i \in \{v, a, l\}$. Besides, we also use an LSTM network to fuse the acoustic and visual features for capturing high-level sentiment semantics and obtain $\mathbf{h}^{va} = \{h_t^{va} : 1 \le t \le n_l, h_t^{va} \in \mathbb{R}^{d_h^{va}}\}$.

$$
\begin{aligned}
\mathbf{h}^l &= \mathrm{BERT}(\mathbf{x}^{\mathrm{l}}) \\
\mathbf{h}^v &= \mathrm{LSTM}_{\mathrm{v}}(\mathbf{u}^{\mathrm{v}}) \\
\mathbf{h}^a &= \mathrm{LSTM}_{\mathrm{a}}(\mathbf{u}^{\mathrm{a}}) \\
\mathbf{h}^{va} &= \mathrm{LSTM}_{\mathrm{va}}([\mathbf{u}^{\mathrm{v}}; \mathbf{u}^{\mathrm{a}}])
\end{aligned}
\tag{1}
$$

Subsequently, We propose the multimodal gating

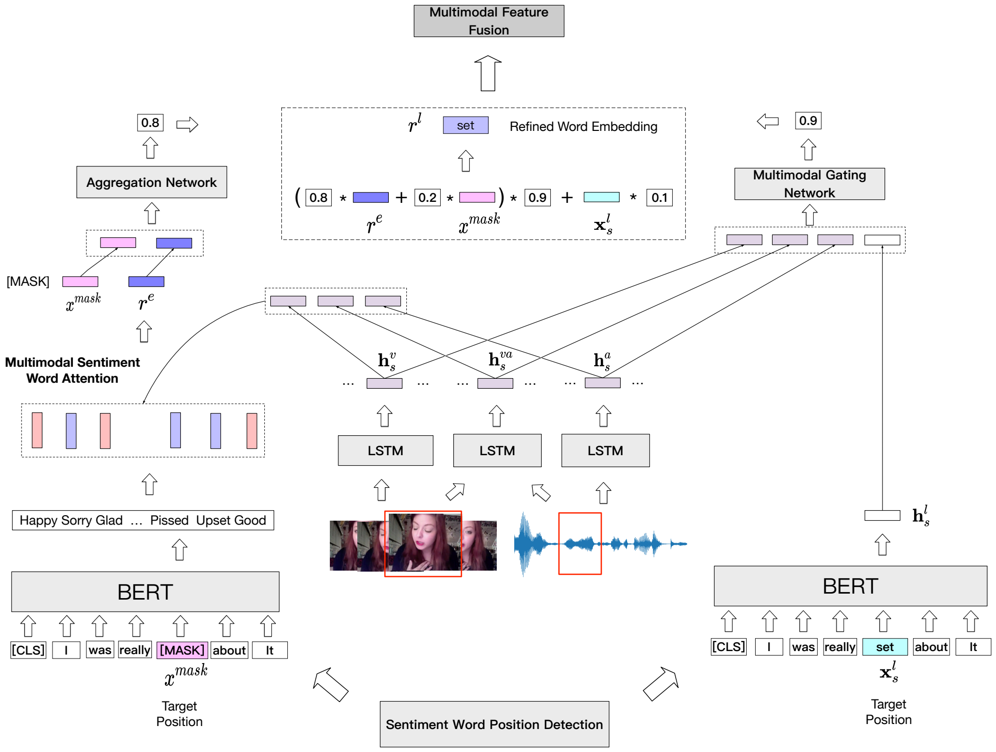

Figure 2: Illustration of our proposed model.

.

network to filter the word embedding, which is implemented by a non-linear layer. The motivation is that the ASR model may recognize incorrectly the sentiment word resulting in the corrupted sentiment semantics of the text. Therefore, we leverage the multimodal sentiment information to decide how much information of the input word embedding to pass. Specifically, we concatenate the unimodal context-aware representations, $\mathbf{h}_s^l$, $\mathbf{h}_s^v$, $\mathbf{h}_s^a$, and bimodal representation $\mathbf{h}_s^{va}$ in the detected position s and feed them into a non-linear neural network, producing the gate value g^v. And then the gate value is used to filter out the useless information from the word embedding. To make the model ignore the impossible one, we use the gate mask p to achieve it.

$$\begin{aligned} g^v &= Sigmoid(W_1([\mathbf{h}_s^l; \mathbf{h}_s^v; \mathbf{h}_s^a; \mathbf{h}_s^{va}]) + b_1) \\ r^v &= (1 - g^v p)\mathbf{x}_s^l \end{aligned} \tag{2}$$

where $W_1 \in \mathbb{R}^{1 \times \sum_{i \in \{l,v,a,va\}} d_h^i}$, $b_1 \in \mathbb{R}^1$ are the parameters of the multimodal gating network.

Furthermore, we propose a novel multimodal sentiment word attention network to leverage the sentiment-related information from the candidate words, more than half of which are sentiment words, generated by the BERT model to complement the word embeddings. For example, the ASR model recognizes the “upset" as “set", we first want to remove the useless information of “set" and then incorporate the information of negative sentiment words to reconstruct the original sentiment semantics. We use a linear layer to implement the multimodal sentiment word attention network. We first concatenate the word embedding $x^{c_t^s}$ of the candidate word c_t^s and multimodal representations, $\mathbf{h}_s^v$, $\mathbf{h}_s^a$, and $\mathbf{h}_s^{va}$ at the most possible time step s. Then, we pass them to the linear layer and obtain the attention score g_t^e. The attention scores are fed into a softmax function to obtain the attention weights. Finally, we apply the weights to the candidate word embeddings and get the sentiment embedding r^e.

$$\begin{aligned} g_t^e &= W_2([x^{c_t^s}; \mathbf{h}_s^v; \mathbf{h}_s^a; \mathbf{h}_s^{va}]) + b_2 \\ w_t^e &= \frac{e^{g_t^e}}{\sum_{t=1}^{k} e^{g_t^e}} \\ r^e &= \sum_{t=1}^{k} w_t^e x^{c_t^s} \end{aligned} \tag{3}$$

where $W_2 \in \mathbb{R}^{1 \times (d_x^l + \sum_{i \in \{v,a,va\}} d_h^i)}$, $b_2 \in \mathbb{R}^1$ are the parameters of the multimodal sentiment word attention network.

In addition, there may not be suitable words in the candidate words. Hence, we incorporate the embedding of the special word $[\mathrm{MASK}]$, x^{mask}, to let the BERT model handle this problem based on the context. We then design an aggregation network to balance the contributions of the special word embedding x^{mask} and the sentiment embedding r^e. Finally, we add the r^{add} to the filtered word embedding u_s^l and obtain the refined word embedding r_l for the target word.

$$\begin{aligned} g^{mask} &= Sigmoid(W_3([r^e; x^{mask}]) + b_3) \\ r^{add} &= g^{mask} r^e + (1 - g^{mask}) x^{mask} \\ r^l &= (g^v p) r^{add} + r^v \end{aligned} \tag{4}$$

where $W_3 \in \mathbb{R}^{1 \times 2d_x^l}$, $b_3 \in \mathbb{R}^1$ are the trainable parameters.

3.3 Multimodal Feature Fusion

We describe our multimodal feature fusion module in the section and it is noted that our proposed refinement approach only modifies the textual input token embeddings, which makes it easy to be adapted for other multimodal feature fusion models based on BERT, such as MISA (Hazarika et al., 2020).

We first use the BERT model to encode the refined word embeddings $\mathbf{z}^{\mathbf{l}} = \{x_1^l, x_2^l, ..., r^l, .., x_{n_l}^l\}$ and take the representation of [CLS] as the textual representation, which is denoted as v^l. And then we use two LSTM networks to encode the visual and acoustic features and take the representations of the first words as the visual representation v^v and acoustic representation v^a. Finally, we fuse them using a non-linear layer to capture the interactions between them.

$$\begin{aligned} v^l &= \mathrm{BERT}_{\mathrm{textual}}(\mathbf{z}^{\mathrm{l}}) \\ v^v &= \mathrm{LSTM}_{\mathrm{visual}}(\mathbf{x}^{\mathrm{v}}) \\ v^a &= \mathrm{LSTM}_{\mathrm{acoustic}}(\mathbf{x}^{\mathrm{a}}) \\ v^f &= Relu(W_4([v^l; v^v; v^a]) + b_4) \end{aligned} \tag{5}$$

where $W_4 \in \mathbb{R}^{d_v^f \times (d_v^l + d_v^a + d_v^v)}$, $b_4 \in \mathbb{R}^{d_v^f}$ are the trainable parameters of the fusion network.

We utilize a linear layer to predict the final sentiment regression labels.

$$p_f = W_5 v^f + b_5 \tag{6}$$

where $W_5 \in \mathbb{R}^{1 \times d_v^f}$, $b_5 \in \mathbb{R}^1$ are the trainable parameters of the prediction network.

Besides, to enhance the model to capture unimodal sentiment information, we use the Unimodal Label Generation Module (ULGM) (Yu et al., 2021) to generate pseudo unimodal sentiment labels and adopt them to train our model in a multi-task learning manner. For more details, we refer you to Yu et al. (2021).

4 Experiment

4.1 Datasets

We build three real-world datasets including MOSI-SpeechBrain, MOSI-IBM, and MOSI-iFlytek, on CMU-MOSI(Zadeh et al., 2016).

CMU-MOSI CMU multimodal opinion-level sentiment intensity (CMU-MOSI) consists of 93 videos collected from the YouTube website. The length of the videos varies from 2-5 mins. These videos are split into 2,199 short video clips and labeled with sentiment scores from -3 (strongly negative) to 3 (strongly positive). For multimodal features, we extract the visual features using Facet, which can extract the facial action units (Ekman et al., 1980) from each frame. The acoustic features are obtained by applying COVAREP (Degottex et al., 2014), which includes 12 Mel-frequency cepstral coefficients (MFCCs) and other low-level features.

However, the provided texts of the utterances in the MOSI dataset are manually transcribed from the corresponding videos by the expert transcribers, which is unrealistic for the real-world applications to obtain the texts in such a way. To evaluate the models in the real world, we replace the manually gold texts in the dataset with the texts output by the ASR models. We adopt a strong ASR model and two widely used commercial APIs to produce the texts. The utilized ASR model released by Ravanelli et al. (2021) is built on the transformer encoder-decoder framework and trained on the Librispeech dataset(Panayotov et al., 2015). The commercial APIs used by us are IBM[2] and iFlytek[3] speech-to-text APIs, which are wildly used by researchers and software developers. Finally, we apply the three ASR models to transcribe the videos into texts and construct three new datasets, namely MOSI-SpeechBrain, MOSI-IBM,

and MOSI-iFlytek. We report the WER results of the adopted ASR models on MOSI in Appendix A. Noted that, we do not adopt MOSEI (Bagher Zadeh et al., 2018), because it does not provide the original video clips for the extracted features and annotated sentiment labels, and we can not process the original audios.

4.2 Training Details

We use Adam as the optimizer and the learning rate is 5e-5. The batch size is 64. The sentiment threshold is set to 0.5 while detecting the sentiment word position. The number of the candidate words k is 50. The other hyper-parameters of the model are reported in Appendix B. All experiments are run on an Nvidia Tesla P100 GPU. We run five times and report the average performance. The random seeds we used are 1111,1112, 1113, 1114, and 1115.

4.3 Evaluation Metrics

For the MOSI-SpeechBrain, MOSI-IBM, and MOSI-iFlytek datasets, following previous work (Yu et al., 2021), we take 2-class accuracy(Acc-2), F1 score(F1), mean absolute error (MAE), and correlation(Corr) as our evaluation metrics. And for Acc-2 and F1-Score, we calculate them in two ways, negative/non-negative (Non0-Acc, Non0-F1) and negative/positive (Has0-Acc, Has0-F1). As the prediction results are real values, we obtain the sentiment classification labels by mapping the sentiment scores into labels.

4.4 Baselines

We compare our proposed model with the following baselines [4]. **TFN** (Zadeh et al., 2017) uses the three-fold Cartesian product to capture unimodal, bimodal, and trimodal interactions. **LMF** (Liu et al., 2018) uses the low-rank tensors to accelerate the multimodal feature fusion process. **MulT** (Tsai et al., 2019) uses the cross-modal transformers to fuse multimodal features. **MISA** (Hazarika et al., 2020) adopts multi-task learning to map different modal features into a shared subspace. **Self-MM** (Yu et al., 2021) first generates the pseudo unimodal sentiment labels and then adopts them to train the model in a multi-task learning manner.

5 Results and Analysis

5.1 Quantitative Results

In Table 1, we show the results on the MOSI-SpeechBrain, MOSI-IBM, MOSI-iFlytek datasets.

---

[4] Because applying the force-alignment using the errorous ASR texts leads to cascading errors resulting in poor aligned features, we only take the models using unaligned features as our baselines for a fair comparison.

Models	Has0-Acc ↑	Non0-Acc ↑	MAE ↓
SWRM	**74.58**	**75.70**	**90.56**
w/o Position	73.59	74.57	93.67
w/o Attention	74.17	75.42	91.53
w/o Multi-modal	73.82	75.09	91.22

Table 2: Ablation analysis of our proposed model evaluated on the MOSI-SpeechBrain dataset. The best results are in **bold**.

And we also list the results of the SOTA model, Self-MM, on the original MOSI dataset in the last row of the table for the performance comparison between Self-MM in the ideal world and real world. As we can see from the results, Self-MM obtains the best results on the MOSI-Gold dataset than the other datasets, which demonstrates that the ASR errors hurt the MSA models. We also observe that the better ASR model can help the MSA models achieve better performance. But it should be noted that, according to the analysis in the previous section, current ASR models still can not produce satisfactory results for the MSA models in the real world.

Comparison between the feature-based models including TFN, LMF, and MulT and finetuning-based baselines such as MISA and Self-MM, we can find that finetuning-based models obtain better results. We consider that the finetuning-based models can adapt the BERT encoder to the target task and learning more informative textual representations, which also makes them benefit more as the quality of texts increases.

Comparing to the baselines especially Self-MM, our model achieves better performance in all evaluation metrics since our model can detect the substitution error of the sentiment words and then refine the word embeddings to reconstruct the sentiment semantics in the textual modality by filtering out useless information from the input words and incorporating useful information from the candidate words generated by the language model. We also observe that the improvement of our model compared with Self-MM on MOSI-iFlytek is smaller. We consider that the main reason is fewer sentiment word substitution errors on MOSI-iFlytek.

5.2 Ablation Study

We conduct the ablation experiments to distinguish the contribution of each part. There are several different variants of our model. **SWRM** is our proposed full model. **SWRM w/o Position** does not use the sentiment word position location module and only uses the information of the special word [MASK] to dynamically refine all words. **SWRM w/o Attention** only incorporates the information of the special word [MASK] to refine the word in the multimodal sentiment word refinement module. **SWRM w/o Multi-modal** only performs the multimodal sentiment word attention and multimodal gating network based on the textual features without the acoustic and visual features.

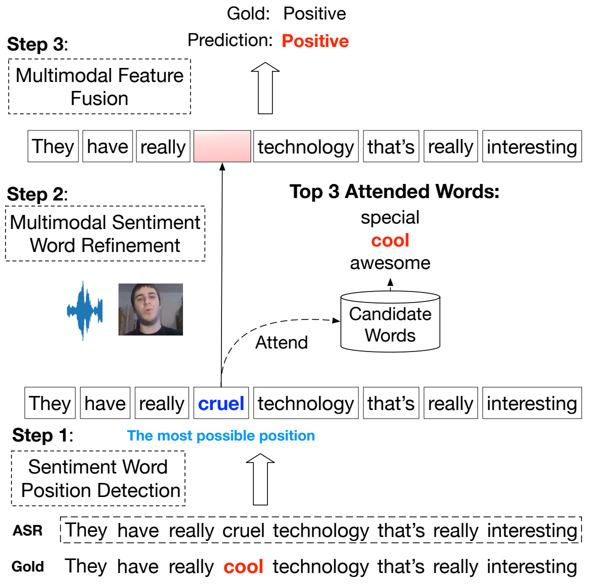

Figure 3: Case study for the SWRM.

.

Table 2 shows the results of the variants of our model. After ablating the sentiment word position location module, SWRM w/o Position obtains worse results than SWRM, which indicates that finding the right word for refinement is very important. The comparison between SWRM w/o Attention and SWRM w/o Position further demonstrates this conclusion. SWRM w/o Attention first detects the right position and then incorporates the information of the special word [MASK], which achieves better performance than SWRM w/o Position. But SWRM w/o Attention is still worse than SWRM, which shows using the attention network to incorporating extra information from the candidate words is useful for refinement. Comparing the SWRM w/o Multi-modal between SWRM, we can find that the model benefits from the visual and acoustic features. It is in line with our expectations since the sentiment information provided by the multimodal features can help the model detect the sentiment word and incorporate the sentiment-related information from the candidate words.

5.3 Case Study

To have an intuitive understanding of our proposed model, we show a case in Figure 3. We can see that our model first detects the most possible position based on the context and then finds that the input word in the position may be recognized incorrectly since there is a mismatch between the negative word “cruel" and either the smile or the excited tone. Hence our model decides to incorporate the related sentiment information from the candidate words to refine the word embedding. As shown in Figure 3, our model pays more attention to the candidate words "special", "cool", and "awesome". The word "cool" is exactly the gold word and the others have the same sentiment polarity as it. Beneficial from the attended candidate words, our model refines the input word and reconstructs its sentiment semantics. Finally, the refined word embeddings are fed into the multimodal feature fusion module to predict the sentiment label.

6 Conclusion

In this paper, we observe an obvious performance drop when the SOTA MSA model is deployed in the real world, and through in-depth analysis, we find that the sentiment word substitution error is a very important factor causing it. To address it, we propose the sentiment word aware multimodal refinement model, which can dynamically refine the word embeddings and reconstruct the corrupted sentiment semantics by incorporating the multimodal sentiment information. We evaluate our model on MOSI-SpeechBrain, MOSI-IBM, and MOSI-iFlytek and the results demonstrate the effectiveness of our approach. For future work, we will explore leveraging the multimodal information to detect the sentiment word positions.

Abstract

Medical code prediction from clinical notes aims at automatically associating medical codes with the clinical notes. Rare code problem, the medical codes with low occurrences, is prominent in medical code prediction. Recent studies employ deep neural networks and the external knowledge to tackle it. However, such approaches lack interpretability which is a vital issue in medical application. Moreover, due to the lengthy and noisy clinical notes, such approaches fail to achieve satisfactory results. Therefore, in this paper, we propose a novel framework based on medical concept driven attention to incorporate external knowledge for explainable medical code prediction. In specific, both the clinical notes and Wikipedia documents are aligned into topic space to extract medical concepts using topic modeling. Then, the medical concept-driven attention mechanism is applied to uncover the medical code related concepts which provide explanations for medical code prediction. Experimental results on the benchmark dataset show the superiority of the proposed framework over several state-of-the-art baselines.

ICD-9 code: 250
Disease name: Diabetes mellitus

Wikipedia Document:
Diabetes mellitus (DM), commonly referred to as **diabetes**, is a group of **metabolic disorders** in which there are **high blood sugar** levels over a prolonged period. Symptoms of high blood sugar include **frequent urination**, **increased thirst**, and **increased hunger**…
Diabetes is due to either the pancreas not producing enough **insulin**, or the cells of the body not responding properly to the insulin produced… Type 1 diabetes must be managed with **insulin injections**… Type 2 diabetes may be treated with medications such as **insulin sensitizers** with or without insulin.

Clinical Note:
Pt had been on **insulin** in past… Patient reports **frequent urination**, 10-15 times per day… You have been started on Lantus **Insulin** 25 units **injection** at bedtime. Please check your **blood sugars** twice daily, before breakfast and before nighttime insulin dose.

Figure 1: An example of a clinical note annotated with 3-digit ICD-9 code "250" and the corresponding Wikipedia document, where words in red are medical concept-indicative words which can be employed as evidences to infer medical codes.

1 Introduction

Medical codes, also known as ICD codes, are organized by International Classification of Diseases (ICD, recent versions are ICD-9 and ICD-10) taxonomies. Each medical code corresponds to a disease, procedure or sign, and so on. Medical codes can abstract away fine details of free-text clinical notes, which provide great convenience for analyzing clinical data directly (Shull, 2019; Bai and Vucetic, 2019). It is time consuming, costly and error-prone for manual medical coding due to the large menu of options (over 15,000 codes in ICD-9) and the complex lengthy clinical notes (Adams et al., 2002; Lang, 2007). Medical code prediction aims at automatically associating the relevant medical codes with the clinical notes.

Treating medical code prediction as a multi-label text classification problem, many machine learning based approaches have been proposed including Bayesian-based (Larkey and Croft, 1995) and Support Vector Machine based (Lita et al., 2008; Perotte et al., 2014). With the success of deep learning, many researchers propose neural networks with attention mechanism (Mullenbach et al., 2018; Li and Yu, 2020; Vu et al., 2020) to identify representative words in clinical notes and those with large weights serve as evidence for prediction. Li and Yu (2020) utilize convolutional neural networks with several fixed window sizes to capture various medical patterns, then identify representative ones through label attention mechanism.

Rare code problem, the medical codes with low occurrences, is prominent in medical code prediction. It was pointed out in (Bai and Vucetic, 2019) that among 942 3-digit ICD-9 codes occurring in the MIMIC-III database (the largest publicly-available medical database), the least com-

---

[*] corresponding author

Findings of the Association for Computational Linguistics: ACL 2022, pages 1407 - 1416

mon 437 codes account for only 1% of code occurrences. To tackle the rare code problem, Cao et al. (2020) leverage the code hierarchy and code cooccurrences information to aid predict rare codes. Vu et al. (2020) introduce a hierarchical joint learning architecture using the hierarchical relationships among codes to alleviate the rare code problem. Bai and Vucetic (2019) incorporate the external Wikipedia knowledge to enhance semantic information of the rare codes. The matching score between a clinical note and a medical code is calculated based on the code's related Wikipedia document.

However, most of the approaches mentioned above lack interpretability, which is vital for medical-related tasks. Moreover, most of these approaches fail to achieve satisfactory results because of the noisy and lengthy clinical notes (containing an average of 1,596 words). To address these challenges, we propose to explore latent medical concepts (including signs, symptoms, treatments, etc.) related to diseases, hidden in the clinical notes and Wikipedia knowledge. As shown in Figure 1, we can identify the informative medical concepts related to '*diabetes mellitus*', including signs '*high blood sugar*' and '*not enough insulin*', typical symptoms '*frequent urination, increased thirst, increased hunger*', and typical treatments '*insulin injection*' and '*insulin sensitizer*' based on the Wikipedia document describing ICD-9 code "*250*". Obviously, medical concepts mentioned above in clinical notes provide the effective evidences to infer disease '*diabetes mellitus*'. Moreover, based on the extracted medical concepts, the lengthy and noisy clinical notes can be alleviated.

Therefore, in this paper, we propose a novel framework based on medical concept driven attention (**MCDA**) to predict medical codes. Specifically, both the clinical notes and Wikipedia documents are fed as a whole corpus into the topic model to extract medical concepts. Both the Wikipedia documents and the clinical notes are represented as the distributions over the hidden topics (medical concepts) instead of the lengthy texts. Then, the medical concept-driven attention mechanism is applied, consisting of note-specific and label-specific concept-driven attention. On the one hand, the note-specific concept-driven attentions capture the salient medical concepts hidden in a specific clinical note. On the other hand, the label-specific concept-driven attentions focus on relevant medical concepts in a clinical note for each medical code. Experimental results show that the proposed framework outperforms a number of state-of-the-art models on a benchmark dataset.

The main contributions of this paper are listed as follows:

- A novel framework based on medical concept driven attention (**MCDA**) is proposed to predict medical codes. Moreover, the medical concept-driven attention mechanism, consisting of note-specific and label-specific concept-driven attention, is proposed to uncover the medical code related concepts hidden in the lengthy and noisy clinical notes. To the best of our knowledge, our work is the first attempt to explore latent medical concepts hidden in both the clinical notes and the external knowledge for explainable medical code prediction.

- Experimental results show that the proposed framework significantly outperforms several state-of-the-art models in all evaluation metrics. Moreover, it outperforms several state-of-the-art frameworks incorporating external knowledge in most evaluation metrics on the benchmark dataset.

2 Related work

Medical code prediction, also known as automatic ICD coding, is a challenging and important task in the limelight of medical informatics community.

Many traditional machine learning methods have been proposed including Bayesian-based (Larkey and Croft, 1995) and Support Vector Machine based (Lita et al., 2008; Perotte et al., 2014). Fueled by deep learning, many researchers have proven the effectiveness of convolutional neural network (CNN) and long short-term memory (LSTM) for medical code prediction. For example, Baumel et al. (2018) apply hierarchical attention networks for predicting medical codes. Mullenbach et al. (2018) propose a CNN with attention mechanism to capture relevant information in source text for each code. To find the specific evidence in the lengthy and noisy text for predicting accurately, researchers use CNN and variants (including multi-filter convolution, dilated convolution) with label attention mechanism to capture codes' relevant text patterns (*i.e.* n-grams) in clinical notes (Mullenbach et al., 2018; Li and Yu, 2020; Ji et al., 2020). Vu et al. (2020) focus on label-specific words in notes via LSTM with customized label attention mechanism.

To tackle the rare code problem, different kinds of knowledge, such as label structure, label co-occurrence statistics, label descriptions and Wikipedia are employed. For example, the hierarchical tree structure of ICD-9 ontology is firstly exploited by (Perotte et al., 2014). Xie et al. (2019) employ graph convolutional network (GCN) to capture the hierarchical relationships among medical codes. Cao et al. (2020) construct a co-graph to incoporate code co-occurrence prior.

Instead of employing internal knowledge such label structure and label co-occurrence, some external knowledge are incorporated. Regarding label descriptions, Shi et al. (2017) apply character-aware neural network to match medical codes and clinical notes. Xie and Xing (2018) develop tree LSTM to use label descriptions. Zhou et al. (2021) train a teacher network with label descriptions and model the code co-occurrence through interactive shared attention. Regarding Wikipedia, Bai and Vucetic (2019) propose Knowledge Source Integration (KSI) framework to integrate Wikipedia documents describing medical codes during training of any baseline models. Compared with other external knowledge, Wikipedia knowledge is more informative and accessible.

Regarding incorporating the Wikipedia knowledge, the proposed approach is similar to KSI (Bai and Vucetic, 2019), but with the following significant differences: (1) we propose medical concept-driven attention to find note-specific and label-specific medical concepts in clinical notes as explainable evidences. While KSI simply calculates the matching score between a clinical note and a medical code's related Wikipedia document, unable to locate evidences in the context of clinical notes; (2) we make the most of Wikipedia knowledge through medical concepts, while KSI only considers the intersection of words in a clinical note and a Wikipedia document when predicting the corresponding medical code.

3 Methodology

3.1 Problem Setting

Given a collection of Q clinical notes denoted as $\mathcal{D} = \{d_1, d_2, \ldots, d_Q\}$. Each clinical note d_j consists of a sequence of words and is accompanied with a set of associated medical codes. We denote the size of medical code set $L = \{l_1, l_2, \ldots, l_{|L|}\}$ as $|L|$. In addition, we construct an external knowledge source $\mathcal{Z} = \{z_1, z_2, \ldots, z_{|L|}\}$ which consists of Wikipedia documents describing the medical codes. Each unique medical code l_i corresponds to a Wikipedia document z_i. Given a clinical note d_j, the goal is to predict the associated medical codes via the external knowledge source $\mathcal{Z}$, which can be treated as a multi-label text classification problem. Therefore, in the rest of the paper, medical codes are called labels for simplicity.

3.2 The Framework

The overall architecture of the proposed framework (**MCDA**) is shown in Figure 2, which consists of five parts:

(1) *Medical Concept Extraction Module* which extracts medical concepts from the clinical notes and Wikipedia documents; (2) *Embedding Layer* which includes word embeddings, medical concept embeddings and label embeddings; (3) *Encoder Layer* which includes backbone encoder and concept encoder; (4) *Concept-Driven Attention Layer* which calculates the note-specific and label-specific attention scores with the aid of medical concepts; (5) *Output Layer* which predicts the medical codes.

3.2.1 Medical Concept Extraction Module

The medical concepts are extracted via Latent Dirichlet Allocation (LDA) (Blei et al., 2003).

At first, as the focuses and writing styles of Wikipedia documents and clinical notes are different, we pre-process both the Wikipedia documents and clinical notes. Words appearing in both the Wikipedia documents and clinical notes are retained.

Then, we feed the pre-processed $\mathcal{D}$ and $\mathcal{Z}$ as a whole corpus with vocabulary size V^c, into LDA to generate medical concepts. The granularity of the extracted medical concepts is controlled by the predefined K, the number of medical concepts.

Based on LDA, we obtain overall medical concept-word distribution matrix $\boldsymbol{C} \in \mathbb{R}^{K \times |V^c|}$. For the single clinical note d_j, the note-concept distribution $\boldsymbol{p}_j = (p_{j1}, p_{j2}, \ldots, p_{jK})$ represents the probability of the clinical note over each medical concept. Likewise, for a single Wikipedia document z_i (corresponding to label l_i), the label-concept distribution $\boldsymbol{w}_i = (w_{i1}, w_{i2}, \ldots, w_{iK})$ represents the probability of the label over each medical concept. Thereby, the labels-concept distribution matrix is represented as $\boldsymbol{W} \in \mathbb{R}^{|L| \times K}$.

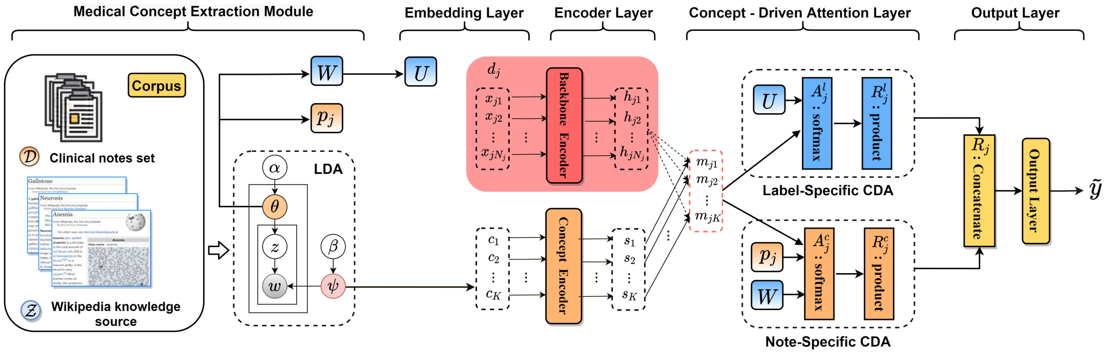

Figure 2: The architecture of the proposed **MCDA** Framework. $\mathcal{Z}$ and $\mathcal{D}$ denote the Wikipedia knowledge source and clinical notes set respectively. Label-Specific CDA represents label-specific concept-driven attention, and Note-Specific CDA represents note-specific concept-driven attention. It is worth noting that Backbone Encoder can be any neural encoders.

3.2.2 Embedding Layer

Embedding layer contains word embeddings, medical concept embeddings and label embeddings.

As for word embeddings, a clinical note d_j with N_j words is represented as $d_j = \{x_{j1}, x_{j2}, \dots, x_{jN_j}\}$ using pre-trained word embeddings.

As for medical concept embeddings, the k^{th} medical concept's embedding $\boldsymbol{c}_k$ can be obtained from the overall medical concept-word distribution matrix $\boldsymbol{C}$.

With respect to the label embeddings matrix $\boldsymbol{U} \in \mathbb{R}^{|L| \times K}$, we use the labels-concept distribution matrix $\boldsymbol{W}$ as the initialization of $\boldsymbol{U}$ since LDA can capture the medical concepts information hidden in labels and implicitly model correlations between labels and clinical notes by projecting them into the same feature space.

3.2.3 Encoder Layer

Encoder layer contains both the backbone encoder and the concept encoder.

As for the backbone encoder, theoretically it can be any neural encoders, such as CNN based encoders, RNN based encoders or Transformer (Vaswani et al., 2017) based encoders. Given the clinical note $d_j = \{x_{j1}, x_{j2}, \cdots, x_{jN_j}\}$, the hidden state of each word is generated by the backbone encoder. Thereby, the clinical note d_j can be encoded as $\boldsymbol{h}_j = (h_{j1}, h_{j2}, \dots, h_{jN_j})^\top \in \mathbb{R}^{N_j \times t}$, where t is the dimension of the hidden state.

As for the concept encoder, concept representations are produced by a fully connected layer followed by ReLU activation function taking the medical concept-word distribution matrix $\boldsymbol{C}$ as inputs. Hence, each concept representation $\boldsymbol{s}_k \in \mathbb{R}^t$ is obtained according to the medical concept embedding $\boldsymbol{c}_k$, $k \in \{1, 2, 3, \dots, K\}$.

3.2.4 Concept-Driven Attention Layer

Not all words in the clinical note contribute equally to the decision of medical diagnosis. Moreover, not all medical concepts hidden in the clinical note contribute equally for medical code prediction. Therefore, attention weights are utilized to enhance clinical note representations according to both word representations and concept representations. We aggregate the representations of medical concepts-indicative words to form the clinical note representation.

Given the k^{th} concept representation $\boldsymbol{s}_k$, we can measure the interaction of words in the clinical note d_j and the medical concept by an attention weight vector $\boldsymbol{m}_{jk}$, which can be computed as the inner product of $\boldsymbol{s}_k$ and $\boldsymbol{\varphi}_j$ as follows,

$$\begin{aligned} \boldsymbol{\varphi}_j &= \tanh\left(\boldsymbol{h}_j \boldsymbol{W}^c + \boldsymbol{b}^c\right) \\ \boldsymbol{m}_{jk} &= \boldsymbol{\varphi}_j \, \boldsymbol{s}_k \end{aligned} \tag{1}$$

where $\boldsymbol{h}_j = \left(h_{j1}, h_{j2}, \dots, h_{jN_j}\right)^\top$ stands for the combination of all hidden states of words in the clinical note d_j, $\boldsymbol{W}^c \in \mathbb{R}^{t \times t}$ and $\boldsymbol{b}^c \in \mathbb{R}^t$ are trainable parameters, $\boldsymbol{\varphi}_j = (\varphi_{j1}, \varphi_{j2}, \dots, \varphi_{jN_j})$ refers to $\boldsymbol{h}_j$. The attention weight vector $\boldsymbol{m}_{jk}$ indicates how much attention the k^{th} medical concept pays to each word of the clinical note d_j.

Then, we propose two kinds of attention mechanisms including *Note-Specific Concept-Driven At-*

tention and *Label-Specific Concept-Driven Attention* based on $\boldsymbol{m}_{jk}$ in (1).

Note-Specific Concept-Driven Attention:

The note-specific concept-driven attention mechanism is employed to attend to note-specific medical concept words distributed in the clinical note. It leverages the note-specific medical concept information based on the note-concept distribution $\boldsymbol{p}_j = (p_{j1}, p_{j2}, \ldots, p_{jK})$ with each dimension representing the level of prominence of the corresponding medical concept occurred in the clinical note d_j. Then, it leverages the label-concept distribution matrix $\boldsymbol{W} \in \mathbb{R}^{|L| \times K}$ to generate an attention weight vector for each label. Given the clinical note d_j, for the i^{th} label, the note-specific concept-driven attention is calculated as follows,

$$\begin{aligned} \boldsymbol{a}^c_{ji} &= \text{softmax}\left(\sum_{k=1}^{K} \boldsymbol{m}_{jk}\boldsymbol{p}_{jk}\boldsymbol{W}_{ik}\right) \\ \boldsymbol{r}^c_{ji} &= \left(\boldsymbol{a}^c_{ji}\right)^\top \boldsymbol{h}_j \end{aligned} \tag{2}$$

for the i^{th} label, $\boldsymbol{a}^c_{ji}$ stands for the attention weight after incorporating the note-concept distribution $\boldsymbol{p}_j$ along with the label-concept distribution $\boldsymbol{W}_i$, to discover medical concept keywords that a single clinical note concerns for the specific label. The final note-specific concept-driven clinical note representation matrix $\boldsymbol{R}^c_j = \left(r^c_{j1}; r^c_{j2}; \ldots; r^c_{j|L|}\right)$ is constructed with the sum of hidden states $\boldsymbol{h}_j$ weighted by $\boldsymbol{A}^c_j = \left(\boldsymbol{a}^c_{j1}, \boldsymbol{a}^c_{j2}, \ldots, \boldsymbol{a}^c_{j|L|}\right)$. Each i^{th} row $\boldsymbol{r}^c_{ji}$ of the matrix $\boldsymbol{R}^c_j$ is the note-specific clinical note representation regarding the i^{th} label.

Label-Specific Concept-Driven Attention:

The label-specific concept-driven attention mechanism is proposed to capture label relevant medical concept words hidden in clinical notes using label embeddings. Given the clinical note d_j, for the i^{th} label, label-specific concept-driven attention is calculated as follows,

$$\begin{aligned} \boldsymbol{a}^l_{ji} &= \text{softmax}\left(\sum_{k=1}^{K} \boldsymbol{m}_{jk}\boldsymbol{U}_{ik}\right) \\ \boldsymbol{r}^l_{ji} &= \left(\boldsymbol{a}^l_{ji}\right)^\top \boldsymbol{h}_j \end{aligned} \tag{3}$$

We construct the label-specific clinical note representation matrix $\boldsymbol{R}^l_j = \left(\boldsymbol{r}^l_{j1}; \boldsymbol{r}^l_{j2}; \ldots; \boldsymbol{r}^l_{j|L|}\right)$ with the sum of hidden states $\boldsymbol{h}_j$ weighted by $\boldsymbol{A}^l_j = \left(\boldsymbol{a}^l_{j1}, \boldsymbol{a}^l_{j2}, \ldots, \boldsymbol{a}^l_{j|L|}\right)$.

Frequency range	Number of medical codes	Percentage of code occurrences
1-10	80	0.1%
11-50	73	0.6%
51-100	25	0.6%
101-500	82	6.7%
>500	84	92.0%

Table 1: Label frequency distribution

3.2.5 Output Layer

At last, we concatenate both representations calculated by note-specific and label-specific concept-driven attention to obtain final representation matrix $\boldsymbol{R}_j = [\boldsymbol{R}^c_j, \boldsymbol{R}^l_j]$ of clinical note d_j. $\boldsymbol{R}_j$ is then fed to a multi-layer perceptron (MLP) followed by the Sigmoid activation function for predicting all associated medical codes. This process can be formalized as follow,

$$\tilde{\boldsymbol{y}} = Sigmoid(MLP(\boldsymbol{R}_j)) \tag{4}$$

The training objective is to minimize the binary cross entropy loss between the prediction score $\tilde{\boldsymbol{y}}$ and the target $\boldsymbol{y}$:

$$Loss = -\sum_{i=1}^{|L|} \left\{ y_i \log\left(\tilde{y}_i\right) + \left(1 - y_i\right) \log\left(1 - \tilde{y}_i\right) \right\} \tag{5}$$

4 Experiments

In this section, we describe the datasets, evaluation metrics, baselines and implementation details, before discussing the experimental results.

4.1 Dataset

The dataset is constructed based on clinical notes in MIMIC-III dataset and Wikipedia documents of ICD-9 diagnosis codes following the same way[1] in (Bai and Vucetic, 2019). There are 52,722 condensed clinical notes in MIMIC-III (Johnson et al., 2016) dataset. On average, each note has 1,596 words. All medical codes are grouped by their first three digits. A subset of 344 medical codes is kept where each medical code has the corresponding Wikipedia document. On average, each Wikipedia document has 1,058 words. The whole word vocabulary contains 60,968 unique words, out of which only 12,173 can be found in clinical notes. It can be deduced that both the clinic notes and Wikipedia

---

[1] https://github.com/tiantiantu/KSI

documents share significantly different word distributions.

4.2 Evaluation Metrics

We evaluate the proposed method using micro and macro AUC, F1 metrics and Top-10 recall following the same way in (Bai and Vucetic, 2019). As shown in Table 1, medical codes in the dataset is highly imbalanced, the most common 84 codes account for 92% of all code occurrences. We employ macro metrics to emphasize on rare code prediction.

4.3 Baselines

We choose four state-of-the-art models as the baselines, which employ the label attention mechanism over neural word encoders. Moreover, for fair comparison, all the baselines (as backbone encoder) are combined with KSI framework (Bai and Vucetic, 2019) and the proposed framework (MCDA) respectively to incorporate Wikipedia knowledge. Details of the baselines are described as follows:

KSI: Bai and Vucetic (2019) proposed the Knowledge Source Integration framework to integrate the Wikipedia knowledge. It can be combined with some medical code prediction baselines.

CAML: Mullenbach et al. (2018) proposed the convolutional attention network, which learns attention distribution for each medical code.

MultiResCNN: Li and Yu (2020) utilized the multi-filter convolutional layer to capture variable medical patterns and residual block to enlarge model's receptive field, incorporating the label attention mechanism to generate label-aware representations.

DCAN: Ji et al. (2020) integrated dilated convolutions and residual connections to capture complex medical patterns and also incorporated label attention mechanism.

LAAT: Vu et al. (2020) proposed the customized label attention model to learn attention distributions over BiLSTM encoding hidden states for each medical code.

4.4 Implementation Details

We use word2vec (Mikolov et al., 2013) to pre-train word embeddings with the size of 100 from clinical notes. The number of extracted medical concepts K is set to 100. We utilized default Adam optimizer (Kingma and Ba, 2014) to minimize the loss function. Regarding the training of the baseline models, we perform a grid search over hyperparameters according to their default parameter setting.

4.5 Results

Table 2 shows the performance comparisons among baselines and their counterparts under KSI framework and the proposed MCDA framework.

Overall, it can be observed that by employing the KSI or MCDA framework, the performances of all the baseline models are improved, which shows the effectiveness and necessity of incorporating the Wikipedia knowledge for medical codes. It is worth noting that, compared with KSI, MCDA improves baselines more significantly in most metrics. The great improvement of top-10 recall demonstrates the effectiveness of the proposed framework in recommending relevant medical codes for clinicians. It is noteworthy that MCDA outperforms most baselines with a larger margin than KSI (except MultiResCNN) on the macro metric. As the performance on the macro metric shows how well the rare codes problem is handled, we can deduce that MCDA captures precisely the representations of labels and notes based on the medical concept from the external Wikipedia documents, which is crucial for rare codes.

To further validate this deduction, we divide medical codes into 5 groups based on their frequencies in the dataset as shown in Table 1: [1, 10], [11, 50], [51, 100], [101, 500] and [500, $+\infty$). We calculate macro-averaged AUC of each medical code group for all baselines and their counterparts under KSI framework and our MCDA framework. The results are summarized in Figure 3. It can be observed that both KSI and MCDA bring major improvements of AUC on the least common [1-10] and [11-50] group. For DCAN and CAML, MCDA improves much more than KSI on [1-10] group, 7.8% of DCAN and 2.8% of CAML. For the best baseline LAAT, MCDA improves 5.1% on [1-10] group and 2.1% on [11-50] group, which is better than 2.6% and 1.4% of KSI. The results demonstrate the benefit of incorporating medical concept driven attention than KSI in handling rare codes.

For MultiResCNN, though MCDA brings improvements on [1-10] group, it performs worse on [11-50], [51-100] group and the overall dataset. The possible reason is that, MultiResCNN concatenates outputs from 6 kernels with different sizes to generate hidden state h_i. Therefore, h_i is the simple concatenation of 6 n-grams' hidden states, not

the hidden state of the ith word (or n-gram) in other baselines. Actually when the number of kernels decrease to 1, MultiResCNN degrades to CAML. It performs better on macro metrics which indicates that MultiResCNN is unsuitable for MCDA framework.

In addition, we also try Transformer (Vaswani et al., 2017) and pre-trained BERT (Devlin et al., 2018) as backbone encoder. However, no Transformer based models work well in this task mainly due to excessively long text. This conclusion is also reported in (Li and Yu, 2020), (Ji et al., 2020) and (Pascual et al., 2021).

4.6 Ablation Study

To further evaluate the effectiveness of each component, we conduct some ablation experiments on LAAT+MCDAM. The ablation results are shown in Table 3. It can be observed that:

Effectiveness of Medical Concept Without medical concept (w/o medical concept in Table 3), medical concept-driven attention degrades to the label attention mechanism proposed in LAAT. The performance drops on all metrics, especially on macro metrics, indicating a significant reduction in the ability to predict rare codes.

Effectiveness of Label-Specific Concept-Driven Attention When discarding the label-specific concept-driven attention (w/o label-specific in Table 3), the performance drops dramatically on all metrics, especially on F1 metric. It shows the effectiveness of label-specific concept driven attention in capturing desired labels' relevant information in lengthy and noisy clinical notes.

Effectiveness of Note-Specific Concept-Driven Attention When discarding the note-specific concept-driven attention (w/o note-specific in Table 3), the performance drops obviously. To further

Concept. (a) **Concept. (b)**

investigate the contribution of note-concept distribution p_j and labels-concept distribution matrix W, we remove them separately. Both the performances drop slightly. It can be concluded that they both are complementary for note-specific concept-driven attention.

5 Discussion

Medical Concept Visualization

We randomly select two medical concepts with their top-20 weighted words. The corresponding word clouds are shown in Figure 4, where the size of a word is proportional to its assigned weight. **Concept (a)** is a medical concept about disease 'diarrhea' accompanied with symptoms including 'vomiting', 'nausea', 'chills', 'pain', etc. **Concept (b)** is diseases of 'biliary and pancreatic' which also includes 'pancreatitis', 'ercp' (a medical test technique), 'bile duct' (organ), etc. These medical concepts can aggregate medical information including diseases, symptoms, diseased organs, treatments and so on, which can be used to describe clinical notes concisely and provide interpretability.

Case Study of Interpretability

To further explore interpretability of the proposed approach, the attention distribution visualization over a clinical note for LAAT and its counterparts under KSI and our MCDA is shown in Figure 5.

It can be observed that LAAT (Vu et al., 2020) with customized label attention mechanism only captures scattered label-related words like **'stone'** and **'cholecystectomy'** for inferring **'gallstone'**, while it fails to find valid relevant evidence for inferring **'anemia'**. KSI (Bai and Vucetic, 2019) can additionally aid LAAT to find out keywords relevant to the medical codes in the intersection of the corresponding Wikipedia document and the clinical note. However, KSI represents the intersection as a binary vector encoding the presence of words, which inevitably causes a great loss of information in the clinical note, and is unable to aid LAAT locate evidence in the context of the clinical notes for predicting corresponding medical code.

Clinical Note: The patient was taken for an ERCP the day after admission, where he was found to have a **stone** in the **common** bile duct treated with sphincterotomy and **stone** extraction … he then appeared to bleed from his **sphincterotomy**. His initial hematocrit was 40 and it then fell to 25. He received 2 units of transfusion let him go home with a planned return for an elective **cholecystectomy**.
-- (LAAT)

Intersection: number liver sex **the** broad within **common** last **hematocrit** first several name **bleed** treat following total …
Intersection: number liver upper **stone** sphincterotomy right **pain** within **bile duct** ercp surgery history surrounding acute …
-- (LAAT+KSI)

Clinical Note: The patient was taken for an **ERCP** the day after admission, where he was found to have a stone in the common bile duct treated with **sphincterotomy** and stone extraction … he then appeared to bleed from his sphincterotomy. His initial hematocrit was 40 and it then **fell** to 25. He received 2 units of **transfusion**.
-- (LAAT+MCDA)

Medical Codes: **285 (anemia);** **574 (gallstone);**

Figure 5: The attention distribution visualization over a clinical note with two medical codes for LAAT and its counterparts under KSI and MCDA framework. Regarding LAAT, the words in bold represent highly weighted ones by its label attention. Regarding KSI, the bold words are extracted keywords in the intersection with high attention weights. Regarding MCDA, the words in bold represent highly weighted ones by note-specific attention, while the words with underlines are highly weighted ones by label-specific attention.

In contrast, MCDA's label-specific concept-driven attention guides LAAT discover the sign **'stone'** in **'bile duct'** which directly leads to **'gallstone'**. Moreover, based on note-specific concept-driven attention, some important medical concepts are retrieved and focused, such as **'ERCP'** (a medical test technique) and **'sphincterotomy'** (a specific surgery) which are strongly related to **'gallstone'**. Regarding medical code **'anemia'**, based on label-specific concept-driven attention, medical concepts **'bleed'** and **'hematocrit'** related to **'anemia'** are captured, and the medical sign **'hematocrit fell'** and treatment **'transfusion'** which can infer disease **'anemia'** are found based on note-specific concept-driven attention. Therefore, through medical concept-driven attention mechanism, different kinds of medical concepts are focused which provide more interpretability.

6 Conclusions

We have presented a novel framework based on medical concept driven attention for explainable medical code prediction from clinical notes. To the best of our knowledge, our work is the first attempt to uncover and explore latent medical concepts guided by the external knowledge while medical concept-indicative words serve as the evidences for explainable medical code prediction. Experimental results show that MCDA improves significantly several state-of-the-art models in most evaluation metrics on the benchmark dataset. In future, more Wikipedia documents will be incorporated and other ways of incorporating will be explored to promote medical code prediction task.

Abstract

Unsupervised constrained text generation aims to generate text under a given set of constraints without any supervised data. Current state-of-the-art methods stochastically sample edit positions and actions, which may cause unnecessary search steps. In this paper, we propose PMCTG to improve effectiveness by searching for the best edit position and action in each step. Specifically, PMCTG extends perturbed masking technique to effectively search for the most incongruent token to edit. Then it introduces four multi-aspect scoring functions to select edit action to further reduce search difficulty. Since PMCTG does not require supervised data, it could be applied to different generation tasks. We show that under the unsupervised setting, PMCTG achieves new state-of-the-art results in two representative tasks, namely keywords-to-sentence generation and paraphrasing.

1 Introduction

Constrained text generation is the task of generating text that satisfies a given set of constraints, and it serves many real-world text generation applications, such as dialogue generation (Li et al., 2016) and summarization (See et al., 2017). There are broadly two types of constraints: Hard constraints such as including a set of given words or phrases in the generated text. Example 1 in Table 1 shows that the keywords "*You*" and "*beautiful*" must occur in the generated sentence. Soft constraints such as acquiring the generated text to be semantically similar to the original text. Example 2 in Table 1 shows a pair of paraphrases where "*What are the effective ways to learn cs?*" and "*How to learn cs effectively?*" share a similar meaning.

Conventional approaches model the task in an encoding-decoding paradigm with a supervised setting (Prakash et al., 2016; Gupta et al., 2018).

No.	Original Text	Generated Text
1	You, beautiful	You are so beautiful .
2	How to learn cs effectively?	What are the effective ways to learn cs?

Table 1: Examples on constrained text generation.

However, these methods have certain shortcomings for two constrained generation tasks. For hard constrained text generation, without external constrained means, these methods are difficult to guarantee that the generated text can satisfy all constraints. For soft constrained one, conventional methods treat it as a machine translation (MT) task (Sutskever et al., 2014) and require massive parallel supervised data for training. Unfortunately, constructing such datasets is resource-intensive. In addition, domain-specific supervised models may be difficult to transfer to new domains. (Li et al., 2019).

Recently, unsupervised text generation is proposed to address the above challenges. There are mainly two research directions: Beam search-based method aims to generate candidates in order from left to right that satisfy the constraints in each step, inspired by MT methods (Hokamp and Liu, 2017; Post and Vilar, 2018). However, the search space of MT systems is relatively small, while when applied to other generation tasks, such as paraphrase, this approach does not work as optimally as expected because of a much larger search space (Sha, 2020). Local edit-based method represented by CGMH (Miao et al., 2019) and USPA (Liu et al., 2020) is another effective solution. These methods propose stochastic local edit strategies to search for reasonable sentences in a huge search space based on the given constraints. One main concern is that these methods may take a long time to search for the optimal solution because they are based on stochastic strategies. Intuitively, they need more search

Findings of the Association for Computational Linguistics: ACL 2022, pages 1417 - 1427
May 22-27, 2022

steps to converge. G2LC (Sha, 2020) utilizes gradients to determine edit positions and actions to improve search effectiveness. But it still relies on supervised data.

Dedicated to improving the local edit-based methods, in this paper, we propose a framework PMCTG (**P**erturbed **M**asking for **C**onstrained **T**ext **G**eneration) for constrained text generation. PMCTG focuses on controlling the search direction and reducing the search steps by searching for the best edit position and action at each step. Specifically, PMCTG extends perturbed masking (Wu et al., 2020) from a pre-trained BERT model (Devlin et al., 2019) to find the best edit position in the sequence. Perturbed masking aims to estimate the correlation between tokens in a sequence, which can be naturally used to find the edit location. We also propose a series of scoring functions for different tasks to select the edit action. PMCTG does not rely on supervised data and only needs a pre-trained BERT model to perform perturbed masking.

We evaluate PMCTG in two constrained text generation tasks, namely keywords-to-sentence generation and paraphrasing. Experimental results show that PMCTG tends to achieve new state-of-the-art performance over multiple baselines. In summary, the contributions are as follows:

1. We extend perturbed masking to constrained text generation which can find edit positions more effectively.
2. We design different scoring functions to select the best action effectively. With different scoring functions, PMCTG can be extended to various generation tasks (Kikuchi et al., 2016; Ficler and Goldberg, 2017; Hu et al., 2017).
3. We demonstrate our method's state-of-the-art performance in keywords-to-sentence generation and paraphrasing tasks.

2 Related Work

2.1 Constrained Text Generation

Constrained text generation is formulated as a supervised sequence-to-sequence problem under the encoding-decoding paradigm (Sutskever et al., 2014). For example, (Prakash et al., 2016) and (Li et al., 2019) respectively propose a stacked residual LSTM network and a transformer-based model (Vaswani et al., 2017), and (Gupta et al., 2018) propose to leverage a combination of variational autoencoders (VAEs) with LSTM models to generate paraphrases. A new sentence generation model is proposed by (Guu et al., 2018), where a prototype sentence is first extracted from the training corpus and then edited into a new sentence. However, these methods do not support constraint integration (Miao et al., 2019). Later, some works have attempted to add constraints to the generated models. (Wuebker et al., 2016) and (Knowles and Koehn, 2016) utilize prefixes to guide the target text generation. (Mou et al., 2016) use pointwise mutual information (PMI) to predict a keyword and treat it as a constraint to generate target text. However, these methods always bind the constraints to the original model and are therefore difficult to apply to new domains and new generation models (Li et al., 2019). Moreover, the above approaches rely on an adequate parallel supervised corpus, which is hard to obtain in real-world application scenarios.

Unsupervised constrained text generation has become a research hotspot due to its low training cost and mitigation of insufficient training data. VAEs and their variants (Bowman et al., 2016; Roy and Grangier, 2019) are leveraged to generate sentences from a continuous latent space. These methods can effectively get rid of the reliance on supervised datasets but remain difficult to control and incorporate generative constraints.

Beam search is a representative approach for unsupervised constrained text generation. Grid Beam Search (GBS) (Hokamp and Liu, 2017) is an algorithm that extends beam search by allowing the inclusion of pre-specified lexical constraints. (Post and Vilar, 2018) propose Dynamic Beam Allocation (DBA), a much faster beam search-based method with hard lexical constraints. (Zhang et al., 2020) propose an insertion-based approach consisting of insertion-based generative pre-training and inner-layer beam search. For the tasks where the search space is limited (represented by machine translation), these methods work well. However, when faced with a large search space, they do not work as optimally as expected (Sha, 2020).

Local edit-based methods have attracted attention recently, as they can help to reduce search spaces. CGMH (Miao et al., 2019) applies the Metropolis-Hastings algorithm (Metropolis et al., 1953) to unsupervised constrained generation. UPSA (Liu et al., 2020) is another local edit-based method. It directly models paraphrasing as an optimization problem and uses simulated annealing to solve it. However, these models may require many steps and running time to generate reasonable sentences since they are based on stochastic strategies. (Sha, 2020) proposes a gradient-guided method G2LC that uses token gradients to determine the edit actions and positions, making the generation process more controllable. However, a problem with G2LC is that it still relies on the supervised corpus to train a binary classification model to serve their semantic similarity objective.

2.2 Perturbed Masking

Perturbed masking (Wu et al., 2020) is a parameter-free probing technique to analyze and interpret pre-trained models. Based on a pre-trained BERT-based model with masked language modeling (MLM) objective, it can measure the impact a token has on predicting another word. It is originally used in syntax-based tasks such as syntactic parsing and discourse dependency parsing.

In this paper, we extend perturbed masking to constrained text generation. For the edit-based approach edits only one token at each step, we need to find the token with the highest incongruency to edit. Our insight is to use perturbed masking to present the congruency between different words. We believe that the token with the weakest correlation with its adjacent tokens has the highest incongruency and thus it is the most probable to edit. Perturbed masking can evaluate the impact of one token on another and a high impact factor means that the token has a high impact on its adjacent tokens and we consider these chunks (the current token with its adjacent tokens) are congruent. Therefore, we can edit the tokens in chunks with low impact to make these chunks more congruent.

3 Methodology

In this section, we would introduce the proposed PMCTG by first introducing the specific process of using perturbed masking to select edit positions, and then explaining the proposed scoring functions and the use of them to select the edit actions.

3.1 Edit Position Selection

Most previous works select edit locations stochastically, which lead to many unnecessary search steps. To reduce the search steps, we propose to use perturbed masking (Wu et al., 2020) to sample the edit position.

Background. Perturbed masking technique is proposed to assess the inter-token information (i.e., the impact one token has on another token in a sequence) based on masked language modeling (MLM). It is originally used for dependency parsing.

Formally, given a sequence with n tokens $\boldsymbol{x} = \{x_i\}_{i=1}^{n}$ and a pre-trained BERT-based model (Devlin et al., 2019) trained with MLM objective, we obtain contextual representations for each token $H(\boldsymbol{x})_i$. To quantify the impact a token x_j has on another token x_i, we conduct the following three-step calculation:

1. Replace x_i with $[MASK]$ token and feed the new sequence $\boldsymbol{x}\backslash\{x_i\}$ into BERT, a contextual representation denoted as $H(\boldsymbol{x}\backslash\{x_i\})_i$ for x_i is obtained.
2. Replace x_i and x_j with $[MASK]$ token and feed the new sequence $\boldsymbol{x}\backslash\{x_i, x_j\}$ into BERT, another contextual representation denoted as $H(\boldsymbol{x}\backslash\{x_i, x_j\})_i$ for x_i is obtained.
3. Given a distance metric $d(,)$, compute the difference between two vectors $I(\boldsymbol{x}|x_j, x_i) = d(H(\boldsymbol{x}\backslash\{x_i\})_i, H(\boldsymbol{x}\backslash\{x_i, x_j\})_i)$. Cosine similarity is leveraged in this paper.

$I(\boldsymbol{x}|x_j, x_i)$ indicates the impact x_j has on x_i, where a higher value indicates a lower impact, and vice versa. Intuitively, if $H(\boldsymbol{x}\backslash\{x_i\})_i$ and $H(\boldsymbol{x}\backslash\{x_i, x_j\})_i$ are similar, it means that the presence or absence of x_j has little effect on the prediction of x_i, thus reflecting the low importance of x_j to x_i.

Position Selection. It is natural to apply perturbed masking to select the edit position for constrained text generation. Based on perturbed masking technique, we compute the edit score for each token in the sequence and then sample the token with the highest score to edit. The token with minimal impact on its adjacent tokens indicates that it has the weakest correlation with adjacent tokens and therefore requires edit. We add the special tokens $[CLS]$ and $[SEP]$ to the original sentence and then use the pre-trained BERT to calculate the edit score for each token:

$$ES_i = 1 - \frac{1}{2}(I(\boldsymbol{x}|x_i, x_{i+1}) + I(\boldsymbol{x}|x_i, x_{i-1})) \tag{1}$$

Then we can get an edit score vector $\boldsymbol{ES} = \{ES_i\}_{i=0}^{n}$. Later, we feed it into a softmax layer and obtain the edit probabilities:

$$p_i^{edit} = \frac{exp(ES_i)}{\sum_j exp(ES_j)} \tag{2}$$

After that, the $\boldsymbol{p^{edit}}$ is utilized as the weights to sample the edit position x_e in $\boldsymbol{x}$ where e indicates the edit position index.

3.2 Edit Action Selection

After sampling the edit position, next we need to determine the edit action. The three edit actions we focus on are: insert, replace and delete. Specifically, our strategy in this step is to pre-implement the three actions first and then sample the actions based on their action scores. When scoring insertion action, we simply make the equal probability of the front or back of the position for token insertion. We first introduce the scoring functions for different tasks and then explain the edit action selection based on the action scores.

3.2.1 Scoring Function Design

We propose multiple scoring functions to improve the generated text. Given the initial sentence $\boldsymbol{x_0}$ with n tokens and the generated sentence $\boldsymbol{x_*}$ with m tokens, the scoring functions include fluency, editorial rationality, semantic similarity, and diversity.

Fluency. The primary condition for a reasonable sentence is fluency, thus we use the average negative log-likelihood to estimate a sentence's fluency based on a forward language model. The score is calculated as:

$$S_{flu}(\boldsymbol{x_*}) = -\frac{1}{m}\sum_{i=1}^{m} logp_{LM}(x_{*,i}|x_{*,<i}) \tag{3}$$

Editorial Rationality. Since the sentence generation process is based on local edits, we further use perturbed masking to design a local edit score for different actions to evaluate their rationality. After a replacement action is executed at index i in $\boldsymbol{x_0}$, we obtain the sentence $\boldsymbol{x_*} = \{x_{0,1}, x_{0,2}, \ldots x_{0,i-1}, x', x_{0,i+1}, \ldots, x_{0,n}\}$, where x' is the replaced token and $m = n$. Then we define the edit score as:

$$S_{edit}(\boldsymbol{x_*}) = \frac{1}{2}(I(\boldsymbol{x_*}|x', x_{0,i+1}) + I(\boldsymbol{x_*}|x', x_{0,i-1})) \tag{4}$$

Similarly, after an insertion action, we obtain $\boldsymbol{x_*} = \{x_{0,1}, x_{0,2}, \ldots x_{0,i}, x', x_{0,i+1}, \ldots, x_{0,n}\}$, where x' is the inserted token and $m = n + 1$. The edit score is calculated as:

$$S_{edit}(\boldsymbol{x_*}) = \frac{1}{2}(I(\boldsymbol{x_*}|x', x_{0,i+1}) + I(\boldsymbol{x_*}|x', x_{0,i})) \tag{5}$$

After a deletion action, we obtain $\boldsymbol{x_*} = \{x_{0,1}, x_{0,2}, \ldots x_{0,i-1}, x_{0,i+1}, \ldots, x_{0,n}\}$, where $m = n - 1$. The edit score calculated for deletion is a little different from replacement and insertion action:

$$\begin{aligned} S_{edit}(\boldsymbol{x_*}) = \frac{1}{2}(I(\boldsymbol{x_*}|x_{0,i-1}, x_{0,i+1}) + \\ I(\boldsymbol{x_*}|x_{0,i+1}, x_{0,i-1})) \end{aligned} \tag{6}$$

Semantic Similarity. The semantic similarity consists of keyword similarity and sentence similarity. We use KeyBERT (Grootendorst, 2020) to extract the keyword set K from $\boldsymbol{x_0}$. And the pre-trained BERT is leveraged to encode $\boldsymbol{x_0}$ and $\boldsymbol{x_*}$, where $ik = idx(k)$ indicates the index of keyword k in $\boldsymbol{x_0}$. The keyword similarity is defined as finding the closest token in $\boldsymbol{x_*}$ by computing their cosine similarity:

$$\begin{aligned} & S_{sem,key}(\boldsymbol{x_*}, \boldsymbol{x_0}) = \\ & \frac{1}{|K|}\sum_{k\in K} \max_i(cos(H(\boldsymbol{x_0})_{ik}, H(\boldsymbol{x_*})_i)) \end{aligned} \tag{7}$$

As for the sentence similarity, assuming that $H(x)$ indicates the $[CLS]$ representation in x from BERT and is leveraged to present the whole sentence (Devlin et al., 2019), we define the sentence similarity $S_{sem,sen}(\boldsymbol{x_*}, \boldsymbol{x_0})$ as:

$$S_{sem,sen}(\boldsymbol{x_*}, \boldsymbol{x_0}) = cos(H(\boldsymbol{x_0}), H(\boldsymbol{x_*})) \tag{8}$$

Altogether, the semantic similarity score is:

$$S_{sem}(\boldsymbol{x_*}, \boldsymbol{x_0}) = S_{sem,key}(\boldsymbol{x_*}, \boldsymbol{x_0}) + S_{sem,sen}(\boldsymbol{x_*}, \boldsymbol{x_0}) \tag{9}$$

Diversity. Followed (Liu et al., 2020), a BLEU-based (Papineni et al., 2002) function is adopted to evaluate the expression diversity of the original and generated sentence.

$$S_{exp}(\boldsymbol{x_*}, \boldsymbol{x_0}) = (1 - BLEU(\boldsymbol{x_*}, \boldsymbol{x_0})) \tag{10}$$

3.2.2 Action Scoring

As mentioned above, after sampling the edit position i, we need to determine the edit action by re-implementing three actions and sampling the actions based on their action scores. We generate the inserted and replaced candidate x' from a language model such as LSTM (Hochreiter and Schmidhuber, 1997) and GPT (Radford et al., 2019).

$$p_{candidate} = p_{LM}(x_{0,i}|x_{0,<i}) \tag{11}$$

We use $p_{candidate}$ as weights to sample x'.After obtaining the edit position i and candidate x', we need to calculate the edit score for each action. We adopt S_{flu} and S_{edit} the our scoring function for keywords-to-sentence generation:

$$S_{hard}(\boldsymbol{x}_*) = \lambda_{flu}S_{flu} + \lambda_{edit}S_{edit} \tag{12}$$

and S_{flu}, S_{sem}, S_{exp} and S_{edit} for paraphrasing:

$$\begin{aligned} S_{soft}(\boldsymbol{x}_*) =& \lambda_{flu}S_{flu} + \lambda_{edit}S_{edit} + \\ & \lambda_{sem}S_{sem} + \lambda_{exp}S_{exp} \end{aligned} \tag{13}$$

Notably, since different scores are in different magnitudes, they need to be normalized to avoid the dominance of one specific score. After scoring different actions, we use the scores as weights to sample the edit action.

3.3 Overall Searching Process

With $\boldsymbol{x}_0$ (given keywords in the keywords-to-sentence generation task or original sentence in the paraphrasing task) as input, we repeat the above steps including edit position selection with perturbed masking and edit action selection with scoring functions for local edit. Until the maximum searching steps, we choose the sentence that achieves the highest score as the final output, according to (12) for keywords-to-sentence generation task or (13) for paraphrasing task respectively.

4 Experiments

We evaluate our method on two constrained text generation tasks, namely keywords-to-sentence generation and paraphrasing.

4.1 Keywords-to-sentence Generation

Experimental Setting. Keywords-to-sentence generation aims to generate a sentence containing the given keywords which is a representative hard constrained text generation task. We conduct keywords-to-sentence generation experiments on the One-Billion-token dataset[1] (Chelba et al., 2014). Two language models for generation, namely two-layer LSTM (followed as (Miao et al., 2019; Sha, 2020)) and GPT (Radford et al., 2019), are evaluated. Following (Gururangan et al., 2020), in order to adapt the language models to the specific domain, we randomly sample 5 million sentences to continually pre-train BERT-based-cased[2] and GPT2[3]. 3 thousand sentences are held out as the test set.

Score	Description
1.00	Completely fluent.
0.75	Generally fluent with a few grammatical errors.
0.50	Generally fluent with many grammatical errors.
0.25	The whole sentence are not fluent, but parts of it do.
0.00	Not readable.

Table 2: Fluency scoring guideline.

As for hyperparameters, for each test sentence, we randomly sample 1 to 4 keywords as hard constraints. Following previous works (Miao et al., 2019; Sha, 2020), the initial sentence for searching is the concatenation of the keywords. The maximum searching step set in this task is 100. And λ_{flu} and λ_{edit} are set as 1 in equation (12). Besides, when the keyword indexes are sampled as edit positions, we directly conduct insert action since the keywords cannot be replaced and deleted.

As for evaluation metrics, the generated target sentence is measured by negative log-likelihood (NLL) loss. NLL is given by a third-party language model which is an n-gram Kneser-Ney language model (Heafield, 2011) trained in a monolingual English corpus from WMT18[4]. In addition to automatic evaluation metrics, we also introduce human evaluation. Specifically, we invite 3 experts who are fluent English speakers to score the generated sentences according to their quality. The score ranges from 0 to 1 with an accuracy of two decimal places, where 1 indicates the best score. The automatic and human evaluation criteria are consistent with previous works (Sha, 2020). The scoring guideline is shown in Table 2.

Baseline. We compare our method with several advanced methods:

- **sep-B/F** (Mou et al., 2016) is a variant of the backward forward model. In sep-B/F, the backward and forward sequences respectively behind and after the keyword are generated separately. It supports only one keyword.

PMCTG-LSTM	**6.92**	**7.33**	7.93	**7.68**	**7.47**	**0.53**	0.69	0.68	**0.74**	**0.66**

Table 3: Performance on keywords-to-sentence generation task. Lower NLL and higher score indicate better result. 1,2,3 and 4 present the keyword numbers and avg indicates the average score.

- **asyn-B/F** (Mou et al., 2016) is similar to sep-B/F. The difference is that the two sequences are generated asynchronously, i.e., the backward sequence is first generated, and then the forward sequence is generated based on the backward one.
- **GBS** (Hokamp and Liu, 2017) is a searching approach that aims to search for a valid solution in the constrained search space of the generator with grid beam search.
- **DBA** (Post and Vilar, 2018) is another beam search-based approach with a higher search speed.
- **CGMH** (Miao et al., 2019) is a stochastic search method based on Metropolis-Hastings sampling.
- **G2LC** (Sha, 2020) is a gradient-guided approach. It improves CGMH by leveraging gradient to decide the edit positions and actions.

Automatic and Human Evaluation Results. Table 3 shows the performance of multiple methods on keywords-to-sentence generation task. Among different kinds of methods, we can see that the local edit-based methods work better than beam search-based methods, indicating their superior searching ability. CGMH can narrow the search space and make it easy to find higher-quality sentences. G2LC and PMCTG outperform CGMH, which illustrates the importance of determining the correct edit position and action for each step. Exploration and strategies for these two issues can better guide the model to find a more optimal solution, while also greatly reducing the waste of potentially non-essential search steps. Overall, the proposed PMCTG model outperforms other methods on average in both automatic and human evaluation metrics. PMCTG utilizes perturbed masking technology to identify edit locations and reflect the reasonableness of edit actions more intuitively and practically.

Compared to previous baselines, our approach may either require fewer steps to search for the optimal sentence or equal steps to achieve better results. In this task, our method needs to run only 100 steps while CGMH needs 200 steps for each sample and our method can achieve better results (7.47 vs 7.70 in average NLL). Besides, although G2LC also only needs to run 100 steps for each sample, our method (PMCTG-LSTM) gives better results (7.47 vs 7.56 in average NLL). Although the process requires another BERT model for perturbed masking, we transform a sentence to a batch of vectors and only need to call the BERT model once per search step to calculate the perturbed masking scores for all words. Compared to CGMH and UPSA, our method makes full use of each search step to a certain extent, reducing the extra time spent on random strategies.

Interestingly, PMCTG-LSTM seems to be superior to PMCTG-GPT2 in this task. For one thing, part of the superiority of GPT2 to LSTM is in the semantic richness of the generated sentences. However, in the target dataset, the sentence form and semantics are relatively simple, and therefore the performance of LSTM is comparable to that of GPT2 in cases where there is no need to generate sentences with complex semantics. For another, since keywords are locally ill-formed and semantically distant, the information of keywords may be difficult to support GPT2 to generate reasonable candidates without taking backward probability into account. In contrast, the two-layer LSTM considers both forward and backward probabilities and may be more suitable for generating candidates

Keywords	Sentences
worried	We are very worried about there .
agreement	To achieve such an agreement , it is important .
competition, action	The shots of competition and action are on display here .
change, hours	This will change it in the next 24 hours .
The,greatest, court	The world's greatest size court will be presented to you .
I,things, him	I can do lots of things for him .
body, advanced, July,funeral	The body was found advanced in July and funeral were held in September .
Miley,more, final,spots	But Miley Cyrus has played more than three times in the finaltwo spots .

Table 4: Generated examples of PMCTG-LSTM in keywords-to-sentence generation task.

Score	Description
1.00	Two sentences have the completely same meanings.
0.75	Two sentences have similar meanings with some different details.
0.50	Two sentences generally have similar meanings with many different details.
0.25	Two sentences generally have different meanings with some identical details.
0.00	Two sentences have completely different meanings.

Table 5: Relevance scoring guideline.

between two less correlated tokens.

We find that more keywords may lead to better results, one possible reason is that more keywords can further narrow the search space and facilitate the search of the model.

Case Study. Some generated examples of PMCTG-LSTM are shown in Table 4. We observe that the proposed model can generate fluent and meaningful sentences while containing the given keywords.

4.2 Paraphrasing

Experimental Setting. Paraphrasing aims to convert a sentence to a different surface form but with the same meaning. We evaluate PMCTG on two paraphrase datasets, namely Quora[5] and Wikianswers (Fader et al., 2013). The Quora question pair dataset consists of 140 thousand parallel sentences pairs and 640 thousand non-parallel sentences. The Wikianswers dataset contains 2.3 million question pairs scrawled from the Wikipedia website. We also conduct an experiment on two-layer LSTM (followed as (Miao et al., 2019; Liu et al., 2020; Sha, 2020)) and GPT2 for better comparison. Following previous works (Liu et al., 2020) again, we randomly sample 20 thousand sentences respectively in two datasets as test sets and use the other sentences to continually pre-train BERT-based-cased and GPT2 for domain adaption as (Gururangan et al., 2020).

As for hyperparameters, the maximum searching step set in this task is 50 and λ are all set as 1 in equation (13). The initial sentence for searching is the original sentence in the datasets.

In terms of evaluation metrics, we leverage the representative metrics sentence-level BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) as the basic metrics. In addition, as stated in (Sun and Zhou, 2012), standard BLEU and ROUGE could not reflect the diversity between the generated and original sentences. Therefore, we adopt iBLEU (Sun and Zhou, 2012) which penalizes the generated sentences with high similarity with the original ones as an additional evaluation metric. Besides, we also invite experts to evaluate the generated paraphrases. Specifically, we sample 300 sentences from the Quora test set and ask 3 experts to score each sentence according to two aspects: relevance and fluency. The evaluation criterion is again consistent with the previous works (Miao et al., 2019; Liu et al., 2020). The scoring guidelines are shown in Table 2 and Table 5.

Baseline. We compare our methods with three types of baseline:

- **Supervised methods** are original sequence-to-sequence models trained in in-domain supervised data, including ResidualLSTM (Prakash et al., 2016), VAE-SVG-eq (Gupta et al., 2018), Pointer-generator (See et al., 2017), the Transformer (Vaswani et al., 2017), and DNPG (the decomposable neural paraphrase generation) (Li et al., 2019).
- **Domain-adapted supervised methods** train models in one domain and then adapt them to another domain, including shallow fusion (Gülçehre et al., 2015) and multi-task learning (MTL) method (Domhan and Hieber, 2017).

Table 6: Performance on paraphrasing task. R1 and R2 respectively indicate ROUGE1 and ROUGE2. In this table, this first/second/third blocks respectively indicate the results of supervised/domain-adapted supervised/unsupervised methods.

- **Unsupervised methods** that are free of any supervised data and easily adapted to multiple new domains, including VAE (Kingma and Welling, 2014), CGMH (Miao et al., 2019), UPSA (Liu et al., 2020), and the recurrent state-of-the-art method G2LC (Sha, 2020). Notably, G2LC has two variants of G2LC-Generator and G2LC-Recognizer.

Automatic Evaluation Results. Table 6 presents the results of multiple methods on the paraphrasing task. From the first part of Table 6, we can see that supervised methods significantly outperform the other two kinds of methods. The supervised models were trained on 100 thousand question pairs for Quora and 500 thousand question pairs for Wikianswers. Their superiority indicates the effectiveness of learning knowledge from massive parallel data. However, such in-domain supervised data is hard to obtain in real-world applications.

Besides, the second section of Table 6 shows the domain-adapted supervised models' performance. These models are trained in one domain (Quora or Wikianswers) and then evaluated in another domain (Wikianswers or Quora). Their performances are much lower than in-domain supervised models' performances. This demonstrates the poor generalizability of supervised models and calls for the need for unsupervised methods.

The last section of Table 6 shows the results of multiple unsupervised methods. VAE seems to work worst on both datasets, which suggests that paraphrasing by latent space sampling performs not as well as local edit methods. PMCTG achieves the best performance in most cases, which indicates the effectiveness of PMCTG again. Unsupervised PMCTG does not require parallel data and can easily generalize to new domains, thus some unsupervised methods tend to achieve higher performance than the domain-adapted supervised models. In addition, it is worthwhile to note that the performance of some unsupervised methods (UPSA, G2LC, and PMCTG) is even better than some supervised methods (Residual LSTM and VAE-SVG-eq), which indicates that the gap between supervised and unsupervised methods has narrowed due to the effective searching strategies of the local edit-based methods. In addition, different from the keywords-to-sentence generation task, GPT2 works better than two-layer LSTM in the paraphrasing task. We believe that given a partially

Method	Relevance	Fluency
VAE	0.53	0.64
CGMH	0.62	0.70
UPSA	0.75	0.73
G2LC(Recognizer)	0.79	0.77
G2LC(Generator)	**0.81**	0.78
PMCTG-GPT2	0.76	**0.81**

Table 8: Generated examples of PMCTG-GPT2 in paraphrasing task.

fluent text, GPT2 can generate more reasonable candidates due to its powerful language modeling capability.

Human Evaluation Results. From Table 7, we show PMCTG-GPT2 achieves state-of-the-art performance in terms of fluency, but still suffers from relevance. We plan to improve its relevance in future research.

Case Study. Table 8 lists some representative generated examples from PMCTG-GPT2. They show the four most common types of paraphrasing for the proposed method. The first type is the change of syntax such as the interchange of "*what can...*" and "*how to...*" as in the first example. The second type is the change of adjective such as the second example where the "*possible*" is changed into "*good*". The third type is the change of personal pronouns such as the interchange of "*you*" and "*I*" in the third example. The last type is the change of tense, the most common is the interchange of general past tense and general present tense as the last example. In general, one limitation of the proposed model is the relatively low expressive diversity of generated sentences. One possible reason is that since each search step modifies only one token, and the unit of conversion from one expression to another is usually phrases or sentence blocks, thus the model may be biased not to search in that direction.

5 Conclusion

We propose a method PMCTG to improve the previous stochastic searching methods in the topic of unsupervised constrained generation. PMCTG leverages perturbed masking technique to find the best edit position and leverages newly designed multiple scoring functions to decide the best edit action. We evaluate the proposed method on two representative tasks: keywords-to-sentence generation (hard constraints) and paraphrasing (soft constraints). Experimental results demonstrate the effectiveness of the proposed method which achieves competitive results on three datasets over multiple advanced baseline methods. We plan to improve the diversity and relevance of the generated sentences in future work.

Combining (Second-Order) Graph-Based and Headed-Span-Based Projective Dependency Parsing

Abstract

Graph-based methods, which decompose the score of a dependency tree into scores of dependency arcs, are popular in dependency parsing for decades. Recently, Yang and Tu (2022) propose a headed-span-based method that decomposes the score of a dependency tree into scores of headed spans. They show improvement over first-order graph-based methods. However, their method does not score dependency arcs at all, and dependency arcs are implicitly induced by their cubic-time algorithm, which is possibly sub-optimal since modeling dependency arcs is intuitively useful. In this work, we aim to combine graph-based and headed-span-based methods, incorporating both arc scores and headed span scores into our model. First, we show a direct way to combine with $O(n^4)$ parsing complexity. To decrease complexity, inspired by the classical head-splitting trick, we show two $O(n^3)$ dynamic programming algorithms to combine first- and second-order graph-based and headed-span-based methods. Our experiments on PTB, CTB, and UD show that combining first-order graph-based and headed-span-based methods is effective. We also confirm the effectiveness of second-order graph-based parsing in the deep learning age, however, we observe marginal or no improvement when combining second-order graph-based and headed-span-based methods [1].

1 Introduction

Dependency parsing is an important task in natural language processing. There are many methods to tackle projective dependency parsing. In this paper, we focus on two kinds of *global methods*: graph-based and headed-span-based methods. They both score all parse trees and globally find the highest scoring tree. The difference between the two is how they score dependency trees. The simplest first-order graph-based methods (McDonald et al., 2005) decompose the score of a dependency tree into the scores of dependency arcs. Second-order graph-based methods (McDonald and Pereira, 2006) additionally score adjacent siblings, i.e., pairs of adjacent arcs with a shared head. There are many other higher-order graph-based methods (Carreras, 2007; Koo and Collins, 2010; Ma and Zhao, 2012). In contrast, the headed-span-based method (Yang and Tu, 2022) decomposes the score of a dependency tree into the scores of *headed spans*: in a projective tree, a headed span is a word-span pair such that the subtree rooted at the word covers the span in the surface order. Fig. 1 shows an example projective parse tree and all its headed spans.

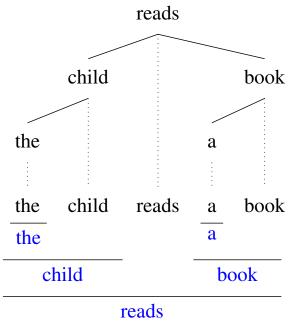

Figure 1: An example projective dependency parse tree with all its headed spans.

First-order graph-based parsers have difficulties in incorporating sufficient subtree information before the deep learning era. Dozat and Manning (2017) show that first-order graph-based parsers with neural encoders and biaffine scorers can obtain high parsing accuracy. Falenska and Kuhn (2019) argue that powerful neural encoders—such as BiLSTMs (Hochreiter and Schmidhuber, 1997)—can encode rich subtree information implicitly, questioning the utility of high-order features. However, recent works found that high-order graph-based

methods can outperform first-order graph-based methods (Fonseca and Martins, 2020; Zhang et al., 2020; Wang and Tu, 2020) even with powerful neural encoders, indicating the insufficient subtree modeling of first-order graph-based methods. To encode more subtree information, in contrast to the line of work on higher-order parsing, Yang and Tu (2022) choose to model headed spans, which consist of all words within the corresponding subtrees. Thus their model can utilize more subtree information than first-order graph-based methods. However, to retain the cubic parsing complexity, they abandon modeling arcs as the parsing complexity would be $O(n^4)$ otherwise (§3.1). Modeling dependency arcs can capture the direct interactions between two words and is thus useful. Therefore, it is intuitively helpful to combine first-order graph-based and headed-span-based methods.

To decrease the parsing complexity, inspired by the classical head-splitting trick (Eisner, 1997), we propose to decompose the score of a headed span into two terms, assuming that the score of the left span boundary is independent of that of the right span boundary for each headword. This allows us to adapt the Eisner algorithm to parse in cubic time considering both arc and headed span scores (§3.2) at the cost of imposing a stronger independence assumption. More interestingly, we can also combine second-order graph-based and headed-span-based methods and need only cubic time to parse (§3.3), which would be much slower (to the best of our knowledge, $O(n^7)$) if we do not apply the head-splitting trick.

We conduct extensive experiments on PTB, CTB, and UD. We find that combining first-order graph-based and headed-span-based methods is effective, and applying the head-splitting trick or not result in a similar performance, thus it is more advantageous to apply this trick to enjoy a lower parsing complexity. We also confirm the effectiveness of second-order parsing in the deep learning age, however, we observe only marginal improvement or even no improvement when combining second-order graph-based and headed-span-based methods.

2 Scoring and Learning

2.1 Scoring

Given an input sentences $x_1, ..., x_n$, we add <bos> (beginning of sentence) and <eos> (end of sentence) as x_0 and x_{n+1}. We apply mean-pooling at the last layer of BERT (Devlin et al., 2019) (i.e., averaging all subwords embeddings) to obtain the word-level embeddings e_i[2]. Then we feed $e_0, ..., e_{n+1}$ into a three-layer BiLSTM network to get $c_0, ..., c_{n+1}$, where $c_i = [f_i; b_i]$, f_i and b_i are the forward and backward hidden states of the last BiLSTM layer at position i respectively. We use $h_k = [f_k, b_{k+1}]$ to represent the kth boundary lying between x_k and x_{k+1}, and use $e_{i,j} = h_j - h_{i-1}$ to represent span (i, j) from position i to j inclusive where $1 \leq i \leq j \leq n$. Then we compute:

- $s^{\text{arc}}_{i,j}$ (for arc $x_i \rightarrow x_j$, used in all three models) by feeding c_i, c_j into a deep biaffine function (Dozat and Manning, 2017).
- $s^{\text{span}}_{i,j,k}$ (for headed-span (i, j, k) where x_k is the headword of span (i, j), used in §3.1) by feeding $e_{i,j}, c_k$ to a deep biaffine function.
- $s^{\text{left}}_{k,i}$ and $s^{\text{right}}_{k,j}$ (for headed-span (i, j, k), used in §3.2 and §3.3) by feeding c_k, h_{i-1} and c_k, h_j into two different deep biaffine functions.
- $s^{\text{sib}}_{i,j,k}$ (for adjacent siblings $x_i \rightarrow \{x_j, x_k\}$ with $k < j < i$ or $i < j < k$, used in §3.3) by feeding c_i, c_k, c_j into a deep triaffine function (Zhang et al., 2020).

2.2 Learning

We decompose the training loss L into $L_{\text{parse}} + L_{\text{label}}$. For L_{parse}, we use the max-margin loss (Taskar et al., 2004):

$$L_{\text{parse}} = \max(0, \max_{y' \neq y}(s(y') + \Delta(y', y) - s(y)) \tag{1}$$

where Δ measures the difference between the incorrect tree and gold tree y. Here we let Δ to be the Hamming distance (i.e., the total number of mismatches of arcs, sibling pairs, and (split) headed-spans depending on the setting). We use cost-augmented inference (Taskar et al., 2005) to compute Eq. 1, which involves the use of parsing algorithms described in the next section. We use the same label loss L_{label} in Dozat and Manning (2017).

3 Parsing

We use the parsing-as-deduction framework (Pereira and Warren, 1983) to describe the parsing algorithms of our proposed models.

---

[2] For some datasets requiring the use of gold POS tags, we additionally concatenate the POS tag embedding to obtain e_i

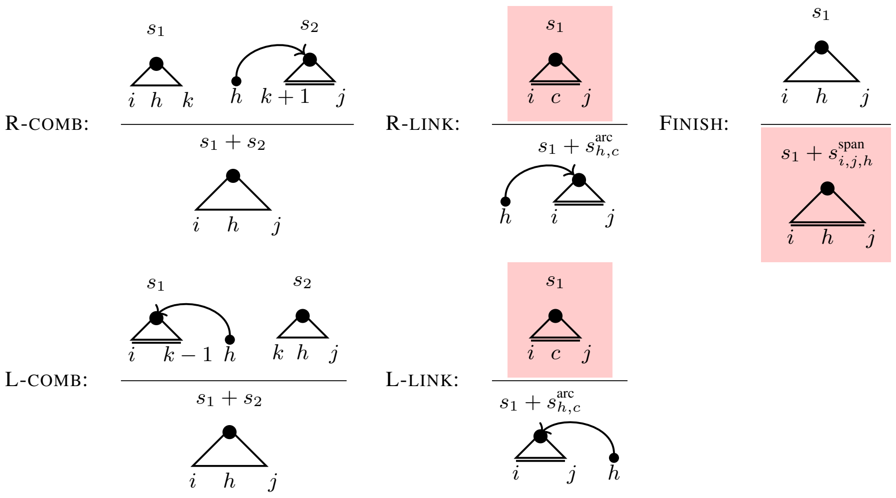

Figure 2: Deduction rules for our modified Eisner-Satta algorithm (Eisner and Satta, 1999). Our modifications are highlighted in red. All deduction items are annotated with their scores. Note that “finished” spans are marked by double underlines, whereas “unfinished’ spans take the original triangle notations.

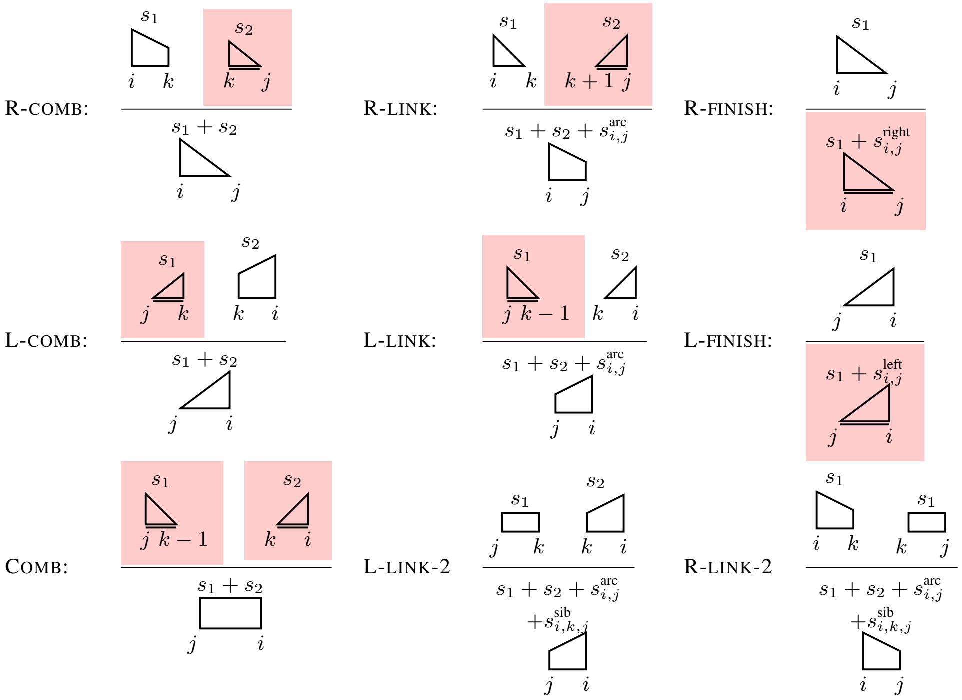

Figure 3: Deduction rules for our modified Eisner algorithm (Eisner, 1997) (first two rows) and its second-order extension (McDonald and Pereira, 2006) (all rows). Our modifications are highlighted in red. All deduction items are annotated with their scores. Note that “finished” (in)complete spans are marked by double underlines.

3.1 $O(n^4)$ modified Eisner-Satta algorithm

In this case, we combine first-order graph-based parsing and headed-span-based parsing. The score of a dependency tree y is defined as:

$$s(y) = \sum_{(x_i \to x_j)\in y} s^{\text{arc}}_{i,j} + \sum_{(l_i,r_i,x_i)\in y} s^{\text{span}}_{l_i,r_i,i}$$

We adapt the Eisner-Satta algorithm for parsing. The $O(n^4)$ Eisner-Satta algorithm (Eisner and Satta, 1999, Sec. 3) is originally defined with bilexicalized PCFGs. Still, we can leverage its dynamic programming substructure to incorporate both arc scores and headed span scores, similar to the relationship between span-based constituency parsing (Stern et al., 2017) and PCFG parsing. The axiom items are  with initial score 0 and the deduction rules are listed in Fig. 2. Unlike the original Eisner-Satta algorithm, we distinguish between "finished" spans and "unfinished" spans. An "unfinished" span can absorb a child span to form a larger span, while in a "finished" span, the headword has already generated all its children, so it cannot expand anymore and corresponds to a headed-span for the given headword. By explicitly distinguishing between "unfinished" spans and "finished" spans, we can incorporate headed-span scores s^{span} into parsing via the newly introduced rule `FINISH`. We then modify the rule `L-LINK` and `R-LINK` accordingly as only a "finished" span can be attached.

3.2 $O(n^3)$ modifed Eisner algorithm

In order to decrease the parsing time complexity from $O(n^4)$ to $O(n^3)$, we decompose $s^{\text{span}}_{l,r,i}$ into two terms:

$$s(y) = \sum_{(x_i \to x_j) \in y} s^{\text{arc}}_{i,j} + \sum_{(l_i, r_i, x_i) \in y} (s^{\text{left}}_{i,l_i} + s^{\text{right}}_{i,r_i})$$

and modify the Eisner algorithm accordingly. The axiom items are $\underset{i \quad i}{◺}$ and $\underset{i \quad i}{◿}$ with initial score 0 and the deduction rules are shown in the first two rows of Fig. 3. Similar to the case in the previous subsection, the original Eisner algorithm does not distinguish between "finished" complete spans and "unfinished" complete spans. An "unfinished" complete span can absorb another complete span to form a larger incomplete span, while a "finished" complete span has no more child in the given direction and thus cannot expand anymore. We introduce new rules `L-FINISH` and `R-FINISH` to incorporate the left or right span boundary scores respectively, and adjust other rules accordingly.

3.3 $O(n^3)$ modified second-order Eisner algorithm

We further enhance the model with adjacent sibling information:

$$s(y) = \sum_{(x_i \to x_j) \in y} s^{\text{arc}}_{i,j} + \sum_{(x_i \to \{x_j, x_k\}) \in y} s^{\text{sib}}_{i,j,k} + \sum_{(l_i, r_i, x_i) \in y} (s^{\text{left}}_{i,l_i} + s^{\text{right}}_{i,r_i})$$

where for each adjacent sibling part $x_i \to \{x_j, x_k\}$, x_j and x_k are two adjacent dependents of x_i.

Similarly, we modify the second-order extension of the Eisner algorithm (McDonald and Pereira, 2006) by distinguishing between "unfinished" and "finished" complete spans. The additional deductive rules for second-order parsing are shown in the last row of Fig. 3 and the length of the "unfinished" complete span is forced to be 1 in the rule `L-LINK` and `R-LINK`.

4 Experiments

4.1 Setup

We conduct experiments on in Penn Treebank (PTB) 3.0 (Marcus et al., 1993), Chinese Treebank (CTB) 5.1 (Xue et al., 2005) and 12 languages on Universal Dependencies (UD) 2.2. Implementation details are shown in appendix A. The reported results are averaged over three runs with different random seeds.

4.2 Main result

Table 1 and 2 show the results on UD, PTB and CTB respectively. We additionally reimplement `Biaffine+2O+MM` by replacing the TreeCRF loss of Zhang et al. (2020) with the max-margin loss for fair comparison. We refer to our proposed models as `1O+Span` (§3.1), `1O+Span+Headsplit` (§3.2), and `2O+Span+Headsplit` (§3.3) respectively.

We draw the following observations. (1) Second-order information is still helpful even with powerful encoders (i.e., BERT). `Biaffine+2O+MM` outperforms `Biaffine+MM` in almost all cases. (2) Combining first-order graph-based and headed-span-based methods is effective. Both `1O+Span` and `1O+Span+Headsplit` beat `Biaffine+MM`, `Span` in almost all cases; have similar performance to `Biaffine+2O+MM`. (3) Decomposing the headed-span scores is useful. `1O+Span+Headsplit` has similar performance to `1O+Span` while manages to decrease the parsing complexity from $O(n^4)$ to $O(n^3)$. We speculate that powerful encoders mitigate the issue of independent scoring. (4) Combining second-order graph-based and headed-span-based methods has marginal effects. We speculate that the utility of adjacent sibling information and headed span information is overlapping.

4.3 Error analysis

Following (McDonald and Nivre, 2011), we plot UAS as a function of sentence length; F1 scores as functions of distance to root and dependency length

on the CTB test set. We also follow (Yang and Tu, 2022) to plot F1 score as a function of span length.

Fig. 4a shows that compared with first-order graph-based method (i.e., Biaffine+MM), headed-span-based method (i.e., Span) has an advantage in predicting long sentences (of length > 30) but has a difficulty in predicting short sentences (of length < 20). By combining first-order graph-based and headed-span-based methods, `1O+Span` can predict both short and long sentences correctly. It achieves the best results for all sentence length intervals except for 30-39. Fig. 4b shows that 1O+Span achieves the best performance for almost all cases, indicating its strong ability in predicting complex subtrees with high tree depth. Also, Fig. 4c shows that 1O+Span achieves the best performance for almost all cases, especially for dependency arcs of length $\geq$ 6, showing its ability in capturing long-range dependencies. Fig. 4d shows that `Span` has the best performance in identifying the range of a subtree, although it has no direct relation to the final performance.

(c) (d)

Figure 4: Error analysis on the CTB test set.

5 Conclusion

In this paper, we have studied different ways to combine graph-based and headed-span-based methods. We found that applying the head-splitting trick can retain the cubic parsing complexity and meanwhile improve parsing performance when combining first-order graph-based and headed-span-based methods. We also confirmed the effectiveness of second-order parsing, however, we observed marginal or no improvement when combining it with the headed-span-based method.

A Implementation details

We use "bert-large-cased" for PTB, "bert-base-chinese" for CTB, and "bert-multilingual-cased" for UD. We set the hidden size of BiLSTM to 1000. We set the hidden size of biaffine functions to 600/300 for spans,arcs/labels. We set the hidden size of triaffine functions to 400. We add a dropout layer after the embedding layer, LSTM layers, and MLP layers with dropout rate 0.33. We use Adam (Kingma and Ba, 2015) as the optimizer with $\beta_1 = 0.9, \beta_2 = 0.9$ to train our model for 10 epochs with gradient clipping of 5. The maximal learning rate is $lr = 5e - 5$ for BERT and $lr = 25e - 5$ for other components. We linearly warmup the learning rate to their maximal value for the first epoch and gradually decay them to zero for the rest of the epochs. We batch sentences of similar lengths so that the token number is 4000 for each batch.

End-to-End Speech Translation for Code Switched Speech

Abstract

Code switching (CS) refers to the phenomenon of interchangeably using words and phrases from different languages. CS can pose significant accuracy challenges to NLP, due to the often monolingual nature of the underlying systems. In this work, we focus on CS in the context of English/Spanish conversations for the task of speech translation (ST), generating and evaluating both transcript and translation. To evaluate model performance on this task, we create a novel ST corpus derived from existing public data sets.[1] We explore various ST architectures across two dimensions: cascaded (transcribe then translate) vs end-to-end (jointly transcribe and translate) and unidirectional (source $\rightarrow$ target) vs bidirectional (source $\leftrightarrow$ target). We show that our ST architectures, and especially our bidirectional end-to-end architecture, perform well on CS speech, even when no CS training data is used.

1 Introduction

Over half of the world's population is estimated to be bilingual. [2] Those that know multiple languages are prone to code switch, i.e., to interchangeably use words and phrases from two (or more) languages in situations such as casual dialog, while traveling abroad, or simply to use a word they find more fitting (Myers-Scotton and Ury, 1977; Heredia and Altarriba, 2001). In CS, the base language is referred to as the *matrix* language while the contributing language is called the *embedded* language (Myers-Scotton, 1995), where speakers often use the matrix language the majority of the time.

Code switched language is challenging to both automatic speech recognition (ASR) and machine translation (MT) - and therefore also to the composite task of speech translation (ST). While a rich amount of prior works exist on CS in the context of ASR (Lyu et al., 2006; Ahmed and Tan, 2012; Vu et al., 2012; Johnson et al., 2017; Yue et al., 2019) and MT (Sinha and Thakur, 2005; Winata et al., 2021; Zhang et al., 2021; Yang et al., 2020), there is little prior work in the context of ST.

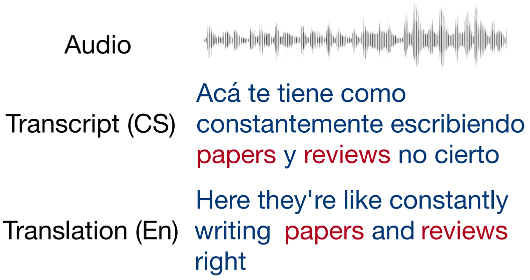

Figure 1: An example instance of the joint speech recognition and translation task for code-switching (CS). Red indicates English words in the transcript and their corresponding words in the translation, whereas blue indicates Spanish words in the transcript and their corresponding translation.

The aforementioned challenges to ASR, MT and ST arise largely due to the lack of CS data as well as the often monolingual nature of ASR systems, and of encoders of MT and ST systems. The lack of CS data is often addressed via synthetic data, e.g. as seen in Xu and Yvon (2021); Nakayama et al. (2019). Instead, in this work we derive two novel natural CS datasets from existing public corpora. CS is also difficult for modeling due to its mixed multilingual nature. In order to support multiple languages on the utterance level, automatic language identification (LID) is often performed before applying monolingual systems on a per utterance basis. However, this does not address within-utterance CS, where embedded foreign words and phrases result in recognition errors for monolingual ASR systems, making multilingual models an attractive alternative. Furthermore, CS increases speech recognition errors, significantly increasing the problem of error propagation (Ruiz and Fed-

erico, 2014) in cascaded ST systems, where MT is then performed on the erroneous ASR output. Thus, multilingual end-to-end (E2E) ST systems may be especially appropriate to tackle CS speech.

As both the transcript and translation are important in many CS ST use cases, we focus on the joint transcription and translation ST setting (Anastasopoulos and Chiang, 2018; Weller et al., 2021), extending it to CS data. We follow the methodology of these previous works and focus on the triangle E2E ST model to jointly generate both a transcript of the CS utterance and a translation of that utterance into text containing only one language (c.f. Figure 1 for an illustration). We perform a comparison along two axes: (1) comparing this E2E model to the standard cascaded ST systems, and (2) exploring the difference between bilingual systems and primarily monolingual systems gated by utterance-level LID. Following recent work that has shown the effectiveness of pre-trained models for ST (Li et al., 2020; Gállego et al., 2021), we use Wav2Vec 2.0 (Baevski et al., 2020) as our encoder model and the multilingual mBART 50-50 (Tang et al., 2020) as our decoder model.

We also make several modeling contributions in order to use these pre-trained models for joint transcription and translation. For the E2E ST model, we extend Li et al. (2020) to adapt the mBART decoder to jointly produce both transcription and translation. Furthermore, we introduce a triangle E2E ST model with a shared bilingual decoder and show that this improves transcription and translation accuracy. Our model analysis shows a surprising amount of robustness to CS speech, with the amount (or proportion) of CS words in a sentence not affecting model accuracy. Overall, we observe strong accuracy scores (WER, BLEU) on the CS task, both without CS training data and in the low-resource setting. We believe this opens the door to new and exciting progress in this area.

2 Related Work

Code-switching in NLP has seen a rise of interest in recent years, including a dedicated workshop starting in 2014 (Diab et al., 2014) and still ongoing (Solorio et al., 2021). CS in machine translation also has a long history (Le Féal, 1990; Climent et al., 2003; Sinha and Thakur, 2005; Johnson et al., 2017; Elmadany et al., 2021; Xu and Yvon, 2021), but has seen a rise of interest with the advent of large multilingual models such as mBART (Liu et al., 2020) or mT5 (Xue et al., 2020; Gautam et al., 2021; Jawahar et al., 2021). Due to the lack of available CS data and the ease of single-word translation, most of these recent related MT works have synthetically created CS data for either training or testing by translating one or more of the words in a sentence (Song et al., 2019; Nakayama et al., 2019; Xu and Yvon, 2021; Yang et al., 2020). We differ from those works by using naturally occurring CS data (Section 3) which models the real-world CS distribution rather than arbitrary language mixing.

For spoken input, as present in ASR and ST, synthetically creating realistic CS data is more challenging than it is for MT. However, dedicated ASR corpora that contain natural CS exist, including the Bangor Miami (Deuchar et al., 2014), SEAME (Zeng et al., 2018), and the recent large-scale ASRU 2019 task (Shi et al., 2020). These corpora generally do not contain translations of the ASR annotations, since they were designed for the ASR task only. However, there exist two exceptions, which we leverage to derive our ST CS data set, described in Section 3.

There also exists a wide range of prior modeling work on CS in ASR models, for a variety of strategies (Lyu et al., 2006; Ahmed and Tan, 2012; Seki et al., 2018; Luo et al., 2018; Lu et al., 2020; Du et al., 2021; Zhang et al., 2021). However, the recently introduced large multilingual models for speech, such as Wav2Vec, Wav2Vec 2.0, Schneider et al. (2019); Baevski et al. (2020) and HuBERT (Hsu et al., 2021), are still underexplored with regards to their CS performance.

Handling mixed languages also requires understanding what languages are being spoken. Systems that support mixed language input therefore require some form of automatic LID – either as an explicit component on the utterance (Mabokela et al., 2014; Xu and Yvon, 2021) or word-level (Lyu and Lyu, 2008a; Nakayama et al., 2019), or implicitly learned by the underlying model(s) via a multi-task learning setup (Lyu and Lyu, 2008b; Watanabe et al., 2017; Hou et al., 2020). In our work, we leverage both, exploring utterance-level LID components as well as implicit learning of utterance and word level LID.

In both MT and ASR, prior publications have also included the study of intra-word mixing of languages (Yılmaz et al., 2018; Mager et al., 2019), a phenomenon we do not explore in our work.

Finally, our work builds off of advances made by Gállego et al. (2021); Li et al. (2020) that show that combining large multilingual speech and text models provide consistent improvements. We differ however, by exploring ST in the novel CS setting.

3 Task Description & Data Used

3.1 Task Description

We investigate systems suitable for bilingual English/Spanish conversational scenarios where some of the English and Spanish utterances may include some amount of words and phrases of the respective other language. That is, we are focusing on ST systems that can automatically and seamlessly handle utterances that are either purely English, purely Spanish, English with some Spanish words/phrases embedded or Spanish with some English words/phrases embedded. For transcription, we aim for models to generate the exact mixed-language transcript with each word written in its original spoken language. For translation, we aim to generate purely monolingual translations. See Figure 1 for an example. The experiments and results presented in this paper focus on translating into monolingual English only due to data availability, although we expect similar results for Spanish translations, due the bidirectional model training on standard ST data (Appendix D). We will leave it to future work to more closely examine translation into Spanish – or even a third language not present in the original utterance.

It must be noted that word-level language categorization is sometimes ambiguous. A word in one language may also be considered part of a different language. That is for example true for *loan words* (Baugh, 1935), e.g., *e-mail* in many non-English languages such as German. This issue can be further complicated by attempting to categorize what language named entities fall under: is a Spanish speaker saying *Joe Biden* or *New York* code-switching? Although we acknowledge the complexity of separating words between languages, our work, following previous work (Modipa et al., 2013; Nakayama et al., 2018), uses data annotated by crowd-sourced workers, counting any sentence annotated as having a least one foreign word as being CS. This approach also makes intuitive sense for speech, as the CS words (classified as foreign) will have phonemes that will align more with the embedded language, while the non-CS phonemes will align more with the matrix language.

3.2 Code-Switched Speech Datasets

We use the Fisher (Cieri et al., 2004) and Bangor Miami[3] (Deuchar et al., 2014) corpora for CS data, as they are the only publicly available corpora we are aware of that contains both annotated CS ASR transcripts, as well as translations of those transcripts (Table 1). Although these corpora contain the translations, to our knowledge they have not been used to study CS translation before.

The Miami corpus was collected for linguistic code-switching analysis and gathered from recorded conversations between bilingual English/Spanish speakers in casual settings, primarily in Miami, Florida. These conversations include a high proportion of naturally occurring CS speech. However, in order to collect these naturally occurring conversations, the participants were recorded throughout their day using a small digital recorder worn on belts and lapels. Due to this, the Miami audio contains lower audio quality and much noiser background conditions than standard ASR datasets.

The Fisher dataset was collected for ASR and was gathered by pairing sets of Spanish speakers, located in the U.S. and Canada, to each other through phone calls. Although the Fisher dataset is not a CS focused dataset, we found that it contains a large amount of (annotated) CS utterances, due to the speakers being situated in English-speaking contexts. The recording method (phone recordings in 2004) makes this a noisy ASR dataset, although significantly less so than Miami.

To prepare the data for the joint ST CS task, we separate the data with CS utterances (utterances that contain at least one word annotated as CS) from those with none, creating a CS set and a monolingual set for each dataset. We note that for the Miami dataset the monolingual split contains both English-only and Spanish-only monolingual audio. As the Miami corpus was also annotated with both ambiguous and unambiguous code-switching, we only include utterances in the CS set if the annotations were tagged as unambiguously code-switched (i.e. excluding words such as *ok*, *aha*, and named entities). The Fisher CS dataset consists of majority (matrix[4]) Spanish 77% of the time, English-majority 17%, and 6% evenly

---

[3] Online audio files can be found at `https://biling.talkbank.org/access/Bangor/Miami.html`

[4] For simplicity, we use the terms majority/matrix language and minority/embedded language interchangeably.

Dataset	Raw Transcript	Clean Transcript
Fisher	un <foreign lang="English"> show <\foreign>, a mi me gusta ver mucho estos <foreign lang="English"> shows <\foreign> de la medicina forense	un show, a mi me gusta ver mucho estos shows de la medicina forense
Miami	hay una [/] una que dice (.) it's@s:eng five@s:eng o'clock@s:eng somewhere@s:eng	hay una una que dice it's five o'clock somewhere

Table 1: Examples of the raw and clean data for Miami and Fisher. Text in red indicates English text while blue text indicates Spanish. The Miami dataset uses the CHAT annotation format (MacWhinney and Snow, 1990).

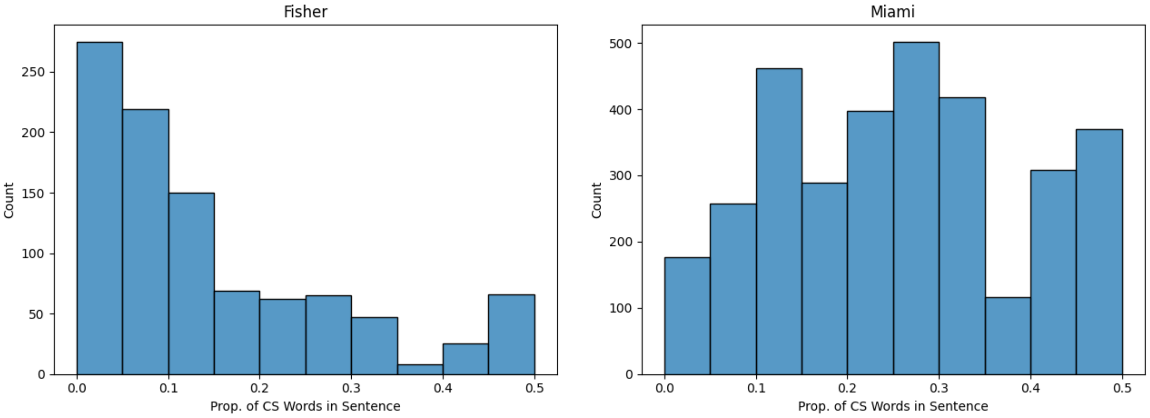

Figure 2: Histogram of the proportions of code-switched words in a sentence for the CS test sets (Fisher on the left, Miami on the right). For example, 0.2 means that 20% of the words in the sentence are CS.

Dataset	Split	Type	Hours	Instances
Miami	Train	Mono	3.60	6,489
	Test	CS	2.82	3,296
		Mono	3.61	6,490
Fisher	Train	CS	13.28	7,398
		Mono	157.3	130,600
	Dev	CS	1.45	821
	Test	CS	1.63	986
		Mono	12.15	10,595

Table 2: Dataset Statistics. CS stands for Code-Switched and Mono for Monolingual.

split between English/Spanish. For the Miami CS dataset the languages are more evenly distributed, with 51% majority-Spanish, 35% majority-English, and 9% evenly split.[5]

The Fisher data consists of three evaluation sets (Dev/Dev2/Test) that together contain approximately a thousand instances of CS with corresponding translations in monolingual English. We combine them into a Fisher CS *Test* set. The Fisher dataset also contains a large amount of CS utterances in the training set (appx. 8k or 15 hrs) which we use as fine-tuning (90%) and validation data (10%). As the Miami dataset contains no splits, we use all CS data for the test set and split the monolingual data into even train/test sets. We include basic summary statistics in Table 2. Note that when compared to standard ST datasets, these CS ST datasets would be considered low-resource settings.

In Figure 2, we see the proportion of CS words in a sentence for the CS test sets. We note that there are no sentences with more than 50% of the words CS since the minority language cannot be more than 50% by definition. For instances that are exactly 50% code switched their language identification was chosen by randomly selecting either English or Spanish. We see that for the Fisher dataset there are more sentences with less than 15% CS with a small uptick around 50%. For Miami it is more uniform, with a large amount of sentences being approximately 25% CS.

To prepare our models for Spanish-English CS, we use the CoVoST (Wang et al., 2020a,b) and MuST-C (Cattoni et al., 2019) datasets for standard

---

[5] To make these CS datasets reproducible for the broader ST community, we provide a file with instructions for gathering the data (as Fisher is part of the LDC library) as well as files containing a mapping between the original dataset indices to the CS data splits.

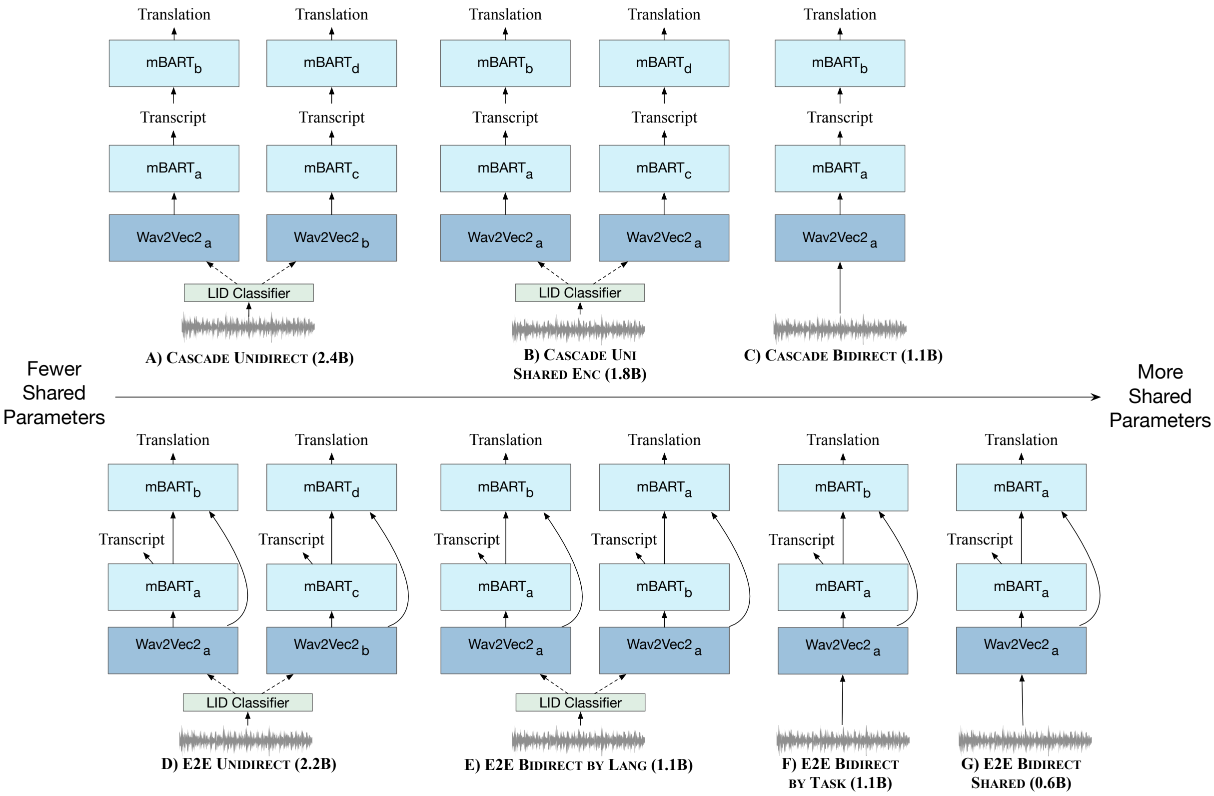

Figure 3: Illustration of model architectures, with cascaded architectures on the top and E2E architectures on the bottom. Left to right shows the progression of models with the least and the most amount of shared parameters respectively. Subscripts are present to indicate shared modules within each model. Dotted lines indicate a decision where only one path is chosen using the LID. Note that there is no cascade equivalent to the BIDIRECTIONAL E2E SHARED model, as the cascaded model by definition generates transcript then translation separately. The numbers in parentheses stands for the number of model parameters in billions.

ST training, as CoVoST contains only Es→En and MuST-C contains only En→Es. Although high scores on these datasets are not our primary target, we note that our scores come close to or improve the state of the art (SoTA) on these tasks (see Appendix A, Table 9) albeit with different data used in training, showing that our base ST models are representative of current SoTA techniques.

4 Experimental Settings

4.1 Models

Joint Transcript/Translation Models Many different types of E2E models exist for joint transcript/translation ST (Sperber and Paulik, 2020). Here, we focus on the *triangle* E2E architecture due to its strong performance in previous work (Anastasopoulos and Chiang, 2018; Sperber et al., 2020). Following recent work (Gállego et al., 2021; Li et al., 2020) we use pre-trained modules as a starting place for our ST model, using a Wav2Vec 2.0 (Baevski et al., 2020) encoder and a mBART 50-50 (Liu et al., 2020; Tang et al., 2020) decoder.

Because our task involves joint ASR and ST, we need to adapt the pre-trained decoder to work with the E2E triangle architecture. Specifically, the triangle model's second decoder computes cross attention separately over both the first decoder and the encoder states. We place an additional cross-attention layer after each encoder-attention layer in mBARTs decoder blocks, initializing them with the pre-trained encoder-attention weights. To make sure these weights converge properly, we freeze the entire model for approximately the first epoch while training only the bridge and additional cross attention layers (c.f. Appendix A).

As described in Section 3, our task involves modeling intra-sentence CS. This means that any model used for this task must either explicitly or implicitly learn to model the language of each word in the sentence. Furthermore, as more than one language is being modeled, each sub-component of the model can either be unidirectional or bidirectional. We can thus categorize potential models by how much information is shared within the parameters: the least shared models would be unidirectional and joined together by explicit LID, whereas the most shared would be bidirectional models that learn the LID implicitly. Models and their categorization along this scale are shown in Figure 3.

For cascade models, the most basic would be separate unidirectional cascaded models joined by an LID model. The LID model will explicitly decide what the matrix language is and send the utterance to the model that is best equipped to handle that language (Figure 3A). Note that this approach may suffer from error propagation issues due to incorrect LID. A more parameter-shared version of this model is to make the cascaded model encoder shared between both unidirectional models (Figure 3B). Finally, we can examine a bidirectional cascade model that shares each component across both languages. This architecture implicitly learns to model the language of the input, removing the need for an explicit LID model (Figure 3C).

We also examine similar analogues for the E2E triangle model: unidirectional models joined by LID (Figure 3D) and a bidirectional model with LID and a shared encoder (Figure 3E). We can also use the standard triangle model (see Anastasopoulos and Chiang (2018) for implementation details) that includes one encoder and two decoders (one for each sub-task) (Figure 3F). Furthermore, we propose to alter the standard triangle model and share both decoder parameters for both languages with a joint bidirectional decoder (Figure 3G, note that the cascade model cannot do this due to the definition of the cascade). By doing so, we hope to provide an inductive bias for the model to more easily handle code-switched data, as the weights of that decoder will already be used to handling multiple languages for both tasks (compared to the bidirectional cascade model, which only shares multilingual parameters for each task of transcript and translation).

Language Identification Model We train the language identification (LID) model to identify the matrix language. For consistency with our other models (and similar to concurrent work, e.g. Tjandra et al. (2021)), we use a pre-trained Wav2Vec2 along with a classifier layer to predict whether the utterance is majority Spanish or majority English. We train the model in the same fashion as the joint transcription and translation models (Section 4.1 and Appendix A) but train on the LID data instead.

The data for the LID model was gathered by taking the CS data[6] from the training set of the Fisher corpus and combining it with randomly sampled data from several different datasets in order to help the model learn despite the domain of the audio. We use MuST-C English audio, CoVoST English audio, CoVoST Spanish audio, and the monolingual Spanish audio from the training sets of Fisher and Miami. We found that upsampling the CS training set by 2 and using the same amount of data (2x the number of the CS set) for CoVoST and MuST-C provided the best results: 98%+ accuracy on CoVoST and MuST-C, 89% on the Fisher CS validation and test sets, and 72% on the Miami CS test set (due to the noisy data). As a large proportion of the CS data is close to 50% code-switched (see Figure 2), it becomes more difficult for the model to predict the matrix language correctly.

4.2 Training Process and Evaluation

For all dataset evaluations, we use word error rate (WER) and character error rate (CER) for the transcript and Charcut (CCT) (Lardilleux and Lepage, 2017) and sacreBLEU (Post, 2018) for the translation. However, we found that there was no difference in conclusions between each of the two metrics (WER vs CER and BLEU vs Charcut) and thus we only report BLEU/WER in the main text (see Appendix A for implementation details). For tables showing all metrics, see Appendix E.

We evaluate our models on the Fisher and Miami test sets (with both CS-only and monolingual-only test sets) in two different settings: (1) without fine-tuning them on CS data (No-FT) and (2) after fine-tuning the already trained ST models on the Fisher CS Training set (FT). For models consisting of two monolingual sub-models we fine-tune both on the CS data. During fine-tuning we employ the same hyperparameters as in the original experiment, but perform early stopping on the Fisher CS Dev set. We use significance tests to verify the reliability of our results (Koehn, 2004). We run bootstrap resampling tests against the best performing model, using $\alpha = 0.05$. More training parameters such as learning rates, etc. can be found in Appendix A.

5 Results

5.1 Scores on Test Sets

In this section, we explore the results of doing ST for CS data along the two axes of unidirectional vs

---

[6] For the No-FT case (Section 4.2), we exclude the CS data when training the LID model.

Table 4: Test set scores, with results from the Fisher corpus on the top half and the Miami corpus on the bottom half. Bold scores indicate the best score in the column, while asterisks indicate results that are statistically similar to the best score in the column group using a bootstrap resampling test with $\alpha = 0.05$.

bidirectional and end-to-end vs cascade.

We see results for models using explicit LID prediction in Table 3, showing that models that use the **predicted LID perform worse than those that use Oracle LID** (e.g. 36.6 vs 35.7 WER for the E2E Unidirect). This provides a slight advantage for the bidirectional models that learn LID implicitly. However, the predicted LID case is the realistic setting, and thus we use it for the remainder of our experiments.

When we examine the models along the scale of unidirectional to bidirectional, we see that **higher amounts of shared parameters are correlated with higher scores**, e.g. bidirectional is better. We see that on all datasets and evaluation settings (Table 4) that the E2E Bidirect Shared model is either statistically similar or outperforms all other models, except for the Miami Monolingual FT case, where it comes in 3rd. Thus, the inductive bias of sharing the multilingual task parameters provides a gain of approximately 3.5 WER points (33.8 vs 37.3) and 1.5 BLEU points (23.3 vs 21.9) for the E2E Bidirect Shared model over the E2E Unidirect model on the Fisher dataset, with similar

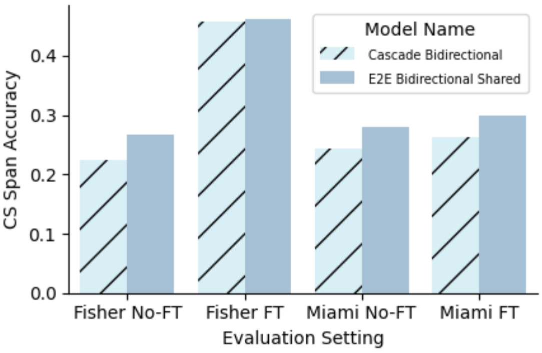

Figure 4: Accuracy of the models in generating the CS spans. Note that this excludes all non-exact matches and is a lower bound on performance.
