In Table 3 we show a concrete example of the segmentation results of SLM and our proposed method. Both two methods basically give correct word segments. The disagreement mainly lies in “送交市政府” (give to the city government). Compared with other words, “ 送交” can be relatively rare and bears very similar meaning with the single character “送”, which makes SLM wrongly segment “送交” apart. On the contrary, our method is built based on BERT trained on a large corpus, which makes our model able to recognize these relatively rare words. For the part “市政府”, where our model chooses to split, we assume that this is because similar contexts are often seen such as “ 北京市” (Beijing City), where “市” should be separated from “政府” (government). Furthermore, separating “市政府” into two words does not affect the understanding of the original text, and is more dependent on the segmentation fineness.

5 Conclusion

In this paper, we propose a BERT oriented Probing and Transformation method for unsupervised Word Segmentation. Our proposed model reveals the semantic information encoded in PLM into word boundary information by probing and transforming the token representations into explicit sequence labels. Experiment results on two benchmark CWS datasets show that our method achieves state-of-the-art F1 score. The proposed method works in an unsupervised manner, which can help understand low resource and endangered languages and thus protecting language diversity.

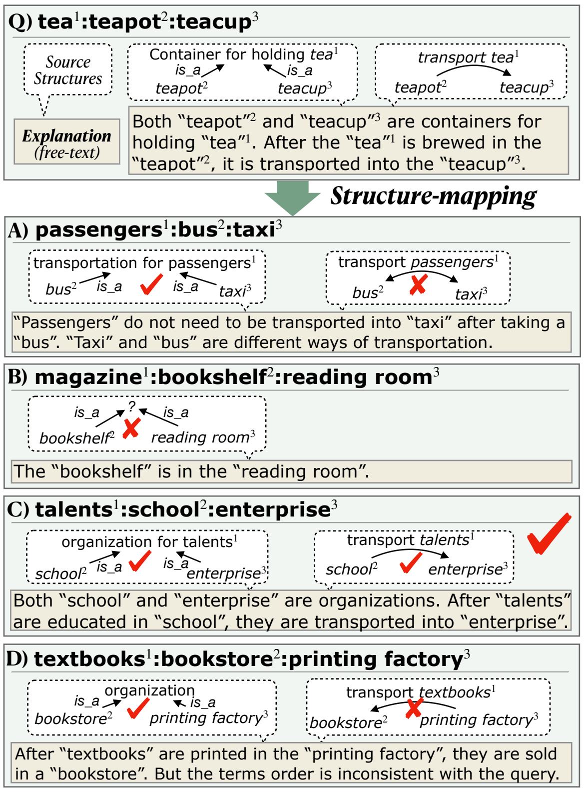
Abstract

The ability to recognize analogies is fundamental to human cognition. Existing benchmarks to test word analogy do not reveal the underneath process of analogical reasoning of neural models. Holding the belief that models capable of reasoning should be right for the right reasons, we propose a first-of-its-kind Explainable Knowledge-intensive Analogical Reasoning benchmark (**E-KAR**). Our benchmark consists of 1,655 (in Chinese) and 1,251 (in English) problems sourced from the Civil Service Exams, which require intensive background knowledge to solve. More importantly, we design a free-text explanation scheme to explain whether an analogy should be drawn, and manually annotate them for each and every question and candidate answer. Empirical results suggest that this benchmark is very challenging for some state-of-the-art models for both explanation generation and analogical question answering tasks, which invites further research in this area. Project page of **E-KAR** can be found at `https://ekar-leaderboard.github.io`.

1 Introduction

Analogy holds a vital place in human cognition, driving the discovery of new insights and the justification of everyday reasoning (Johnson-Laird, 2006; Gentner and Smith, 2012; Bartha, 2013; Bengio et al., 2021). Due to their unique value in many fields such as creativity (Goel, 1997) and education (Thagard, 1992), analogy and analogical reasoning have become a focus in AI research. The grand question is, are artificial neural networks also capable of recognizing analogies?

Relatively little attention has been paid in NLP to answer this question. The problem of recognizing analogies is mainly benchmarked in the form of (A:B::C:D) (Turney et al., 2003; Mikolov et al., 2013b; Gladkova et al., 2016; Li et al., 2018a) and targeted for testing the ability of pre-trained word embeddings. Given a tuple of terms as *query* (e.g., `tea:teapot:teacup`) and a list of *candidate answers* as in Figure 1, a model needs to find the most analogous candidate to the query, which is C in the example since it matches the relations inherent in the query better than others.



Both "teapot"^{2} and "teacup"^{3} are containers for holding "tea"^{1}. After the "tea"^{1} is brewed in the "teapot"^{2}, it is transported into the "teacup"^{3}.

"Passengers" do not need to be transported into "taxi" after taking a "bus". "Taxi" and "bus" are different ways of transportation.

The "bookshelf" is in the "reading room".

Both "school" and "enterprise" are organizations. After "talents" are educated in "school", they are transported into "enterprise".

After "textbooks" are printed in the "printing factory", they are sold in a "bookstore". But the terms order is inconsistent with the query.

Figure 1: An example in **E-KAR**. The explanations in **E-KAR** explain the *structure-mapping* process for analogical reasoning, where source structures are drawn from the query and mapped onto each candidate answer for decision-making.

Most methods (Mikolov et al., 2013a; Levy and Goldberg, 2014; Pennington et al., 2014) hold a

connectionist assumption (Feldman and Ballard, 1982) of *linear analogy* (Ethayarajh et al., 2019), that the relation between two words can be estimated by vector arithmetic of word embeddings. For example, $\vec{\texttt{king}} - \vec{\texttt{man}} + \vec{\texttt{woman}} = \vec{\texttt{queen}}$. However, current benchmarks focus on the recognition of binary analogies such as syntactic, morphological and direct semantic (e.g., *is_a* and *synonym_of*) relations. And the analogical reasoning procedure behind them is far beyond the scope of this line of research.

In addition, how to explain and rationalize analogical reasoning remains to be the major challenge. Psychological literature (Gick and Holyoak, 1983; Gentner, 1983; Minnameier, 2010) suggests that analogical reasoning follows the *structure-mapping* process. That is, a target (the domain where a problem must be solved, i.e., candidates) and a source (the domain where the analogy is drawn, i.e., the query) are matched, and the relevant features of the source have to be mapped onto the target. In Figure 1, source structures are drawn (or *abduced*) from the query and mapped onto candidates, and candidates A, B, D all fail at certain structures. We argue that such a process can be verbalized into natural language to explain analogical reasoning.

Moving from simply recognizing analogies to exploring human-like reasoning for neural models, we emphasize the importance of a new kind of analogical reasoning benchmark. To fill in this blank, we propose a first-of-its-kind benchmark for **E**xplainable **K**nowledge-intensive **A**nalogical **R**easoning (**`E-KAR`**). We collect 1,655 analogical reasoning problems sourced from the publicly available Civil Service Examinations (CSE) of China. These CSE problems are challenging multiple-choice problems designed by human experts, thus solving them requires the intensive involvement of linguistic, commonsense, encyclopedic, and cultural (e.g., idiom and historical) knowledge.

To justify the reasoning process, we follow the aforementioned guidelines from psychological theories and manually annotate free-text explanations for each query and candidate answers in **`E-KAR`**. Since the annotation requires intensive involvement of knowledge and reasoning, we carefully design a *double-check* procedure for quality control. We also translate this dataset into an English version, resulting in 1,251 problems after discarding language and cultural specific cases.

In summary, our contributions include:

- We advance the traditional setting of word analogy recognition by introducing a knowledge-intensive analogical reasoning benchmark (**`E-KAR`**) in Chinese and English, which is first-of-its-kind and challenging.
- To justify the analogical reasoning process, we design free-text explanations according to theories on human cognition, and manually annotate them.
- In **`E-KAR`**, we define two tasks (analogical QA and explanation generation) in two modes (EASY and HARD) and report the performance of some state-of-the-art language models. We discuss the potentials of this benchmark and hope it facilitates future research on analogical reasoning.

2 Related Work

Word Analogy Recognition in NLP Benchmarks for word analogy recognition (Turney et al., 2003; Mikolov et al., 2013b; Gladkova et al., 2016; Li et al., 2018a) examine mostly linear relations between words (Ethayarajh et al., 2019). Such analogies can often be effectively solved by vector arithmetic for neural word embeddings, such as Word2Vec (Mikolov et al., 2013a) and GloVe (Pennington et al., 2014). Recent studies (Brown et al., 2020; Ushio et al., 2021) also test such ability of pre-trained language models (PLMs) (Radford et al., 2019; Devlin et al., 2019; Brown et al., 2020) on these benchmarks. An exceptional benchmark is Li et al. (2020), where they build a knowledge-enhanced analogy benchmark that leverages word sense definitions in a commonsense knowledge base (Ma and Shih, 2018). However, these benchmarks are mainly set up for evaluating learned representations, and few of them ever investigated the analogical reasoning skills for neural models. Thus, the goal of this work largely differs from this line of research, as we aim to build a knowledge-intensive benchmark to teach neural models analogical reasoning for correct thinking.

Reasoning Benchmarks from Examinations There are abundant benchmarks derived from human examinations to facilitate the study of machine reasoning (Clark et al., 2016; Schoenick et al., 2017). For example, RACE (Lai et al., 2017) is collected from the English exams for middle and high school students, focusing on skills of passage summarization and attitude analysis. ARC (Clark et al., 2018) contains natural, grade-school science questions authored for human tests. MCQA (Guo et al., 2017), GeoSQA (Huang et al., 2019) and GCRC (Tan et al., 2021) are sourced from national college entrance exams of China, measuring a comprehensive set of reasoning abilities. LogiQA (Liu et al., 2020a) consists of logical reading comprehension problems from Civil Service Exams of China, which is also our source of analogical problems. ReClor (Yu et al., 2020) and LR-LSAT (Wang et al., 2021), collected from Law School Admission Test, aim for testing logical reasoning abilities. In our work, we focus on analogical reasoning skills for machines and additionally equip **`E-KAR`** with annotated explanations to rationalize reasoning.

Explainable NLP Datasets One of the most prominent objectives in machine reasoning is giving reasons for a prediction. In current datasets for explainable NLP, such reasons can be categorized into three classes (Wiegreffe and Marasović, 2021): *1) highlights explanations* (Camburu et al., 2018; Yang et al., 2018; Thorne et al., 2018; Kwiatkowski et al., 2019), which are subsets of the input elements to explain a prediction, e.g., words or sentences; *2) free-text explanations* (Camburu et al., 2018; Zellers et al., 2019; Aggarwal et al., 2021) that are textual explanations for justification; *3) structured explanations* (Mihaylov et al., 2018; Khot et al., 2020; Clark et al., 2020; Jhamtani and Clark, 2020; Geva et al., 2021), which are not fully free-text and generally follow certain structures such as a chain of facts. The explanations can be utilized to augment (Rajani et al., 2019), supervise (Camburu et al., 2020) and evaluate (DeYoung et al., 2020) model predictions. In this work, we phrase analogical reasoning itself as an instance of machine reasoning tasks with free-text rationales, advancing the research on analogical reasoning from the perspectives of data collection.

3 Explainable Analogical Reasoning

In this work, we consider a classic setting of analogical reasoning within NLP: recognizing word/term analogies.[1] This task can be formulated as multiple-choice question-answering. Given a query tuple Q with k (two or three) terms, and m candidate answer tuples $A = \{A_i\}_{i=1}^{m}$, the goal is to find the most analogous one in the candidates to the query.

We advocate that reasoning is about giving reasons explaining a prediction. In order to teach machines to analogize as humans do, we draw inspiration from theories in cognitive psychology to design the forms of explanations.

3.1 Analogical Reasoning: A Psychological Perspective

Before designing suitable forms of explanations, we introduce some important theories from cognitive psychology for a better understanding of analogical reasoning. In the psychological literature, analogical reasoning is described as a *schema-induction* (Gick and Holyoak, 1983) or *structure-mapping* (Gentner, 1983) process. Peirce (1896) claimed that analogy is a combination of abductive and inductive reasoning. Minnameier (2010) further developed the inferential process of analogy into three steps, which we take as the guidelines for designing explanations:

1. A possibly suitable structure in the source domain is abduced from the target domain, which might also work for the target;
2. The specific concepts of the source structure have to be replaced by suitable target concepts (by an inductive inference);
3. The validity of the transformation is judged w.r.t. solving the target problem.

Take Figure 1 for example: Source structures can be abduced that both term 2 (`teapot`) and term 3 (`teacup`) belong to a concept, and term 1 (`tea`) can be transported from term 2 to term 3. The mapping naturally reveals the validity, for example, candidate A is wrong because `passengers` do not follow a unidirectional transportation (i.e., from `bus` to `taxi`) but a bidirectional one.

3.2 Explanations for Analogical Reasoning

Following the above guidelines, the explanations for the analogical reasoning task should also include three parts:

1. *Abduction*: description of suitable structures for the query;
2. *Mapping*: how the structure is mapped onto candidates, analogous to template-filling;
3. *Validation*: justification for the correctness of the counterfactual mapping.

To this end, we define *free-text explanation* for analogical reasoning, which is one of the most expressive and commonly-used explanations (Wiegreffe and Marasović, 2021). We ensure the free-text explanations are self-contained, knowledge-rich, and

---

[1] Here, "term" corresponds to "word" in previous analogy benchmarks, but allows for multiple words.

sufficient to solve the problem as a substitute for the original input.

Specifically, for each query (Q) and candidate (A_i), we define free-text explanations $\mathcal{E}_Q$ and $\mathcal{E}_{A_i}$. Following the guidelines in §3.1, $\mathcal{E}_Q$ should describe the best suited inherent structure of a query abduced from the problem. $\mathcal{E}_{A_i}$ should decide the correctness in mapping the counterfactual A_i into structure expressed in $\mathcal{E}_Q$, while providing facts as support evidence.

Dataset	Lang.	Data Size (train / val / test)	# of Terms in Cand.	Has Expl.
SAT	En	0 / 37 / 337	2	✗
Google	En	0 / 50 / 500	2	✗
BATS	En	0 / 199 / 1,799	2	✗
`E-KAR`	Zh	1,155 /165 / 335	$2_{(64.5\%)}$, $3_{(35.5\%)}$	✓
	En	870 / 119 / 262	$2_{(60.5\%)}$, $3_{(39.5\%)}$	✓

Table 1: Comparison between **`E-KAR`** and previous analogy benchmarks: language, data sizes in different splits, number of terms in a query or candidate answer, and whether the benchmark has explanations.

4 The `E-KAR` Benchmark

4.1 Dataset Collection

We build our dataset upon the publicly available problems of Civil Service Exams of China (CSE), which is a comprehensive test for candidates' critical thinking and problem-solving abilities. CSE consists of problems that test various types of reasoning skills, such as graphical reasoning, logical reasoning and comprehension (Liu et al., 2020b), analogical reasoning, etc.

We collect in total 1,655 Chinese analogical reasoning problems from CSE over the years, each of them consisting of a query term tuple and *four* candidate answer tuples of terms (as shown in Figure 1). One of the prominent features in CSE problems is the intensive involvement of commonsense, encyclopedic, and idiom knowledge. For example, one needs to be aware of the fact that "the `tide` is caused by both `Lunar gravity` and `Solar gravity`". More importantly, one needs to know a *negated fact* (Barker and Jago, 2012; Hossain et al., 2020; Hosseini et al., 2021) in order to reject a candidate, such as the fact that "`husband` is *not* a `job`" or "a `car` is *not* made of `tires`". We keep mainly those requiring knowledge and reasoning skills. The rest is manually removed, such as the ones testing mathematics, morphology, and phonics, as well as the problems with the number of terms larger than three.

4.2 Manual Annotation of Explanations

We work with a private company for annotating the explanations defined in §3.2. Before annotation starts, we conduct a training session for all annotators to fully understand the requirements and pick the capable ones based on a selection test. The selected workers are allocated into two teams, a team of explanation constructors and a team of checkers, where the checkers achieves better scores in the test. All of them are paid above the local minimum wage. The annotation consists of two stages: *1)* the construction stage for writing explanations, and *2)* the double-check stage for quality control.

Construction During annotation, each problem is assigned to a constructor to build five sentences of explanations: one for query and four for candidate answers. The explanations are required to be: *1)* fluent and factually correct, *2)* able to solve the problem on their own, and *3)* knowledge-rich. To reduce the labeling difficulty, we allow them to use the search engine for querying the Internet.

First-round Checking Afterward, a problem with five annotated explanations is fed to a checker for a first-round checking. The checker decides whether to accept an explanation sentence according to the criteria in the construction stage. The rejected ones are sent back to the construction team for revision along with reasons to reject, which serve to re-train the construction team. The process repeats until a batch reaches 90% accuracy (i.e., decided to be correct according to the checker). Then, a second-round checking initiates.

Second-round Checking A verified batch is presented to authors for double-checking. Authors conduct random inspections for 50% samples of a batch, and unqualified annotations are sent back with reasons to the check team to fine-tune their checking criteria, which in turn regularize the construction team. The process also repeats until a batch reaches 95% accuracy.

In the end, the authors manually calibrate every explanation and acquire 1,655 analogical problems and a total number of 8,275 (5×1,655) free-text explanations, with an average of 31.9 Chinese characters per sentence.

4.3 Bilingual `E-KAR`: English and Chinese

For a broader impact of this work, we also build an English version of **`E-KAR`** via translation.

To translate the Chinese **`E-KAR`** into English, we ask three Chinese undergraduate students majoring in English to post-edit the machine-translated results of **`E-KAR`** by Google. Besides translation fluency, we also make sure that *1)* terms in options and explanations have the same word stems; *2)* the parts of speech of terms in a query or candidate answer are encouraged to be the same.

However, in practice, we notice that some samples in the Chinese dataset can not be accurately translated into English, such as ones involving idioms, poems, and other knowledge of Chinese culture. Such samples could be hard for non-Chinese people and models to understand without culture-specific knowledge. Therefore, in the English **`E-KAR`**, we manually remove or rewrite these samples, resulting in 1,251 problems and 6,255 (5×1,251) explanations that would require mostly commonsense and factual knowledge and reasoning skills that are universal across cultures and languages. Nevertheless, those removed samples are valid ones, and the cultural knowledge within them could be of unique value to the Chinese NLP community. Thus, we keep all samples in the Chinese **`E-KAR`** to encourage the research of Chinese NLP.

In the end, we have a bilingual **`E-KAR`** for rationalizing analogical reasoning. Both versions of **`E-KAR`** are randomly split into training, development, and test set at the ratio of 7:1:2. The statistics of **`E-KAR`** as well as comparison between previous benchmarks are reported in Table 1, including SAT (Turney et al., 2003), Google (Mikolov et al., 2013b) and BATS (Gladkova et al., 2016). There are 35.5%/39.5% problems with three terms in **`E-KAR`**, whereas previous ones only consist of two, making **`E-KAR`** even more challenging.

4.4 Shared Tasks in `E-KAR`

Given input $\mathcal{X} = (Q, A)$, the ultimate goal is to make the correct choice $\mathcal{Y}$, while producing rational explanations $\mathcal{E} = \{\mathcal{E}_Q, \mathcal{E}_A = \{\mathcal{E}_{A_i}\}_i\}$. To this end, we define two shared tasks, *multiple-choice question-answering* (QA) and *explanation generation* (EG), for teaching models how to analogize.

Moreover, to reduce the difficulty of this task as well as follow the structure-mapping process (as in §3), we propose an easier task form of the shared tasks by adding $\mathcal{E}_Q$ into input $\mathcal{X}$. Next, we will elaborate on these settings.

Task 1: Analogical QA The analogical QA task is formulated as $P_{\text{QA}}(\mathcal{Y}|\mathcal{X})$. The QA task requires an understanding of the relationship between the query and each of the candidates to find the correct answer. For evaluation, we directly use the *accuracy* of multiple-choice QA.

Note that all candidates may be related to the query tuple from certain perspectives. The challenge lies in finding the *most* related one, i.e., to identify the inherent connections and relations between terms in the query and candidates, considering properties such as linguistic features, order of terms, commonsense knowledge, etc. For example, the error for candidate D in Figure 1 can be attributed to the incorrect term order, though three terms follow similar relations as in the query. Hence, the best choice is C.

Task 2: Explanation Generation This task aims to produce a *pipelined rationalization* for analogical reasoning, formulated as $P_{\text{EG}}(\mathcal{E}|\mathcal{X})$. The generated explanations $\mathcal{E}$ can be further utilized for the analogical QA, i.e., $P_{\text{QA}}(\mathcal{Y}|\mathcal{X}, \mathcal{E})$. Note that the EG task does *not* generate post-hoc explanations for the QA task, therefore there will not be any predicted choice labels in the input $\mathcal{X}$. Rather, it indicates that the model should make implicit label predictions in explanations (Wiegreffe et al., 2021). The generated explanations can be directly evaluated the same as text generation tasks. Or, indirectly, we can follow a pipelined rationalization paradigm and see how generated explanations can help downstream QA tasks.

Task Mode: EASY vs. HARD The abduction of *source structure* (query explanation $\mathcal{E}_Q$) is critical but difficult for making rational analogical reasoning. Therefore, we propose two task modes:

- *HARD mode*: the original setting, where only Q and A are available in $\mathcal{X}$;
- *EASY mode*: in addition to Q and A, $\mathcal{E}_Q$ is allowed as part of the given input $\mathcal{X}$.

Essentially, EASY mode sets a much clearer playground for evaluating a system's ability to validate counterfactuals (as in §3.2): *What if candidate terms follow the structures in the query instead of query terms? Will they hold logically?* Therefore, we believe it to be an important supplement for **`E-KAR`** benchmark.

5 Methods

In this section, we describe the baseline methods in both QA and EG tasks in EASY and HARD modes. We mainly evaluate some of the state-of-the-art language models for solving tasks in **E-KAR**. Some implementation details are reported in Appendix A.

5.1 Baselines for Analogical QA

Pre-trained Methods As pre-trained-only baselines, we adopt three static word embeddings that have shown their effectiveness in previous analogy tasks: Word2Vec (Mikolov et al., 2013a), GloVe (Pennington et al., 2014) and FastText (Bojanowski et al., 2017). We also test contextualized embeddings from PLMs, including BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). The averaged token representation is taken as the term representation. A query or a candidate is estimated by the sum of the representations of each term pair, which is represented as the embedding vector differences (Hakami and Bollegala, 2017; Ushio et al., 2021). The candidate with the highest cosine similarity to the query is chosen as the answer.

Fine-tuned Methods We also set up fine-tuned baselines for QA with PLMs (BERT and RoBERTa). Since previous benchmarks do not have a training set, we only fine-tune the models on their development set. The query and candidates are respectively *verbalized* into text using simple prompts, and an example prompt can be found in Appendix A.1. Each candidate is concatenated with the query into one sentence, which is fed into a PLM for contextualized representation learning. Averaged hidden states are then fed to an MLP layer and a softmax layer for classification.

Human Evaluation We ask three students to solve the QA task in **E-KAR**, who are undergraduate or graduate students and fluent in English and Chinese. We randomly sample 100 problems from **E-KAR** of each language. Subjects are asked to first solve them in HARD mode then in EASY mode, in order to reveal the change in performance of the same problem when prompted with the query explanation. The averaged score is reported as the human baseline.

5.2 Baselines for Explanation Generation

We formulate the EG task in a Seq2Seq paradigm, instantiated with state-of-the-art pre-trained language models for Seq2Seq tasks, including BART (Lewis et al., 2020; Shao et al., 2021) and T5 (Raffel et al., 2020; Zhang et al., 2021).

Although the explanation is individually specific to each query and candidate, the generator has to take into account the whole problem for generating with the *best* source structure (as in §3.1) and thus finding the most analogous candidate. Similar to fine-tuned methods in QA task, the EG model takes as input the concatenation of the query Q and all candidate answers A (and the query explanation $\mathcal{E}_Q$ if in EASY mode). Note that in HARD mode, we switch the prefix of input from generating for Q or A_i in order to distinguish between generating explanations for the query or candidate answer. An example prompt is presented in Appendix A.1.

Evaluation for the EG Task In HARD mode, both the generated explanations for query $\mathcal{E}_Q$ and candidate answers $\mathcal{E}_A$ should be evaluated. In EASY mode, since $\mathcal{E}_Q$ is fed into the model as input, only $\mathcal{E}_A$ are required for evaluation. The generated text can be evaluated with text generation metrics such as ROUGE (Lin, 2004), BERTScore[2] (Zhang et al., 2020), BLEURT (Sellam et al., 2020) and MoverScore (Zhao et al., 2019). However, we would like to highlight that great challenges remain for automatically evaluating semantic-rich text generation (Celikyilmaz et al., 2020).

We also follow the pipelined rationalization paradigm and calculate the gain on QA accuracy as a supplement evaluation metric, i.e., the accuracy drop of $P_{\text{QA}}(\mathcal{Y}|\mathcal{X}, \mathcal{E})$ over $P_{\text{QA}}(\mathcal{Y}|\mathcal{X}, \mathcal{E}_{\texttt{gold}})$. This metric is denoted as **Acc** (**Δ**), where Acc is the QA accuracy when including generated explanations $\mathcal{E}$ as input during inference, and Δ reflects the accuracy drop. Here we fix a trained QA model $P_{\text{QA}}(\cdot)$ based on a large-version RoBERTa. This model is designed to be *different* from the ones in the QA task, as it is fine-tuned by concatenating gold explanations to the corresponding query or candidates as input during training (prompt detail can be found in Appendix A.1). As an evaluation metric, we alter the input explanations to the model from *gold* $\mathcal{E}$ to *generated* $\mathcal{E}$, and see their performance drops over gold. Note that the query explanation $\mathcal{E}_Q$ is still the input for all settings in EASY mode.

---

[2] We use the code of BERTScore at `https://github.com/Tiiiger/bert_score`, where English BERTScore is based on a RoBERTa (large) and Chinese one is based on a BERT (base).

6 Results and Analysis

In the experiments, we wish to answer two questions: *Q1)* Can models do knowledge-intensive analogical QA? *Q2)* Can models generate rational reasons for analogical thinking?

Categorization of Problems We first manually categorize the relational types of problems in `E-KAR` according to a pre-defined schema. Unlike free text, we are unable to induce a comprehensive set of relations that covers all candidates due to the complexity of CSE problems. As a result, we carefully assign at least one relation to each query. To facilitate analysis, we also try to assign relations to each candidate and query *in the development and test set*, ending up covering 76% of the candidates and 100% of the queries.

We refer to several sources of word analogy definitions and textbooks for analogy tests (listed in Appendix B), and categorize the relations into five *meta-relations* (as well as their coverage in the test set) and several accompanying *sub-relations*:

1. *Semantic* (R1, 8.36% for Zh, 4.12% for En), the similarity or difference in the meaning of terms, including *synonym_of* and *antonym_of*;
2. *Extension* (R2, 41.25% for Zh, 42.30% for En), the relation between the extension of terms, including *is_a*, *contradictory_to*, etc.;
3. *Intension* (R3, 37.94% for Zh, 40.21% for En), terms relate to each other by inherent properties, including *made_of*, *has_function*, etc.;
4. *Grammar* (R4, 6.36% for Zh, 6.72% for En), the grammatical relations between terms, including *subject-predicate*, *head-modifier*, etc.;
5. *Association* (R5, 6.08% for Zh, 6.65% for En), logical association between terms, including *result_of*, *sufficient_to*, etc.

Complete sub-relations are presented in Appendix B, as well as their definitions and examples.

6.1 Can models do knowledge-intensive analogical reasoning?

Table 2 reports the accuracy results of baseline methods on previous analogy tasks and the QA task in `E-KAR`.

How do machines solve analogical reasoning problems? To answer this question based on Table 2, the findings can be summarized as:

Method	SAT	Google	BATS	`E-KAR` (H/E)	
				Zh	En
Pre-trained Word Embeddings					
Word2Vec†	41.5	93.2	63.9	28.2/-	25.6/-
GloVe†	**47.7**	96.0	67.6	30.9/-	27.8/-
FastText†	47.1	**96.6**	**72.0**	**31.4/-**	**28.2/-**
Pre-trained Language Models					
BERT$^\dagger_b$	32.9	80.8	61.5	34.5/-	30.4/-
RoBERTa$^\dagger_b$	42.4	90.8	69.7	41.7/-	37.4/-
RoBERTa$^\dagger_l$	**45.4**	**93.4**	**72.2**	**44.6/-**	**39.0/-**
Fine-tuned Language Models					
BERT$_b$	38.9	86.6	68.0	41.8/46.7	37.9/42.2
RoBERTa$_b$	47.7	93.8	75.2	46.9/51.1	42.2/48.1
RoBERTa$_l$	**51.6**	**96.9**	**78.2**	**50.1/54.8**	**46.7/50.5**
Human	-	-	-	77.8/83.3	

Table 2: Accuracy results on previous analogy tasks and the QA task in `E-KAR`. `E-KAR` (H/E) denotes HARD or EASY mode of analogical QA. Method† is not tuned. PLM$_b$ or PLM$_l$ denote *base* or *large* version, respectively.

1) We find contextualized word embeddings from PLMs not very competitive against static word embeddings in previous analogy tasks, which is consistent with the findings in Peters et al. (2018).

2) In a more knowledge-intensive `E-KAR`, the opposite conclusion can be made, with PLMs prevailing over static word embeddings.

3) Furthermore, performance from contextualized representations can be improved in all tasks through fine-tuning, especially for `E-KAR`, where accuracy increases by roughly 5 to 6 points.

4) When incorporating gold source structure (i.e., EASY mode), the QA results significantly improve by roughly 5 points in both languages.

5) Moreover, despite our efforts to eliminate culture-specific samples in English `E-KAR`, the accuracy still falls behind its Chinese counterpart, which could be attribute to: *a)* fewer training samples, *b)* language-specific pre-training and *c)* language-specific information noise by translation.

How do humans solve analogical reasoning problems? In contrast to machines, humans achieve in `E-KAR` 77.8% accuracy in HARD mode and 83.3% in EASY mode, indicating the challenge of this task as well as showing that current SOTA language models still fall far behind human performance. We also find the trend of human performance is generally aligned with machines, with accuracy boost (also ∼5 points) when prompted with query explanations.

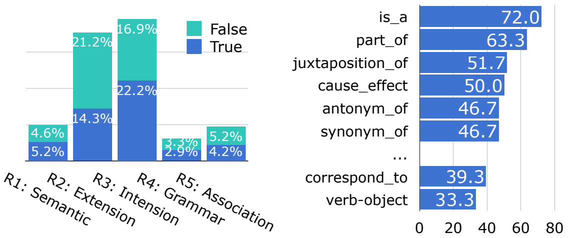
Table 3: Results of explanation generation models w.r.t. ROUGE-2, BERTScore, BLEURT, MoverScore and Acc (Δ) on the analogical QA task, where EASY mode (✓) incorporates gold $\mathcal{E}_Q$ as part of the model input. Note that the QA model here is trained as described in §5.2, and we switch input explanations during inference.



(a) Meta-relations distributions and their error ratios.

(b) Sub-relations in a sorted order of error rate.

Figure 2: Error analysis of different query relations. The results are predicted by a fine-tuned RoBERTa (large) in §5.1 on **`E-KAR`** (Zh).

Error Analysis for QA We further conduct an error analysis based on the results in **`E-KAR`** (Zh) predicted by a fine-tuned RoBERTa (large). The erroneous ones are classified based on the manually annotated meta-relations and sub-relations of *queries*, which is a fine-grained tool for analyzing a model's predictions.

Figure 2(a) shows that the model performs poorly on nearly all meta-relations, with R2 (Extension) being the most error-prone one (only 40.3% accuracy, normalized) and R3 (Intension) being the least one (56.8% accuracy). One of the most prominent reasons is that R2 and R3 rely heavily on commonsense and encyclopedic knowledge and reasoning skills such as commonsense and world knowledge, at which current models easily fail.

Figure 2(b) shows the error rate of sub-relations with more than 10 samples. Consistent with Figure 2(a), the three most error-prone sub-relations (*is_a*, *part_of* and *juxtaposition_of*) all belong to R2 (Extension). Besides, the model seems to do well in linguistic knowledge, with *verb-object* achieving only 33.3% error rate. These findings may shed light on future directions for knowledge-intensive reasoning with language models.

6.2 Can models rationalize analogical thinking?

We report the automatic evaluation results of generated explanations in Table 3. However, such results hardly mean anything due to the incapability to evaluate the semantic-rich text of current automatic metrics. Therefore, the following analyses mainly focus on Acc (Δ) and human evaluation.

Can (generated) explanations benefit analogical QA? To start with, we highlight again that the QA model in Table 3 is different from the one in Table 2 since the training of the former involves gold explanations. When exposing gold explanations to the QA model, it achieves 97.7% accuracy on **`E-KAR`** of both languages coincidentally.

However, the QA model performs poorly when removing the explanations during inference (i.e., *None*). This is because the pipelined rationalization in training makes the QA model rely heavily on the rationales (explanations) than the problem itself, and the removal of them causes severe performance degradation. When we switch the explanations to generated ones during inference, the accuracy gap (Δ) between gold results slightly narrows, with the gain in EASY mode being more significant than in HARD mode. To conclude, current SOTA generative language models still fall short of rationalizing analogical reasoning, which would be a challenging but interesting future direction.

Error Analysis for EG We also randomly select 100 sentences generated by a BART (large) for manual inspection by the authors. Aside from

Q)	氧气 (oxygen):臭氧 (ozone)
A)	盐 (salt):氯化钠 (sodium chloride)
B)	硫酸 (sulfuric acid):硫 (sulfur)
C)	石墨 (graphite):金刚石 (diamond)
D)	石灰水 (lime water):氢氧化钙 (calcium hydroxide)
$\mathcal{E}_Q$	氧气和臭氧都只由氧元素组成。Both oxygen and ozone are made of only the oxygen element.
$\mathcal{E}_Q^\dagger$	臭氧是氧气的一种。Ozone is a kind of oxygen.
$\mathcal{E}_\mathrm{A}$	氯化钠是盐的主要成分，盐和氯化钠不是只由一种元素组成。Sodium chloride is the main component of salt. Neither salt nor sodium chloride is made of only one element.
$\mathcal{E}_\mathrm{A}^\dagger$	氯化钠是盐的一种。Sodium chloride is a kind of salt.

Table 4: Case study of EG in HARD mode, where $\mathcal{E}_*$ is gold and $\mathcal{E}_*^\dagger$ is generated by a BART (large).

the common errors in generation models such as repetition, we find that task-specific errors for generated explanations can be roughly categorized into three classes: *1) unable to generate negated facts to refute source structure*; *2) generating factually incorrect statements*; *3) biasing towards common patterns*, e.g., "`term 1` and `term 2` have similar meanings" and "`term 1` is a `term 2`". For example, in Table 4, both generated $\mathcal{E}_Q$ (only in HARD mode) and $\mathcal{E}_\mathrm{A}$ are factually incorrect, and the model fails to generate the negated fact that "both are not exclusively made of one component."

We dig further into the first class of errors (w.r.t. negation), which is important to refute a candidate, as mentioned in §4.1. We find ∼90% gold explanations of wrong candidates contain negated statements. Yet, the number drops to 14.9% (Zh) and 22.1% (En) in the generated ones in HARD mode, and 21.3% (Zh) and 38.6% (En) in EASY mode. An interesting conclusion can be drawn that current generative models do not seem to know how to generate a negated yet truthful fact, such as "`feeling` can *not* guide `psychological reaction`." since feeling *is* a reaction. And exposing source structure to the model (EASY mode) seems to alleviate this problem.

The fact also questions the astonishing QA performance by adding gold explanations (97.7%), as the model could be biased towards surface-level negation. To debias this, we conduct a simple ablation study by directly removing the clauses containing the negation word "不" (*not*) from the gold explanations in the test set, and still achieve 92.5% in QA accuracy. This finding indicates that the QA model with correct rationales would not be very much biased towards negation in the explanation.

7 Conclusion and Discussion

In this work, we propose a first-of-its-kind benchmark **E-KAR** (in both Chinese and English) for explainable analogical reasoning, which sets a concrete playground and evaluation benchmark to boost the development of human-like analogical reasoning algorithms. The **E-KAR** benchmark is featured by its rich coverage in knowledge and well-designed free-text explanations to rationalize the analogical reasoning process. Preliminary experiments show that this benchmark provides a rather difficult challenge for prevailing language models.

However, there are still many open questions to be addressed. For example, humans solve the analogy problems in a trial-and-error manner, i.e., adjusting the abduced source structure and trying to find the most suited one for all candidate answers. However, the explanation annotation process in **E-KAR** (not the EG task) is mostly post-hoc and reflects only the result of reasoning. Such explanations cannot offer supervision for intermediate reasoning, though it is an interesting question whether an intelligent model should be deeply supervised at every step (Tafjord et al., 2021). Furthermore, **E-KAR** only presents one feasible explanation for each problem, whereas there may be several.

This benchmark also invites reasoning models that can effectively interact with extra knowledge. It remains to be a great challenge to generate and evaluate factually correct explanation text. Especially, how to generate negated facts is relatively under-explored in the research community but of much importance. Finally, whether the analogical QA system can *correctly* exploit explanations and background knowledge is also worth investigating, which may intersect with research on debiasing (Tang et al., 2020; Niu et al., 2021).

We hope this work to be a valuable supplement to future research on natural language reasoning, especially for research on analogical reasoning and explainable NLP.

Acknowledgement

We thank the anonymous reviewers for their valuable suggestions. We also thank Ruxin Yu for the logo design. This work was supported by National Key Research and Development Project (No. 2020AAA0109302), Shanghai Science and Technology Innovation Action Plan (No.19511120400) and Shanghai Municipal Science and Technology Major Project (No.2021SHZDZX0103).

Ethical Considerations

This paper proposes a new kind of analogical benchmark with explanations to rationalize models' predictions. The dataset is collected from Civil Service Exams of China, which is publicly available and has been used in other public datasets before, such as LogiQA (Liu et al., 2020a). The annotated explanations for each problem in our dataset are crowd-sourced by working with ByteDance. The construction team remains anonymous to the authors, and the annotation quality is guaranteed by the double-check strategy as mentioned in §4.2. We ensure that all annotators' privacy rights are respected in the annotation process. All annotators have been paid above local minimum wage and consented to use the datasets for research purposes covered in our paper.

A Implementation Details

The pre-trained word embeddings are provided by Li et al. (2018b), and the checkpoints for PLMs are hosted in HuggingFace (Wolf et al., 2020). Most of the parameters in the baseline models take the default values from HuggingFace's Transformers library, and we keep the best checkpoint on the validation set for testing. The Chinese version of BERT (whole word masking) and RoBERTa (whole word masking extended) are provided by Cui et al. (2020), BART by Shao et al. (2021) and T5 by Zhang et al. (2021).[3] Thus the EG results of T5 in **E-KAR** (zh) can be attributed to both Raffel et al. (2020) and Zhang et al. (2021).

A.1 Example Prompts in **E-KAR**

We denote terms in a query Q or a candidate $A^* \in \{A, B, C, D\}$ as $t^{\{1,2\}}_{Q/A^*}$. The example prompts for the QA and EG tasks in **E-KAR** are:

- *A Prompt for the QA Task*: "`(context:` $\mathcal{E}_*$`,) question:` $t^1_Q : t^2_Q$`, options:` $t^1_A : t^2_A$`,` $t^1_B : t^2_B$`,` $\cdots$ `or` $t^1_D : t^2_D$".
- *A Prompt for the EG Task*: "`query =` t^1_Q `:` t^2_Q `</s> (query explanation =` $\mathcal{E}_Q$`) </s> candidate =` t^1_A `:` t^2_A `</s> candidate =` $t^1_B : t^2_B$ `</s>` $\cdots$ `</s> candidate =` t^1_D `:` t^2_D `</s> generate the explanation of` Q/A_i`:`".
- *A Prompt for the QA model in Acc* Δ: concatenating explanations to the query and each candidate answer, such as "t^1_Q `:` t^2_Q `</s> explanation:` $\mathcal{E}_Q$" and "$t^1_A : t^2_A$ `</s> explanation:` $\mathcal{E}_A$".

B Detailed Relation Definitions

To design the relation taxonomy, we refer to a number of sources that categorize types of analogy tests, including MAT[4], Fibonicci[5], Offcn Education (in Chinese)[6] and Huatu Education (in Chinese)[7], etc.

The complete set of meta-relations and sub-relations are presented in Table 5.

---

[3] Note that the Chinese T5 (Mengzi) does not have large version, as they claim to be lightweight but ingenious.

Abstract

Relation linking (RL) is a vital module in knowledge-based question answering (KBQA) systems. It aims to link the relations expressed in natural language (NL) to the corresponding ones in knowledge graph (KG). Existing methods mainly rely on the textual similarities between NL and KG to build relation links. Due to the ambiguity of NL and the incompleteness of KG, many relations in NL are implicitly expressed, and may not link to a single relation in KG, which challenges the current methods. In this paper, we propose an implicit RL method called ImRL, which links relation phrases in NL to relation paths in KG. To find proper relation paths, we propose a novel path ranking model that aligns not only textual information in the word embedding space but also structural information in the KG embedding space between relation phrases in NL and relation paths in KG. Besides, we leverage a gated mechanism with attention to inject prior knowledge from external paraphrase dictionaries to address the relation phrases with vague meaning. Our experiments on two benchmark and a newly-created datasets show that ImRL significantly outperforms several state-of-the-art methods, especially for implicit RL.

1 Introduction

The past few years have witnessed the rapid development of knowledge-based question answering (KBQA), which aims to answer natural language (NL) questions over knowledge graph (KG), e.g., DBpedia (Auer et al., 2007) and Freebase (Bollacker et al., 2008). In many KBQA systems (Singh et al., 2018; Kapanipathi et al., 2021), as a fundamental module, relation linking (RL) seeks to link a relation phrase expressed in NL to a corresponding relation in KG, which has a great impact on the accuracy of subsequent steps like query construction and even the entire KBQA systems.

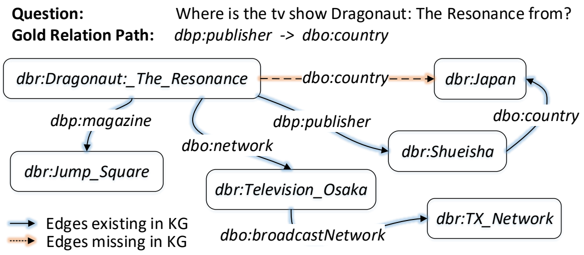

Figure 1: An example of RL to DBpedia. There is no explicit relation between *dbr:Dragonaut:_The_Resonance* and *dbr:Japan*. We expect to implicitly link the phrase "from" to an indirect relation path *dbp:publisher* → *dbo:country*.

Previous studies (Mulang et al., 2017; Singh et al., 2017; Naseem et al., 2021) focus on the similarities between the relation phrases and the text descriptions (e.g., local names) of relations in KG, and use the textual measures to link them. We refer to these studies as *explicit* RL, because they all assume that the relations in NL are explicitly expressed and can be recognized by existing NLP tools. However, according to (Sakor et al., 2019), while existing RL methods perform well on several benchmark datasets, they are still challenged by *implicit* relations prevalent in the real world.

Figure 1 illustrates a motivating example derived from (Azmy et al., 2018). Assuming that the entity phrase "Dragonaut: The Resonance" has already been linked to *dbr:Dragonaut:_The_Resonance*,[1] a typical method, e.g., EARL (Dubey et al., 2018), conducts RL with three steps: detecting the relation phrases in the question, generating the candidate relations in KG according to each phrase, and ranking them by calculating the similarities. However, handling the above question faces two challenges: (1) KG (e.g., DBpedia) is incomplete, which leads

---

[1] We denote entities and relation phrases in NL by "quotation marks", and entities and relations in KG by *italics*. *dbr:*, *dbo:* and *dbp:* refer to `http://dbpedia.org/resource/`, `http://dbpedia.org/ontology/` and `http://dbpedia.org/property/`, respectively.

Findings of the Association for Computational Linguistics: ACL 2022, pages 3956 - 3968
May 22-27, 2022 ©2022 Association for Computational Linguistics

to the situation that there is no direct relation between the entity *dbr:Dragonaut:_The_Resonance* and the answer *dbr:Japan*. Therefore, it is only possible to link them through an implicit relation path expressing a similar meaning as *dbo:country*. (2) Due to the diversity of NL, there does not exist any explicit relation phrase except the word "from", but "from" has a vague meaning and cannot do much for disambiguation. Obviously, the expressions of relation phrase "from" and relation path *dbp:publisher* → *dbo:country* in this example are very different, which leads to the poor performance of existing methods, since they rely on the textual similarity. Besides, according to the statistics in (Stadelmaier and Padó, 2019), 93.8% of people in Freebase do not have *place of birth*, and 78.5% of people do not have *nationality*, which shows that the situation of RL through implicit relation paths may occur in question answering frequently.

In this paper, we focus on the problem of *implicit RL*, where an implicit relation means the one not explicitly expressed in NL or cannot be linked to a single relation in KG. This is different from the studies, e.g., (Qiu et al., 2020), which use multiple explicit relations for multi-hop reasoning. To address such implicitness, we propose a new RL method called **ImRL** that links relation phrases in NL to relation paths in KG. To find proper relation paths, we propose a novel path ranking model that captures both textual information in the word embedding space and structural information in the KG embedding space, and align them between relation phrases in NL and relation paths in KG. In this way, in addition to the textual information from word embeddings, ImRL can also use the structural information possessed by KG embeddings to capture the correlation between single relations and relation paths, thereby expressing the missing relations through similar relation paths in the incomplete KG. Considering the work (Xue et al., 2020) that constructs a dictionary of paraphrases and establishes a mapping relationship between NL phrases and relations in KG, which can be prior knowledge for implicit relation phrases with vague meanings, ImRL leverages a gated mechanism with attention to inject prior knowledge from external dictionaries into the model, and integrates all the information to predict the links between implicit relation phrases and relations (or relation paths) in KG.

In summary, our contributions are threefold:

- We propose a novel ranking model, with the aim to eliminate the influence of incomplete KG. It aligns the textual information in the word embedding space and the structural information in the KG embedding space between relation phrases in NL and relation paths in KG.
- We explore a variety of ways to inject the knowledge in a paraphrase dictionary into the model, and choose a gate-based method with attention mechanism for knowledge injection, which can provide auxiliary information for the relation phrases with vague meanings.
- We conduct experiments on three datasets, including two benchmark datasets and a newly-created dataset that particularly focuses on implicit RL. Our results show that ImRL outperforms several state-of-the-art competitors, especially for linking implicit relations.

2 Related Work

Existing RL approaches mainly focus on two tasks: relation candidate generation and relation disambiguation. For the first task, ReMatch (Mulang et al., 2017), SIBKB (Singh et al., 2017) and EERL (Pan et al., 2019) generate candidates by running a textual similarity-based method over pre-built dictionaries constructed by analyzing the NL patterns contained in massive text corpora through frequent item mining or crowdsourcing. Several widely-used dictionaries include PATTY (Nakashole et al., 2012), PPDB (Ganitkevitch et al., 2013), Paraphrase (Xue et al., 2020), etc.

As for the second task, EARL (Dubey et al., 2018) leverages the connection density of KG for ranking. Falcon (Sakor et al., 2019) uses several fundamental principles of English morphology to obtain auxiliary information, and exploits an alignment model for linking. With the development of deep learning, a few deep learning-based methods appear. SLING (Mihindukulasooriya et al., 2020) leverages abstract meaning representation (AMR) to capture the semantic relationships in a question, and ranks the candidates with a Transformer-based model, which is trained in a distantly supervised manner. SimReL (Naseem et al., 2021) also uses AMR, and trains a BERT-based model for relation disambiguation. In addition to the aforementioned studies using DBpedia, there are also some studies, e.g., KBPearl (Lin et al., 2020) and Falcon 2.0 (Sakor et al., 2020), towards other KGs such as Wikidata (Vrandecic and Krötzsch, 2014).

Despite some literature (Pan et al., 2019; Sakor et al., 2019; Mihindukulasooriya et al., 2020) mentions the issue of implicit relations, there is still much left for improvement. For instance, EERL discovers the implicit relations by using the domains and ranges of properties in KG, but it cannot handle the issue of RL through relation paths. Falcon and SLING mainly focus on the implicit relations in phrases expressing the meaning about country, e.g., "Spanish movie". However, they perform poorly for other kinds of implicit relations, and cannot handle RL through relation paths either.

In recent years, KG embedding has become a popular area of research (Wang et al., 2017). Its main idea is to encode entities and relations in KG into a continuous low-dimensional embedding space. These embeddings can be further applied to various tasks, such as KG completion and KBQA. Many studies in the KG completion field (Bordes et al., 2013; Lao and Cohen, 2010; Lao et al., 2011) predict the possibility of the establishment of a specific triple through the embedding of entities and relations. Recently, researchers in the KBQA field have also begun to leverage KG embeddings. The studies (Huang et al., 2019; Saxena et al., 2020) try to learn a deep model that maps a NL question into a KG embedding space, and combine the KG embeddings of topic entities in the question with the question embedding to infer the answer. To the best of our knowledge, there is no prior work focusing on using KG embedding for implicit RL.

3 Implicit Relation Linking

A knowledge graph (KG), denoted by $\mathcal{G}$, can be defined as a triple $\mathcal{G} = (\mathcal{E}, \mathcal{R}, \mathcal{T})$, where $\mathcal{E}$ is the entity set, $\mathcal{R}$ is the relation set, and $\mathcal{T} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ denotes the relational triple set. Each entity in $\mathcal{E}$ is denoted by e, and each relation in $\mathcal{R}$ is denoted by r. If there exists a set of m triples $\{(e_0, r_1, e_1), \dots, (e_{m-1}, r_m, e_m)\} \subseteq \mathcal{T}$, we say that there is an m-hop relation path p between e_0 and e_m, denoted by $p = (r_1, \dots, r_m)$. The goal of RL can be formulated as: Given a NL question q and a KG $\mathcal{G}$, linking a relation phrase s in q to its corresponding relation r or relation path p in $\mathcal{G}$. Figure 2 shows the architecture of our method.

3.1 Path Generation

The path generation module consists of three steps:

Entity linking aims to link the phrases in NL that represent real-world objects to the corresponding entities in KG. Recent studies (Singh et al., 2018) have shown that entity linking can affect RL. To reduce the influence of entity linking on RL, we use the existing tool Falcon (Sakor et al., 2019) to link entities in advance, which has shown accurate results on entity linking (around 0.83 of F1-score on the LC-QuAD dataset as reported). The results are then fed into subsequent steps.

Relation identification is to determine whether there is any relation phrase in a question with entity connected to it. Inspired by (Hu et al., 2018), which demonstrates that using rules to transform the dependency tree into a directed graph and using a heuristic search to find the shortest path between two nodes can effectively decompose the complex question into multiple simple triples, thereby discovering the relations. We use a similar method to identify the relations in a question. Furthermore, we use a dictionary-based method (Deng et al., 2015) to identify those phrases that can be linked to classes in KG. In particular, wh-words, e.g., "what" and "when", are also regarded as class phrases. For each pair of nodes in the graph, we consider there is a relation between them if and only if (1) both nodes are phrases linked to entities or classes; (2) all intermediate nodes in the path between the nodes are not linked to entities or classes. The word sequence composed of intermediate nodes is obtained by the breadth-first-search (BFS) algorithm, and regarded as a relation phrases. For more details, please refer to Algorithm 1. In this way, we can obtain some relation phrases with entities connected to them. Furthermore, according to (Mihindukulasooriya et al., 2020), AMR can effectively capture the semantic information at the sentence level, thus we use a similar method for relation phrase extension. For example, for a phrase like "German actor", "country" can be recognized as the relation phrase contained in it through AMR. We refer the reader to (Mihindukulasooriya et al., 2020) for more details.

Candidate generation. Existing RL methods only consider single relations when generating candidates. However, KG is widely acknowledged as incomplete (Wang et al., 2017), which makes it fail to find the corresponding single relations in KG for some phrases and needs to be expressed by relation paths. We extend the RL task to link phrases to relation paths, where conventional RL can be regarded as a simpler case when the path is one hop. We enumerate the relation path candidates in different

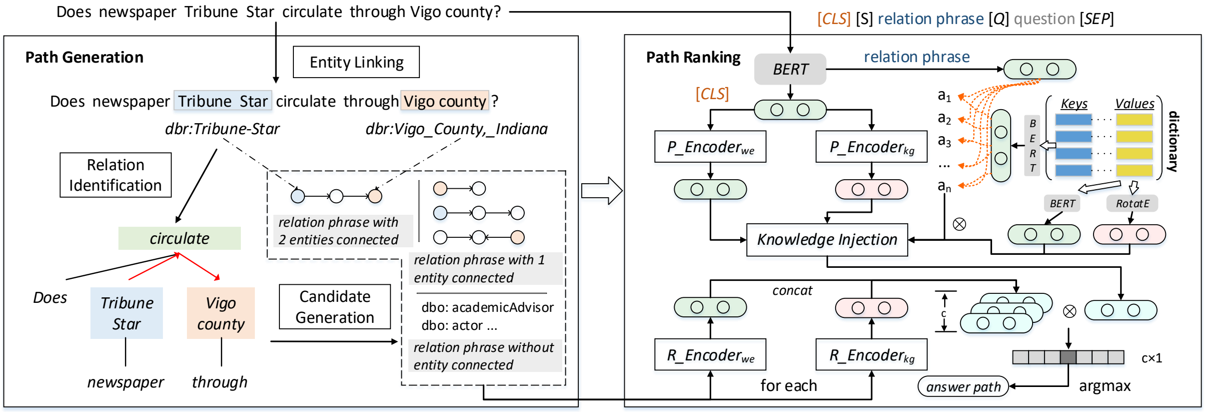

Figure 2: Overview of our method. The method has two parts: (1) *Path generation* parses the input question and finds the relation path candidates in the KG, by entity linking, relation identification and candidate generation. (2) *Path ranking* encodes the relation phrase in the question and path candidates in the KG in the BERT embedding space and RotatE embedding space, utilizes a ranking model to rank those candidates, and takes the one with the highest similarity score as answer. It also leverages a gated mechanism with attention to inject prior knowledge from external dictionaries to help relation disambiguation.

ways according to the number of connected entities of a phrase: (1) If a relation phrase is connected with two entities, all the paths between them are regarded as candidates. (2) If there is only one entity, all the paths within M-hop are considered as candidates. (3) Otherwise, if there is any phrase without any entity association, all possible common single relations in KG are considered as candidates. In order to effectively reduce the input size of subsequent modules, we select c candidate paths whose local names are most similar to the relation phrases, where c is a hyperparameter and the similarity is calculated with cosine similarity between the word embeddings of phrases and local names.

3.2 Path Ranking

We propose a novel ranking model to find the relation path most relevant to the given relation phrase. Different from those studies using path ranking algorithm for KG completion (Lao et al., 2011; Gardner et al., 2014; Mazumder and Liu, 2017; Das et al., 2018), which leverage the entities and relations in the KG for path reasoning, our path ranking model additionally considers the relation phrase in the question for ranking.

Relation path encoder. The relations in KG can provide rich information. Most existing RL methods mainly focus on the local names of KG relations, and leverage language models to capture the semantics. However, they ignore the structural information in massive triples. In order to make use of both information, we use this relation path encoder to model relation paths in the word embedding space, denoted by $R\_Encoder_{we}$, and the KG embedding space, denoted by $R\_Encoder_{kg}$.

$R\_Encoder_{we}$ consists of a BERT encoder (Devlin et al., 2019) and a feed-forward neural network (FFNN). For each relation path candidate $p = (r_1, \dots, r_m)$, the sequence of local names $input_p$ of p is denoted by $\langle [CLS], name_{r_1}, [SEP], \dots, name_{r_m}, [SEP] \rangle$, which is fed to the encoder to obtain the embedding $\mathbf{p}_{we} \in \mathbb{R}^{d_{we}}$:

$$\mathbf{p}_{we} = \sigma(\mathbf{W}_1 \mathrm{BERT}(input_p) + \mathbf{b}_1), \quad (1)$$

where $\sigma()$ is the ReLU activation, $\mathbf{W}_1$ is the weight matrix of FFNN, and $\mathbf{b}_1$ is the bias vector.

$R\_Encoder_{kg}$ uses a KG embedding model to encode the relations in KG. Considering that RotatE (Sun et al., 2019) has been proven to achieve good results in existing work (Huang et al., 2019), and have the properties of composition and symmetry of relations, we choose it as the KG embedding model. According to (Wang et al., 2017), KG embeddings have a certain ability for reasoning. Thus, the KG embedding of a relation path with d_{kg} dimension $\mathbf{p}_{kg} \in \mathbb{R}^{d_{kg}}$ can be obtained by merging all the KG embeddings of single relations within the path through composition operation:

$$\mathbf{p}_{kg} = \mathrm{ROTATE}(r_1) \circ \dots \circ \mathrm{ROTATE}(r_m), \quad (2)$$

where $\circ$ denotes the Hadamard product.

Phrase encoder. In order to compare with the relation paths in KG equally, the relation phrases

Algorithm 1 Relation Identification

```
Input: $Q$: Natural language question; $EC$: Result set of entity and class linking; $subj\_relations$: [subj, nsubj, nsubjpass, csubj, csubjpass, xsubj, poss, partmod]; $obj\_relations$: [obj, pobj, dobj, iobj];
Output: Related entities/classes and relation between them;
    Use dependency analysis to obtain an undirected tree $T$;
    for $ec_i$ in $EC$ do
        Combine nodes representing $ec_i$ in $T$ into one;
        Delete all the edges which are related to the combined node, update $T$;
    end for
    Build a new empty graph $G$, copy nodes in $T$ to $G$;
    for $t_i$ in $T$ do    ▷ $t_i$ stands for $(node_1, r, node_2)$
        if $r$ in $subj\_relations$ then
            Add an edge from node1 to $node_2$, weight is the number of entity/class between $node_1$ and $node_2$;
        else if $r$ in $obj\_relations$ then
            Add an edge from $node_2$ to $node_1$;
        else
            Add both edges mentioned above;
        end if
    end for
    Update distance between nodes with the Floyd shortest path algorithm;
    for $node_i, node_j$ in $G$ do
        if $distance(node_i, node_j) = 2$ and $node_i$, $node_j$ are both entities/classes then
            Use the BFS algorithm to obtain the relation $r$ between them, return $(node_i, r, node_j)$;
        end if
    end for
```

in NL questions also need to be encoded into two spaces to capture different aspects of information.

$P\_Encoder_{we}$ aims to encode the relation phrase s with its context in a question q into an embedding $\mathbf{s}_{we} \in \mathbb{R}^{d_{we}}$. It has the same architecture as $R\_Encoder_{we}$. The difference is that the input sequence is added with two special tokens $[S]$ and $[Q]$ to separate the relation phrase and its question context, i.e., $input_s = \langle [CLS], [S], s, [Q], q, [SEP] \rangle$:

$$\mathbf{s}_{we} = \sigma(\mathbf{W}_2 \text{BERT}(input_s) + \mathbf{b}_2), \tag{3}$$

where $\mathbf{W}_2$ and $\mathbf{b}_2$ are two learnable parameters.

$P\_Encoder_{kg}$ aims to encode the relation phrase and the question into a KG embedding $\mathbf{s}_{kg} \in \mathbb{R}^{d_{kg}}$. It first uses BERT to encode the whole $input_s$, and pick the embedding of $[CLS]$, which is then fed to a multi-layer perceptron $\text{MLP}_{we \to kg}$ with a 3-layer FFNN and ReLU activation to obtain $\mathbf{s}_{kg}$. In a question, a relation phrase s creates a connection between entities, and we expect the KG embedding $\mathbf{s}_{kg}$ to reflect the KG embedding of the relation path in KG connecting these entities, i.e., $\phi(\mathbf{e}_1, \mathbf{s}_{kg}, \mathbf{e}_2) \approx 0$, where ϕ denotes the score function of RotatE, and $\mathbf{e}_1, \mathbf{e}_2$ are the KG embeddings of two connected entities. This is equivalent to directly using the KG embedding of relation path between the two entities to train the model. Thus, during the training phase, we use the KG embedding of relation path $\mathbf{p}_{kg}$ corresponding to the relation phrase s to guide the learning of $\mathbf{s}_{kg}$, and the loss function is mean-square error loss:

$$\mathcal{L}_\alpha = \frac{1}{|\mathcal{D}|} \sum_{(s,q,p) \in \mathcal{D}} \|\mathbf{s}_{kg} - \mathbf{p}_{kg}\|_2^2, \tag{4}$$

where D is the training set, $\mathbf{s}_{kg}$ is the KG embedding of relation phrase s, $\mathbf{p}_{kg}$ is the KG embedding of relation path p, and $\| \cdot \|_2$ is the L_2-norm.

Knowledge injection. The previous works (Nakashole et al., 2012; Xue et al., 2020) pre-collect some paraphrase pairs (e.g., "be born in" is a paraphrase for relation *hometown*) between relation phrases in NL and KG relations through frequent item mining or crowdsourcing. These paraphrases can be considered as prior knowledge about the diverse meanings of NL. For example, if we have some prior examples of linking "in" to KG relations, e.g., *locatedIn*, we can use such knowledge to enhance the meanings of implicit relation phrases "in". In this paper, we choose a predicate paraphrase dictionary called Paraphrase (Xue et al., 2020) as the knowledge source. Paraphrase maps NL patterns to DBpedia relations, which currently covers 2,284 relations and 31,130 paraphrase pairs.

We regard the NL patterns in Paraphrase as *Keys*, and corresponding relations as *Values*. *Keys* provide textual knowledge from the perspective of NL, while *Values* provide both textual and structural knowledge of NL and KG. Same as the previous step, *Keys* is encoded as $\mathbf{K} \in \mathbb{R}^{d_e \times d_{we}}$ using BERT, *Values* is encoded as $\mathbf{V}_{we} \in \mathbb{R}^{d_e \times d_{we}}$ and $\mathbf{V}_{kg} \in \mathbb{R}^{d_e \times d_{kg}}$ using BERT and RotatE, respectively. Here, d_e denotes the number of most similar paraphrase pairs to be selected. In this way, given a relation phrase, which is then encoded by BERT as $\mathbf{Q} \in \mathbb{R}^{1\times d_{we}}$, we can use the attention mechanism (Vaswani et al., 2017) to find the most relevant NL patterns in Paraphrase and integrate their corresponding knowledge into the original embedding:

$$\mathbf{k}_{we} = \text{SOFTMAX}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_{we}}})\mathbf{V}_{we}, \tag{5}$$

$$\mathbf{k}_{kg} = \text{SOFTMAX}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_{kg}}})\mathbf{V}_{kg}. \tag{6}$$

We also explore a variety of ways to inject the knowledge into our model. Taking the fusion of $\mathbf{p}_{kg}$ and $\mathbf{k}_{kg}$ as an example, we use the following three methods:

- **Element-wise mean (MEAN)** is the most straightforward way to add two embeddings and take the average over each element:

$$\mathbf{y}_{kg} = \frac{1}{2}(\mathbf{s}_{kg} + \mathbf{k}_{kg}). \tag{7}$$

- **Concatenation (CAT).** By concatenating the two embeddings and feeding them to a linear layer, all the information can be reserved:

$$\mathbf{y}_{kg} = \mathbf{W}_3[\mathbf{s}_{kg}\,;\,\mathbf{k}_{kg}] + \mathbf{b}_3, \tag{8}$$

  where ; denotes the concatenation operation. $\mathbf{W}_3$ and $\mathbf{b}_3$ are two learnable parameters.

- **Gated mechanism (GATE).** To retain the valuable original information and absorb new knowledge, a gated mechanism can be used for a trade-off between them:

$$g = \delta(\mathbf{W}_4[\mathbf{s}_{kg}\,;\,\mathbf{k}_{kg}] + \mathbf{b}_4), \tag{9}$$

$$\mathbf{y}_{kg} = g\cdot\mathbf{s}_{kg} + (1-g)\cdot\mathbf{k}_{kg}, \tag{10}$$

  where $\delta()$ denotes the sigmoid activation. $\mathbf{W}_4$ and $\mathbf{b}_4$ are two learnable parameters.

Then, given two fused embeddings, $\mathbf{y}_{we}$ and $\mathbf{y}_{kg}$ of a relation phrase s in question q, and the embeddings of a relation path candidate p, $\mathbf{r}_{we}$ and $\mathbf{r}_{kg}$, the score function $\psi()$ can be formulated as

$$\psi(s,q,p) = [\mathbf{y}_{we}\,;\,\mathbf{y}_{kg}]\cdot[\mathbf{p}_{we}\,;\,\mathbf{p}_{kg}]. \tag{11}$$

We select the cross entropy loss between the one-hot vector of ground truth and the score vector:

$$\mathcal{L}_\beta = -\sum_{(s,q,p)\in\mathcal{D}} \log\frac{e^{\psi(s,q,p)}}{e^{\psi(s,q,p)} + \sum_{p'\in\mathcal{N}_p} e^{\psi(s,q,p')}}, \tag{12}$$

where $\mathcal{N}_p$ denotes the set of negative relation paths obtained by negative sampling based on p. The negative sampling is implemented by randomly sampling N relations or relation paths in KG which are different from p.

Finally, the overall loss function is defined as

$$\mathcal{L} = \mathcal{L}_\alpha + \lambda\mathcal{L}_\beta. \tag{13}$$

4 Experiments and Results

4.1 Dataset Construction

Due to the high correlation between RL and KBQA, we follow the works (Mihindukulasooriya et al., 2020; Naseem et al., 2021) to reuse the KBQA datasets as the benchmarks to evaluate the performance of RL. We briefly introduce them as follows:

- **LC-QuAD 1.0** (Trivedi et al., 2017) is a large complex questions dataset for KBQA, which contains 5,000 questions and corresponding SPARQL queries over DBpedia (version 2016-04). Only 1% of the questions involve implicit relation links.
- **QALD-9** (Usbeck et al., 2018) is a popular benchmark dataset for KBQA over DBpedia. It provides 408 training questions and 150 test questions, 6% of which need implicit RL.
- **Path-based SimpleQuestions dataset** (PathSQ) is a new dataset constructed by ourselves for implicit RL evaluation. It is based on DBpedia (version 2016-04) and contains 400 questions that need to be linked through a two-hop relation path. Table 1 lists an example, and we explain its construction details below.

Construction of PathSQ. Existing benchmarks contain few implicit relations and cannot be used to evaluate implicit RL well. As for other KBQA datasets, e.g., ComplexWebQuestions (Talmor and Berant, 2018), the proportion of implicit relations is also small. Thus, we decide to construct a new dataset by ourselves for implicit RL evaluation.

In SimpleQuestions (Bordes et al., 2015), some questions have corresponding single relations in Freebase but need to be expressed using multiple relations in DBpedia. Based on this observation, we collect the questions in SimpleQuestions that must map each relation phrase in NL to a relation path in DBpedia. We only consider two-hop relation paths, since paths with more relations are generally rare and spurious (Azmy et al., 2018). We construct PathSQ with the following three steps:

Question	What is Claire Stansfield's nationality?
Head entity	*dbr:Claire_Stansfield*
Relation phrase	nationality
Implicit relation	*dbo:birthPlace* → *dbo:country*
Answer	*dbr:United_Kingdom*

Table 1: An example in the PathSQ dataset.

(1) We remove the question and answer pair in SimpleQuestions such that the entity in the question or the answer entity cannot be mapped to DBpedia. We use the officially released file[2] to achieve this goal, which contains the entity mappings between Freebase and DBpedia. (2) For each remaining question and answer pair, we construct a SPARQL query to determine whether there exists a direct relation between the entity in the question and the answer entity. If exists, we remove this pair. (3) We construct another SPARQL query to obtain all the two-hop paths between the two entities for each remaining pair. Among all the paths, we manually label the correct ones and try our best effort to mine 400 questions for experiments.

4.2 Comparative Methods

We compare our ImRL with six state-of-the-art methods. All of them support RL over DBpedia.

- **SIBKB** (Singh et al., 2017) uses PATTY as the underlying knowledge source, and establishes a bipartite graph index from common phrases in NL to KG relations for RL.
- **Rematch** (Mulang et al., 2017) exploits WordNet and dependency parsing to model relation phrases with their underlying parts of speech, and uses various similarity metrics for ranking.
- **EARL** (Dubey et al., 2018) models the linking problem as the generalized traveling salesman problem, and uses connection density to link entities and relations jointly.
- **Falcon** (Sakor et al., 2019) enhances entity and relation linking through cross-KG entity and relation alignment and basic principles of English morphology.
- **SLING** (Mihindukulasooriya et al., 2020) leverages AMR for preprocessing, trains a Transformer-based model based on distant supervision, and integrates several complementary signals for RL.
- **SimReL** (Naseem et al., 2021) also uses AMR for question representation, and employs a Siamese network with BERT to link relations in an end-to-end manner.

4.3 Experiment Setup

We implement ImRL in Python 3. All experiments are conducted on a workstation with two Xeon Silver 4215R CPUs, 384GB memory and an NVIDIA TITAN RTX graphics card. We use the API of Falcon (Sakor et al., 2019) to link entities to DBpedia, and use StoG (Zhang et al., 2019) to generate AMR graphs in relation identification. For word embeddings, we use the pre-trained BERT-base model (Wolf et al., 2020) with $d_{we} = 768$ to initialize the parameters and freeze them in the experiments. For KG embeddings, we extract 200,000 popular entities and their related triples from DBpedia as the training corpus, and employ RotatE with $d_{kg} = 200$ for embedding learning.

As for the hyperparameters, the maximum number of relation path candidates is empirically set to $c = 30$, the maximum length of path candidates is set to $M = 2$, the number of negative sampling relations is set to $N = 29$, and the number of selected paraphrase pairs is set to $d_e = 10$. For all the experiments, we assign the learning rate to $3e^{-4}$ and the batch size to 256. The weight λ in loss function is set to 1. The previous works evaluate the performance of RL with precision, recall and F1-score. For consistency, we use the same metrics in our experiments. For LC-QuAD and QALD-9, we use the training set to train the model, and evaluate on the testing set. For PathSQ, due to the small scale, we treat all the dataset as the testing set, and use the training sets of LC-QuAD and QALD-9.

4.4 Main Results

Table 2 lists the results of all the methods. From the table, ImRL achieves the state-of-the-art results on LC-QuAD and QALD-9.

Take QALD-9 for example, 94% of the questions are with explicit single relations. For those questions, the F1-score of ImRL can reach 0.48, showing that even without a specific design for explicit RL, ImRL still performs well for it. The reason is that leveraging word embeddings and KG embeddings is common to both implicit and explicit relations. For explicit relations, since they usually contain a single relation, both $R\_Encoder$ and $P\_Encoder$ only need to encode one relation phrase or relation local name, which makes the matching of word embeddings easier. In addition,

	SimReL	0.51	0.51	0.51	0.46	0.44	0.45	0.39	0.19	0.26
	ImRL (ours)	**0.59**	0.49	**0.54**	**0.51**	0.46	**0.48**	**0.46**	**0.41**	**0.43**

Table 2: Relation linking performance comparison. We mark the best scores in **bold** and second-best underlined.

due to the use of KG embeddings and external knowledge of paraphrase dictionary as additional information, ImRL outperforms the latest method SimReL without the two information. However, since the path generation may cause correct relation paths missing in the candidate set, the recall of ImRL is lower than precision.

For the remaining 6% questions with implicit relations in QALD-9, the F1-score of our method can reach 0.47. In order to further verify the performance of ImRL on implicit relations, we conduct another experiment on PathSQ. As shown in Table 2, ImRL dominates in terms of all the three evaluation metrics, while the other methods obtain rather poor results. This is because all the questions in PathSQ need to be linked through implicit relation paths, which is challenging for the existing methods. By contrast, ImRL can achieve the reasoning of relation paths according to the composition property of KG embeddings, thereby effectively improving the accuracy of implicit RL.

Furthermore, ImRL can also handle unseen relations in the inference phase. Taking QALD-9 as an example, there are 46 questions in the testing set whose relations have never appeared in the training set. Still, ImRL can correctly predict 10 of them, which shows the generalization of ImRL.

4.5 Detailed Analysis

We conduct more experiments to validate the proposed method. All the following experiments are based on QALD-9 dataset.

Ablation study of embedding models. To measure the contribution of each embedding model in ImRL, we remove the module of obtaining KG embeddings and word embeddings in turn for ablation study. By removing the use of KG embeddings, the F1-score drops by 0.04, while by removing the use of word embeddings, it drops by 0.09. This shows that in our model, the word embeddings play a more important role than the KG embeddings. We believe that the root cause to the phenomenon is that pre-trained language models, e.g., BERT, are trained on huge corpora with several downstream tasks, thus the word embeddings can provide more prior knowledge. While the KG embedding model used by ImRL, i.e., RotatE, is trained on a small-scale corpus, and the obtained embeddings more focus on limited structural information, which leads to that the KG embeddings provide relatively less information than the word embeddings.

Methods	P↑	R↑	F1↑
ImRL	**0.51**	**0.46**	**0.48**
w/o KG embeddings	0.46	0.42	0.44
w/o word embeddings	0.42	0.37	0.39
w/o KG and word embeddings*	0.28	0.26	0.27

$*$ denotes using string matching without embeddings.

Table 3: Results of different embedding models.

Different knowledge injection methods. We explore three methods of injecting external knowledge from the paraphrase dictionary into ImRL, and compare them with the method without using the dictionary. The result is shown in Table 4. All methods with injection achieve better results than those without it, which verifies the effectiveness of knowledge injection. Among all the methods, ImRL with a gated mechanism achieves the best results. This shows that the knowledge in the dictionary may also bring noises, thus by combining part of the external knowledge and the original embeddings of the phrases, more accurate external knowledge can be supplemented to enhance the representations of implicit relation phrases. It should be mentioned that utilizing paraphrase dictionaries also has certain limitations. For instance, different dictionaries target different KGs, and may need to be adjusted according to the schema of the KG.

Methods	P↑	R↑	F1↑
ImRL (GATE)	**0.51**	**0.46**	**0.48**
ImRL (MEAN)	0.50	0.44	0.47
ImRL (CAT)	0.48	0.43	0.46
ImRL (None)	0.47	0.42	0.45

Table 4: Results of different injection methods.

Error propagation in pipeline. In order to reduce the impact of previous steps, and only evaluate the performance of the ranking model, we conduct an experiment assuming that the input to the Path Ranking module is the gold standard. That is, the correct relation path is always in relation path candidate set, which is the input of the Path Ranking module. Under this assumption, the F1-score of the model can reach 0.57, which shows that the aforementioned steps have a great impact on the model. Meanwhile, this also shows that the gap between the relations expressed in NL and those in KG is quite large. Even if lots of additional information is considered, it is still difficult to pick the most correct one from a set of relation path candidates, which reveals the challenge of RL task.

Improvement to KBQA performance. As a vital module of KBQA, it is necessary to integrate ImRL into some existing KBQA systems for validation. We conduct the experiment on the most popular KBQA dataset LC-QuAD (Trivedi et al., 2017). We choose gAnswer (Hu et al., 2018) as the baseline KBQA system, and replace its RL module with ImRL, which results in about 3.2% increase of F1-score, verifying that our method can indeed help the existing KBQA systems. As a reference, SimReL reports its F1-score improvement on LC-QuAD as 2.4% (Naseem et al., 2021). It is worth noting that the same process can also be migrated to other KGs, e.g., Freebase, for further use.

Case study. Table 5 shows two real examples to help understanding. In the first case from PathSQ, the relation phrase "involved in" needs to be expressed using the relation path *dbo:commander* → *dbo:militaryBranch* according to the gold standard. The state-of-the-art method SimReL returns *dbo:militaryBranch*, as it can only find the single relation whose meaning is most similar to the meaning of the whole question as the answer. Differently, ImRL leverages the path ranking model to find the path that best expresses the meaning of "army ... involved in". In the second case, there is no entity in this question of QALD-9, which causes that SimReL cannot enumerate any candidate relations since it depends on the result of entity linking. Although the method of generating candidates of ImRL is more robust, the absence of entities also has a great impact on it, making it give the wrong answer *dbo:origin*. Linking this relation requires understanding the meaning of the noun phrase, which is incapable for all existing RL methods including ImRL. We leave this in future work.

Case 1	What army was involved in Siege of Clonmel?
Gold	*dbo:commander* → *dbo:militaryBranch*
SimReL	*dbo:militaryBranch*
ImRL	*dbo:commander* → *dbo:militaryBranch*
Case 2	Give me all animals that are extinct.
Gold	*dbo:conservationStatus*
SimReL	*null*
ImRL	*dbo:origin*

Table 5: Case study of linking results.

5 Conclusion

In this paper, we propose ImRL, an implicit RL method that can better deal with the linking of implicit relations in NL and incomplete KG. We extend the RL task to implicit relation path linking, and propose a novel ranking model with knowledge injection. We evaluate our model on three datasets. The results show that our method achieves superior performance on LC-QuAD and QALD-9, where the relations are mostly explicit, and PathSQ, where the relations are all implicit, demonstrating that ImRL can not only deal with relation phrases that are not explicitly expressed in NL, but also perform relation path reasoning in KG. In future work, we will explore how to combine entity linking and implicit RL for improvement.

A Sensitivity Analysis of Candidate Path Number

In order to assess the sensitivity of ImRL to the number of candidate paths, we report the empirical analyses using different numbers of candidate paths c on QALD-9. The metrics are mean reciprocal rank (MRR), Hits@c and F1-score. MRR represents the multiplicative inverse of the rank of the gold path in the candidate path list. Hits@c indicates the proportion of the questions where the gold path ranks in the top-c in the candidate list. F1-score represents the performance of ImRL on QALD-9. As shown in Table 6, with the increase of c, MRR, Hits@c and F1-score all increase. However, when c reaches 30, the increment of c has little influence on the model performance. Thus, we choose to set $c = 30$.

Candidate path number c	MRR ↑	Hits@c ↑	F1 ↑
10	0.30	0.46	0.39
30	0.31	0.70	0.48
50	0.31	0.73	0.48

Table 6: Results of sensitivity analysis.

B Case Study of KBQA Results

By replacing the relation linking component in gAnswer (an open-source KBQA system) with ImRL, we conducted KBQA experiments over DBpedia. Compared with the original gAnswer, the overall F1-score increases by 3.2%. Figure 3 and Figure 4 show two interesting cases. In Figure 3, the relation linking module of gAnswer incorrectly links the relation in the question to *dbo:birthPlace*, which leads to the wrong SPARQL query and the wrong answer. In contrast, ImRL can correctly identify the relation *dbo:birthDate*, modify the SPARQL query and return the correct answer. The main reason is that ImRL can capture the context information "date" with the language model. In Figure 4, although ImRL does not recognize the same relation *dbo:foundedBy* as the gold SPARQL query, it recognizes *dbp:founder*, which is actually equivalent to *dbo:foundedBy*. Due to the organizational structure of DBpedia, namespaces *dbo* and *dbp* have different representations of the same relations. However, with the help of KG representation learning, the embeddings of the two kinds of relations can be learned to have similar meanings. Thus, ImRL can capture similar relationships between *dbo* and *dbp* through the KG embedding module, which also shows that ImRL can leverage the structural information in the KG.

C Detailed Analysis of PathSQ

Since the questions in PathSQ all need to be linked through a multi-hop relation path in DBpedia, we further conduct a visualization experiment on PathSQ to validate whether KG embedding can eliminate the influence of incomplete KGs. We use embeddings obtained through $R\_Encoder_{kg}$ as the input of Embedding Projector[3] to perform dimension reduction and obtain two-dimensional embeddings. Take the question "which european nation is Rudi Hedman from?" as an example, we enumerate the top-30 candidate relation paths of entity *dbr:Rudi_Hedman*. However, since entity *dbr:Rudi_Hedman* does not have relation *dbo:nationality* in DBpedia, the gold relation path *dbo:nationality* is missing in the candidate list. As the phrase "nation" should be linked to *dbo:nationality*, we compare these candidate relation paths with it. In the KG embedding space, through the visualization (see Figure 5), we find that the embedding of the relation path *dbo:birthPlace* → *dbo:location* (color: red) is most similar to that of the relation *dbo:nationality* (color: orange). It shows that ImRL achieves implicit RL by expressing missing relation *dbo:nationality* between the entities with relation path *dbo:birthPlace* → *dbo:location*.

Abstract

Attention mechanism has become the dominant module in natural language processing models. It is computationally intensive and depends on massive power-hungry multiplications. In this paper, we rethink variants of attention mechanism from the energy consumption aspects. After reaching the conclusion that the energy costs of several energy-friendly operations are far less than their multiplication counterparts, we build a novel attention model by replacing multiplications with either selective operations or additions. Empirical results on three machine translation tasks demonstrate that the proposed model, against the vanilla one, achieves competitable accuracy while saving 99% and 66% energy during alignment calculation and the whole attention procedure. Code is available at: https://github.com/NLP2CT/E-Att.

1 Introduction

Attention mechanism (ATT, Bahdanau et al., 2015; Vaswani et al., 2017; Yang et al., 2018) has demonstrated huge success in a variety of natural language processing tasks (Su et al., 2018; Kitaev and Klein, 2018; Tan et al., 2018; Yang et al., 2019a; Devlin et al., 2019; Zhang et al., 2020). The module learns hidden representations of a sequence by serving each word as a query to attend to all keys in the target sentence, then softly assembling their values. It is a de-facto standard to achieve this via performing linear projections and dot products on representations of queries and keys (Vaswani et al., 2017), resulting in large amount of multiplications. In spite of its promising quality, such kind of paradigm may be not the preferred solution from the energy consumption aspect (Horowitz, 2014; Raffel et al., 2020). How to build a high energy-efficient ATT still remains a great challenge.

Operation (FP32)	**ASIC**	**FPGA**
Addition	0.9	0.4
Multiplication	3.7	18.8

Table 1: Energy cost ($10^{-12} Joule$) of addition and multiplication on ASIC/FPGA chips (You et al., 2020). The representative of ASIC chip is Google's TPU, while Microsoft cloud employs FPGA chips.

Our work starts from in-depth investigations on approaches in ATT context with respect to model compression (Hinton et al., 2015; Jiao et al., 2020) and complexity optimization (Yang et al., 2019b; Raganato et al., 2020; Beltagy et al., 2020; Tay et al., 2021). These approaches can potentially alleviate the problem of high energy consumption in ATT. Nevertheless, intentions of all these methods are not exactly from the energy-friendly perspective, thus overlooking the origin of energy consumed, i.e., basic arithmetic operations in electric equipments. Massive multiplications still remain, consuming far more energy than its additive counterpart on modern devices (Table 1, Li et al., 2020).

To this end, we propose to approach this problem from a new direction – replacing massive multiplications in ATT with cheaper operations. Concretely, we propose a novel energy-efficient attention mechanism (E-ATT). It equips binarized selective operations instead of linear projections over input hidden states, and measures attentive scores using L_1 distance rather than dot-product. Consequently, E-ATT abandons most of multiplications to reach the goal of energy cost reduction.

We examine our method with TRANSFORMER model (Vaswani et al., 2017), and conduct experiments on three machine translation tasks. Compared with conventional ATT, our E-ATT can save more than 99% energy of the vanilla alignment calculation and around 66% energy of the whole

May 22-27, 2022

attention model. In the meanwhile, our models yield acceptable translation qualities across language pairs. Extensive analyses also demonstrate that E-ATT can functionally model semantic alignments without using multiplications.

2 Preliminary

Conventional Attention Mechanism Given input representations $\mathbf{X} \in \mathbb{R}^{l_1 \times d}$ and $\mathbf{Y} \in \mathbb{R}^{l_2 \times d}$ with l_1, l_2 being sequence length, and d is the input dimensionality. Note l_1 and l_2 may be equal for self-attention pattern, and represent lengths of target and source sequence in cross-attention. ATT first projects the inputs into three representations[1]:

$$\mathbf{Q} = \mathbf{X}\mathbf{W}_Q, \quad [\mathbf{K}; \mathbf{V}] = \mathbf{Y}[\mathbf{W}_K; \mathbf{W}_V], \tag{1}$$

where $\{\mathbf{W}_Q, \mathbf{W}_K, \mathbf{W}_V\} \in \mathbb{R}^{d \times d}$ are trainable parameters. $\mathbf{Q} \in \mathbb{R}^{l_1 \times d}$, $\{\mathbf{K}, \mathbf{V}\} \in \mathbb{R}^{l_2 \times d}$ are query, key and value representations, respectively. The attention alignment is calculated with dot-product multiplication and softmax activation:

$$\mathbf{M}_{ij} \propto \exp(\frac{\mathbf{Q}_i \mathbf{K}_j^\top}{\sqrt{d}}) \in \mathbb{R}^{l_1 \times l_2}. \tag{2}$$

Then, the output is derived by multiplying attention weights with value representation $\hat{\mathbf{V}}$:

$$\mathbf{O} = \mathbf{M}\mathbf{V} \in \mathbb{R}^{l_1 \times d}. \tag{3}$$

As seen, matrix multiplications are massively exploited into conventional ATT.

Related Work Several related approaches potentially alleviate the power-hungry drawback of ATT. One direction relies on model compression by pruning redundant parameters (Denton et al., 2014; Wang et al., 2016; Zhuang et al., 2018) or distilling the learned knowledge from a large model to a smaller one (Hinton et al., 2015; Yim et al., 2017), which still maintains multiplicative operations. Another direction aims at reducing the computational complexity of attention module, e.g. linearly projecting input (Dense, Tay et al., 2021), or randomly initializing and training attention weights (RandInit, Tay et al., 2021). To give a full comparison of energy consumption of these approaches, we conduct the number of multiplicative operations and energy costs across modules in Table 2. As seen, vanilla ATT (Vaswani et al., 2017) involves the most multiplicative operations, and requires the most energy than other methods. Although Dense and RandInit significantly reduce the energy consumption, Tay et al. (2021) point out that these approaches fail to be employed into cross-attention networks, since neither linear transition nor randomly initialized matrix is able to exactly model alignment information across languages.

Model	**Alignment**		**Attention**	
	# mul	$\Delta_A(\%)$	**# mul**	$\Delta_A(\%)$
Vanilla	$2ld^2 + l^2d$	100.00	$3ld^2 + 2l^2d$	100.00
Dense	$ld^2 + l^2d$	51.10	$2ld^2 + 2l^2d$	67.59
RandInit	0	0.00	$ld^2 + l^2d$	33.80
E-ATT	0	0.44	$ld^2 + l^2d$	34.10

Table 2: Calls of multiplication (mul) and energy consumption ratio on ASIC chip (Δ_A) of vanilla ATT, Dense, RandInit, and our model. “Alignment” and “Attention” indicate the statistics are conducted at the level of alignment calculation and the whole attention model, respectively. l and d are sequential length and model size. Please refer to Appendix A for more details.

3 Energy-Efficient Attention Mechanism

In this section, we describe E-ATT by pertinently reducing the multiplicative operations of ATT, including selective operation and L_1 distance.

3.1 Feature Selection with Discreteness

Since the linear transitions of queries and keys (Equation 1) involve massive multiplications within conventional ATT, we propose to modify them with binarized quantization (Liu et al., 2018; Qin et al., 2020). Concretely, the inputs $\mathbf{X}$ and $\mathbf{Y}$ are turned into discrete value with a threshold function $f(\cdot)$:

$$f(x) = \begin{cases} 1 & x > \tau, \\ 0 & \text{otherwise}, \end{cases} \tag{4}$$

where τ and d are threshold and hidden size, respectively. The derived representations $\tilde{\mathbf{X}} = f(\mathbf{X})$ and $\tilde{\mathbf{Y}} = f(\mathbf{Y})$ contain discrete features composing of zeros and ones. Since this procedure is undifferentiable, we need to predefine a pattern of gradient calculation for $\mathbf{X}$ when receiving back-propagated gradient $\mathbf{Z}$. Wu et al. (2018) pointed out that, when simulating the back-propagated progress across discrete activations, those patterns which peak at the medium of domain reveal better training stabilization and model performance. We thus use a modified Gaussian function during back-propagation

---

[1] For simplicity, we omit the bias in linear projections, as well as splits and concatenations in multi-head mechanism.

following Wu et al. (2018):

$$\nabla \mathbf{X} = \sqrt{\frac{2}{\pi}} e^{-2(\mathbf{Z}-\tau)^2}, \tag{5}$$

and the same procedure is applied for $\mathbf{Y}$. Then given parameters $\mathbf{W}_Q, \mathbf{W}_K \in \mathbb{R}^{d\times d}$, we derive query and key representations $\mathbf{Q}, \mathbf{K}$ by applying masked selection function:

$$\tilde{\mathbf{Q}} = g(\tilde{\mathbf{X}}, \tilde{\mathbf{W}_Q}) \in \mathbb{R}^{l_1\times d\times d}, \tag{6}$$

$$\tilde{\mathbf{K}} = g(\tilde{\mathbf{Y}}, \tilde{\mathbf{W}_K}) \in \mathbb{R}^{l_2\times d\times d}, \tag{7}$$

$$\mathbf{Q} = \sum_{i=1}^{d} \tilde{\mathbf{Q}}_{\cdot,i,\cdot}; \quad \mathbf{K} = \sum_{i=1}^{d} \tilde{\mathbf{K}}_{\cdot,i,\cdot}, \tag{8}$$

where $\tilde{\mathbf{W}_Q} \in \mathbb{R}^{l_1\times d\times d}$ and $\tilde{\mathbf{W}_K} \in \mathbb{R}^{l_2\times d\times d}$ are derived by tiling $\mathbf{W}_Q, \mathbf{W}_K$ with l_1 and l_2 times, respectively. $g(\cdot,\cdot)$ represents indexed feature selection defined as follows:

$$g(\mathbf{U}, \mathbf{P}) = \begin{cases} \mathbf{U}_{i,j,\cdot} & \mathbf{P}_{i,j} = 1, \\ \mathbf{0} & \text{otherwise.} \end{cases} \tag{9}$$

3.2 Pairwise L_1 Distance

As the dot-product multiplication can be viewed as similarity calculation between $\mathbf{Q}$ and $\mathbf{K}$, we argue that other similarity estimation methods can play this role as well. Accordingly, we further propose to use pairwise L_1 distance instead, which does not require any multiplication. Attention score calculation in Equation 2 is then modified as:

$$\mathbf{M}_{ij} \propto \exp(-\frac{||\mathbf{Q}_i - \mathbf{K}_j||_1}{\sqrt{d}}), \tag{10}$$

where $||\cdot||_1$ denotes the L_1 norm of inputted vector. Here we use negative L_1 value to ensure that larger distance contributes lower attention score.

4 Experiments

4.1 Dataset Preprocessing

In this paper we evaluate our approach with three widely used machine translation datasets: IWSLT'15 English -Vietnamese (En-Vi), WMT'14 English - German (En-De) and WMT'17 Chinese - English (Zh-En). All datasets are segmented into subwords by byte-pair encoding (BPE, Sennrich et al., 2016) with 32k merge operations. Specially, for the former two tasks, we apply joint BPE for both source and target languages.

Dataset	**Train**	**Dev**	**Test**
En-Vi	13.3K	1,553	1,268
En-De	4.50M	3,000	3,003
Zh-En	20.6M	2,002	2,001

Table 3: Dataset statistics. Each cell represents the number of examples. K: thousand, M: million.

4.2 Experimental Setting

We apply TRANSFORMER-*Base* (Vaswani et al., 2017) setting for all experiments. The model dimensionality is 512, and 6 layers are engaged in both encoder and decoder side. The inner-connection dimensionality for feedforward block is 2,048, and the number of heads in multi-head attention networks is 8. We share the source embedding, target embedding and target softmax projection weight for En-Vi task, and share the latter two matrices for En-De. We modify the learning rate schedule as: $lr = 0.001 \cdot \min\left(\frac{t}{8000}, 1, (\frac{20000}{t})^{0.5}\right)$, where t denotes the current step. Across all tasks, we determine the threshold τ as 1.0.

For both baseline and our model, En-Vi, En-De and Zh-En tasks take 50k, 150k and 200k updates, and each batch contains 4,096, 32,768 and 32,768 source tokens. The dropout ratio is determined as 0.3, 0.1 and 0.1, respectively. All experiments are conducted over 4 NVIDIA V100 GPUs. For each task, we choose the best model over dev set, defining beam size as 4, 4, 10 and decoding alpha as 1.5, 0.6 and 1.5, respectively.

4.3 Experimental Results

As shown in Table 4, vanilla model achieves best performance over all translation tasks. However, replacing conventional attention networks with E-ATT does not lead to significant performance drop, with small decrease of 0.15∼0.78 BLEU score. Besides, after referring the statistics from Table 1 and 2, our E-ATT module takes 34.10%/33.83% energy of conventional ATT. These results reveal that, E-ATT can achieve competitive translation quality, and more importantly, significantly reduce the energy consumption of attention.

4.4 Ablation Study

We further conduct ablation experiments on En-Vi task. As seen in Table 5, using discrete feature selection instead of linear transition slightly harms performance, with 0.61 BLEU score de-

Attention mechanism	En-Vi	En-De	Zh-En	ASIC (%)	FPGA (%)
Vanilla	30.26 ± 0.07	27.60 ± 0.04	24.28 ± 0.08	100.00	100.00
E-ATT	29.48 ± 0.08	27.45 ± 0.04	24.23 ± 0.06	**34.10**	**33.83**

Table 4: Averaged BLEU scores (%) upon test set on IWSLT'15 En-Vi, WMT'14 En-De and WMT'17 Zh-En tasks over 5 independent runs. E-ATT gives comparable results against conventional ATT, reducing the energy cost at 65.90%/66.17% on ASIC/FPGA chip in attention procedure. Since the energy cost is difficult to be empirically evaluated, we report the theoretical values following the common practice (Chen et al., 2020; You et al., 2020).

Model	BLEU (%)
Vanilla	**28.12**
Replace with discrete selection	27.51
Replace with L_1 distance	28.05
E-ATT	27.45

Table 5: Model performance with component replacements over En-Vi dev set. Using L_1 distance as similarity measurement dose not harm model performance.

-	Vanilla	Dense	RandInit	E-ATT
Vanilla	**28.12**	19.92	19.31	27.72
Dense	27.48	19.43	19.21	27.60
RandInit	27.36	18.98	18.83	27.48
E-ATT	28.08	19.85	19.67	27.45

Table 6: BLEU score (%) of different model hybrids with modifying self-attention (horizontal) and cross-attention (vertical) network upon En-Vi dev set. E-ATT can achieve good performance when applied as cross-attention modules, whereas Dense or RandInit can not.

crease. Besides, replacing dot-product attention with L_1 distance does not significantly affect model performance. We can conclude that: 1) the performance gap between E-ATT and vanilla model mainly stems from the usage of discrete feature selection; and 2) L_1 distance can measure the similarity of vectorized representations and give modest performance compared to baseline.

5 Analyses

5.1 Hybrid Attention Networks

We conduct a series of experiments involving hybrids of attention networks among vanilla ATT, Dense, RandInit, and E-ATT module in Table 6. As shown, the conventional attention network performs the best among all models. Our module performs well when served as either self-attention or cross-attention modules. Besides, for all cases applying Dense/RandInit as cross-attention modules, models perform significantly worse, identical with the findings in Tay et al. (2021). On the contrary, E-ATT module can give better performance with marginal performance drop comparing with baseline, indicating that E-ATT module is capable of providing adequate semantic alignments across languages for translation. Besides, it is encouraging to see that our method works compatibly with other modules with marginal performance drop.

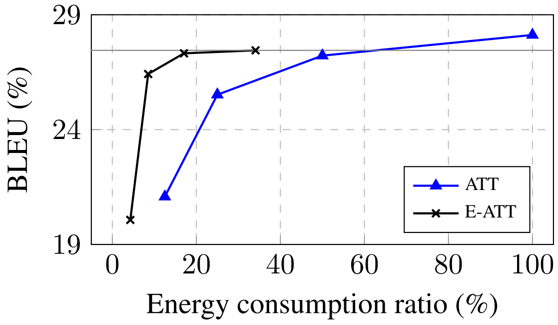

Figure 1: Performance and energy consumption of different models with knowledge distillation on En-Vi dev set. We regard the energy consumption of ATT baseline as 1, and accumulatively halve the dimensionality of model till untrainable (from 512 to 64). Energy consumption is estimated over ASIC. E-ATT requires far less energy to meet up the baseline performance.

5.2 Knowledge Distillation

Knowledge distillation is a representative of model compression approach (Hinton et al., 2015; Tang et al., 2019). We further conduct experiments on ATT models with various dimensionalities compressed by knowledge distillation. Figure 1 shows the energy consumption and performance of different models with modified dimensionality d. As seen, by accumulatively halving d from 512, both ATT and E-ATT progressively loses the quality. However, E-ATT can give a better trade-off between model performance and energy consumption than knowledge distillation methods.

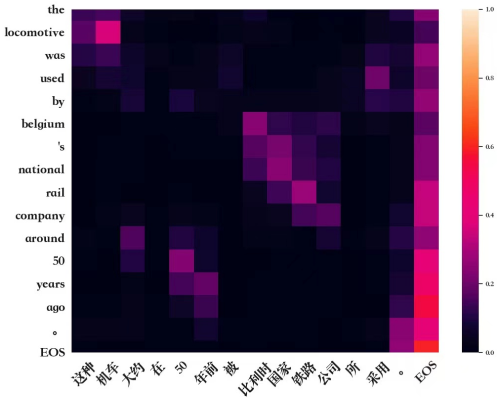

Figure 2: Case study from WMT'17 Zh-En dev set. E-ATT performs well on cross-lingual alignments.

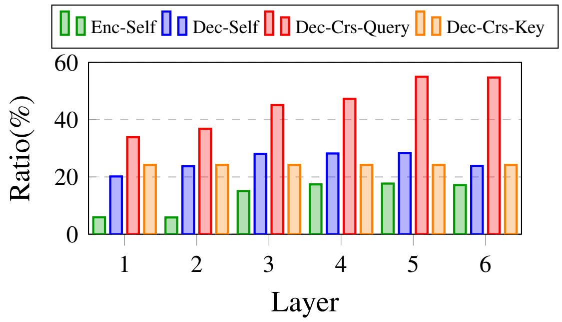

Figure 3: Ratio of nonzero values in the representations of E-ATT. Enc-Self: encoder self-attention ; Dec-Self: decoder self-attention; Dec-Crs-Query/Key: query/key representation for decoder cross-attention. Query representations in cross-attention are the most active.

5.3 Case Study

We visualize the averaged attention values over one case from WMT'17 Zh-En dev set. As seen, our model can give good aligned information, where preposition phrase "around 50 years ago" is arranged at the end of sentence in English, while its aligned phrase is at the front in Chinese. This reveals that, our E-ATT can perform well on modeling the cross-lingual alignments.

5.4 Binarization Statistics

We further collect the ratio of nonzero values ρ for each attention module in Figure 3, we can see that it increases with the number of encoder layers, denoting that more information is arranged into attentive calculation at higher layer of source side. However, for decoder E-ATT, the ratio meets its peak at middle layers, revealing that decoder E-ATT are most active at the middle term of semantic processing. Interestingly, ratio in the query of cross-attention modules, which align source and target semantics, is higher for the layer closer to output. As the binarized key representation of each cross-attention module is equivalent, higher ratio of nonzero values in query representation means that, E-ATT at higher decoder layer provides more information for cross-lingual alignments, thus enrich the information for translation.

6 Discussion and Conclusion

In this paper, we empirically investigate the high energy-consumption problem in ATT. We argue that the alignment modeling procedure can be achieved with additions other than multiplications, thus reducing the energy costs. Extensive analyses suggest that: 1) Binarized representations marginally harm the feature extraction procedure; and 2) L_1 distance can be efficiently exploited to measure alignment among queries and keys. Compared to baseline, our approach can yield considerable quality of translations, and significantly save energy in attention mechanism. Although we have shown the superiority of E-ATT, considering the whole TRANSFORMER block[2], the use of E-ATT brings 17% energy reduction. We hope this work can attract more researches on energy-efficient models. It is worth to further design techniques that reduce the energy cost of other modules in TRANSFORMER.

A Energy Ratio Calculation

We calculate the energy cost following the common practice (Chen et al., 2020; You et al., 2020). Note that, we follow suggestions in Song et al. (2021) to omit the energy calculation of activate functions, such as relu and softmax, because they are specially designed over some modern AI chips, which requires far less energy than additive operation.

For the common case where input $\mathbf{X} \in \mathbb{R}^{l_1 \times d}$ is projected into $\mathbf{Q} \in \mathbb{R}^{l_1 \times d}$ with $\mathbf{W} \in \mathbb{R}^{d \times d}$:

$$\mathbf{Q} = \mathbf{X}\mathbf{W}^\top + b, \tag{11}$$

the number of multiplicative operations is $l_1 \times d \times d + l_1 \times d = l_1 d^2 + l_1 d$. For the number of additive operations, it is also $l_1 d^2 + l_1 d$. Specially, if $d \gg 1$, we can omit the term $l_1 d$ for simplicity.

We calculate the energy cost from three levels: the alignment calculation which is used to measure the attention score, the whole attention model which is the core of our work, and the widely used TRANSFORMER (Vaswani et al., 2017) block, which contains a multi-head attention layer and a feedforward layer. We simply set the sequence length of inputs $\mathbf{X}$ and $\mathbf{Y}$ to l. Then:

Calculation Level	Δ_A	Δ_F
Alignment Calculation	0.45	0.05
Attention Model	34.09	33.83
TRANSFORMER Block	83.17	83.10

Table 7: Energy consumption ratio (%) at each calculation level on En-Vi translation task compared to conventional TRANSFORMER design.

Alignment Calculation Two linear prjections are arranged to obtain query and key representations, yielding $2ld^2$ additive/multiplicative operations. Both query and key representations are used to derive attention logits. In dot-product, the number of required multiplicative operations is $l \times d \times l = l^2 d$. The total numbers of additive/multiplicative operations are both $2ld^2 + l^2 d$.

Attention Model In order to obtain value representations, attention model requires ld^2 additive/multiplicative operations. Besides, applying weighted sum over value representations with attention weights requires $l^2 d$ multiplicative/additive operations. Overall, the numbers of multiplicative/additive operations in the whole attention model are $3ld^2 + 2l^2 d$.

TRANSFORMER Block Although representations in multi-head attention are splitted into h heads, in which dimension is d_h ($d = h \times d_h$), the number of multiplicative/additive operations is also $h \times l \times d_h \times l = l^2 h d_h = l^2 d$. There are one output linear transition for the output of multiple heads and two additional linear transitions in feedforward layer, resulting in $ld^2 + 4ld^2 + 4ld^2 = 9ld^2$ additional additive/multiplicative operations. The overall multiplication operations in a TRANSFORMER Block is $9ld^2 + 3ld^2 + 2l^2 d = 12ld^2 + 2l^2 d$.

Same as the steps above, we can calculate the required energy consumption of other modules. For example, considering our proposed E-ATT, the numbers of additive and multiplicative operations are $2ld + l^d$ and 0 in alignment calculation, $ld^2 + 2ld + 2l^2 d$ and $ld^2 + l^2 d$ in attention model, $10ld^2 + 2ld + 2l^2 d$ and $10ld^2 + l^2 d$ in TRANSFORMER block.

In this way, we can calculate the ratio of energy cost referring to the statistics in Table 1. For example, the ratio between E-ATT and conventional attention model on ASIC chip is:

$$\Delta_A = \frac{0.9(ld^2 + 2ld + 2l^2d) + 3.7(ld^2 + l^2d)}{0.9(3ld^2 + 2l^2d) + 3.7(3ld^2 + 2l^2d)} \quad (12)$$

Similarly, that on FPGA chip is:

$$\Delta_F = \frac{0.4(ld^2 + 2ld + 2l^2d) + 18.8(ld^2 + l^2d)}{0.4(3ld^2 + 2l^2d) + 18.8(3ld^2 + 2l^2d)} \quad (13)$$

For the IWSLT'15 En-Vi task, with d being 512, the averaged length of dataset is $\bar{l} = 22$. We can get the result Δ_A = 34.09%, Δ_F = 33.83%, thus the energy reduction ratio is $1 - \Delta_A$ = 65.91%, $1 - \Delta_F$ = 66.17%. Similarly, energy consumption ratios at the level of alignment calculation are 99.55% and 99.95%. Those of TRANSFORMER block are 83.17% and 83.10%, respectively.

Probing BERT's priors with serial reproduction chains

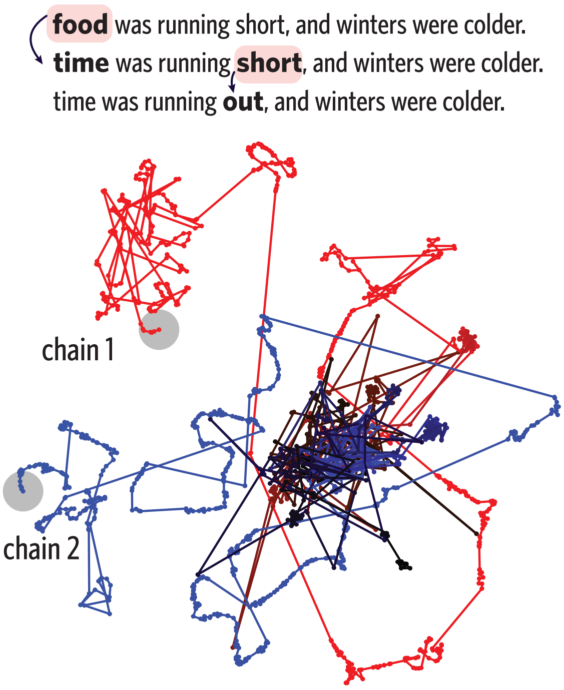
Abstract

Sampling is a promising bottom-up method for exposing what generative models have learned about language, but it remains unclear how to generate representative samples from popular masked language models (MLMs) like BERT. The MLM objective yields a dependency network with no guarantee of consistent conditional distributions, posing a problem for naive approaches. Drawing from theories of iterated learning in cognitive science, we explore the use of *serial reproduction chains* to sample from BERT's priors. In particular, we observe that a unique and consistent estimator of the ground-truth joint distribution is given by a Generative Stochastic Network (GSN) sampler, which randomly selects which token to mask and reconstruct on each step. We show that the lexical and syntactic statistics of sentences from GSN chains closely match the ground-truth corpus distribution and perform better than other methods in a large corpus of naturalness judgments. Our findings establish a firmer theoretical foundation for bottom-up probing and highlight richer deviations from human priors[1].



food was running short, and winters were colder.
time was running **short**, and winters were colder.
time was running **out**, and winters were colder.

Figure 1: We use a *serial reproduction* method to probe BERT's prior over possible sentences (visualization of reproduction chains obtained by running t-sne on sentence embeddings; chains are color-coded and fade to black across their burn-in period).

1 Introduction

Large neural language models have become the representational backbone of natural language processing. By learning to predict words from their context, these models have induced surprisingly human-like linguistic knowledge, from syntactic structure (Linzen and Baroni, 2021; Tenney et al., 2019; Warstadt et al., 2019) and subtle lexical biases (Hawkins et al., 2020) to more insidious social biases and stereotypes (Caliskan et al., 2017; Garg et al., 2018). At the same time, efforts to probe these models have revealed significant deviations from natural language (Braverman et al., 2020; Holtzman et al., 2019; Dasgupta et al., 2020). Observations of incoherent or "weird" behavior may often be amusing, as when a generated recipe begins with "1/4 pounds of bones or fresh bread" (Shane, 2019), but also pose significant dangers in real-world settings (Bender et al., 2021).

These deviations present a core theoretical and methodological puzzle for computational linguistics. How do we elicit and characterize the full *prior*[2] that a particular model has learned over possible sentences in a language? A dominant approach has been to design benchmark suites that

---

[1] Code and data are available at `https://github.com/taka-yamakoshi/TelephoneGame`

[2] We use the term *prior* to refer to graded linguistic knowledge assigning probabilities to all possible sentences. While we focus on text, this prior is also the foundation for more grounded, pragmatic language use.

Findings of the Association for Computational Linguistics: ACL 2022, pages 3977 - 3992
May 22-27, 2022

Type of unnaturalness		Example
word-level	morphological	Higher education school **xur** divided into six institutions.
phrase-level	syntactic	Swallowing hard, Verity stared **at the these**, desperately wanting to see if they congealed.
	semantic	The west section is a **fig octagon**.
		A private apartment with nothing but **hot cooled** water.
	predication	He already **costumes his relationship** with my mother carefully.
		Voices rapped on the **incremental door**.
sentence-level	out-of-context	Like a **cataract**, Horatius responds, "You are better than me."
	self-contradictory	The newspaper is published **weekly** and **biannually**.
	pragmatic	She grew up with **three sisters** and **ten sisters**.
		It should apply between **the extreme** and **the extreme**.

Table 1: Examples of sentences sampled from BERT's prior that received low naturalness ratings from our participants, including sources forms of unnaturalness like predicability or category errors (e.g. doors typically do not have the property of "incrementality"), semantic incoherence ("hot cooled water"), or contradictory constructions (especially for longer sentences). More examples can be found in table S2 and in the online supplement.

probe theoretically important aspects of the prior, and compare model behavior to human behavior on those tasks (e.g. Warstadt et al., 2020; Ettinger, 2020). Yet this approach can be restrictive and piecemeal: it is not clear ahead of time which tasks will be most diagnostic, and many sources of "weirdness" are not easily operationalized (Kuribayashi et al., 2021).

A more holistic, bottom-up alternative is to directly examine samples from the model's prior and compare them against those from human priors. However, many successful models do not explicitly expose this distribution, and many generation methods optimize the "best" sentences rather than theoretically meaningful or representative ones. For example, masked language models (MLMs) like BERT (Devlin et al., 2018) are *dependency networks* (Heckerman et al., 2000; Toutanova et al., 2003), trained to efficiently learn an independent collection of conditional distributions without enforcing consistency between them. In other words, these conditionals may not correspond to any coherent joint distribution at all, leading recent work to focus on other score-based sampling objectives (Goyal et al., 2021).

Here, we explore the use of serial reproduction chains (see Fig. 1) to overcome these challenges. While a naive (pseudo-)Gibbs sampler is indeed problematic for MLMs, the literature on Generative Stochastic Networks (GSNs; Bengio et al., 2014) has formally shown that a simple algorithmic variant we call *GSN sampling* produces a stationary distribution that is, in fact, a unique and consistent estimator of the ground-truth joint distribution. Furthermore, while the independent conditionals learned by dependency networks may be arbitrarily inconsistent in theory, empirical work has found that these deviations tend to be negligible in practice, especially on larger datasets (Heckerman et al., 2000; Neville and Jensen, 2007). Thus, we argue that it is both theoretically and empirically justified to take these samples as uniquely representative of the model's prior over language.

We begin in Section 2 by introducing the serial reproduction approach and clarifying the problem of re-constructing a joint distribution from a dependency network. We then validate that our chains are well-behaved (Section 3) and compare the statistics of samples from BERT's prior to the lexical and syntactic statistics of its ground-truth training corpus to measure distributional similarity (Section 4). Finally, in Section 5, we present a large-scale behavioral study eliciting naturalness judgments from human speakers and identify features of the generated sentences which most strongly predict human ratings of "weirdness" (see Table 1). We find that GSN samples closely approximate the ground-truth distribution and are judged to be more natural than other methods, while also revealing areas of improvement that have been difficult to quantify with top-down benchmarks.

2 Approach

2.1 Serial reproduction

Our approach is inspired by serial reproduction games like Telephone, where an initial message is

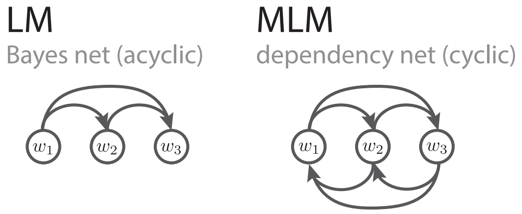


Figure 2: While autoregressive language models (LMs) are Bayes nets, masked language models (MLMs) are dependency networks with cyclic dependencies.

gradually relayed along a chain from one speaker to the next. At each step, the message is changed subtly as a result of noisy transmission and reconstruction, and the final version of the message often differs drastically from the first. This serial reproduction method, initially introduced to psychology by Bartlett (1932), has become an invaluable tool for revealing human *inductive biases* (Xu and Griffiths, 2010; Langlois et al., 2021; Sanborn et al., 2010; Harrison et al., 2020). Because reconstructing a noisy message is guided by the listener's prior expectations, such chains eventually converge to a stationary distribution that is equivalent to the population's prior, reflecting what people expect others to say (Kalish et al., 2007; Griffiths and Kalish, 2007; Beppu and Griffiths, 2009). For example, Meylan et al. (2021) recently evaluated the ability of neural language models to predict the changes made to sentences by human participants at each step of a serial reproduction chain. Thus, while serial reproduction is commonly used to probe *human* priors, and to compare models against human data, it is not yet in wide use for probing the models themselves.

2.2 BERT as a dependency network

There has been considerable confusion in the recent literature over how to interpret the MLM objective used to train models like BERT, and how to interpret samples from such models. Wang and Cho (2019) initially observed that BERT was a Markov Random Field (MRF) and proposed a Gibbs sampler that iteratively masks and reconstructs different sites k by sampling from the conditional given the tokens at all other sites $\hat{P}(w_k|w_{-k})$. As observed by Goyal et al. (2021), however, this procedure does not actually correspond to inference in the MRF. Unlike auto-regression language models (LMs) like GPT-3 (Brown et al., 2020), which define an acyclic dependency graph (or Bayes net) from left-to-right, MLMs have cyclic dependencies (see Fig. 2) and are therefore usefully interpreted as dependency networks rather than Bayes networks (Heckerman et al., 2000). Because dependency networks estimate independent conditionals, there is no guarantee that these conditionals are consistent (i.e. they may violate Bayes rule) and therefore do not represent a coherent joint distribution.

Still, it is possible to re-construct a joint distributions from these conditionals. For example, Heckerman et al. (2000) proved that if sites are visited in a fixed order, a (pseudo-)Gibbs chain similar to the one used by Wang and Cho (2019) does converge to a stationary distribution that is a well-formed joint. The problem is that different orders may yield different joint distributions, making it difficult to interpret any distributions as definitive. This ambiguity was resolved by the Generative Stochastic Network framework proposed by Bengio et al. (2014). Instead of visiting sites in a fixed order, a GSN sampler randomly chooses which site to visit at each step (with replacement), thus preserving aperiodicity and ergodicity. Specifically, this algorithm begins by initializing with a sequence $\{w_1^0, \ldots, w_n^0\}$. At each step t of the chain, we randomly choose a site $k \in 1, \ldots, n$ to mask out, and we sample a new value w_k^{t+1} from the conditional distribution $P(w_k|w_{-k}^t)$ with the other $n-1$ sites fixed.

A key theorem of Bengio et al. (2013, 2014) proves that the stationary distribution arising from the GSN sampler defines a unique joint distribution, and furthermore, this stationary distribution is a consistent estimator of the ground-truth joint distribution[3]. Importantly, this stationary distribution differs from the one given by the Metropolis-Hastings (MH) approach suggested by Goyal et al. (2021), which uses the GSN sampler as a *proposal* distribution but accepts or rejects proposals based on an energy-based pseudo-likelihood defined by the sum of the conditional scores at each location (Salazar et al., 2020). This MH sampler instead converges to an implicit stationary distribution defined by the energy objective[4].

---

[3] Technically, the proof only holds if the dependency network was trained using consistent estimators for the conditionals, which is the case for the cross-entropy loss used by BERT; see also McAllester (2019).

[4] Although our focus is on evaluation rather than algorithmic performance characteristics, we note that because GSN sampling does not require calculating energy scores to determine the acceptance probability for each sample, it is significantly faster, especially for longer sequences.

2.3 Mixture kernels

In practice, Markov chain sampling methods have many failure modes. Most prominently, because samples in the chains are not independent, it is challenging to guarantee convergence to a stationary distribution, and the chain is easily "stuck" in local regions of the sample space (Gelman et al., 1992). Typically, samples from a *burn-in* period (e.g. the first m epochs) are discarded to reduce dependence on the initial state, and a *lag* between samples (e.g. recording only every l epochs) is introduced to reduce auto-correlation. However, the problem is particularly severe for language models like BERT where there are strong mutual dependencies between words at different sites. For example, once the chain reaches a tri-gram like 'Papua New Guinea', it is unlikely to change any single word while keeping the other words constant. To ensure ergodicity, we use a mixture kernel introducing a small constant probability ($\epsilon = 0.001$) of returning to the initial distribution of `[MASK]` tokens on each epoch, allowing the chain to burn in again.

3 Validating the stationary distribution

In this section, we validate that the samples produced by our serial reproduction method are representative of the stationary prior distribution. More specifically, we consider two basic properties of the chain: *convergence* and *independence*. For these analyses, we consider samples from the pretrained `bert-base-uncased` model with 12 layers, 12 heads, and 110M parameters[5].

3.1 Convergence

We begin by checking the convergence time for chains generated by GSN sampling. Theoretical bounds derived for serial reproduction chains give a convergence time of $n \log n$, where n is the number of sites (see Rafferty et al., 2014). To check these convergence bounds in practice, we set $n = 21$ and select 20 sentences from Wikipedia to serve as initial states, and run 10 chains initialized at each sentence. We ensured that half of these sentences have high initial probability (under BERT's energy score) and half have low initial probability. We find that these distributions indeed begin to quickly mix in probability (see Figure S1). Because longer sentences may require a longer burn-in time, we conservatively set our burn-in window to $m = 1000$ epochs for our subsequent experiments.

3.2 Independence

Second, we want to roughly ensure independence of samples, so that the statistics of our distribution of samples isn't simply reflecting auto-correlation in the chain. For a worst-case analysis of a local minimum, suppose $P(w_i|w_{-i}) < \delta$ $(0 < \delta < 1)$ for all $i \in [1, \ldots, k]$, where k is the sentence length in tokens. Then the probability of re-sampling the same sentence is roughly $< \delta^{k \cdot n}$ after n epochs. We can solve for the number of epochs n we need to bound the probability of re-sampling the exact same sentence under ϵ for a given worst-case δ. For example, if $\delta = 0.99$ and we want to ensure that the probability of re-sampling the same sentence is below a threshold $\epsilon = 0.01$, then $n = 47$ epochs will likely suffice. Ensuring complete turnover in the worst case scenario requires much longer lags, i.e. $[1 - (1 - \delta)^k]^n < \epsilon$.

To evaluate the extent to which these cases arise in practice, we examine auto-correlation rates on longer chains (50,000 epochs). We calculate correlations between the energy scores at each epoch as a proxy for the state: when the chain gets stuck re-sampling the same sentence, the same scores appear repeatedly. We find that auto-correlation is generally high, but our mixture kernel prevents the worst local minima for both the MH chain (Goyal et al., 2021) and our GSN chain (see Fig. S2), although we still found higher auto-correlation rates for the MH chain. To further examine these minima, we examined edit rates: the number of changes made to the sentence within an epoch. Without the mixture kernel, we observe long regions of consistently low edit rates (e.g. in some cases, 5000 epochs in a row of exactly the same sentence) which disappear under the mixture kernel (see Fig. S3).

Based on these observations, we set the lag to $l = 500$ epochs to maintain relatively high independence between samples.

4 Distributional comparisons

In this section, we examine the extent to which higher-order statistics of sentences from BERT's prior are well-calibrated to the data it was trained on. This kind of comparison provides a richer sense of what the model has learned or failed to learn than traditional scalar metrics like perplexity (Takahashi and Tanaka-Ishii, 2017; Meister and Cotterell, 2021; Takahashi and Tanaka-Ishii, 2019; Pillutla et al., 2021).

---

[5] https://huggingface.co/bert-base-uncased

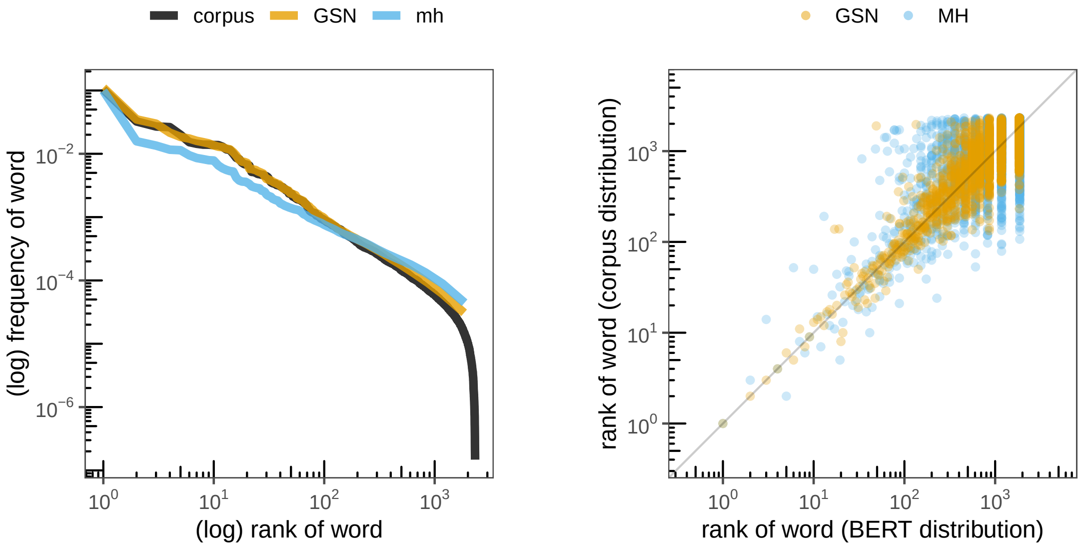

Figure 3: The lexical frequencies of our GSN samples (A) closely match the Zipfian distribution of the corpus and (B) closely correlate with the corresponding frequencies of the corpus distribution.

4.1 Corpus preparation

The version of BERT we analyzed in the previous section was trained on a combination of two corpora: *Wikipedia* and *BookCorpus*. In order to make valid comparisons between human priors and machine priors, we needed to closely match BERT-generated sentences with a comparable subset of human-generated sentences from these combined corpora. There are two technical challenges we must overcome to ensure comparable samples, concerning the *sentencizer* and *tokenizer* steps.

First, because our unit of comparison is the *sentence*, we needed to control for any artifacts that may be induced by how we determine what sentences are (e.g. if our Wikipedia sentences were systematically split on abbreviations, skewing the distribution toward fragments). We therefore applied the same `punkt` sentencizer to create our distribution of Wikipedia sentences and to check our BERT samples for cases where the generated sequence contained multiple sentences or ended with a colon or semicolon.

Second, we needed a tokenizer that equates sentence length. Because bi-directional models like BERT operate over sequences of fixed length, all samples drawn from a single chain have the same number of tokens.

Critically, however, BERT chains are defined over sequences of *WordPiece* tokens, so once these sequences are decoded back into natural language text, they may yield sentences of varying length, depending on how the sub-word elements are combined together[6] (see Fig. S5). We solve this alignment problem by using the *WordPiece* tokenizer to extract sentences of fixed sub-word token length from our text corpora, yielding equivalence classes of corpus sentences that are all tokenized to the same number of WordPiece tokens. We ran GSN and MH chains over sentences of $n = 11$ tokens, representing the modal lengths of sentences in BookCorpus (see Fig. S4). We obtained 5,000 independent sentences from each sampling method after applying our conservative burn-in and lag, and combined the Wikipedia and BookCorpus sentences together into a single corpus that is representative of BERT's training regime.

4.2 Lexical distributions

We begin by comparing the *lexical frequency* statistics of our samples from BERT against the ground-truth corpus statistics. First, we note that the relationship between rank and frequency of tokens in the GSN sampling matches the Zipfian distribution of its training corpus better than those produced by MH sampling (see Fig. 3A). However, it is possible to produce the same overall distribution without

---

[6] One additional complexity is that the mapping between WordPiece tokens and word tokens is non-injective. There exist multiple sequences of sub-word tokens that render to the same word (e.g. the WordPiece vocabulary contains a token for the full word 'missing' but it is also able to generate 'missing' by combining the sub-word tokens 'miss'+'#ing'). However, these cases are rare.

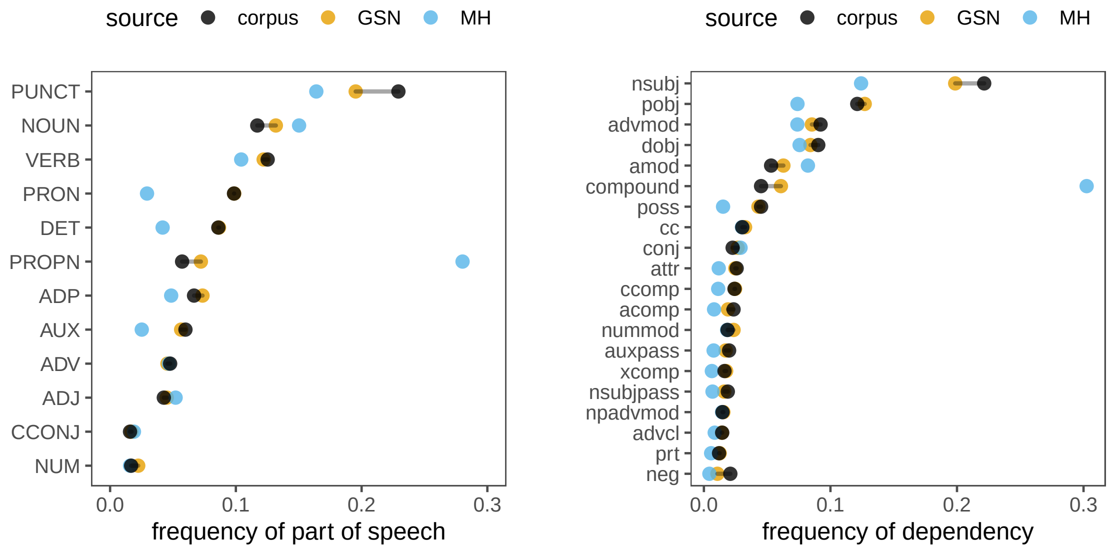

Figure 4: The relative frequencies of different parts of speech (left) and dependencies (right) in the ground-truth training corpora closely matched for GSN samples. In all cases, the GSN frequencies fell closer to the ground-truth than the MH frequencies.

matching the empirical frequencies of individual words. We next examined the respective ranks of each word across the two distributions. Overall, the word ranks in the GSN samples had a strong Spearman rank correlation of $r = 0.75$ with the word ranks in the ground-truth corpus; the MH samples had a significantly lower correlation of $r = 0.48$ (Pearson $z = 17, p < 0.001$, Fig 3B). Most disagreements lay in the tails where frequency estimates are particularly poor (e.g. many words only appeared once in our collection of samples). Indeed, among words with greater than 10 occurrences, the correlation improved to $r = 0.83$ for GSN and $r = 0.65$ for MH.

To understand this relationship further, we conducted an error analysis of lexical items which were systematically over- or under-produced by BERT relative to its training corpus. We found that certain punctuation tokens (e.g. parentheses) were over-represented in both the GSN samples and the MH samples, while contractions like *'s* and *'d* were under-represented. The MH samples specifically over-produced proper names such as *Nina* and *Jones*. Finally, due to the use of sub-word representations, we found a long tail of morphologically complex words that did not appear at all in the training corpus (e.g. names like Kyftenberg or Streckenstein and seemingly invented scientific terms like lymphoplasmic, neopomphorus, or pyranolamines).

4.3 Syntactic distributions

While the lexical distributions were overall well-matched for GSN samples, our error analysis suggested potential structure in the deviations. In other words, entire grammatical *constructions* may be over- or under-represented, not just particular words. To investigate these patterns, we used the `spacy` library to extract the parts of speech and dependency relations that are present within each sentence. We are then able to examine, in aggregate, whether certain classes of constructions are disproportionately responsible for deviations. Our findings are shown in Fig. 4. Overall, the distributions are close, but several areas of misalignment emerge. For parts of speech, we observe that the GSN sampler is slightly over-producing nouns (and proper nouns) while under-producing verbs and prepositions. We also observe that it is over-producing noun-related dependencies (e.g. compound nouns and appositional modifiers, which are noun phrases modifying other noun phrases, as in “Bill, my brother, visited town”). This pattern suggests that BERT's prior may be skewed toward (simpler) noun phrases while neglecting more complex constructions.

4.4 Sentence complexity

One hypothesis raised by comparing distributions of syntactic features is that BERT may be *regularizing* the complex structure of its input toward

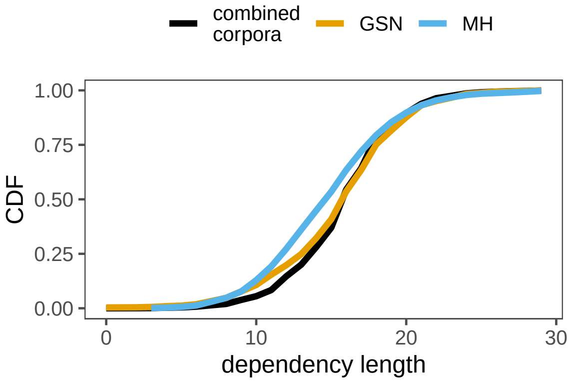

Figure 5: Cumulative probability distribution of dependency lengths across sentences from BERT chains and from the training corpus.

simpler constructions. To test this hypothesis, we operationalize syntactic complexity using a measure known as the average *dependency length* of a sentence (Futrell et al., 2015; Grodner and Gibson, 2005). This measure captures the (linear) distance between syntactically related words, which increases with more complex embedded phrase structures. We found that the distribution of dependency distances in the sentences produced by GSN sampling is overall more similar to those in its training corpus than the MH (Fig. 5), although closer analysis suggests it is still skewed slightly simpler (see Fig. S6).

5 Human judgments

Finally, while our corpus comparisons highlighted particular ways in which samples from BERT's prior were well-calibrated to the high-level statistics of its training distribution, it is unclear whether these agreements or deviations 'matter' in terms of naturalness. In this section, we elicit human naturalness judgments in order to provide a more holistic measure of potential 'weirdness' with BERT sentences.

5.1 Experimental methods

We recruited 1016 fluent English speakers on the Prolific platform and asked them to judge the naturalness of 4040 unique sentences from three length classes: short (11 tokens), medium (21 tokens), and long (37 tokens). 1675 of these sentences were from the stationary state of the different chains, 2339 were from the burn-in phase (i.e. < 1000 epochs), and the remainder were baseline sentences (149 from Wikipedia, 48 from a 5-gram model, and 42 from an LSTM model; see Appendix for details). Each participant was shown a sequence of 25 sentences in randomized order, balanced across different properties of the stimulus set[7]. On each trial, one of these sentences appeared with a slider ranging from 0 ("very weird") to 100 ("completely natural")[8]. After excluding 8 participants who failed the attention check (i.e. failed to rate a scrambled sentence below the midpoint of the scale and a human-generated sentence above the midpoint), we were left with an average of 7.3 responses per sentence.

5.2 Behavioral results

We begin by comparing the naturalness of sentences from the stationary GSN distribution to other baselines (see Fig. 6), using a linear regression model predicting trial-by-trial judgments as a function of categorical variables encoding sentence length (short, medium, long) and the source of the sentence (Wikipedia, GSN, MH, LSTM, or n-gram). First, we find that the naturalness of sentences from GSN declines by 14 points at longer sentence lengths, $p < 0.001$, while the naturalness of Wikipedia sentences is unaffected by length (interaction term, $p < 0.001$), consistent with results reported by Ippolito et al. (2020). Furthermore, among short sentences, where we included additional baselines, we find that GSN sentences tend to be rated as slightly less natural than sentences from Wikipedia (+10 points, $p < 0.001$) but more natural than those produced by an n-gram model (-52 points, $p < 0.001$), LSTM model (-25 points, $p < 0.001$); or MH sampling from the same BERT conditionals (-15 points, $p < 0.001$; see Table S1). MH samples also deteriorate significantly in naturalness for longer sentences compared to GSN samples ($p < 0.001$). Finally, we examine naturalness ratings across the the burn-in period, finding that ratings decline steadily across the board as the chain takes additional steps (linear term: $t(7297) = -12.4, p < 0.001$), suggesting gradual deviation away from the initial distribution of Wikipedia sentences toward the stationary distribution (shown as the green and grey regions, respectively, in Fig. S7).

---

[7] In a later batch, we increased the number of sentences per participant to 40. The task was approximately 10 minutes and participants were paid $2.50, for an average compensation rate of $15/hr.

[8] See Clark et al. (2021) for a discussion of the merits of phrasing the question in terms of naturalness instead of asking participants to judge whether it was produced by a human or machine.

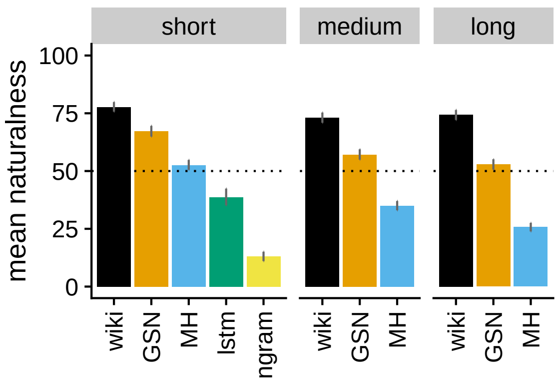

Figure 6: Empirical naturalness ratings elicited from the stationary GSN distribution, compared to different baselines at different sentence lengths. Error bars are bootstrapped 95% CIs.

5.3 Predicting naturalness

Given that sentences from the stationary GSN distribution are judged to be less natural than human-generated sentences overall, we are interested in explaining *why*. Which properties of these sentences make them sound strange? We approach this problem by training a regression model to predict human judgments from attributes of each sentence. We include all part of speech tag counts and dependency counts, as well as the sentence probability scored under BERT, and the sentence length. We use a cross-validated backwards feature selection procedure to select the most predictive set of these features for a linear regression (Kuhn and Johnson, 2013)[9].

The best-fitting model used 26 features and achieved an (adjusted) $R^2 = 0.21$. The only features associated with significantly *lower* ratings were the use of adpositions (e.g. *before*, *after*) and coordinating conjunctions. Importantly, we found that including a categorical variable of corpus (i.e. Wikipedia vs. GSN) significantly improved model fit even after controlling for all other features, $\chi^2(1) = 7135, p < 0.001$, suggesting that sources of "weirdness" are not being captured by typical statistics. We show some of these low-naturalness sentences in Table 1 and S2.

6 Discussion

6.1 Probing through generation

A core idea of our serial reproduction approach is to use generation as a window into a model's prior over language. While a variety of metrics and techniques have been proposed to quantify the "quality" of generation, especially in the domains of open-ended text generation and dialogue systems (Caccia et al., 2020; Li et al., 2020; Guidotti et al., 2018; Celikyilmaz et al., 2020), these metrics have typically been applied to compare specific generation algorithms and operationalize specific pitfalls, such as incoherence, excess repetition, or lack of diversity. Consequently, it has been difficult to disentangle the extent to which deviations resulting from generations are an artifact of specific decoding algorithms (e.g. greedy search vs. beam search) or run deeper, into the prior itself. For the purposes of probing, we suggest that it is important to ask not only how to generate the highest-scoring sentences but how to generate sentences that may be interpreted as representative of the model's prior, as formal results on GSNs have effectively provided.

6.2 GSN vs. energy-based objectives

We found that the prior distribution yielded by the GSN sampler more closely approximated the lexical and syntactic distributions of the ground-truth corpus and also sounded more "natural" to humans than the samples yielded by MH. These results are in contrast to findings by Goyal et al. (2021), showing that MH produced high-quality BLEU scores on a Machine Translation (MT) task compared to a degenerate (pseudo-)Gibbs sampler. There are several possible reasons for this discrepancy. One possibility may be task-specific: while we focused on unconditional generation, Goyal et al. (2021) focused on a neural machine translation (MT) task, where sentence generation was always conditioned on a high-quality source text and thus remained within a constrained region of sentence space. Another possibility is that we ran substantially longer chains (50,000 epochs compared to only 33 epochs) and the pitfalls of MH sampling only emerged later in the chain.

More broadly, our corpus comparisons and human evaluations suggest serious limitations of simple "quality" metrics like energy values. We found that the best-scoring states were often degenerate local minima with mutually supporting n-grams (such as repetitive phases and names like "Papua New Guinea"). Indeed, there was only a loose relationship between energy scores and participants' judgments in our study, with many poorer-scoring sentences judged to be more natural than better-scoring sentences (e.g. overall, the distribution

---

[9] Specifically, we used the `lmStepAIC` procedure implemented in the `caret` R package, with $k = 10$ folds.

of Wikipedia sentences tended to be much lower-scoring under the energy function despite being rated as more natural). We empirically validated that the stationary distribution of the GSN chain successfully approximates even higher-order statistics of the ground-truth corpus, suggesting that the raw conditionals of the dependency network may implicitly acquire the joint distribution, without requiring guarantees of consistency.

6.3 Other architectures

Serial reproduction methods are particularly useful for probing models that do not directly generate samples from their prior. For auto-regressive models like GPT-2, these samples are obtained more directly by running the model forward (and, indeed, ancestral sampling produces text that better balances the precision-recall tradeoff than other algorithms; Pillutla et al., 2021). While we focused on BERT, this method may be particularly useful for encoder-decoder architectures like BART (Lewis et al., 2020) which more closely resemble the human Telephone Game task, requiring full reconstruction of the entire sentence from noisy input rather than reconstruction of a single missing word. Indeed, these architectures may overcome an important limitation of serial reproduction with BERT: because these chains operate over a fixed sequence length, the resulting prior is not over all of language but only over sentences with the given number of WordPiece tokens. Finally, while we focused on unconditional generation, the GSN sampler also generalizes straightforwardly to conditional generation, where a subset of sites are fixed and the masked site is chosen from the remaining set.

6.4 Conclusions

Serial reproduction paradigms have been central for exposing human priors in the cognitive sciences. In this paper, we drew upon the theory of iterated learning and of Generative Stochastic Networks (GSNs) to expose the priors of large neural language models, which are often similarly inscrutable. We hope future work will consider other points of contact between these areas and draw more extensively from the theory developed to understand dependency networks. More broadly, as language models become increasingly adaptive and deployed in increasingly unconstrained settings, bottom-up probing has the potential to reveal a broader spectrum of "weirdness" than top-down evaluative benchmarks.

Appendix A: Baseline details

Wikipedia sentences were randomly selected from the full sentencized corpus English Wikipedia that tokenized to 12, 21, and 37 WordPiece tokens for the short, medium, and long conditions, respectively. These sentences were also chosen to span a broad range of sentence probabilities under BERT (i.e. $\log P(p_1, \ldots, p_n) = \sum_k \log P(p_k|p_{-k})$).

For our ngram baseline, we trained a 5-gram model with Kneser-Ney smoothing (Kneser and Ney, 1995) on English Wikipedia using the `kenlm` library (Heafield, 2011), and generated sentences of length 10 by sampling from the resulting conditional distributions. Because this model stripped punctuation, and was therefore unable to emit an "end of sentence" token, we expected it to serve as a lower bound on the naturalness scale.

For our LSTM baseline, we used the network pre-trained by Gulordava et al. (2018) on English Wikipedia. This model was trained to emit an end of sentence (`<eos>`) token, allowing us to rejection sample to obtain sentences that were exactly 10 words long with no unknown words (i.e. `<unk>` tokens). Because it was not trained with a `<start>` token, however, we needed to initialize it with the initial word of the sentence. We randomly selected this initial word from a small set of common sentence openers (e.g. `the`, `a`, `it`, `his`, `her`). As a result of our initial token selection, this model does not precisely sample from its true prior over sentences. Thus, it is best viewed as another baseline of sentences rather than as a careful architectural comparison.

Because we were asking participants to judge the naturalness of complete *sentences*, we did not want to include samples which clearly violated sentencehood, as these would not be informative (e.g. fragments from Wikipedia that were incorrectly sentencized and ended with an abbreviation, bibliographic text like "korsakov (1976) r.s.," or table markdown with pipes like "| a | b |"). We automatically removed any sentences containing pipes or ending with colons or semicolons, as these were associated with sentencizer inconsistency, as well as sequences that contained multiple sentences (according to our sentencizer). Finally, the authors took a manual pass to exclude other non-sentential fragments from the stimulus set.

Appendix B: Corpus details

We downloaded cleaned Wikipedia data provided by GluonNLP (https://github.com/dmlc/gluon-nlp/tree/master/scripts/datasets/pretrain_corpus), and BookCorpus data from HuggingFace Datasets (https://huggingface.co/datasets/bookcorpus).

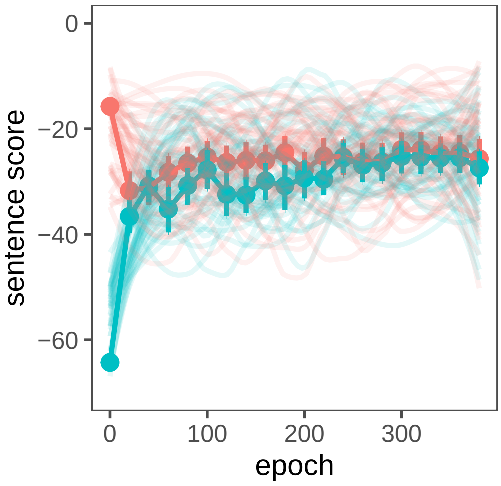

Figure S1: We examine the convergence time by initializing different chains at different classes of sentences (red is high probability under BERT's energy function, blue is low probability). Faint lines show smoothed trajectories for individual chains and error bars are bootstrapped 95% confidence intervals across chains.

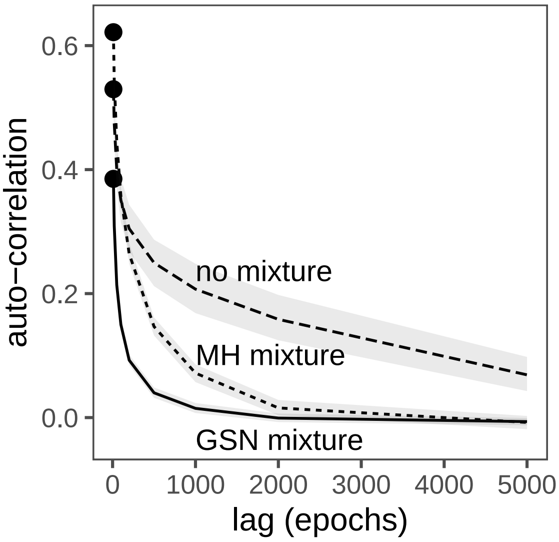

Figure S2: MCMC methods like GSN and MH sampling tend to get stuck in local regions with high autocorrelation. We find that a minimal autocorrelation is achievable with lower lag (500 epochs between samples) using a mixture kernel with a constant probability of resetting the chain. Error ribbons are 95% confidence intervals.

	term	estimate	std.error	statistic	p.value
1	(Intercept)	67.33	1.14	59.08	< 0.001
2	short vs. long (GSN)	-14.49	1.60	-9.08	< 0.001
3	short vs. medium (GSN)	-10.21	1.60	-6.39	< 0.001
5	GSN vs. LSTM (short)	-28.60	2.04	-14.05	< 0.001
6	GSN vs. MH (short)	-14.76	1.59	-9.26	< 0.001
7	GSN vs. ngram (short)	-54.26	2.00	-27.07	< 0.001
8	GSN vs. wiki (short)	10.40	1.70	6.13	< 0.001
13	interaction (short vs. long; GSN vs. MH)	-12.31	2.23	-5.51	< 0.001
14	interaction (short vs. medium; GSN vs. MH)	-7.33	2.23	-3.29	< 0.001
17	interaction (short vs. long; GSN vs. wiki)	11.22	2.39	4.70	< 0.001
18	interaction (short vs. medium; GSN vs. wiki)	5.56	2.37	2.35	0.02

Table S1: Fixed effect estimates for regression on human scores. Length class and source are dummy coded with short lengths and GSN as baselines.

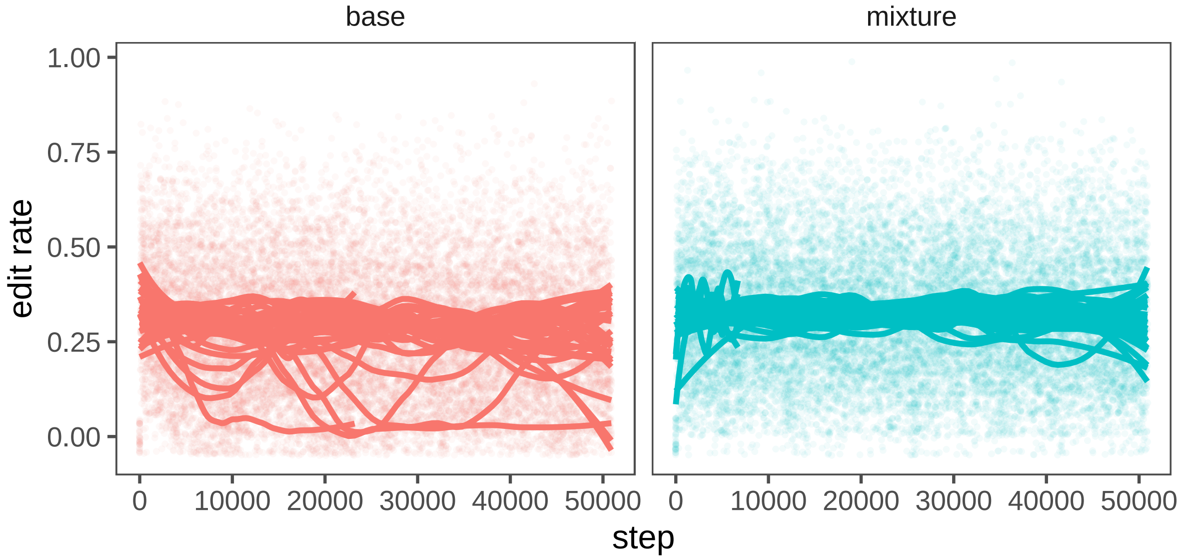

Figure S3: Without mixing in a constant probability of returning to the initial distribution, the GSN chain (and MH chain, not shown) goes through periods of stasis with low edit rates (red curves), contributing to high autocorrelations.

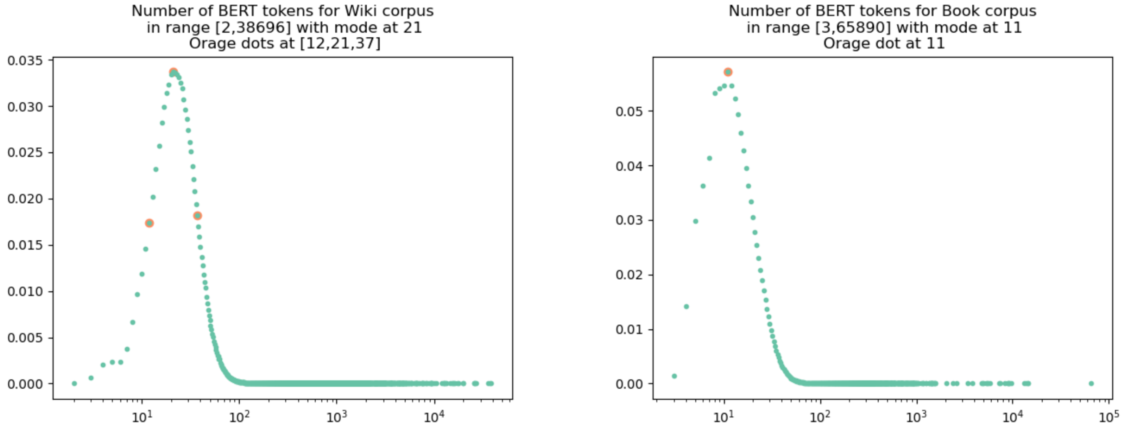

Figure S4: Empirical distribution of sentence lengths in Wikipedia and BookCorpus training corpora, after WordPiece tokenization. For our corpus comparisons, we selected the modal Wikipedia sentence length of 21 tokens and the modal BookCorpus length of 11 tokens. For our human judgment experiment, we included baseline sentences only from Wikipedia for shorter (12 tokens) and longer sentences (37 tokens), with roughly equal prevalence in the corpus (orange dots).

types of unnaturalness		examples
character-level		He preened on a レ drink of copper.
phrase-level	semantic	The little wattled songbird, also called the Chink Warbler, Orange Garver or Quickcumber is a **socially luscious** and habituated bird species.
sentence-level	construction	There were two hours before he **made the walk**.
	out-of-context word	No need to focus on **bicycling**.
	self-contradictory	The symbols $(\cdot\cdot\cdot)$ read as $(\cdot\cdot\cdot)$ and $(\cdot)$ are written as $(\cdot\cdot\cdot\cdot\cdot)$, not as $(\cdot)$.
	repetition	The college of arts and sciences, adjacent to the business school, is majoring in business.
		He saw Cronus and Cronus, Cronus and James Cronus he saw Cronus and Cronus and Cronus and Cronus Cronus when he saw Cronus.

Table S2: More examples of sentences from BERT's prior with low naturalness ratings.

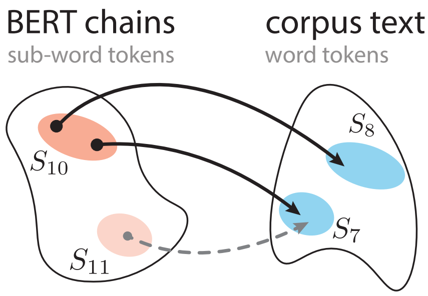

Figure S5: There is a misalignment between the space of sentences obtainable by a BERT chain of a fixed token length (in sub-word tokens) and natural language sentences of a fixed length (in words). We consider the distribution of corpus sentences that are obtainable from a fixed-length BERT chain, which may decode to different lengths in natural text (black arrows).

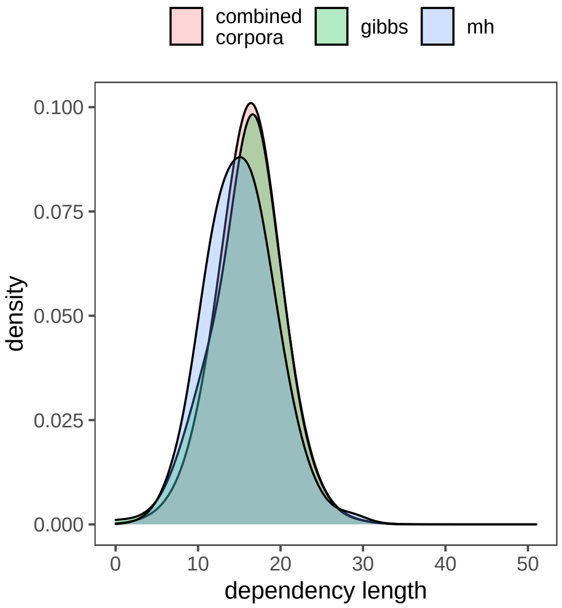

Figure S6: Dependency distances are similar for sentences sampled from BERT's prior and sentences from its training corpus, but the BERT distribution is more bimodal and tends to skew simpler.

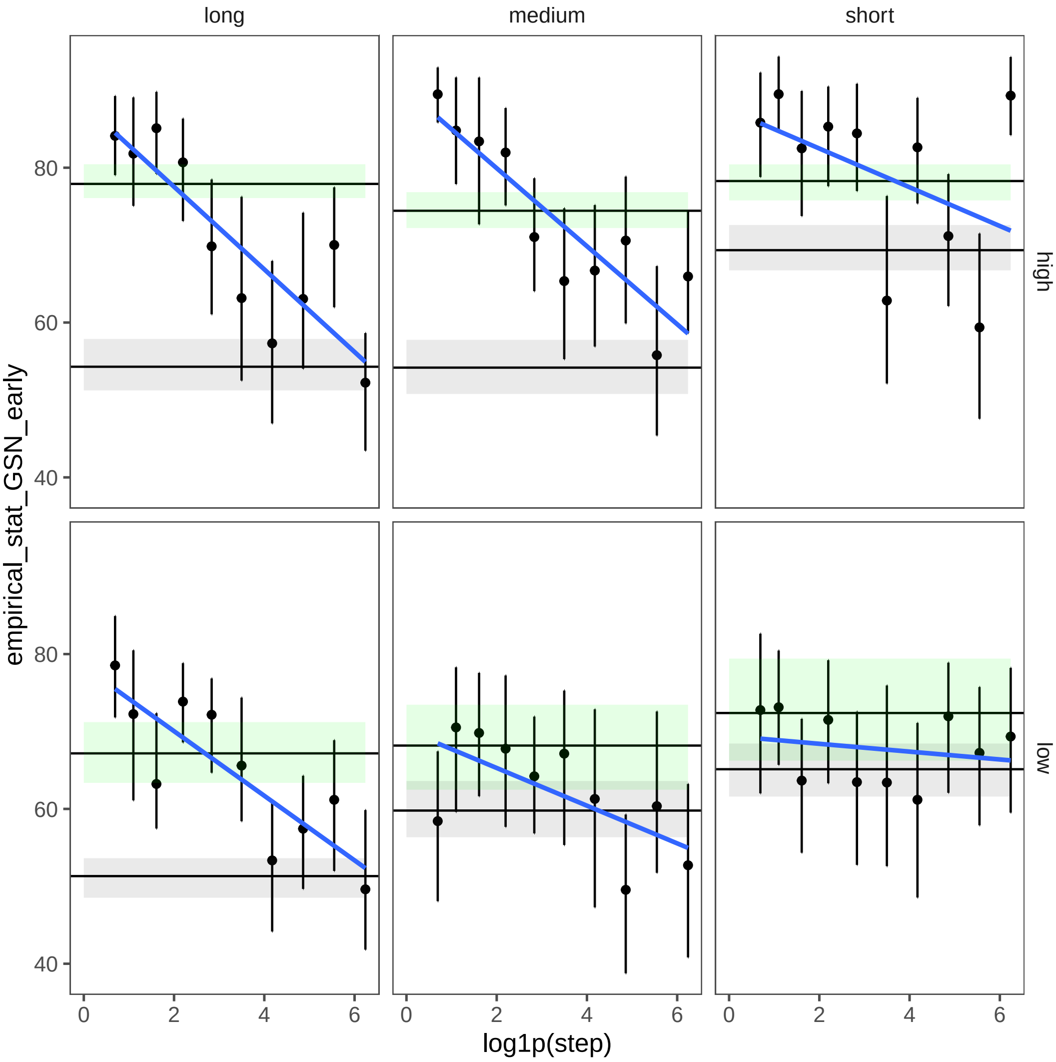

Figure S7: Sentences gradually drift away from the initial distribution across the burn-in period. Light green region represents the 95% confidence interval for the mean naturalness of Wikipedia sentences while grey region represents the same interval around the stationary distribution of the converged chain. Top row represents chains that are initialized at high-probability states, while bottom row is initialized in low-probability states.

Interpreting the Robustness of Neural NLP Models to Textual Perturbations

Abstract

Modern Natural Language Processing (NLP) models are known to be sensitive to input perturbations and their performance can decrease when applied to real-world, noisy data. However, it is still unclear why models are less robust to some perturbations than others. In this work, we test the hypothesis that the extent to which a model is affected by an unseen textual perturbation (robustness) can be explained by the learnability of the perturbation (defined as how well the model learns to identify the perturbation with a small amount of evidence). We further give a causal justification for the learnability metric. We conduct extensive experiments with four prominent NLP models — TextRNN, BERT, RoBERTa and XLNet — over eight types of textual perturbations on three datasets. We show that a model which is better at identifying a perturbation (higher learnability) becomes worse at ignoring such a perturbation at test time (lower robustness), providing empirical support for our hypothesis.

1 Introduction

Despite the success of deep neural models on many Natural Language Processing (NLP) tasks (Liu et al., 2016; Devlin et al., 2019; Liu et al., 2019b), recent work has discovered that these models are not robust to noisy input from the real world and thus their performance will decrease (Prabhakaran et al., 2019; Niu et al., 2020; Ribeiro et al., 2020; Moradi and Samwald, 2021). A reliable NLP system should not be easily fooled by slight noise in the text. Although a wide range of evaluation approaches for robust NLP models have been proposed (Ribeiro et al., 2020; Morris et al., 2020; Goel et al., 2021; Wang et al., 2021), few attempts have been made to *understand* these benchmark results. Given the difference of robustness between models and perturbations, it is a natural question why models are more sensitive to some perturbations than others. It is crucial to avoid over-sensitivity to input perturbations, and understanding why it happens is useful for revealing the weaknesses of current models and designing more robust training methods. To the best of our knowledge, a quantitative measure to *interpret* the robustness of NLP models to textual perturbations has yet to be proposed. To improve the robustness under perturbation, it is common practice to leverage data augmentation (Li and Specia, 2019; Min et al., 2020; Tan and Joty, 2021). Similarly, how much data augmentation through the perturbation improves model robustness varies between models and perturbations. In this work, we aim to investigate two Research Questions (RQ):

- **RQ1:** *Why are NLP models less robust to some perturbations than others?*
- **RQ2:** *Why does data augmentation work better at improving the model robustness to some perturbations than others?*

We test a hypothesis for RQ1 that the extent to which a model is affected by an unseen textual perturbation (robustness) can be explained by the learnability of the perturbation (defined as how well the model learns to identify the perturbation with a small amount of evidence). We also validate another hypothesis for RQ2 that the learnability metric is predictive of the improvement on robust performance brought by data augmentation along a perturbation. Our proposed learnability is inspired by the concepts of Randomized Controlled Trial (RCT) and Average Treatment Effect (ATE) from Causal Inference (Rubin, 1974; Holland, 1986). Estimation of perturbation learnability for a model consists of three steps: ① randomly labelling a dataset, ② perturbing examples of a particular pseudo class with probabilities, and ③ using ATE to measure the ease with which the model learns the perturbation. The core intuition for our method is to frame an RCT as a perturbation identification task and formalize the notion of learnability

Exp No.	Measurement	Label	Perturbation	Training Examples	Test Examples
0	Standard	original	$l \in \varnothing$	$(x_i, 0), (x_j, 1)$	$(x_i, 0), (x_j, 1)$
1	Robustness	original	$l \in \{0, 1\}$	$(x_i, 0), (x_j, 1)$	$(x_i^*, 0), (x_j^*, 1)$
2	Data Augmentation	original	$l \in \{0, 1\}$	$(x_i, 0), (x_j, 1)$ $(x_i^*, 0), (x_j^*, 1)$	$(x_i^*, 0), (x_j^*, 1)$
3	Learnability	random	$l' \in \{1'\}$	$(x_j, 0'), (x_i^*, 1')$	$(x_i^*, 1')$
4		random	$l' \in \{1'\}$	$(x_j, 0'), (x_i^*, 1')$	$(x_i, 1')$

Table 1: Example experiment settings for measuring learnability, robustness and improvement by data augmentation. We perturb an example if its label falls in the set of label(s) in "Perturbation" column. $\varnothing$ means no perturbation at all. Training/test examples are the expected input data, assuming we have only one negative $(x_i, 0)$ and positive $(x_j, 1)$ example in our original training/test set. l' is a random label and x^* is a perturbed example.

as a causal estimand based on ATE. We conduct extensive experiments on four neural NLP models with eight different perturbations across three datasets and find strong evidence for our two hypotheses. Combining these two findings, we further show that data augmentation is *only* more effective at improving robustness against perturbations that a model is more sensitive to, contributing to the interpretation of robustness and data augmentation. Learnability provides a clean setup for analysis of the model behaviour under perturbation, which contributes better model interpretation as well.

Contribution. This work provides an empirical explanation for why NLP models are less robust to some perturbations than others. The key to this question is perturbation learnability, which is grounded in the causality framework. We show a statistically significant inverse correlation between learnability and robustness.

2 Setup and Terminology

As a pilot study, we consider the task of binary text classification. The training set is denoted as $D_{train} = \{(x_1, l_1), ..., (x_n, l_n)\}$, where x_i is the i-th example and $l_i \in \{0, 1\}$ is the corresponding label. We fit a model $f : (x; \theta) \mapsto \{0, 1\}$ with parameters θ on the training data. A textual perturbation is a transformation $g : (x; \beta) \to x^*$ that injects a specific type of noise into an example x with parameters β and the resulting perturbed example is x^*. We design several experiment settings (Table 1) to answer our research questions. Experiment 0 in Table 1 is the standard learning setup, where we train and evaluate a model on the original dataset. Below we detail other experiment settings.

2.1 Definitions

Robustness. We apply the perturbations to test examples and measure the robustness of model to said perturbations as the decrease in accuracy. In Table 1, Experiment 1 is related to robustness measurement, where we train a model on unperturbed dataset and test it on perturbed examples. We denote the test accuracy of a model $f(\cdot)$ on examples perturbed by $g(\cdot)$ in Experiment 1 as $\mathcal{A}_1(f, g, D^*_{test})$. Similarly, the test accuracy in Experiment 0 is $\mathcal{A}_0(f, D_{test})$. Consequently, the robustness is calculated as the difference of test accuracies:

$$\begin{aligned} \text{robustness}(f, g, D) = \mathcal{A}_1(f, g, D^*_{test}) \\ -\mathcal{A}_0(f, D_{test}). \end{aligned} \tag{1}$$

Models usually suffer a performance drop when encountering perturbations, therefore the robustness is usually negative, where lower values indicate decreased robustness.

Improvement by Data Augmentation (Post Augmentation Δ). To improve robust accuracy (Tu et al., 2020) (i.e., accuracy on the perturbed test set), it is a common practice to leverage data augmentation (Li and Specia, 2019; Min et al., 2020; Tan and Joty, 2021). We simulate the data augmentation process by appending perturbed data to the training set (Experiment 2 of Table 1). We calculate the improvement on performance after data augmentation as the difference of test accuracies:

$$\begin{aligned} \Delta_{\text{post\_aug}}(f, g, D) = \mathcal{A}_2(f, g, D^*_{test}) \\ -\mathcal{A}_1(f, g, D^*_{test}). \end{aligned} \tag{2}$$

where $\mathcal{A}_2(f, g, D^*_{test})$ denotes the test accuracy of Experiment 2. $\Delta_{\text{post\_aug}}$ is the higher the better.

Learnability. We want to compare perturbations in terms of how well the model *learns* to identify them with a small amount of evidence. We cast learnability estimation as a perturbation classification task, where a model is trained to identify the perturbation in an example. We define that the learnability estimation consists of three steps, namely ① **assigning random labels**, ② **perturbing with probabilities**, and ③ **estimating model performance**. Below we introduce the procedure and intuition for each step. This estimation framework is further grounded in concepts from the causality literature in Section 3, which justifies our motivations. We summarize our estimation approach formally in Algorithm 1 (Appendix A).

① **Assigning Random Labels.** We randomly assign pseudo labels to each training example regardless of its original label. Each data point has equal probability of being assigned to positive ($l' = 1$) or negative ($l' = 0$) pseudo label. This results in a randomly labeled dataset $D'_{train} = \{(x_1; l'_1), ..., (x_n, l'_n)\}$, where $L' \sim Bernoulli(1, 0.5)$. In this way, we ensure that there is no difference between the two pseudo groups since the data are randomly split.

② **Perturbing with Probabilities.** We apply the perturbation $g(\cdot)$ to each training example in one of the pseudo groups (e.g., $l' = 1$ in Algorithm 1)[1]. In this way, we create a correlation between the existence of perturbation and label (i.e., the perturbation occurrence is predictive of the label). We control the perturbation probability $p \in [0, 1]$, i.e., an example has a specific probability p of being perturbed. This results in a perturbed training set $D'^{*}_{train} = \{(x^*_1, l'_1), ..., (x^*_n, l'_n)\}$, where the perturbed example x^*_i is:

$$
\begin{aligned}
&Z \sim U(0,1), \forall i \in \{1, 2, ..., n\} \\
&x^*_i = \begin{cases} g(x_i) & l'_i = 1 \wedge z < p, \\ x_i & \text{otherwise.} \end{cases}
\end{aligned}
\tag{3}
$$

Here Z is a random variable drawn from a uniform distribution $U(0, 1)$. Due to randomization in the formal step, now the only difference between the two pseudo groups is the occurrence of perturbation.

③ **Estimating Model Performance.** We train a model on the randomly labeled dataset with perturbed examples. Since the only difference between the two pseudo groups is the existence of the perturbation, the model is trained to identify the perturbation. The original test examples D_{test} are also assigned random labels and become D'_{test}. We perturb all of the test examples in one pseudo group (e.g., $l' = 1$, as in step 2.1) to produce a perturbed test set D'^{*}_{test}. Finally, the perturbation learnability is calculated as the difference of accuracies on D'^{*}_{test} and D'_{test}, which indicates how much the model learns from the perturbation's co-occurrence with pseudo label:

$$
\begin{aligned}
\text{learnability}(f, g, p, D) = \mathcal{A}_3(f, g, p, D'^{*}_{test}) \\
-\mathcal{A}_4(f, g, p, D'_{test}).
\end{aligned}
\tag{4}
$$

$\mathcal{A}_4(f, g, p, D'^{*}_{test})$ and $\mathcal{A}_3(f, g, p, D'_{test})$ are accuracies measured by Experiment 4 and 3 of Table 1, respectively.

We observe that the learnability depends on perturbation probability p. For each model–perturbation pair, we obtain multiple learnability estimates by varying the perturbation probability (Figure 3). However, we expect that learnability of the perturbation (as a concept) should be independent of perturbation probability. To this end, we use the $\log AUC$ (area under the curve in log scale) of the p – learnability curve (Figure 3), termed as "average learnability", which summarizes the overall learnability across different perturbation probabilities $p_1, ..., p_t$:

$$
\begin{aligned}
&\text{avg\_learnability}(f, g, D) \coloneqq \log AUC(\{(p_i, \\
&\text{learnability}(f, g, p_i, D)) \mid i \in \{1, 2, ..., t\}\}).
\end{aligned}
\tag{5}
$$

We use $\log AUC$ rather than AUC because we empirically find that the learnability varies substantially between perturbations when p is small, and a log scale can better capture this nuance. We also introduce learnability at a specific perturbation probability (Learnability @ p) as an alternate summary metric and provide a comparison of this metric against $\log AUC$ in Appendix D.

2.2 Hypothesis

With the above-defined terminologies, we propose hypotheses for RQ1 and RQ2 in Section 1, respectively.

Hypothesis 1 (H1): *A model for which a perturbation is more learnable is less robust against the same perturbation at the test time.*

---

[1] Because the training data is randomly split into two pseudo groups, applying perturbations to any one of the groups should yield same result. We assume that we always perturb into the first group ($l' = 1$) hereafter.

This is *not* obvious because the model encounters this perturbation during training in learnability estimation while they do not in robustness measurement.

Hypothesis 2 (H2): *A model for which a perturbation is more learnable experiences bigger robustness gains with data augmentation along such a perturbation.*

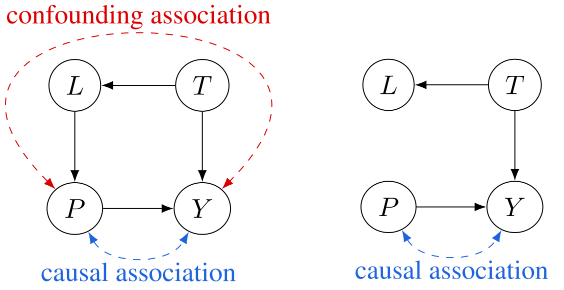
We validate both Hypotheses 1 and 2 with experiments on several perturbations and models described in Section 4.1 and 4.2.

3 A Causal View on Perturbation Learnability

In Section 2.1, we introduce the term "learnability" in an intuitive way. Now we map it to a formal, quantitative measure in standard statistical frameworks. Learnability is actually motivated by concepts from the causality literature. We provide a brief introduction to basic concepts of causal inference in Appendix B. In fact, learnability is the causal effect of perturbation on models, which is often difficult to measure due to the confounding latent features. In the language of causality, this is "correlation is not causation". Causality provides insight on how to fully decouple the effect of perturbation and other latent features. We introduce the causal motivations for step 2.1 and 2.1 of learnability estimation in the following Section 3.1 and 3.2, respectively.

3.1 A Causal Explanation for Random Label Assignment

Natural noise (simulated by perturbations in this work) usually co-occurs with latent features in an example. If we did not assign random labels and simply perturbed one of the *original* groups, there would be confounding latent features that would prevent us from estimating the causal effect of the perturbation. Figure 1a illustrates this scenario. Both perturbation P and latent feature T may affect the outcome Y,[2] while the latent feature is predictive of label L. Since we make the perturbation P on examples with the same label, P is decided by L. It therefore follows that T is a confounder of the effect of P on Y, resulting in non-causal association flowing along the path $P \leftarrow L \leftarrow T \rightarrow Y$. However, if we do randomize the labels, P no longer has any causal parents (i.e., incoming edges) (Figure 1b). This is because perturbation is purely random. Without the path represented by $P \leftarrow L$, all of the association that flows from P to Y is causal. As a result, we can directly calculate the causal effect from the observed outcomes.



(a) Before randomization. (b) After randomization.

Figure 1: Causal graph explanation for decoupling perturbation and latent feature with randomization. P is the perturbation and T is the latent feature. L is the original label and Y is the correctness of the predicted label.

3.2 Learnability is a Causal Estimand

We identify learnability as a causal estimand. In causality, the term "identification" refers to the process of moving from a causal estimand (Average Treatment Effect, ATE) to an equivalent statistical estimand. We show that the difference of accuracies on D'^{*}_{test} and D'_{test} is actually a causal estimand. We define the outcome Y of a test example x_i as the correctness of the predicted label:

$$Y_i(0) := \mathbf{1}_{\{f(x_i)=l'_i\}}. \tag{6}$$

where $\mathbf{1}_{\{\cdot\}}$ is the indicator function. Similarly, the outcome Y of a perturbed test example x_i^* is:

$$Y_i(1) := \mathbf{1}_{\{f(x_i^*)=l'_i\}}. \tag{7}$$

According to the definition of Individual Treatment Effect (ITE, see Equation 9 of Appendix B), we have $ITE_i = \mathbf{1}_{\{f(x_i^*)=l'_i\}} - \mathbf{1}_{\{f(x_i)=l'_i\}}$. We then take the average over all the perturbed test examples (half of the test set)[3]. This is our Average Treatment Effect (ATE):

$$\begin{aligned} ATE &= E[Y(1)] - E[Y(0)] \\ &= E[\mathbf{1}_{\{f(x^*)=l'\}}] - E[\mathbf{1}_{\{f(x)=l'\}}] \\ &= P(f(x^*)=l') - P(f(x)=l') \\ &= \mathcal{A}(f,g,p,D'^{*}_{test}) - \mathcal{A}(f,g,p,D'_{test}). \end{aligned} \tag{8}$$

---

[2] Y is later defined in Section 3.2

[3] The other half of the test set ($l' = 0$) is left unperturbed, following the same procedure in Section 2.1. Model predictions will not change for unperturbed ones, resulting in ITEs with zero values. Therefore, we do not take them into account for ATE calculation.

Perturbation	Example Sentence
None	His quiet and straightforward demeanor was rare then and would be today.
duplicate_punctuations	His quiet and straightforward demeanor was rare then and would be today..
butter_fingers_perturbation	His quiet and straightforward demeanor was rarw then and would be today.

visual_attack_letters	Hiṣ qủiẽt ȁnd strạightṭḟorwẳrɖ dɛmeanoŕ wâṣ rȧre tẖen and wouḷd þə tɵḏầȳ.
leet_letters	His qui3t and strai9htfor3ard d3m3an0r 3as rar3 t43n and 30uld 63 t0da4.

Figure 2: An example sentence with different types of perturbations.

where $\mathcal{A}(f, g, p, D)$ is the accuracy of model $f(\cdot)$ trained with perturbation $g(\cdot)$ at perturbation probability p on test set D. Therefore, we show that ATE is exactly the difference of accuracy on the perturbed and unperturbed test sets with random labels. And the difference is learnability according to Equation 4.

We discuss another means of identification of ATE in Appendix C, based on the prediction probability. We compare between the probability-based and accuracy-based metrics there. We find that our accuracy-based metric yields better resolution, so we report this metric in the main text of this paper.

4 Experiments

4.1 Perturbation methods

Criteria for Perturbations. We select various character-level and word-level perturbation methods in existing literature that simulate different types of noise an NLP model may encounter in real-world situations. These perturbations are non-adversarial, label-consistent, and can be automatically generated at scale. We note that our perturbations do not require access to the model internal structure. We also assume that the feature of perturbation does not exist in the original data. Not all perturbations in the existing literature are suitable for our task. For example, a perturbation that swaps gender words (i.e., female → male, male → female) is not suitable for our experiments since we cannot distinguish the perturbed text from an unperturbed one. In other words, the perturbation function $g(\cdot)$ should be *asymmetric*, such that $g(g(x)) \neq x$.

Figure 2 shows an example sentence with different perturbations. Perturbation of "duplicate_punctuation" doubles the punctuation by appending a duplicate after each punctuation, e.g., "," → ",,"; "butter_fingers_perturbation" misspells some words with noise erupting from keyboard typos; "shuffle_word" randomly changes the order of word in the text (Moradi and Samwald, 2021); "random_upper_transformation" randomly adds upper cased letters (Wei and Zou, 2019); "insert_abbreviation" implements a rule system that encodes word sequences associated with the replaced abbreviations; "whitespace_perturbation" randomly removes or adds whitespaces to text; "visual_attack_letters" replaces letters with visually similar, but different, letters (Eger et al., 2019); "leet_letters" replaces letters with leet, a common encoding used in gaming (Eger et al., 2019).

4.2 Experimental Settings

To test the learnability, robustness and improvement by data augmentation with different NLP models and perturbations, we experiment with four modern and representative neural NLP models: TextRNN (Liu et al., 2016), BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b) and XLNet (Yang et al., 2019). For TextRNN, we use the implementation by an open-source text classification toolkit NeuralClassifier (Liu et al., 2019a). For the other three pretrained models, we use the `bert-base-cased`, `roberta-base`, `xlnet-base-cased` versions from Hugging Face (Wolf et al., 2020), respectively. These two platforms support most of the common NLP models, thus facilitating extension studies of more models in future. We use three common binary text classification datasets — IMDB movie reviews (IMDB) (Pang and Lee, 2005), Yelp polarity reviews (YELP) (Zhang et al., 2015), Quora Question Pair (QQP) (Iyer et al., 2017) — as our testbeds. IMDB and YELP datasets present the task of sentiment analysis, where each sentence is labelled

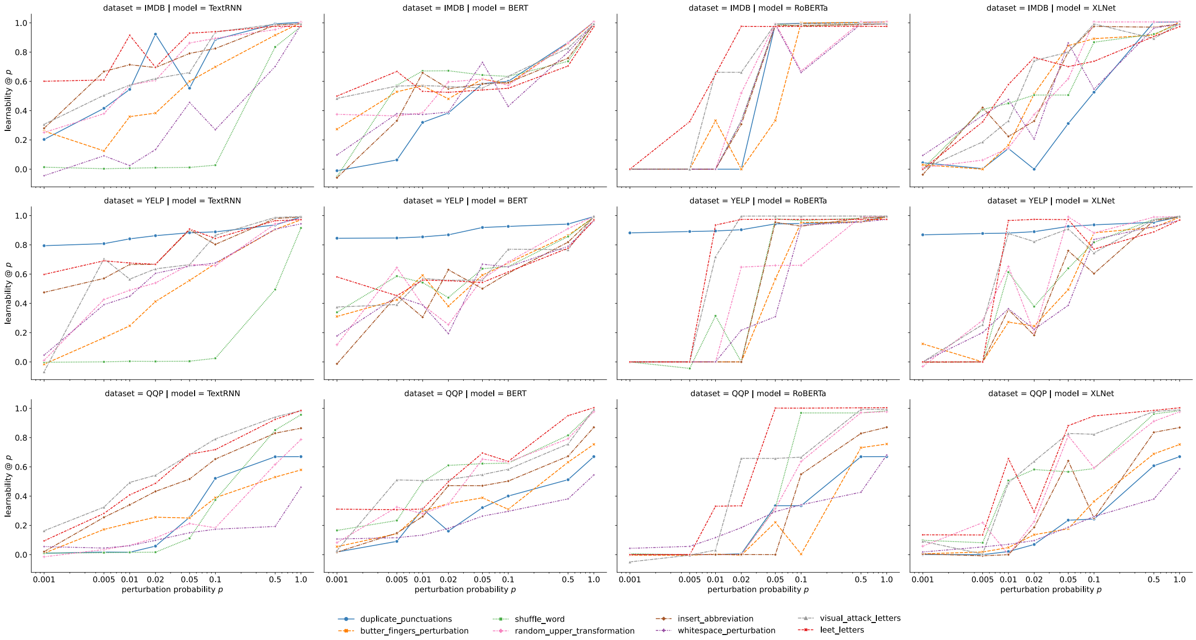

Figure 3: Learnability of eight perturbations for four NLP models on three datasets, as a function of perturbation probability.

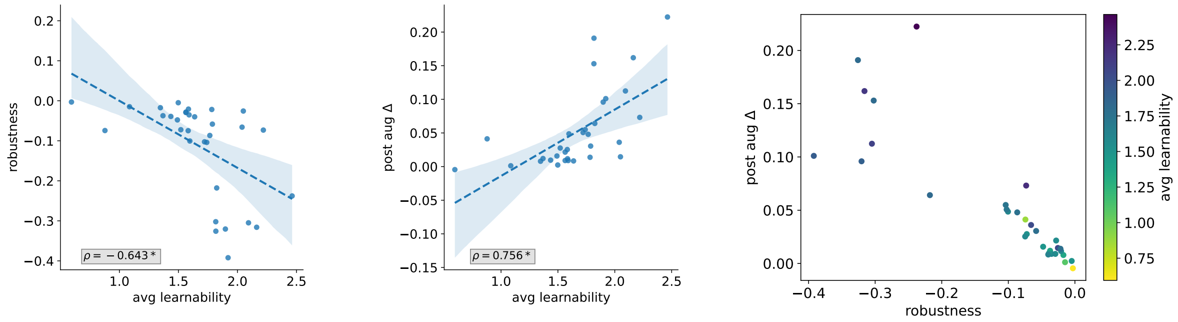
Perturbation	XLNet	RoBERTa	BERT	TextRNN	Average over models
whitespace_perturbation	1.638	1.436	1.492	0.878	1.361
shuffle_word	1.740	1.597	1.766	0.594	1.424
duplicate_punctuations	1.086	1.499	1.347	2.050	1.495
butter_fingers_perturbation	1.590	1.369	1.788	1.563	1.578
random_upper_transformation	1.583	1.520	1.721	2.039	1.716
insert_abbreviation	1.783	1.585	1.564	2.219	1.788
visual_attack_letters	**1.824**	1.921	**1.898**	2.094	1.934
leet_letters	1.816	**2.163**	1.817	**2.463**	**2.065**

Table 2: Average learnability (log AUC of corresponding curve in Figure 3) of each model–perturbation pair on IMDB dataset. Rows are sorted by average values over all models. The perturbation for which a model is most learnable is highlighted in **bold** while the following one is underlined.



(a) Learnability vs. Robustness

(b) Learnability vs. Post Aug Δ

(c) Learn. vs. Robu. vs. Post Aug Δ

Figure 4: Linear regression plots of learnability vs. robustness vs. post data augmentation Δ on **IMDB** dataset. Each point in the plots represents a model-perturbation pair. ρ is Spearman correlation. * indicates high significance (p-value < 0.001).

as positive or negative sentiment. QQP is a paraphrase detection task, where each pair of sentences is marked as semantically equivalent or not. To control the effect of dataset size and imbalanced classes, all datasets are randomly subsampled to the same size as IMDB (50k) with balanced classes. The training steps for all experiments are the same as well. We implement perturbations $g(\cdot)$ with two self-designed ones and six selected ones from the NL-Augmenter library (Dhole et al., 2021). For perturbation probabilities, we choose 0.001, 0.005, 0.01, 0.02, 0.05, 0.10, 0.50, 1.00. We run all experiments across three random seeds and report the average results.

4.3 Perturbation Learnability Analysis

Figure 3 shows learnability as a function of perturbation probability. Learnability @ p generally increases as we increase the perturbation probability, and when we perturb all the examples (i.e., $p = 1.0$), every model can easily identify it well, resulting in the maximum learnability of 1.0. This shows that neural NLP models master these perturbations eventually. At lower perturbation probabilities, some models still learn that perturbation alone predicts the label. In fact, the major difference between different p – learnability curves is the area of lower perturbation probabilities and this provides motivation for using $\log AUC$ instead of AUC as the summarization of learnability at different p (Section 2.1).

Table 2 shows the average learnability over all perturbation probabilities of each model–perturbation pair on IMDB dataset in Figure 3.[4] It reveals the most learnable perturbation for each model. For example, the learnability of "visual_attack_letters" and "leet_letters" are very high for all four models, likely due to their strong effects on the tokenization process (Salesky et al., 2021). Perturbations like "white_space_perturbation" and "duplicate_punctuations" are less learnable for pretrained models, probably because they have weaker effects on the subword level tokenization, or they may have encountered similar noise in the pretraining corpora. We observe that "duplicate_punctuations" already exists in the original text of YELP dataset (e.g., "*The burgers are awesome!!*"), thus violating our assumptions for perturbations in Section 4.1. As a result, the curve for this perturbation substantially deviates from others in Figure 3. We do not count this perturbation on YELP dataset in the following analysis. The perturbation learnability experiments provide a clean setup for NLP practitioners to analyze the effect of textual perturbations on models.

ρ	IMDB	YELP	QQP
Avg. learnability vs. robustness	-0.643*	-0.821*	-0.695*
Avg. learnability vs. post aug Δ	0.756*	0.846*	0.750*

Table 3: Correlations of average learnability vs. robustness vs. post data augmentation Δ. ρ is Spearman correlation. * indicates high significance (p-value < 0.001).

4.4 Empirical Findings

We observe a negative correlation between learnability (Equation 4) and robustness (Equation 1) across all three datasets in Table 2, validating Hypothesis 1. Table 2 also quantifies the trend that data augmentation with a perturbation the model is *less* robust to has *more* improvement on robustness (Hypothesis 2). We plot the correlations on IMDB dataset in Figure 4a and 4b.[5] Both the correlations between 1) learnability vs. robustness and 2) learnability vs. improvement by data augmentation are strong (Spearman $|\rho| > 0.6$) and highly significant (p-value < 0.001), which firmly supports our hypotheses. Our findings provide insight about when the model is less robust and when data augmentation works better for improving robustness.

Figure 4c shows that the more learnable a perturbation is for a model, the greater the likelihood that its robustness can be improved through data augmentation along this perturbation. We argue that this is not simply because there is more room for improvement by data augmentation. From a causal perspective, learnability acts as a common cause (confounder) for both robustness and improvement by data augmentation. This indicates a potential limitation of using data augmentation for improving robustness to perturbations (Jha et al., 2020): data augmentation is *only* more effective at improving robustness against perturbations more learnable for a model.

---

[4] Please refer to Appendix E for benchmark results on YELP (Table 5) and QQP (Table 6) datasets.

[5] For visualizations of correlations on the other two datasets, please refer to Figure 5 for YELP and Figure 6 for QQP in Appendix E.

5 Discussion

Potential Impacts. Our findings seem intuitive but are non-trivial. The NLP models were not trained on perturbed examples when measuring robustness, but still they display a strong correlation with perturbation learnability. Understanding these findings are important for a more principled evaluation of and control over NLP models (Lovering et al., 2020). Specifically, the learnability metric complements to the evaluation of newly designed perturbations by revealing model weaknesses in a clean setup. Reducing perturbation learnability is promising for improving robustness of models. Contrastive learning (Gao et al., 2021; Yan et al., 2021) that pulls the representations of the original and perturbed text together, makes it difficult for the model to identify the perturbation (reducing learnability) and thus may help improve robustness. Perturbation can also be viewed as injecting *spurious* feature into the examples, so the learnability metric also helps to interpret robustness to spurious correlation (Sagawa et al., 2020). Moreover, learnability may facilitate the development of model architectures with explicit inductive biases (Warstadt and Bowman, 2020; Lovering et al., 2020) to avoid sensitivity to noisy perturbations. Grounding the learnability within the causality framework inspires future researchers to incorporate the causal perspective into model design (Zhang et al., 2020), and make the model robust to different types of perturbations.

Limitations. In this work, we focus on the robust accuracy (Section 2.1), which is accuracy on the perturbed test set. We do not assume that the test accuracy of the original test set, a.k.a in-distribution accuracy, is invariant invariant against training with augmentation or not. It would be interesting to investigate the trade-off between robust accuracy and in-distribution accuracy in the future. We also note that this work has not established that the relationship between learnability and robustness is *causal*. This could be explored with other approaches in causal inference for deconfounding besides simulation on randomized control trial, such as working with real data but stratifying it (Frangakis and Rubin, 2002), to bring the learnability experiment closer to more naturalistic settings. Although we restrict to balanced, binary classification for simplicity in this pilot study, our framework can also be extended to imbalanced, multi-class classification. We are aware that computing average learnability is expensive for large models and datasets, which is further discussed in Section 8. We provide a greener solution in Appendix D. We could further verify our assumptions for perturbations with a user study (Moradi and Samwald, 2021) which investigates how understandable the perturbed texts are to humans.

6 Related Work

Robustness of NLP Models to Perturbations. The performance of NLP models can decrease when encountering noisy data in the real world. Recent works (Prabhakaran et al., 2019; Ribeiro et al., 2020; Niu et al., 2020; Moradi and Samwald, 2021) present comprehensive evaluations of the robustness of NLP models to different types of perturbations, including typos, changed entities, negation, etc. Their results reveal the phenomenon that NLP models can handle some specific types of perturbation more effectively than others. However, they do not go into a deeper analysis of the reason behind the difference of robustness between models and perturbations.

Interpretation of Data Augmentation. Although data augmentation has been widely used in CV (Sato et al., 2015; DeVries and Taylor, 2017; Dwibedi et al., 2017) and NLP (Wang and Yang, 2015; Kobayashi, 2018; Wei and Zou, 2019), the underlying mechanism of its effectiveness remains under-researched. Recent studies aim to quantify intuitions of how data augmentation improves model generalization. Gontijo-Lopes et al. (2020) introduce affinity and diversity, and find a correlation between the two metrics and augmentation performance in image classification. In NLP, Kashefi and Hwa (2020) propose a KL-divergence–based metric to predict augmentation performance. Our proposed learnability metric implies when data augmentation works better and thus acts as a complement to this line of research.

7 Conclusion

This work targets at an open question in NLP: why models are less robust to some textual perturbations than others? We find that learnability, which causally quantifies how well a model learns to identify a perturbation, is predictive of the model robustness to the perturbation. In future work, we will investigate whether these findings can generalize to other domains, including computer vision.

8 Ethics Statement

Computing average learnability requires training a model for multiple times at different perturbation probabilities, which can be computationally intensive if the sizes of the datasets and models are large. This can be a non-trivial problem for NLP practitioners with limited computational resources. We hope that our benchmark results of typical perturbations for NLP models work as a reference for potential users. Collaboratively sharing the results of such metrics on popular models and perturbations in public fora can also help reduce duplicate investigation and coordinate efforts across teams.

To alleviate the computational efficiency issue of average learnability estimation, using learnability at selected perturbation probabilities may help at the cost of reduced precision (Appendix D). We are not alone in facing this issue: two similar metrics for interpreting model inductive bias, *extractability* and *s-only error* (Lovering et al., 2020) also require training the model repeatedly over the whole dataset. Therefore, finding an efficient proxy for average learnability is promising for more practical use of learnability in model interpretation.

A Algorithm for Perturbation Learnability Estimation

Algorithm 1 Learnability Estimation

Input: training set $D_{train} = \{(x_1, l_1), ..., (x_n, l_n)\}$, test set $D_{test} = \{(x_{n+1}, l_{n+1}), ..., (x_{n+m}, l_{n+m})\}$, $D = D_{train} \cup D_{test}$, model $f : (x;\theta) \mapsto \{0,1\}$, perturbation $g : (x;\beta) \to x^*$, perturbation probability p

Output: learnability(f, g, p, D)

```
// ① assigning random labels
Initialize an empty dataset $D'$
for $i$ in $\{1, 2, ..., n+m\}$ do
    $l'_i \leftarrow randint[0,1]$
    $D' \leftarrow D' \cup \{(x_i, l'_i)\}$
end for
// ② perturbing with probabilities
Initialize an empty dataset $D'^*$
for $i$ in $\{1, 2, ..., n+m\}$ do
    $z \leftarrow rand(0,1)$
    $x^*_i \leftarrow x_i$
    if $l'_i = 1 \wedge z < p$ then
        $x^*_i \leftarrow g(x_i)$
    end if
    $D'^* \leftarrow D'^* \cup \{(x^*_i, l'_i)\}$
end for
// ③ estimating model performance
$D'_{train}, D'_{test} \leftarrow D'[1:n], D'[n+1:n+m]$
$D'^*_{train}, D'^*_{test} \leftarrow D'^*[1:n], D'^*[n+1:n+m]$

fit the model $f(\cdot)$ on $D'^*_{train}$
$\mathcal{A}(f, g, p, D'^*_{test}) \leftarrow f(\cdot)$ accuracy on $D'^*_{test}$
$\mathcal{A}(f, g, p, D'_{test}) \leftarrow f(\cdot)$ accuracy on $D'_{test}$
return $\mathcal{A}(f, g, p, D'^*_{test}) - \mathcal{A}(f, g, p, D'_{test})$
```

B Background on Causal Inference

The aim of causal inference is to investigate how a treatment T affects the outcome Y. Confounder X refers to a variable that influences both treatment T and outcome Y. For example, sleeping with shoes on (T) is strongly associated with waking up with a headache (Y), but they both have a common cause: drinking the night before (X) (Neal, 2020). In our work, we aim to study how a perturbation (treatment) affects the model's prediction (outcome). However, the latent features and other noise usually act as confounders.

Causality offers solutions for two questions: 1) how to eliminate the spurious association and isolate the treatment's causal effect; and 2) how varying T affects Y, given both variables are causally-related (Liu et al., 2021). We leverage both of these properties in our proposed method. Let us now introduce Randomized Controlled Trial and Average Treatment Effect as key concepts in answering the above two questions, respectively.

Randomized Controlled Trial (RCT). In an RCT, each participant is randomly assigned to either the treatment group or the non-treatment group. In this way, the only difference between the two groups is the treatment they receive. Randomized experiments ideally guarantee that there is no confounding factor, and thus any observed association is actually causal. We operationalize RCT as a perturbation classification task in Section 3.1.

Average Treatment Effect (ATE). In Section 3.2, we apply ATE (Holland, 1986) as a measure of learnability. ATE is based on Individual Treatment Effect (ITE, Equation 9), which is the difference of the outcome with and without treatment.

$$ITE_i = Y_i(1) - Y_i(0). \tag{9}$$

Here, $Y_i(1)$ is the outcome Y of individual i that receives treatment ($T = 1$), while $Y_i(0)$ is the opposite. In the above example, waking up with a headache ($Y = 1$) with shoes on ($T = 1$) means $Y_i(1) = 1$.

We calculate the Average Treatment Effect (ATE) by taking an average over ITEs:

$$ATE = E[Y(1)] - E[Y(0)]. \tag{10}$$

ATE quantifies how the outcome Y is expected to change if we modify the treatment T from 0 to 1. We provide specific definitions of ITE and ATE in Section 3.2.

C Alternate Definition of Perturbation Learnability

In Section 3.2, we propose an accuracy-based identification of ATE. Now we discuss another probability-based identification and compare between them. We can also define the outcome Y of a test example x_i as the predicted probability of (pseudo) true label given by the trained model $f(\cdot)$:

$$Y_i(0) \coloneqq P_f(L' = l'_i \mid X = x_i) \in (0,1). \tag{11}$$

Similarly, the performance outcome Y of a perturbed test data point x_i^* is:

$$Y_i(1) \coloneqq P_f(L' = l_i' \mid X = x_i^*) \in (0,1). \tag{12}$$

For example, for a test example (x_i, l_i') which receives treatment ($l_i' = 1$), the trained model $f(\cdot)$ predicts its label as 1 with only a small probability 0.1 before treatment (it has not been perturbed yet), and 0.9 after treatment. So the Individual Treatment Effect (ITE, see Equation 9) of this example is calculated as $ITE_i = Y_i(1) - Y_i(0) = 0.9 - 0.1 = 0.8$. We then take an average over all the perturbed test examples (half of the test set) as Average Treatment Effect (ATE, see Equation 10), which is exactly the learnability of a perturbation for a model. To clarify, the two operands in Equation 10 are defined as follows:

$$E[Y(1)] \coloneqq \mathcal{P}(f, g, p, D_{test}'^{*}). \tag{13}$$

It means the average predicted probability of (pseudo) true label given by the trained model $f(\cdot)$ on the perturbed test set $D_{test}'^{*}$.

$$E[Y(0)] \coloneqq \mathcal{P}(f, g, p, D_{test}'). \tag{14}$$

Similarly, this is the average predicted probability on the randomly labeled test set D_{test}'.

Notice that the accuracy-based definition of outcome Y (Equation 6) can also be written in a similar form to the probability-based one (Equation 11):

$$Y_i(0) \coloneqq \mathbf{1}_{\{f(x_i)=l_i'\}} = \mathbf{1}_{\{P_f(L'=l_i'|X=x_i)>0.5\}} \in \{0,1\}. \tag{15}$$

because the correctness of the prediction is equal to whether the predicted probability of true (pseudo) label exceeds a certain threshold (i.e., 0.5).

The major difference is that, accuracy-based ITE is a discrete variable falling in $\{-1, 0, 1\}$, while probability-based ITE is a continuous one ranging from -1 to 1. For example, if a model learns to identify a perturbation and thus changes its prediction from wrong (before perturbation) to correct (after perturbation), accuracy-based ITE will be $1 - 0 = 1$ while probability-based ITE will be less than 1. That is to say, accuracy-based ATE tends to vary more drastically than probability-based if inconsistent predictions occur more often, and thus can better capture the nuance of perturbation learnability. Empirically, we find that accuracy-based average learnability varies greatly ($\sigma = 0.375$, Table 4) and thus can better distinguish between different model-perturbation pairs than probability-based one ($\sigma = 0.288$, Table 4). As a result, we choose accuracy-based ATE as the primary measurement of learnability in this paper.

D Investigating Learnability at a Specific Perturbation Probability

Inspired by Precision @ K in Information Retrieval (IR), we propose a similar metric dubbed Learnability @ p, which is the learnability of a perturbation for a model at a specific perturbation probability p. We are primarily interested in whether a selected p can represent the learnability over different perturbation probabilities and correlates well with robustness and post data augmentation Δ.

We calculate the standard deviation (σ) of Learnability @ p and average learnability ($\log AUC$) over all model-perturbation pairs to measure how well it can distinguish between different models and perturbations. Table 4 shows that average learnability is more diversified than all Learnability @ p and diversity (σ) peaks at $p = 0.01$ for accuracy-based/probability-based measurement. Accuracy-based Learnability @ p is generally more diversified across models and perturbations than its counterpart. To investigate the strength of the correlations, we also calculate Spearman ρ between accuracy-based/probability-based learnability @ p vs. average learnability/robustness/post data augmentation Δ over all model-perturbation pairs. Table 4 shows that generally average learnability has stronger correlation than Learnability @ p. Correlations with both robustness and post data augmentation Δ peak at $p = 0.02$ for accuracy-based/probability-based measurements, and the correlations with average learnability (0.816*/0.886*) are also strong at these perturbation probabilities.

Overall, Learnability @ p with higher standard deviation correlates better with average learnability, robustness and post data augmentation Δ. Our analysis shows that if p is carefully selected by σ, Learnability @ p is also a promising metric, though not as accurate as average learnability. One advantage of Learnability @ p over average learnability is that it costs less time to obtain learnability at a single perturbation probability.

Abstract

Dense retrieval (DR) methods conduct text retrieval by first encoding texts in the embedding space and then matching them by nearest neighbor search. This requires strong locality properties from the representation space, e.g., close allocations of each small group of relevant texts, which are hard to generalize to domains without sufficient training data. In this paper, we aim to improve the generalization ability of DR models from source training domains with rich supervision signals to target domains without any relevance label, in the zero-shot setting. To achieve that, we propose Momentum adversarial Domain Invariant Representation learning (MoDIR), which introduces a momentum method to train a domain classifier that distinguishes source versus target domains, and then adversarially updates the DR encoder to learn domain invariant representations. Our experiments show that MoDIR robustly outperforms its baselines on 10+ ranking datasets collected in the BEIR benchmark in the zero-shot setup, with more than 10% relative gains on datasets with enough sensitivity for DR models' evaluation. Source code is available at `https://github.com/ji-xin/modir`.

1 Introduction

Rather than matching texts in the bag-of-words space, Dense Retrieval (DR) methods first encode texts into a dense embedding space (Lee et al., 2019; Karpukhin et al., 2020; Xiong et al., 2021) and then conduct text retrieval using efficient nearest neighbor search (Chen et al., 2018; Guo et al., 2020; Johnson et al., 2021). With pre-trained language models and dedicated fine-tuning techniques, the learned representation space has significantly advanced the first stage retrieval accuracy of many language systems, including web search (Xiong et al., 2021), grounded generation (Lewis et al., 2020), open domain question answering (Karpukhin et al., 2020; Izacard and Grave, 2020), etc.

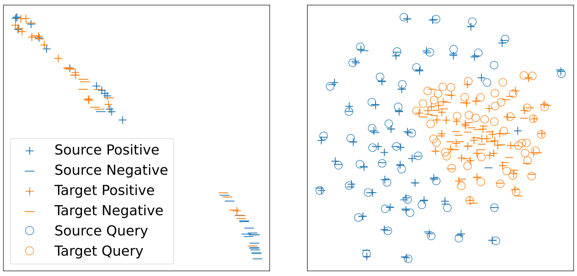

Figure 1: T-SNE plots of embedding space of a BERT reranker for q–d pairs (left) and ANCE dense retriever for queries/documents (right). Both models are trained on web search and transferred to medical search.

Purely using the learned embedding space for retrieval has raised concerns on the generalization ability, especially in scenarios without dedicated supervision signals. Many have observed diminishing advantages of DR models in various datasets if they are not fine-tuned with task-specific labels, i.e., in the zero-shot setup (Thakur et al., 2021). However, in many scenarios outside commercial web search, zero-shot is the norm. Obtaining training labels is difficult, expensive, and sometimes infeasible, especially in special domains (e.g., medical) where annotation requires strong expertise or is even prohibited because of privacy constraints. The lack of zero-shot ability hinders the democratization of advancements in dense retrieval from data-rich domains to everywhere else. Many equally, if not more important, real-world search scenarios still rely on unsupervised exact match methods that have been around for decades, e.g., BM25 (Robertson and Jones, 1976).

Within the search pipeline, the generalization of first stage DR models is notably worse than

---

Findings of the Association for Computational Linguistics: ACL 2022, pages 4008 - 4020
May 22-27, 2022

subsequent reranking models (Thakur et al., 2021). Reranking models, similar to many classification models, only require a decision boundary between relevant and irrelevant query–document pairs (q–d pairs) in the representation space. In comparison, DR needs good local alignments across the entire space to support nearest neighbor matching, which is much harder to learn.

In Figure 1, we use t-SNE (van der Maaten and Hinton, 2008) to illustrate this difference. We show learned representations of a BERT-based reranker (Nogueira and Cho, 2019) and a BERT-based dense retriever (Xiong et al., 2021), in zero-shot transfer from web (Bajaj et al., 2016) to medical domain (Voorhees et al., 2021). The representation space learned for reranking yields two manifolds with a clear decision boundary; data points in the target domain naturally cluster with their corresponding classes (relevant or irrelevant) from the source domain, leading to good generalization. In comparison, the representation space learned for DR is more scattered. Target domain data points are grouped separately from those of the source domain; it is much harder for the learned nearest neighbor locality to generalize from source to the isolated target domain region.

In this paper, we present **Mo**mentum Adversarial **D**omain **I**nvariant **R**epresentations learning (MoDIR), to improve the accuracy of zero-shot dense retrieval (ZeroDR). We first introduce an auxiliary domain classifier that is trained to discriminate source embeddings from target ones. Then the DR encoder is not only updated to encode queries and relevant documents together in the source domain, but also trained adversarially to confuse the domain classifier and to push for a more domain invariant embedding space. To ensure stable and efficient adversarial learning, we propose a *momentum* method that trains the domain classifier with a momentum queue of embeddings saved from previous iterations.

Our experiments evaluate the generalization ability of dense retrieval with MoDIR using 15 retrieval tasks from the BEIR benchmark (Thakur et al., 2021). On these retrieval tasks from various domains including biomedical, finance, scientific, etc., MoDIR improves the zero-shot accuracy of two standard models, DPR (Karpukhin et al., 2020) and ANCE (Xiong et al., 2021). On tasks where evaluation labels have sufficient coverage for DR (Thakur et al., 2021), MoDIR's improvements are robust and significant, despite not using any target domain training labels. We also verify the necessity of the proposed momentum approach, without which the domain classifier fails to capture the domain gaps, and the adversarial training does not learn domain invariant representations, resulting in little improvement in ZeroDR.

We conduct further analyses to reveal interesting properties of MoDIR and its learned embedding space. During the adversarial training process, the target domain embeddings are gradually pushed towards the source domain and eventually absorbed as a subgroup of the source. In the learned representation space, our manual examinations find various cases where a target domain query is located close to source queries with similar information needs. This indicates that ZeroDR's generalization ability comes from the combination of information overlaps of source/target domains, and MoDIR's ability to identify the right correspondence between them.

2 Related Work

In this section, we recap related work in dense retrieval and adversarial domain adaptation.

Dense Retrieval Different from sparse first stage retrieval models, dense retrieval with Transformer-based models (Vaswani et al., 2017) such as BERT (Devlin et al., 2019) conducts retrieval in the dense embedding space (Lee et al., 2019; Chang et al., 2020; Guu et al., 2020; Karpukhin et al., 2020; Luan et al., 2021). Compared with its sparse counterparts, DR improves retrieval efficiency and also provides comparable or even superior effectiveness for in-domain datasets.

One important research question for DR is how to obtain meaningful negative training instances. DPR (Karpukhin et al., 2020) uses BM25 to find stronger negatives in addition to in-batch random negatives. RocketQA (Qu et al., 2021) uses cross-batch negatives and also filters them with a strong reranking model. ANCE (Xiong et al., 2021) uses an asynchronously updated negative index built from the being-trained DR model to retrieve global hard negatives.

Recently, challenges of ZeroDR have attracted much attention (Thakur et al., 2021; Zhang et al., 2021; Li and Lin, 2021). One way to improve ZeroDR is query generation (Liang et al., 2020; Ma et al., 2021), which first trains a doc2query model in the source domain and then applies the NLG model on target domain documents to generate queries.

The target domain documents and generated queries form weak supervision labels for DR models. Our method differs from them and focuses on *directly* improving the generalization ability of the learned representation space.

Adversarial Domain Adaptation Unsupervised domain adaptation (UDA) has been studied extensively for computer vision applications. For example, maximum mean discrepancy (Long et al., 2013; Tzeng et al., 2014; Sun and Saenko, 2016) measures domain difference with a pre-defined metric and explicitly minimizes the difference. Following the advent of GAN (Goodfellow et al., 2014), adversarial training for UDA is proposed: an auxiliary domain classifier learns to discriminate source and target domains, while the main classifier model is adversarially trained to confuse the domain classifier (Ganin and Lempitsky, 2015; Bousmalis et al., 2016; Tzeng et al., 2017; Luo et al., 2017; Vu et al., 2020; Vernikos et al., 2020; Tang and Jia, 2020). The adversarial method does not require pre-defining the domain difference metric, allowing more flexible domain adaptation. MoDIR builds upon the success of UDA methods and introduces a new momentum learning technique that is necessary to learn domain invariant representations in the ZeroDR setting.

3 Training Domain Invariant Representations for Dense Retrieval

In this work, we aim to improve generalization in ZeroDR under the unsupervised domain adaptation setting (UDA) (Long et al., 2016). Given a source domain with sufficient training signals, the goal is to transfer the DR model to a target domain, with access to its queries and documents, but without any relevance label. This is the common case when applying DR in real-world scenarios: in target domains (e.g., medical), example queries and documents are available but annotating relevance is expensive and may require domain expertise; on the other hand, in the source domain (e.g., web search), training signals are available at large scale (Ma et al., 2020; Thakur et al., 2021).

Our method, MoDIR, improves ZeroDR in the UDA setup by encouraging the DR models to learn a domain invariant representation space that facilitates the generalization from source to target. In this section, we describe (1) how to train a vanilla *dense retrieval model*, (2) how to train a *momentum domain classifier* to distinguish the two domains, and (3) how to *adversarially train* the DR model for domain invariant representations.

3.1 Training the Dense Retrieval Model

The standard design of DR is to use a dual-encoder model (Lee et al., 2019; Karpukhin et al., 2020), where an encoder g takes as input a query/document and encodes it into a dense vector. The relevance score of a q–d pair $x = (q, d)$ is computed using a simple similarity function:

$$r(x) = \text{sim}(g(q; \theta_g), g(d; \theta_g)), \tag{1}$$

where θ_g is the collection of parameters of g and sim is a vector similarity function.

The training of DR uses labeled q-d pairs in the source domain $x^s = (q^s, d^s)$. With relevant q–d pair as x^{s+} and irrelevant pair as x^{s-}, the encoder g is trained to minimize the *ranking loss* L_R:

$$\min_{\theta_g} \sum_{x^{s+}, x^{s-}} L_R(r(x^{s+}), r(x^{s-})), \tag{2}$$

where L_R is a ranking loss function. Our model follows its baseline DPR/ANCE to sample irrelevant documents using BM25 or global hard negatives. Without loss of generality, other modeling designs are kept the same with ANCE: g is fine-tuned from RoBERTa$_{\text{BASE}}$ (Liu et al., 2019); the output query/document embeddings are the hidden states of the last layer's `[CLS]` token; L_R is the Negative Log Likelihood (NLL) loss; sim is the dot product.

3.2 Estimating the Domain Boundary with Momentum Domain Classifier

To capture domain differences and enable adversarial learning for domain invariance, MoDIR introduces a domain classifier f to predict the probability of a query/document embedding $\mathbf{e}$ being source or target, and we use a linear classifier as f:

$$f(\mathbf{e}) = \text{softmax}(W_f \mathbf{e}). \tag{3}$$

The linear classifier has sufficient capacity to distinguish the two domains in the high-dimensional representation space—the main challenge is on training. As illustrated in Figure 1, DR's representation space focuses more on locality than forming manifolds, and therefore it is more difficult to learn the domain boundary in this case. If we simply update f using the same amount of data points as g, f fails to accurately estimate the domain boundary; on the other hand, if we naïvely feed in more

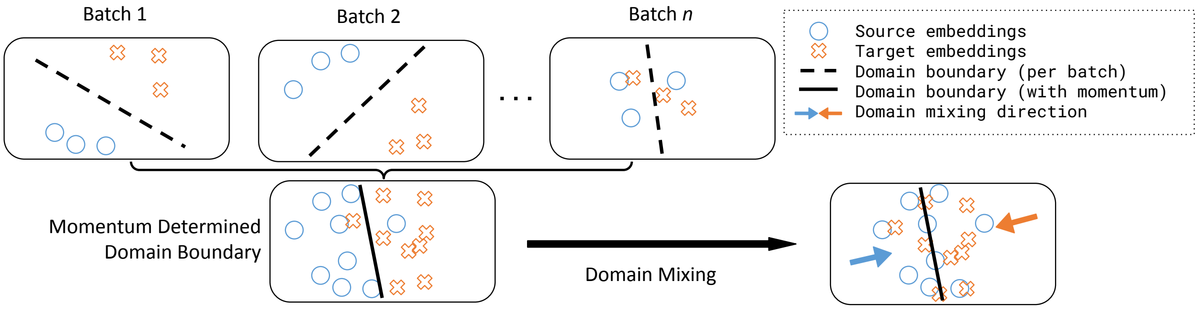

Figure 2: Momentum adversarial training provides a more accurate and robust estimation of the domain boundary in dense retrieval's embedding space.

data points for f, all these data points need to be encoded by the expensive encoder g, which makes the training process infeasibly slow.

To achieve the balance between accuracy and efficiency, we introduce the momentum method for the domain classifier, as shown in Figure 2. We maintain a *momentum queue* Q that records embeddings from multiple previous batches as the additional training data for f. Specifically, at each step, in addition to source domain training data x^s, we sample q–d pairs x^t from the target domain, and add embeddings of x^s and x^t to Q. The momentum queue Q at step k includes embeddings $\mathbf{e}_q/\mathbf{e}_d$ from source and target queries/documents for all recent n batches:

$$Q_k = \{\mathbf{e}_q, \mathbf{e}_d | (q, d) \in B_{k-n+1:k}\}, \tag{4}$$

where $B_{k-n+1:k}$ is the collection of all data points from the past n batches, including both source and target ones, and n is the *momentum step*. For simplicity of sampling, we use the 1:1 ratio between source/target data and also between positive/negative source data.

To ensure efficiency of the momentum method, all embeddings $\mathbf{e}$ from Q are *detached* from the encoder g. Take the query q^s as an example,

$$\mathbf{e}_{q^s} = \Phi(g(q^s; \theta_g)), \tag{5}$$

where Φ is the *stop-gradient* operator, i.e., gradients of $\mathbf{e}_{q^s}$ are not back propagated to θ_g. Since the linear classifier f is significantly smaller and faster than the transformer-based encoder g, this enables efficient training for f.

At each iteration, f is updated by repetitively minimizing the following discrimination loss L_D, computed with *all* embeddings from Q:

$$\min_{W_f} L_D(\mathbf{e}; f), \quad \mathbf{e} \in Q, \tag{6}$$

$$L_D(\mathbf{e}; f) = \begin{cases} -\log f(\mathbf{e}), & \mathbf{e} \text{ from source}, \\ -\log(1 - f(\mathbf{e})), & \mathbf{e} \text{ from target}, \end{cases} \tag{7}$$

where L_D is a standard classification loss. In this way, at each iteration, the domain classifier f is trained with more signals than the encoder g (the entire Q versus only one batch), ensuring accurate estimation of the domain boundary. The detached embeddings from Q also ensures training efficiency.

3.3 Adversarial Learning for Domain Invariant Representations

MoDIR adversarially trains the encoder g to generate domain invariant representations that are hard for f to distinguish. This is done by minimizing the adversarial loss L_M. Here we choose the widely used Confusion loss (Tzeng et al., 2017):

$$L_M(x; g, f) = -\frac{1}{2}\Big(\log f(g(q)) + \log f(g(d)) + \log(1 - f(g(q))) + \log(1 - f(g(d)))\Big), \tag{8}$$

where $x \in \{x^s, x^t\}$ is a q-d pair from either source or target domain. It reaches the minimum when the embeddings are domain invariant so that the domain classifier predict 50%-50% probability for all data. In order for the encoder to learn domain invariance, we freeze the domain classifier and update only the encoder when minimizing L_M:

$$\min_{\theta_g} \lambda \sum_{x \in \{x^s, x^t\}} L_M(x; g, f). \tag{9}$$

The hyperparameter λ balances the learning of DR ranking in the source domain (Equation (2)) and the learning of domain invariance (Equation (9)).

Table 1: Overall performance and label coverage (Hole rate) on tasks from BEIR. Relative improvements of MoDIR over its base DR model DPR/ANCE are shown in percentages. Datasets are ordered by ANCE's Hole rates, and datasets with lower Hole rates provide more accurate evaluation.

To summarize, for each training batch in the source domain, the domain classifier f and the encoder g are optimized by:

$$\min_{W_f} \quad L_D(\mathbf{e}; f), \quad \mathbf{e} \in Q, \tag{10}$$

$$\min_{\theta_g} \sum_{x^{s+}, x^{s-}} L_R(r(x^{s+}), r(x^{s-})) + \lambda \sum_{x \in \{x^s, x^t\}} L_M(x; g, f), \tag{11}$$

where f is trained to estimate the boundary between source/target and g is trained to provide domain invariant representations that also captures relevance matching in the source domain.

4 Experiments

This section describes experimental setups and evaluates the effectiveness of MoDIR. Furthermore, we dive deep into the importance of momentum training and properties of domain invariant embedding space, which provides new insights for ZeroDR.

4.1 Datasets

We choose the MS MARCO passage dataset (Bajaj et al., 2016) as the source domain dataset and choose the 15 publicly available datasets from the BEIR benchmark (Thakur et al., 2021) as target domain datasets (details in Appendix A). These datasets cover a large number of various domains, including biomedical, finance, scientific, etc. We treat each target domain dataset separately and produce an individual model for each of them, following the ZeroDR setting described in Section 3.

4.2 Effectiveness of MoDIR

We build MoDIR on top of DPR and ANCE, but it can also be applied to other DR frameworks similarly. Table 1 shows the Hole rates and nDCG scores on the BEIR benchmark; we omit the Hole rates of MoDIR since they are very similar to its baseline DPR/ANCE's. We first discuss Hole rates and baseline selection, and then discuss effectiveness of each model.

Hole Rates and DR Evaluation A *hole* is an unlabeled q–d pair retrieved by a model, and the percentage of holes among all retrieved q–d pairs is the *Hole rate*. Datasets with high Hole rates for dense models are *less sensitive* to dense models' effectiveness (Xiong et al., 2021), and we therefore consider datasets with low Hole rates more important, since they provide more accurate measurements for ZeroDR. On the other hand, many of BEIR's datasets are annotated with candidates generated by some sparse retrieval models at the time of dataset construction, therefore the evaluation of these datasets is biased towards sparse models. Take TREC-COVID as an example, ANCE underperforms BM25 under the original annotation, but it achieves the state of the art (SOTA) after adding extra labels based on ANCE's prediction (Thakur et al., 2021).

Baselines Our baselines include BM25 (Robertson and Jones, 1976), DPR (Karpukhin et al., 2020), and ANCE (Xiong et al., 2021). The original DPR is trained on NQ (Kwiatkowski et al., 2019), but we instead train DPR on MARCO, which not only eliminates training dataset differences but also provides

Method	L_M	n	TREC-COVID	Touche
Single	Confusion	1	0.650	0.294
Repeat		1k	0.664	0.309
Momentum	Confusion	100	0.649	0.294
		1k	**0.676**	0.315
	Minimax	1k	0.666	0.322
	GAN	1k	0.641	**0.325**
Vanilla ANCE			0.654	0.284

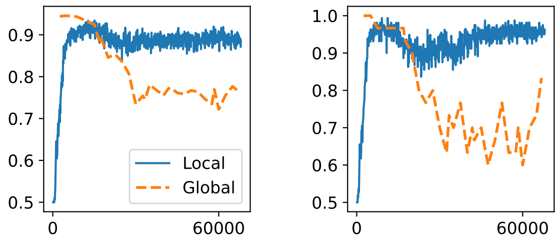
Table 2: Ablation studies show that momentum is critical for learning domain invariant representation. Default settings are underlined and **best** scores are bold.

better overall results. BEIR also reports results of other methods, such as docT5query (Nogueira et al., 2020), TAS-B (Hofstätter et al., 2021), GenQ (Ma et al., 2021), ColBERT (Khattab and Zaharia, 2020), etc. However, they are *not* directly comparable with MoDIR since they involve stronger supervision signals from rerankers (TAS-B), data augmentation from expensive sequence-to-sequence models (docT5query and GenQ), and high-latency late interaction (ColBERT). MoDIR instead directly improves the generalization ability of the representation space, and are orthogonal to these methods and can be combined for better performance.

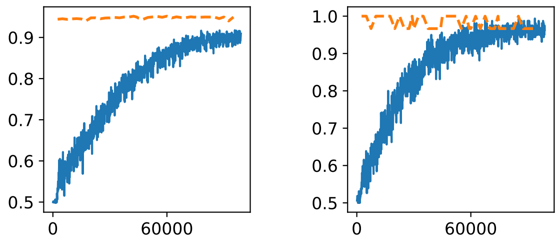
Effectiveness Comparison From Table 1 we can see that MoDIR improves DPR and ANCE's overall effectiveness in the ZeroDR setting. On datasets with low Hole rates, where evaluation is more stable, the gains are significant; on datasets with high Hole rates, the gains are smaller but still stable. Moreover, to present a fair comparison in the realistic ZeroDR setting, results of MoDIR are obtained *without* hyperparameter tuning or checkpoint selection: in the ZeroDR setting, there is no access to relevance labels in the target domain during training/validation. For all target domain datasets, we keep most of the experimental settings the same with ANCE and evaluate checkpoints after the same number of training steps (details in Appendix B). This evaluation setup is the closest to ZeroDR in the real world, but it may not show the full potential and the best empirical results for MoDIR. We further study this in Section 4.5.

4.3 Effectiveness of Momentum Training and Ablation Studies

Our ablation studies evaluate the importance of the momentum method and the effects of other experimental setups. We compare different training setups against vanilla ANCE, using TREC-COVID and Touché which have the best label coverage (lowest Hole rates), and show the results in Table 2.



(a) Documents (b) Queries



(c) Documents (d) Queries

Figure 3: Global and Local Domain-Acc at different training steps with/without momentum (top/bottom).

Firstly, we evaluate the effectiveness of not using the momentum queue: each iteration, the domain classifier is trained either with a *single* batch $n = 1$, or *repeat*[1] the current batch for $n = 1\text{k}$ times. We can see that using a single batch fails to improve over ANCE, indicating the necessity of using more data to train the domain classifier; repeating the current batch also provides smaller improvements than using different batches from the queue. Secondly, we use a smaller momentum step $n = 100$ for momentum training, which also yields little improvement. This shows that n has to be sufficiently large for the momentum method to work, proving the necessity of our efficiency method to detach embeddings before storing them into the queue. Thirdly, we train MoDIR with two other choices of L_M from Equation (9): Minimax and GAN. GAN loss is less stable as described by Tzeng et al. (2017), while Minimax performs comparatively to Confusion. This shows that MoDIR can also be applied with other domain adaptation training methods.

4.4 Convergence of Adversarial Training with Momentum

In this experiment, we study how our momentum method helps adversarial training converge to a

---

[1] Concretely, for *repeat*, we update the domain classifier with the current batch's detached embeddings repetitively for n times (i.e., all using the same input embeddings).

w/ Momentum	5.2%	6.2%	14.0%	17.2%	0.654	0.676	0.689	**0.724**
w/o Momentum	5.2%	5.4%	5.6%	5.6%	0.654	0.650	0.673	0.668

Table 3: K-Nearest Neighbor Source Percentage (KNN-Source%) and nDCG@10 scores after different number of training steps of ANCE with/without momentum, on TREC-COVID.

domain invariant embedding space. To quantify domain invariance, we use *Domain Classification Accuracy* (Domain-Acc), which includes two measurements based on the choice of domain classifier: (1) Directly take the domain classifier used in MoDIR's training (f in Section 3.2) and record its accuracy when applied to a new batch, which leads to *Local* Domain-Acc. (2) Randomly initialize a new domain classifier and train it globally on source and target embeddings, which leads to *Global* Domain-Acc. Global Domain-Acc measures the real degree of domain invariance: it is lower when embeddings of the two domains are not easily separable. Local Domain-Acc is an efficient approximation provided by the domain classifier f.

In Figure 3, we compare Global and Local Domain-Acc on the TREC-COVID dataset when training ANCE with/without momentum (without momentum is the *single* setting described in Section 4.3). With momentum, Local Domain-Acc quickly increases to be comparable with Global Domain-Acc. The domain classifier f (used in MoDIR's training) converges quickly and Global Domain-Acc starts to decrease, showing that embeddings from the two domains become less separable. Note that Local Domain-Acc does not decrease because f has seen and memorized almost all data, while Global Domain-Acc's domain classifier is always tested on unseen data for accurate results. This shows that momentum helps with the balance of adversarial training, ensuring its convergence towards a domain invariant representation space.

On the other hand, when momentum is not used, there exists a long-lasting gap between Local and Global Domain-Acc, showing that f does not capture the domain boundary well. As a result, the two domains remain (almost) linearly separable in the embedding space, as shown by the fact that Global Domain-Acc does not decrease, and the model fails to produce domain invariant representations.

4.5 Impact of Domain Invariance

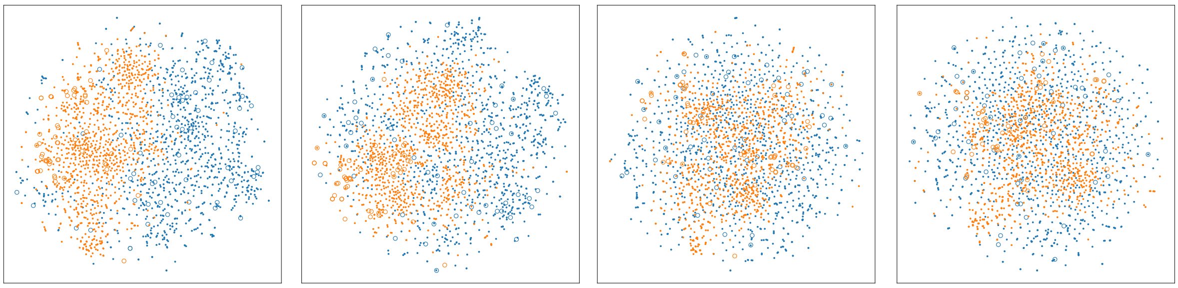
In this subsection, we study the behavior and benefits of ANCE+MoDIR in learning domain invariance. We focus on TREC-COVID as it provides the most robust evaluation for ZeroDR.

Learning Domain Invariance with Momentum We show how the momentum method gradually pushes for a domain invariant representation space. To measure how much the two domains are mixed together, we use *K-Nearest Neighbor Source Percentage* (KNN-Source%): We index source and target documents together; given a target domain query in the embedding space, we retrieve its top-100 nearest documents from the index, and calculate the percentage of source documents from the nearest neighbors; the average percentage for all target domain queries is reported. A higher KNN-Source% means that the target domain embeddings are surrounded by more source domain ones, indicating a more domain invariant representation space.

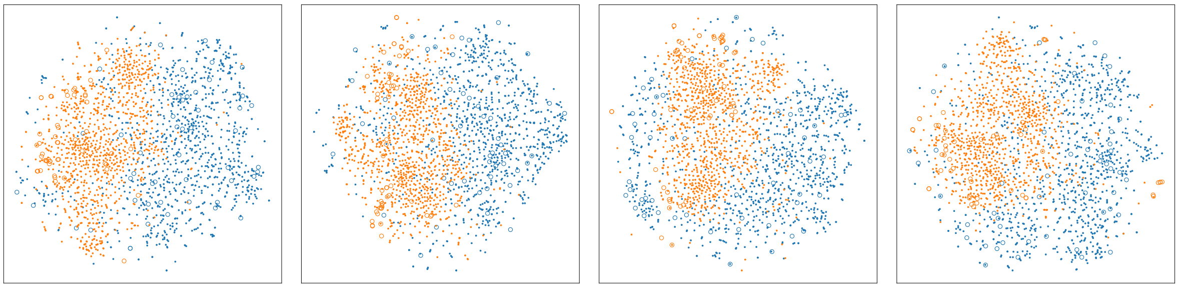
The results are in Table 3. With momentum, both KNN-Source% and nDCG gradually increase as training proceeds. This shows that when target domain embeddings are pushed towards the source domain, the ranking performance of the target domain also improves. On TREC-COVID, MoDIR eventually reaches **0.724**, which is the SOTA for first stage retrievers. On the other hand, without momentum (the *single* setting in Section 4.3), KNN-Source% and nDCG scores hardly increase.

We also use t-SNE (van der Maaten and Hinton, 2008) to visualize the learned representation space at different training steps in Figure 4. Before training with MoDIR, the two domains are well separated in the representation space learned by ANCE. With more MoDIR training steps, the target domains are pushed towards the source domain and gradually becomes a subset of it. Without momentum, the two domains remain separated, which is consistent with observations from Table 3.

ZeroDR Effectiveness VS Domain Invariance We study the correlation between ZeroDR ranking effectiveness and domain invariance. We use Global Domain-Acc as the indicator of domain invariance and plot it with the corresponding ZeroDR nDCG scores during training in Figure 5.

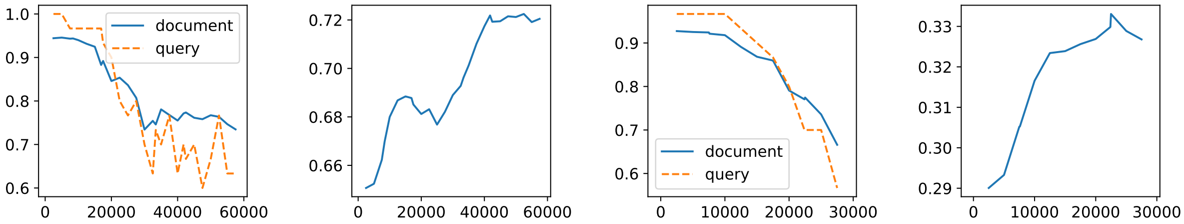


(a) MoDIR (0) (b) MoDIR (10k) (c) MoDIR (30k) (d) MoDIR (50k)



(e) w/o Mom. (0) (f) w/o Mom. (10k) (g) w/o Mom. (30k) (h) w/o Mom. (50k)

Figure 4: T-SNE of the representation space after different training steps (in the parentheses), with/without momentum. Blue: source (MARCO); orange: target (TREC-COVID).



(a) Global Domain-Acc (b) nDCG@10 (c) Global Domain-Acc (d) nDCG@10

Figure 5: Global Domain-Acc and target domain ZeroDR nDCG scores at different training steps: TREC-COVID (left two) and Touché (right two).

Global Domain-Acc starts at near 100% and decreases as training proceeds, showing that source and target embeddings are almost linearly separable at the beginning but are gradually pushed together. ZeroDR accuracy improves as Global Domain-Acc decreases, showing that domain invariance is the source of ZeroDR's improvements. We also record that the DR accuracy on the source domain (MARCO) decreases by no more than 0.5%. This indicates that the high dimensional embedding space has sufficient capacity to learn domain invariant representations while maintaining relevance matching in the source domain.

4.6 Case Study

We show two cases of queries from TREC-COVID and their nearest MARCO queries before and after MoDIR training in Table 4. In the first case, MoDIR pays more attention to "transmission", and potentially retrieves more documents about the transmission of diseases, thereby improving the nDCG score; documents about "coronavirus" are also likely to be retrieved by MoDIR since it is a very noticeable word. In the second case, it focuses on "mRNA" more than "vaccine". However, since the mRNA vaccine is relatively new[2] with few appearances in the MARCO dataset, the shift in focus fails to improve MoDIR for this query.

These examples help reveal the source of generalization ability on ZeroDR. For the DR models to be able to generalize, the source domain itself needs to include relevance information that resembles the target domain's needs; if there is no such information,

---

[2] The first mRNA vaccine was approved in 2020, according to `https://en.wikipedia.org/wiki/MRNA_vaccine`.

Target	what are the transmission routes of coronavirus?	nDCG@10 gain: 0.23
Source Before	• what is the coronavirus • incubation period for coronavirus • what are symptoms of coronavirus	
Source After	• countries where guinea worm is transmitted • what is the most common method of hiv transmission • through which body system are cancer cells able to travel to different locations in the body?	
Target	what is known about an mRNA vaccine for the SARS-CoV-2 virus?	nDCG@10 gain: -0.12
Source Before	• is there a vaccine for hepatitis • is there a vaccine for tuberculosis • shingles vaccination needed for those without chickenpox	
Source After	• what makes rna • what is used to make mrna • what is the mmr vaccine called	

Table 4: Case study: nearest source queries of a target query before and after MoDIR training.

as in the second example, generalization becomes a hard challenge. When the source domain has such coverage, MoDIR is able to align target queries to source ones with similar information needs in its domain invariant representation space, and such alignments enable DR models to generalize.

5 Conclusion and Future Work

In this paper, we present MoDIR, a new representation learning method that improves the zero-shot generalization ability of dense retrieval models. We first show that dense retrieval models differ from classification models in that they emphasize locality properties in the representation space. Then we present a momentum-based adversarial training method that robustly pushes text encoders to provide a more domain invariant representation space for dense retrieval. Our experiments demonstrate that, compared with ANCE, a recent SOTA DR model, MoDIR's improvements are robust overall and significant on datasets where ZeroDR's evaluation is more accurate.

We conduct a series of studies to show the effects of our momentum method in learning domain invariant representations. Without momentum, the adversarial learning is unstable. The inherent variance of the DR embedding space hinders the convergence of the domain classifier. With momentum training, the model fuses the target domain data into the source domain representation space and discovers related information from the source domain, thus improving generalization of ZeroDR.

We view MoDIR as an initial step of zero-shot dense retrieval, an area that democratizes the rapid advancements in search technologies to many real-world scenarios. Our approach inherits the success of domain adaptation techniques and upgrades them by addressing the unique challenges of ZeroDR. Understanding the dynamics of dense retrieval is an important future direction for not only representation learning research but also real-world applications.

A Datasets Details

Target domain datasets used in our experiments are collected in the BEIR benchmark (Thakur et al., 2021) and include the following domains:

- General-domain (Wikipedia): DBPedia (Hasibi et al., 2017), HotpotQA (Yang et al., 2018), FEVER (Thorne et al., 2018), and NQ (Kwiatkowski et al., 2019).
- Bio-medical: TREC-COVID (Voorhees et al., 2021), NFCorpus (Boteva et al., 2016), and BioASQ (Tsatsaronis et al., 2015).
- Finance: FiQA (Maia et al., 2018).
- Controversial arguments: Touché (Bondarenko et al., 2020) and ArguAna (Wachsmuth et al., 2018).
- Duplicate questions: Quora (Thakur et al., 2021) and CQADupStack (Hoogeveen et al., 2015).
- Scientific: SciFact (Wadden et al., 2020), SCIDOCS (Cohan et al., 2020), and Climate-FEVER (Diggelmann et al., 2020)

B Detailed Experimental Settings

We follow the design of ANCE for the DR encoder's modeling and training. We initialize the encoder with the publicly released checkpoints: "ANCE-warmup" for DPR+MoDIR and "ANCE-passage" for ANCE+MoDIR.[3] We randomly initialize the domain classifier. Detailed hyperparameter choices are shown in Table 5. We also use an exponential decay routine for the hyperparameter λ to improve training stability, where the value is reduced continuously and shrunk to half every 10k steps.

Hyperparameter	Value
Same as ANCE	
Learning rate for θ_g	1e-6
Effective batch size	16
Maximum Query Length	64
Maximum Document Length	512
New for MoDIR	
Learning rate for W_f	5e-6
Early stopping steps	10k
Momentum step n	1k
Initial λ	1.0

Table 5: Detailed hyperparameter choices of MoDIR.

Abstract

Previous attempts to build effective semantic parsers for Wizard-of-Oz (WOZ) conversations suffer from the difficulty in acquiring a high-quality, manually annotated training set. Approaches based only on dialogue synthesis are insufficient, as dialogues generated from state-machine based models are poor approximations of real-life conversations. Furthermore, previously proposed dialogue state representations are ambiguous and lack the precision necessary for building an effective agent.

This paper proposes a new dialogue representation and a sample-efficient methodology that can predict precise dialogue states in WOZ conversations. We extended the ThingTalk representation to capture all information an agent needs to respond properly. Our training strategy is sample-efficient: we combine (1) few-shot data sparsely sampling the full dialogue space and (2) synthesized data covering a subset space of dialogues generated by a succinct state-based dialogue model. The completeness of the extended ThingTalk language is demonstrated with a fully operational agent, which is also used in training data synthesis.

We demonstrate the effectiveness of our methodology on MultiWOZ 3.0, a reannotation of the MultiWOZ 2.1 dataset in ThingTalk. ThingTalk can represent 98% of the test turns, while the simulator can emulate 85% of the validation set. We train a contextual semantic parser using our strategy, and obtain 79% turn-by-turn exact match accuracy on the reannotated test set.[1]

1 Introduction

Virtual assistants and task-oriented dialogue agents are transforming how consumers interact with computers. This has led to active research on dialogue state tracking networks (Ren et al., 2019; Zhou and Small, 2019; Zhang et al., 2020; Chen et al., 2020; Heck et al., 2020), and even full neural networks that track dialogue states, implement dialogue policies, and generate agent utterances (Williams and Zweig, 2016; Eric et al., 2017; Zhang et al., 2020; Peng et al., 2020; Hosseini-Asl et al., 2020).

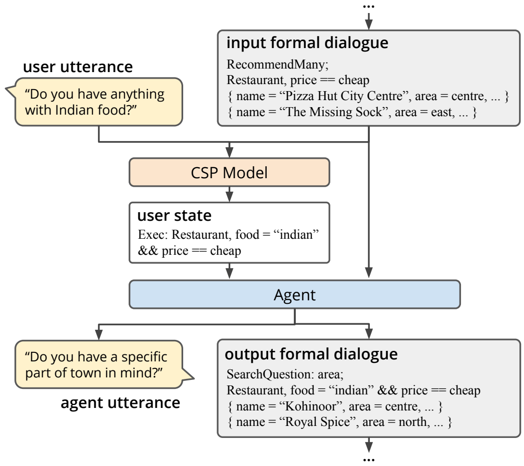

Figure 1: The inference-time flow of a dialogue agent with a contextual semantic parser based on the ThingTalk representation.

Dialogue state tracking on Wizard-of-Oz task-oriented conversations, where humans are asked to simulate both the agent and the user, has proven to be challenging. For example, despite multiple rounds of manual annotation, the MultiWOZ multi-domain task-oriented dataset still contains significant errors which hamper the development of accurate semantic parsers (Zang et al., 2020; Han et al., 2020; Ye et al., 2021a). An approach to bypass manual annotations is to generate dialogues using a simulator and then manually paraphrase them (Shah et al., 2018). Unfortunately, as we shall show in this paper, such dialogue simulators do not exercise many of the possible dialogue flows seen in Wizard-of-Oz conversations. This gap is likely to widen with real-life conversations.

Given the many attempts to create accurate semantic parsers for the MultiWOZ data set, this

Findings of the Association for Computational Linguistics: ACL 2022, pages 4021 - 4034
May 22-27, 2022

paper takes a fresh look at the problem of understanding Wizard-of-Oz conversations. We observe two fundamental flaws with the current approach. Previously proposed state representations such as slot-value pairs and the recently proposed hierarchical forms (Cheng et al., 2020) do not capture critical details in the user utterances, such as logical "or" and negation. Even if the semantic parser is 100% accurate, the agent will not be able to satisfy the user's request. Second, it is easy to make errors. The existing slot representation is ambiguous, so it is not possible to be consistently correct. This leads to poor quality of annotation.

This paper shows that it is possible to create a precise and accurate semantic parser for Wizard-of-Oz conversations in a sample-efficient manner. We introduce the MultiWOZ 3.0 dataset, a reannotation of the full test set and partial validation set of MultiWOZ 2.1 (Eric et al., 2019), using a new, more precise formal representation. The contributions of this paper include:

1. A precise, complete, executable ThingTalk representation for dialogues. In previous work, we proposed the ThingTalk programming language to represent just a single utterance (Campagna et al., 2019). Here we extend it to a full formal representation of a dialogue, including multiple turns of user input, results from the user request (such as a database lookup or API invocation), and the agent's response. We show that the extended ThingTalk for dialogues is precise enough to capture 98% of the turns in MultiWOZ 3.0. In the rest of the paper, we will refer to the extended ThingTalk language as ThingTalk, unless noted otherwise.

We also demonstrate that ThingTalk is a complete representation for dialogues. The agent directly executes the ThingTalk representation to retrieve the results from the databases and APIs, without referring to any of the user utterances. In fact, the same agent code can be used both during simulation and in a real agent deployment.

2. We show that we can obtain a high-quality synthetic training data set with a simulator that adopts the ThingTalk representation. The precision of ThingTalk makes it possible to generate many distinctively different dialogue paths that mirror those in the WOZ conversation. Our experiment shows that our simulator can generate 85% of the user turns.

3. We show that by leveraging synthesized dialogues represented in ThingTalk, we can train an effective semantic parser for WOZ conversations. This is significant since it is difficult to annotate dialogues accurately. ThingTalk does not make it easier to annotate, but it is unambiguous. We annotate manually only a *few-shot* training set, and rely on synthesis for the rest. The few-shot training data is 2% of the typical amount of annotated data.

The few-shot training samples in ThingTalk help the semantic parser generalize from the simulated dialogues to WOZ conversations. Whereas the simulator can only generate a subset of the states representable by ThingTalk, ThingTalk can precisely represent nearly all WOZ data.

Our novel contextual semantic parser, described in Section 5, obtains a turn-by-turn accuracy of 79% on MultiWOZ 3.0. Note that this model generalizes to utterances that fall out of the realm of simulation.

2 Related Work

State Representation for DST *Dialogue State Tracking* is the task of predicting a formal representation of a conversation. The standard representation used in DST contains the values of all slots mentioned in the dialogue (El Asri et al., 2017; Budzianowski et al., 2018). This is inadequate in practice. First of all, the definition is ambiguous, as it could mean "all slots mentioned by the user" or "all slots mentioned by either the user or the agent". This has lead to inconsistency in the annotation. Second, the representation does not track the comparison or logical operators in the request, so it cannot model complex queries.

Recently, Cheng et al. (2020) proposed adopting a formal representation for both the user and agent state, using the TreeDST representation. TreeDST was built to support only dialogues synthesized and paraphrased from a compatible state machine, while ThingTalk supports the full generality of Wizard-of-Oz conversations.

Data Acquisition for DST In recent years, a number of very large DST datasets have been released (Budzianowski et al., 2018; Byrne et al., 2019; Rastogi et al., 2020). The preferred technique to acquire such datasets is through Wizard-of-Oz (Kelley, 1984), a technique in which two humans are instructed to converse with each other, with one person taking the role of the agent. WOZ datasets are expensive, and the annotation quality is poor. A different approach synthesizes a large corpus of dialogues using a state machine, then employs crowdworkers to paraphrase them. Paraphrasing has been applied to semantic parsing (Wang et al., 2015) and dialogues (Shah et al., 2018; Rastogi et al., 2020; Cheng et al., 2020). Paraphrased datasets have less variety than WOZ, and crowdsourced paraphrases are also expensive. Our approach has a significant cost advantage, while matching the variety of WOZ dialogues.

Campagna et al. (2020) found that using data synthesized from a small finite state machine, it is possible to increase the accuracy of DST in the transfer learning setting. Later, Yu et al. (2021) proposed using synthesized data to pre-train a DST model, using a different objective function. They showed modest improvements in MultiWOZ 2.1, using the full training set. We instead propose using the same fine-tuning objective for both synthesized and few-shot annotated data.

(a) Sorting and ranking in ThingTalk

Agent: There are 14 trains that arrive by 12:45. What time would you like to leave?
User: What's the latest train i can take that will still get me there by 12:45?
$u_1 =$ Exec : $\texttt{sort}(\textit{arrive\_by}\ \texttt{desc of}\ \textit{Train}, \textit{arrive\_by} \leq 12{:}45\ \texttt{\&\&}\ \ldots)[1]$

(b) Projection and logical operators in ThingTalk

User: I think i would like to visit both churchill and magdalene colleges. May I have their phone numbers?
$u_1 =$ Exec : $[\textit{phone}]\ \texttt{of}$ Attraction, $\textit{name} =$ “churchill” $||$ $\textit{name} =$ “magdalene”

Figure 2: ThingTalk representations of user utterance examples in the MultiWOZ 3.0 validation set. u_1 denotes the user state.

Agent: [. . .] Would you like me to make you a reservation?
User: Yes, please make a reservation.
$u_1 =$ Exec : Restaurant.MakeReservation($\textit{name} =$ “...”)
Agent: What day and time?
$a_1 =$ SlotFill: *book_day*, *book_time* Restaurant.MakeReservation($\textit{name} =$ “...”)

(a) User answers the question

User: At 17:30 on Friday.
$u_2 =$ Exec : Restaurant.MakeReservation($\textit{name} =$ “...”, $\textit{book\_time} = 17{:}30, \textit{book\_day} =$ friday);

(b) Or, user switches to a new domain instead

User: Nevermind. Not at this time. Can you help me find the postcode for the Holiday Inn Cambridge?
$u_2 =$ Exec : Hotel, $\textit{name} =$ “holiday inn cambridge”;

Figure 3: Examples of a user continuing or abandoning a transaction, adapted from the MultiWOZ 3.0 validation set. The user state u_2 denotes this fact by propagating or discarding the action. a_1 is the agent state.

3 The ThingTalk Dialogue Language

The ThingTalk Dialogue Language is designed to formally capture all relevant information in task-oriented dialogues to interpret what the user says next. This includes the user utterances, the result of the user requests, as well as the agent's replies.

To see why the results and the agent's reply are needed, consider the example in Fig. 1. The user has previously asked for a cheap restaurant, and now asks “Do you have anything with Indian food?”. In the example, the agent noted that there are many cheap restaurants available, so it is likely that the user wants both “Indian” and “cheap”. This is reflected in the query that the command maps to. Conversely, had the agent responded that there are no cheap restaurants, it is likely that the user no longer cares about finding a cheap and only wants Indian. The user query thus would be just:

Exec : Restaurant, $\textit{food} =$ “indian”

This illustrates that the meaning of the user utterance depends on the result and the agent's response, so we must include them in the formal dialogue. The previous slot-based representation captures only what is mentioned by the user; it is not precise enough to handle this example.

Formally, ThingTalk represents (1) the user state $u \in U$ with the semantics of a single user turn, (2) the agent state $a \in A$ with the semantics of the single agent turn, and (3) the formal dialogue $d \in \mathcal{D}$ to capture all information necessary to interpret the user utterance. In this section, we provide the detailed definition of each component. The formal syntax is included in Appendix A.

User State. The formal semantics of a user turn is represented by a *user state* $u \in U$, which consists of an abstract dialogue act and, for dialogue acts that provide or request information, a sequence of *statements*: either database queries, or actions with side effects (such as making a reservation). Queries specify the domain of interest and can use the standard relational operators: selection, projection, aggregation, sorting. Actions specify the domain, the action name, and the parameters necessary for the action. User state examples in Figures 1 and 2 with abstract act “Exec” are all queries, while the example in Fig. 3 uses the action “Restaurant.MakeReservation”.

The user state includes new statements that are implied by the current utterance and statements that the user has previously mentioned and is still interested in pursuing (Fig. 3). Note that a single user utterance may map to multiple ThingTalk statements, possibly in different domains.

Table 1: Comparison of representation power for different lexical features of different formal dialogue languages. TreeDST refers to Cheng et al. (2020), Express refers to Andreas et al. (2020). TT indicates ThingTalk.

Agent State. Analogously, each agent turn has a formal *agent state* $a \in A$ representation, which is computed by the agent policy. The agent state includes an abstract dialogue act, as well as an optional agent statement, which either requests some slots from the user, proposes a new statement to the user, or asks the user to confirm an action.

Formal Dialogue Representation. A formal dialogue $d \in \mathcal{D}$ captures all the information in the conversation needed to interpret the user utterance. Specifically, it contains the current agent state, the accumulated results of executing the user statements in previous turns, and the user statements that the user has asked to execute but that are missing some required parameters. The results for queries are the items retrieved from the database; the results for actions are returned by the API call.

Comparison with previous representations In Table 1 we compare ThingTalk with three existing state representation: the slots and values representation used in MultiWOZ, the TreeDST representation (Cheng et al., 2020), and the Express representation (Andreas et al., 2020; Tellman, 2021). Note that neither Express nor TreeDST are open-source or available to use, whereas ThingTalk is fully open-source and comes with tools that developers can use. Limited documentation exists for Express, so we use "?" for features we do not know are supported or not.

ThingTalk represents user queries and commands as *executable* database queries and API calls. An executable representation is easier to annotate manually. Other approaches require annotators to be familiar with the semantics of each domain, whereas in our approach annotators just need to learn the database query syntax to annotate for different domains. Additionally, the implementation of the agent only needs to execute ThingTalk statements; no custom per-domain logic is necessary.

Furthermore, ThingTalk is *canonicalizable*: the annotation of the semantics of a turn is syntactically unique, regardless of how the turn is phrased, and the unique form can be computed automatically. This is important both to enforce conventions on manually annotated data, as well as to be able to paraphrase: if the annotation depends on the syntactic form of the utterance, the annotation must be changed after paraphrasing. Express, while executable, is not canonicalizable because it represents coreferences explicitly and expresses updates to the dialogue state as edits. Both features lead to syntactically different representations for the same semantics, for example if the coreference is by name, by constraints, or by pronoun.

ThingTalk can represent the full generality of WoZ conversations. For example, ThingTalk can represent turns that have no request, at the beginning and end of the conversation. Neither slots nor TreeDST have a representation for those turns. This oversight highlights the need to design the representation based on real conversations.

One feature present in the previous representation that we drop from ThingTalk is the precise slots mentioned by the agent. For example, in response to a user asking for a restaurant, the agent may mention the restaurant "name" and "address." Such slots do not affect the interpretation of the user utterance. Removing them from the agent state coalesces many more utterances into the same state, and allows to approximate more complex human agent utterances, increasing the state coverage and boosting the accuracy of the semantic parser.

4 Simulator-Agent Architecture

To synthesize data for training, we propose a *simulator-agent* architecture. The state-based simulator takes the role of the human user. The same agent that would be used at deployment time is used during synthesis. The agent is built based on the semantics of ThingTalk, not just the simulator. It can respond correctly to any dialogue $d \in \mathcal{D}$ representable in ThingTalk. On the other hand, the simulator samples a subset space $\mathcal{D}_{\text{Sim}} \subset \mathcal{D}$. We refer to dialogues in $\mathcal{D}_{\text{Sim}}$ as *in-simulation*; other dialogues are *out-of-simulation*.

Formally, the architecture has three components:

Agent$(d, u) : \mathcal{D} \times U \rightarrow \mathcal{D}$: an agent that accepts a formal dialogue $d \in \mathcal{D}$, and the user state $u \in U$ representing the last user utterance, to produce a new dialogue $d' \in \mathcal{D}$. The agent guarantees that if $d \in \mathcal{D}_{\text{Sim}}$ then $d' \in \mathcal{D}_{\text{Sim}}$.

Sim$(d) : \mathcal{D}_{\text{Sim}} \rightarrow X \times U$: a simulator that accepts an in-simulation dialogue $d \in \mathcal{D}_{\text{Sim}}$, and non-deterministically creates a new user utterance $x \in X$ and its user state $u \in U$.

CSP$(d, x) : \mathcal{D} \times X \rightarrow U$, a contextual semantic parsing model that accepts a dialogue $d \in \mathcal{D}$, which may not be in $\mathcal{D}_{\text{Sim}}$, and a user utterance $x \in X$ to predict the user state in U.

In this section, we describe how the components are used to synthesize training data and build a functional dialogue agent.

4.1 Training Data Synthesis

We synthesize training data for CSP as follows:

Syn$(d) : \mathcal{D}_{\text{Sim}} \rightarrow \mathcal{D}_{\text{Sim}} \times X \times U$: the synthesizer accepts a dialogue $d \in \mathcal{D}_{\text{Sim}}$ and returns a training sample produced by using Sim to generate a possible user utterance and a resulting in-simulation dialogue to be predicted, then applying the Agent to continue:

$$\begin{gathered}\text{Syn}(d) = (d', x, u), \text{ where} \\ (x, u) = \text{Sim}(d), d' = \text{Agent}(d, u)\end{gathered}$$

Starting with a null dialogue, we iteratively use Syn to synthesize training samples. During synthesis, the agent is called in a mock execution environment with no side effects, and it uses a non-deterministic policy that generates many possible agent behaviors. It is helpful to include many agent behaviors because it helps model the human WOZ agent.

Following Campagna et al. (2020), both the simulator and the agent policy are implemented using a domain-independent state machine which includes many natural language templates for user and agent utterances. Using the templates and a few natural language phrases for each slot, we can generate dialogues for any new domain with minimal effort.

User: Please book a table for 5 at 14:30 on wednesday at Royal Spice. I also need to find a place to stay.
$u_1 =$ Exec : Restaurant.MakeReservation(
name = "royal spice", *book_people* = 5,
book_time = 14:30, *book_day* = wednesday);
Hotel;
Agent: I was able to book your table successfully. Your reference number is kqmxil0z. Now, what type of accommodations are you looking for today?

Figure 4: Example of an out-of-simulation dialogue from the MultiWOZ 3.0 test set, where the same turn mentions two domains. The simulator never generates such a turn but the agent can reply to it.

4.2 Deployment

After training, the same agent can be used at deploy time to reply to the real user.

Deploy$(d, x) : \mathcal{D} \times X \rightarrow \mathcal{D}$: given the current dialogue, a deployable system uses CSP to map the next user utterance to a formal dialogue, which is then used by Agent to continue the dialogue. Let d_0 be the empty dialogue and user input $x_1, x_2, \ldots$

$$\begin{aligned} d_i &= \text{Deploy}(d_{i-1}, x_i) \\ &= \text{Agent}(d_{i-1}, \text{CSP}(d_{i-1}, x_i)) \end{aligned}$$

4.3 Out-of-simulation Dialogues

While the simulator can cover only the most common dialogue paths, ThingTalk is designed to be general, covering many more possible dialogues. To improve generality, the CSP is trained not only with simulated dialogues but also few-shot data annotated with the full expressiveness of ThingTalk. Correspondingly, the agent is written to handle the full representation of ThingTalk. This design makes our parser and agent more robust than those that only train with simulated dialogues. Fig. 4 shows an out-of-simulation dialogue from the MultiWOZ test set. In the example, the agent must reply to two domains at once.

We show below some of the out-of-simulation dialogue patterns handled by our agent.

- *Domain switch*: the user switches to a new domain in the middle of a discussion about another; the simulator switches domains only after completing the action.
- *Multidomain*: the user refers to two domains in the same utterance; the simulator only refers to one domain at a time.
- *Eager action parameters*: the user specifies parameters for an action before completing the query, ignoring a prompt from the agent to refine the query.

- *Abandoning transactions*: the user abandons a transaction after it has been initiated; the simulator never interrupts a transaction.

These examples illustrate the many plausible ways in which the user can change the course of a dialogue. Trying to simulate all these possibilities is infeasible, nor is it desirable, as it will worsen the distribution of the training data by overemphasizing uncommon patterns. At the same time, handling these cases is important; thus, we train with few-shot annotated data and rely on the model's inherent generalization capability.

5 Contextual Semantic Parsing Model

5.1 Model Architecture

Our CSP neural model is fine-tuned from the pre-trained BART model (Lewis et al., 2020). BART is a Transformer encoder-decoder neural network (Vaswani et al., 2017) pre-trained with the task of reconstructing noised inputs. Our model for the user encodes a concatenation of the formal dialogue and the user utterance, and is trained to generate the user state as its output.

To reduce the length of the input, the formal dialogue is truncated before feeding to the model: only the last executed query and action in each domain are kept, and the rest is discarded. Previous statements are no longer relevant; information that is still relevant is carried over in the last statement. Additionally, we encode at most one result per query. We observe that the user uses either a coreference to refer to the only/first choice, or uses the entity name. The model is trained to copy entity names from the user utterance.

We use BART-Large, with about 400M parameters. We train it with token-level cross-entropy loss and teacher forcing. Hyperparameters and preprocessing details are included in Appendix B.

5.2 Training Data

Data Synthesis. We use Syn to synthesize an initial set of training dialogues, covering all possible combinations of slots at each turn, and many possible paths in $\mathcal{D}_{\text{Sim}}$.

Automatic Paraphrasing. We apply *automatic paraphrasing with filtering* (Xu et al., 2020) to increase the variety of natural language in each turn. We use a pre-trained BART model fine-tuned on the ParaBank2 general-purpose paraphrasing dataset (Hu et al., 2019). Each user utterance is paraphrased individually. We apply *filtering* to ensure that the user state does not change for each utterance: each paraphrased utterance, with its associated formal dialogue, is passed to a model trained on synthesized data; the utterance is discarded if the model predicts a different user state than the annotation before paraphrasing.

Few-Shot Fine-Tuning. To expose the model to the variety in real-world data, we fine-tune the model with a small number of manually annotated dialogues.

Self-Training. Acquiring large fully-annotated WOZ datasets is challenging, because annotations are often erroneous. Acquiring *unannotated* WOZ datasets, on the other hand, is easier. To use such data when available, we propose using *self-training* (McClosky et al., 2006; Einolghozati et al., 2019; Zoph et al., 2020). We apply the model fine-tuned on few-shot data to unannotated input, create a training set using the predicted result as annotations, and use that to further fine-tune the model.

The annotation of WOZ dialogues requires predictions of the agent state as well, unlike the simulated dialogues where the agent state is generated automatically. We apply the same methodology as for the user states to the agent state, so as to annotate the full dialogues for training.

6 Evaluation

Our evaluation attempts to answer these research questions:

1. How well does our ThingTalk representation model Wizard-of-Oz conversations?
2. What accuracy can a model achieve in the task of predicting ThingTalk, given our training data acquisition strategy?
3. How well do our dialogue simulator and our dialogue agent approximate real dialogues?

6.1 Experimental Setting

We conduct our experiments using the MultiWOZ dataset (Budzianowski et al., 2018; Eric et al., 2019). This dataset includes English task-oriented dialogues across five domains: Attraction, Hotel, Restaurant, Taxi, and Train.

We reannotated parts of MultiWOZ 2.1 with ThingTalk annotations, and we name this version MultiWOZ 3.0. The authors of this paper reannotated the full test set and, due to a lack of time, 36% of the validation set, discarding the rest. Our result is thus a lower-bound on the possible accuracy: with more of the validation set annotated, we expect higher test accuracy.

The slot values in our new test set differ from the original annotations in 83% of the turns. This is not surprising because others have already found problems in MultiWOZ 2.1 (Zhou and Small, 2019; Zang et al., 2020; Han et al., 2020), and because ThingTalk and the existing annotations adopt different conventions for when a slot should be included. We found mistakes in the annotations, inconsistent normalization of names, and inconsistent annotation of slots offered by the agent. We dropped 1% of test turns due to unrecoverable human errors, such as the user acting as the agent.

We use four datasets for training:

- *Synthesized* dataset, generated using our state-machine-based simulator and agent, consisting of around 1M dialogues across all five domains. The state machine has 20 abstract transitions for the agent, and 43 for the user.
- *Paraphrase* dataset, obtained by automatically paraphrasing the synthesized data.
- *Few-Shot* dataset, a split of 168 dialogues from the original validation set. This amounts to 2% of the original training set. Another 265 dialogues in the original validation set are used as the 3.0 validation set.
- *Self-Trained* dataset, obtained by self-training on the MultiWOZ training set.

Dataset statistics are detailed in Appendix C.

We use the Genie Toolkit (Campagna et al., 2019) for data synthesis and Hugging Face's Transformers library (Wolf et al., 2020) for the model.

6.2 Precision of ThingTalk

ThingTalk is designed to precisely cover the semantics of Wizard-of-Oz dialogues. We first observe that ThingTalk captures the semantics of the sentences well: it can represent the validation set in its entirety, and 99.8% of the user utterances and 97.6% of the agent utterances in the test set are representable. Overall, that comprises 97.7% of the test turns. ThingTalk cannot represent, for example, out-of-domain questions, questions that cannot be answered using the given database, and agent utterances such as asking the users to wait.

User utterances in the test set that cannot be represented are simply counted as errors, while agent utterances that cannot be represented as marked with a single "invalid" dialogue act, which is given as input to the neural model. The model can choose to ignore the invalid dialogue act and attempt to predict the correct user state regardless.

6.3 Accuracy on the MultiWOZ 3.0 Test Set

Our first experiment evaluates how well our CSP model can understand the user utterances in the MultiWOZ 3.0 dataset on four metrics.

Exact match accuracy requires the predicted user state to identically match the annotation.

Slot accuracy requires the slots provided by the user in the predicted user state to match the annotation, ignoring comparison operators, requested slots, and the dialogue act.

Turn-by-turn accuracy assumes that the gold dialogue up to the current turn is available as input.

Dialogue accuracy requires predicting the correct state for *all* the previous and current turns of a given dialogue. This is a challenging but meaningful metric because in practice, once the model fails, the conversation diverges from the WOZ dialogue.

We train our CSP model on the combination of Synthesized and Paraphrased sets, fine-tune it on the Few-Shot training set, and fine-tune it again on the Self-Trained set. Our model achieves a 79.2% turn-by-turn accuracy and 44.1% dialogue accuracy in exact match (Table 2).

To understand the role of synthesized data, we removed all synthesized data, and train with only the manually annotated few-shot data. The synthesized data improves the turn-by-turn exact match accuracy by 5.5% and the dialogue exact match accuracy by 8.4%. This shows that the low-cost automatically generated training data is effective.

We performed an ablation study on the validation set to evaluate the components of our training strategy (Table 2). We first observe that the validation accuracy is higher than the test accuracy, because we used the validation set to refine our synthesis. Training with only synthesized data already delivers a respectable 61.8% turn-by-turn accuracy; with the augmentation of auto-paraphrasing data, turn-by-turn accuracy improves 0.1%, and dialogue accuracy improves 0.4%.

The few-shot training alone delivers a high accuracy of 75.6%. When the model trained on synthesized and paraphrased data is fine-tuned with few-shot data, the accuracy is 81.0%, showing that these two approaches complement each other. Self-training further improves the turn-by-turn accuracy by 0.4%, with 1% better dialogue accuracy.

Training Strategy		Turn-by-Turn EM	Turn-by-Turn Slot	Dialogue EM	Dialogue Slot
Test	Full training	**79.2%**	**87.5%**	**44.1%**	**61.0%**
	Few-shot only	73.7%	81.6%	35.7%	46.3%
Dev	Full training	**81.4%**	**88.7%**	**51.9%**	**67.2%**
	− self-training	81.0%	88.0%	50.9%	65.3%
	Synth. only	61.8%	73.1%	29.1%	38.0%
	Synth. + para.	61.9%	73.3%	29.5%	37.4%
	Few-shot only	75.6%	81.7%	41.8%	51.6%

Table 2: Turn-by-turn and dialogue accuracy, both exact match (EM) and slot, of the CSP model, on the MultiWOZ 3.0 test and validation sets.

Category	% Turns	Accuracy
Trained	15.5%	93.1%
In-simulation	69.7%	82.4%
Out-of-simulation	14.7%	62.7%
Unknown agent state	6.3%	66.0%
Domain switch	4.0%	84.0%
Eager action parameters	0.9%	73.3%
Multidomain	0.8%	16.7%
Abandon transaction	0.5%	25.0%

Table 3: Turn-by-turn exact match accuracy of validation set, categorized by whether each user utterance is synthesizable by our simulator. For the unsynthesizable category, we further divide in common classes of user behavior not captured by the simulator.

6.4 Generalization of the Dialogue Model

Our strategy is to handle the complexity of Wizard-of-Oz dialogues with a combination of simulated dialogues and few-shot training samples to teach generalization beyond simulated dialogues. We analyze the validation set to understand the difference between the simulated dialogues and the Wizard-of-Oz dialogues, and its effect on accuracy.

The results are shown in Table 3. The validation set is divided into:

1. Trained: 15.5% of the validation set turns share the same formal dialogue and user state with some sample in training (ignoring the slot values). Accuracy obtained: 93.1%.
2. In-simulation: 69.7% of the validation set turns can be represented by the simulator: the formal context is contained in $\mathcal{D}_{\text{Sim}}$, and the user state can be generated by the simulator. Accuracy obtained: 82.4%.
3. Out-of-simulation: 14.7% of the validation turns require the model to generalize beyond $\mathcal{D}_{\text{Sim}}$, either through few-shot or its own generalization capabilities. Accuracy obtained: 62.7%.

Our synthesizer covers the Wizard-of-Oz conversations well. Even though our simulator and agent are built using a state machine with only 54 user transitions and 24 agent transitions, 85.2% of the validation set is in-simulation.

Model	Training Data	Accuracy
TRADE	MultiWOZ 2.1	37.3%
TRADE	0-shot 2.1	12.1%
SUMBT	MultiWOZ 2.1	39.3%
SUMBT	0-shot 2.1	18.3%
STAR	MultiWOZ 2.1	**49.9%**
CSP-NoAgent	MultiWOZ 2.1	45.6%
CSP-NoAgent	0-shot 2.1	13.3%
CSP-NoAgent	+ auto-parap.	12.2%
CSP	MultiWOZ 3.0	37.3%
CSP	Synthesized	23.6%
CSP	+ auto-parap.	25.2%

Table 4: Dialogue slot accuracy on the MultiWOZ 2.1 test set. CSP-NoAgent has no formal agent state; it encodes the previous slots, and the current agent and user utterances. 0-shot 2.1 is the synthesized data by Campagna et al. (2020). CSP was trained on MultiWOZ 3.0 but tested on 2.1.

Research that trains and validates on simulated data is missing a non-trivial population of Wizard-of-Oz dialogues. We found that 14.7% of the validation turns are representable in ThingTalk but are out-of-simulation.

Our training strategy generalizes beyond the simulated dialogues. For the out-of-simulation turns, our model achieves an accuracy of 62.7%. The model can generalize well on validation turns where the agent state is unseen in training, achieving 66% accuracy. This result speaks to the strength of using a formal representation of the agent, which avoids interpreting untrained agent utterances.

The model also reacts well to strong signals in the user utterance. The model achieves 84.1% accuracy when the user switches domains unexpectedly, and 73.3% accuracy when the user starts issuing slots for the action before completing the query.

Finally, when the user issues a command over two domains at once, the model achieves 16.7% accuracy. When the user abandons a booking transaction mid-way, the model achieves 25% accuracy. These kinds of out-of-simulation states are also rare in the few shot training set. The model can generalize, but is biased towards the common cases seen in the training data.

6.5 Dialogue History vs. Formal Context

We wish to evaluate the difference between using dialogue history, as in DST models, and using a formal context. We do so by measuring the dialogue accuracy, which has the same definition for DST and CSP.

Because we do not have the resources to reannotate the training data with ThingTalk, we will use the MultiWOZ 2.1 training set for this experiment. For a DST parser, we use TRADE (Wu et al., 2019), SUMBT (Lee et al., 2019), and STAR (Ye et al., 2021b), three high-performing models for MultiWOZ 2.1. For CSP, we train a model we call CSP-NoAgent, which uses the same neural architecture as our CSP. Because MultiWOZ 2.1 has no formal agent state annotations, CSP-NoAgent uses the original slot-value annotation from the immediately preceding turn as the formal input context. This context, the current agent utterance, and the current user utterance are used to predict all the slots from the dialogue. This is the best approximation to ThingTalk possible given the available data; the results provide a lower bound on CSP with fully annotated training data.

The results are shown in Table 4. We see that CSP-NoAgent outperforms TRADE by 8.3% and SUMBT by 6.3% in dialogue accuracy, and is within 4% of STAR, a highly optimized model. Note that CSP-NoAgent needs *no new annotations*, and the slot representation captures only a small subset of the information in the utterances. This shows the advantage of replacing the dialogue history with a formal context. It also shows that the use of formal contexts can be applied in other representations.

For comparison, we also test our CSP on MultiWOZ 2.1, using self-predicted formal agent states. Our model, trained on MultiWOZ 3.0, reaches 37.3% dialogue accuracy in the MultiWOZ 2.1 test set. This is due to the reannotation of MultiWOZ 3.0, and because the model is trained and tested on data with different annotation conventions. Compared to the dialogue slot accuracy on MultiWOZ 3.0, we observe a gap of about 11%, which serves as a lower bound on the benefit of having experts annotate the test data. Note that our approach does not require manual annotation of a large training set, and therefore expert annotation of test data was feasible.

6.6 Comparison with Previous 0-Shot Model

Our last experiment compares our work with the zero-shot model proposed by Campagna et al. (2020). Their paper only included results with transfer learning on new domains. Here, we evaluate TRADE, SUMBT, and CSP-NoAgent trained with their synthesized data in a zero-shot fashion. The results shown in Table 4 indicate that the previous approach is inadequate, achieving only 12.1% dialogue accuracy with TRADE and 18.3% with SUMBT. CSP-NoAgent achieves 13.3% dialogue accuracy. Our approach, instead, achieves 23.6% dialogue accuracy. Adding automatic paraphrasing increases the turn-by-turn accuracy by about 3% for both models.

This result shows that our approach is much more effective in synthesizing data. In particular, it is important to represent the agent state formally when training with synthesized data, as it eliminates the need to synthesize and parse agent utterances.

7 Conclusion

This paper presents a sample-efficient methodology, based on the extended ThingTalk representation, to predict precise dialogue states in Wizard-of-Oz conversations. We achieve a turn-by-turn exact-match accuracy of 79.2% on the MultiWOZ 3.0 dataset, while using 50x less manually annotated training data than the original MultiWOZ dataset.

The proposed ThingTalk dialogue representation is precise, complete, and executable. It is *precise* enough to cover 98% of the dialogue turns in MultiWOZ. The precision enables automatic synthesis of dialogues covering 85% of the MultiWOZ data set. ThingTalk is *complete* and *executable*, as evidenced by a fully working agent that can simply execute ThingTalk queries without referring to the user input. Furthermore, the agent can handle dialogue flows beyond those that can be simulated.

The accuracy is achieved with a contextual semantic parser (CSP) where the dialogue context is represented in ThingTalk rather than the natural language dialogue history. It is trained first with auto-paraphrased synthetic data, fine-tuned with the few-shot annotated data, then self-trained.

In summary, this paper shows that with ThingTalk, we can predict WOZ dialogues accurately with training data mostly generated from a state machine. Our methodology thus combines the best of the WOZ and M2M approaches, as it can handle the more realistic WOZ dialogues, while having a low data acquisition cost like M2M.

8 Ethical Considerations

We envision that our training strategy will broaden the availability of task-oriented agents for tasks and populations not currently covered by existing large-scale datasets, due to its low annotation requirement. We have open-sourced tool set designed around our representation for bootstrapping affordable contextual semantic parsers for new domains.

Our agent was tuned and evaluated on the MultiWOZ benchmark. MultiWOZ is a crowdsourced Wizard-of-Oz dataset; WOZ datasets are known not to fully represent real-world conversations (Ganhotra et al., 2020). Further research is needed before a dialogue agent based on our methodology can be deployed in the real world. Additionally, the current version of the agent was tuned for English; future work should investigate techniques to automatically localize a contextual semantic parser, analogous to prior research done for single-turn semantic parsers (Moradshahi et al., 2020).

Our training strategy replaces manual annotation of data with automatically obtained data, which requires some additional amount of computation time. In practice, such additional compute is small: data synthesis runs in 5 hours on a single machine with no GPUs; the paraphrase dataset can be obtained in about 5 hours on a machine with 4 Nvidia T4 GPUs; training completes within 8 hours on a machine with one Nvidia V100; self-training requires 2 hours on a single Nvidia T4 GPU, and fine-tuning is another 1.5 hours on one Nvidia V100. Overall, the whole process is done with about 22 hours of compute time, well below the cost of human annotation of equivalent amounts of data. We note that the large amount of synthetic data poses no challenge to convergence in practice, so training models with a large amount of synthesized data has little effect on the compute cost.

The manually annotated portion of our dataset was obtained from the previously released MultiWOZ 2.1 dataset, a crowdsourced dataset. No crowdsourcing was employed in this paper; the data was annotated by the authors.

A ThingTalk Definition

A.1 Syntax

Formal Dialogue d : $a\ \ r^*\ \ s^*$
User State u : $ua\ \ s^*$
Agent State a : $aa\ \ as^?$
User Act ua : Greet | Exec | Cancel | Insist
| AskRecommend | LearnMore
| ActionQuestion | End | Invalid
Agent Act aa : Init | Greet | RecommendOne
| RecommendMany | Propose
| SearchQuestion | SlotFill
| LearnMoreWhat | EmptySearch
| Confirm | ActionSuccess
| ActionError | AnythingElse
| Invalid
User Statement s : q | ac
Result r : $s\ \ [\,\{[sn = v]^+\}\,]*$
Agent Statement as : Request sn^+
| [Propose | Confirm] [q | ac]
Query q : <ThingTalk query>
Action ac : $dn\ ([sn = v]^*)$
Domain Name dn : <identifier>
Slot Name sn : <identifier>
Value v : <constant>

A.2 Agent Definition

The agent is a function $\text{Agent}(d, u) = d'$ that computes the new formal representation of the entire dialogue. The representation is constructed incrementally, starting from the initial dialogue d_0 which is empty.

Let $d = (a, r, s) \in \mathcal{D}$ and $u = (ua, s_\text{u}) \in U$ be the two inputs to the agent. The agent computes the new agent state a as follows:

$$\begin{aligned}(r_\text{u}, is_\text{u}) &= \text{Execute}(s_\text{u})\\ a' &= \text{Policy}(ua, r || r_\text{u}, is_\text{u})\\ d' &= (a', r || r_\text{u}, is_\text{u})\end{aligned}$$

where $||$ denotes concatenation. The Execute function calls the ThingTalk runtime to execute the statements in the user state, s_u. It returns (1) the results r_u by executing all statements in s_u whose required parameters are available, (2) the rest of the (incomplete) statements, is_u. The Policy function determines the agent state a' from the user state ua. all the results r_u appended to previous results r, and is_u. The agent returns the new dialogue d' with the new agent state, all the results and the new incomplete statements. The incomplete statements s in d are discarded. If the user has not changed topics, information in s is incorporated in s_u.

B Training

B.1 Preprocessing

We apply the same preprocessing used by TRADE (Wu et al., 2019) to the input utterances. We also use a rule-based preprocessor to identify time expressions, and replace them with placeholder tokens. All slot values in the result and agent states that have string or time type are replaced with a placeholder when input to the model.

We normalize all slot values in the user state to match the utterance, regardless of typos. When comparing the slot values for equality, we normalize entity names via a database lookup.

B.2 Hyperparameters

Our model uses a BART large model which has 400 million trainable parameters. We use the Adam optimizer, with the Transformer learning rate schedule (800 iterations of warm-up, 0.04 multiplier).

We train our model for 50,000 gradient updates on the synthesized data and choose the model with the highest validation exact-match accuracy. We then fine-tune that model on the few-shot training set for 15,000 gradient updates, and again choose the model with the highest validation accuracy. We repeat this process for another 15,000 updates on the self-train set. Training is done on a single GPU with 16 GB memory and batch size is chosen based on the length of the examples in each batch: we choose as many examples as we can fit in the GPU memory. Gradient accumulation is used to increase the effective batch size by a factor of 20.

C Dataset Statistics

	# dlgs	# turns	# words
Synthesized	968,007	830,792	11,390,957
Paraphrased	592,970	945,946	12,845,548
Few-Shot	168	1,061	14,669
Self-Training	8,420	56,546	760,927
Validation	265	1,582	21,256
Test	995	7,271	100,814

Table 5: Statistics of our training and evaluation sets: number of dialogues, of turns, and of words. For the synthesized dataset, we do not count turns that appear identically in multiple dialogues.

D Annotated Example Dialogue

Here is an example of a dialogue generated by the simulator, between the user U and the agent A. US denotes the user state, D denotes the formal dialogue.

U: List good restaurants which offer Indian.
US: Exec: Restaurant, food = “Indian”;
A: Do you have a specific part of town in mind?
D: SearchQuestion: area;
Restaurant, food = “Indian”
[{ name = “Cocum”, area = west, ... },
{ name = “Rajmahal”, area = east, ... },
...];
U: Yes I’d like near the east.
US: Exec: Restaurant, food = “Indian” && area = east;
A: I have Rajmahal and Curry Prince.
D: RecommendTwo
Restaurant, food = “Indian”
[...];
Restaurant, food = “Indian” && area = east
[{ name = “Rajmahal”, area = east, ... },
{ name = “Curry Prince”, area = east, ... },
...];
U: Is Curry Prince a restaurant serving Indian?
US: Exec: [food] of Restaurant, food = “Indian” && area = east && name = “Curry Prince”;
A: Curry Prince serves Indian. Would you like me to book it?
D: RecommendOne: Propose Restaurant.MakeReservation(name=“Curry Prince”, book_people=6);
Restaurant, food = “Indian”
[...];
Restaurant, food = “Indian” && area = east
[...];
[food] of Restaurant, food = “Indian” && area = east && name = “Curry Prince”
[{ name = “Curry Prince”, food = “Indian” }];
U: I will take it. Please make a reservation at the restaurant on Monday at 13:00.
US: Exec: Restaurant.MakeReservation(name=“Curry Prince”, book_people=6, book_day=Sunday, book_time=13:00)
A: Alright, Consider your request done! Its confirmation number is ay05tzjq. Anything else for you today?
D: ActionSuccess;
Restaurant, food = “Indian”
[...];
Restaurant, food = “Indian” && area = east
[...];
[food] of Restaurant, food = “Indian” && area = east && name = “Curry Prince”
[...];
Restaurant.MakeReservation(name=“Curry Prince”, book_people=6, book_day=Sunday, book_time=13:00)
[{ reference_number = “ay05tzjq” }];
U: Thanks, this is good for now. Goodbye!
US: End

GCPG: A General Framework for Controllable Paraphrase Generation

Abstract

Controllable paraphrase generation (CPG) incorporates various external conditions to obtain desirable paraphrases. However, existing works only highlight a special condition under two indispensable aspects of CPG (i.e., lexically and syntactically CPG) individually, lacking a unified circumstance to explore and analyze their effectiveness. In this paper, we propose a general controllable paraphrase generation framework (**GCPG**), which represents both lexical and syntactical conditions as text sequences and uniformly processes them in an encoder-decoder paradigm. Under GCPG, we reconstruct commonly adopted lexical condition (i.e., *Keywords*) and syntactical conditions (i.e., *Part-Of-Speech sequence*, *Constituent Tree*, *Masked Template* and *Sentential Exemplar*) and study the combination of the two types. In particular, for *Sentential Exemplar* condition, we propose a novel exemplar construction method — Syntax-Similarity based Exemplar (**SSE**). SSE retrieves a syntactically similar but lexically different sentence as the exemplar for each target sentence, avoiding exemplar-side words copying problem. Extensive experiments demonstrate that GCPG with SSE achieves state-of-the-art performance on two popular benchmarks. In addition, the combination of lexical and syntactical conditions shows the significant controllable ability of paraphrase generation, and these empirical results could provide novel insight to user-oriented paraphrasing.

1 Introduction

Paraphrase generation (Madnani and Dorr, 2010) refers to restating a given sentence into an alternative surface form while keeping the semantics unchanged.[1] It is of long-standing interest (McKeown, 1983), with various applications such as question answering (Gan and Ng, 2019), machine translation (Mallinson et al., 2017), and sentence simplification (Martin et al., 2020). However, a sentence can be re-expressed in various surface forms. Lacking control might result in undesirable results (Gu et al., 2019). For example, a sentence that contains an intricate syntactic structure may cause difficulties for aphasic patients (Shewan, 1985). In that case, we could attempt to paraphrase it based on syntactical control.

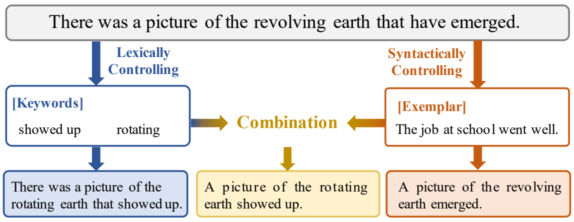

Figure 1: A toy example to explain what effect lexically controlling and syntactically controlling have on paraphrasing.

To obtain desirable surface forms, most recent works focus on controllable paraphrase generation (CPG) by incorporating external conditions. Existing efforts to CPG can be roughly divided into two types: lexically and syntactically CPG. Lexically CPG is concerned with *what to say*, which generates paraphrases that contain pre-specified keywords. As shown in Figure 1, a lexically CPG model needs to generate a paraphrase that contains the given keyword “showed up”. To achieve it, a sequence-to-sequence model equipped with the copy mechanism is commonly used (Zeng et al., 2019). Different from lexically CPG, syntactically CPG concentrates on *how to say it*, generating a paraphrase that conforms to the syntax of a given exemplar (i.e., a sentence illustrating certain syntax patterns). Substantial efforts have been made on constructing syntactical features of the given exemplar. For example, Kumar et al. (2020) incorporate a full syntactic tree of the exemplar to

guide paraphrasing; Bui et al. (2021) construct a masked template to direct generation by masking words with certain Part-of-Speech (POS) type of exemplar; Chen et al. (2019) directly use the sentential exemplar. Since sentential exemplars are only available for testing, they have to manufacture exemplars for training by replacing certain words from the target sentence.[2] Despite the progress on the two types of conditions individually, *what to say* and *how to say it* are both important for CPG (Kumar et al., 2020). Furthermore, there is no unified framework to study the effectiveness of these conditions and their joint utilization.

To fill this gap, we propose a **G**eneral **C**ontrollable **P**araphrase **G**eneration framework (GCPG) to jointly include both lexically and syntactically CPG in a unified model. The key idea is to reconstruct both lexical and syntactical conditions as text sequences and process them in a text-to-text encoder-decoder paradigm. This also allows GCPG to easily utilize the strong language modeling capacity of pre-trained language models (PLMs), which have demonstrated great potential (Bui et al., 2021) yet rarely been explored under the topic of CPG. For the lexical condition, we concatenate the pre-specified keywords as a sequence while exploring different methods to pre-specify keywords from rule-based to model-based. As for syntactical conditions, we reconstruct commonly used syntactic features as sequences, such as Linearised Constituent Tree (Iyyer et al., 2018) and masked template based on word mask (Bui et al., 2021). Besides the manufactured syntax features, we hypothesize that directly using the exemplar is more effective as it can benefit from the powerful sentence modeling capability of PLMs. To construct the exemplar for training, we propose a novel exemplar construction method as **S**yntax-**S**imilarity based **E**xemplar (SSE). Specifically, we use a sentence that is syntactically similar but lexically different from the target sentence, which is retrieved in a self-constructed exemplar dictionary based on the training set. This is different from existing methods that construct exemplar through modifying target sentences (Chen et al., 2019), alleviating exemplar-side words copying problem (Bui et al., 2021) brought by Chen et al. (2019).

We examine GCPG on two popular benchmark datasets. Those discussions include not only performances of different conditions and their combinations, but also the effectiveness of GCPG instantiated by different PLMs. Experiments demonstrate that GCPG consistently shows strong performances when tested by three different methods to pre-specify keywords. For syntactical CPG, GCPG with SSE obtains 13.95/24.31/18.64 ROUGE-1/2/L and 16.38 BLEU-4 over the previous state-of-the-art (SOTA) model (Bui et al., 2021). Also, the combination of lexical and syntactical conditions show encouraging controllability of paraphrase generation in both quantitative and qualitative analysis. The main contributions are as follows:

- We propose **GCPG**, a general framework to jointly include both lexically and syntactically controllable paraphrasing. It is simple but effective, enabling flexible combinations of conditions by reconstructing them into text sequences and processing them in a text-to-text encoder-decoder paradigm. Those properties allow GCPG to easily adapt to mainstream pre-trained language models and utilize powerful language modeling capacity, which is rarely explored in CPG.
- We report a novel exemplar construction method **SSE** under the syntactical condition. It allows GCPG to directly model syntax information from natural sentences without any manufactured syntax features, while alleviating the exemplar-side words copying problem.

2 Related Work

In this section, we summarize existing works on syntactically and lexically CPG. Syntactically CPG generates a paraphrase constrained by a pre-specified sentence of a certain syntax structure namely exemplar. However, the exemplar is only available during inference, resulting in a key challenge: obtaining manual exemplars for existing paraphrasing training datasets is prohibitively expensive. To address this, some of the previous works construct syntactical features from target sentences during training, such as *POS Tagging*, *Constituent Tree*, *mask template* as illustrated in Table 1. For instance, SCPN (Iyyer et al., 2018) makes the first attempt to introduce Linearised Constituent Tree (LCT) of target sentence into paraphrasing, where LCT is predicted based on predefined parse templates. Similarly, GuiG (Li et al., 2020) proposes two models to expand a partial template LCT and generate paraphrasing, respectively. SOW-REAP (Goyal and Durrett, 2020) uses

LCT to reorder the source sentence then paraphrasing. AESOP (Sun et al., 2021) selects target LCT adaptively while paraphrasing. Different from using LCT, SGCP (Kumar et al., 2020) introduces a graph encoder to encode the Constituent Tree of exemplar as the condition. *masked template* replaces several words of the exemplar with a special token to form a template as the condition. BCPG (Liu et al., 2020c) follows BERT (Devlin et al., 2019) to randomly mask exemplar words, ParafraGPT (Bui et al., 2021) further masks exemplar words with certain POS types. However, Chen et al. (2019) advocate to directly utilize the sentential exemplar (the sentence) as the condition, because they believe "any syntactically valid sentence is a valid exemplar". Since exemplar is only available in testing, they construct exemplar by replacing words of the target sentence with others that have the same POS type. In addition, lexical constraints decoding is widely explored in text generation (Liu et al., 2020a, 2019; Hokamp and Liu, 2017a), such as neural machine translation (Hokamp and Liu, 2017b; Post and Vilar, 2018) and text summarizing. CTRLsum (He et al., 2020) uses target entity words as keywords to hint model while summarizing. However, lexically CPG constraints paraphrasing with pre-specified keywords, which is rarely explored but undoubtedly indispensable in CPG. Zeng et al. (2019) make the first attempt to integrate keywords with copy mechanism. Despite their progress, existing works only focus on a special condition under either lexically or syntactically CPG. In comparison, GCPG jointly includes lexically and syntactically CPG.

3 Methodology

3.1 GCPG Framework

Before introducing GCPG, we first give the definition of controllable paraphrase generation with external conditions. Given a source sentence $\boldsymbol{x}$ and a variety of conditions $\boldsymbol{c}$, the model generates paraphrase $\boldsymbol{y} = (y_1, y_2, ..., y_T)$ by:

$$p(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{c}) = \prod_{t=1}^{T} p(y_t|y_{<t}, \boldsymbol{x}, \boldsymbol{c}; \theta), \quad (1)$$

where θ are the model parameters trained by maximizing the conditional likelihood of outputs in a parallel corpus. Given this definition, the forms of conditions $\boldsymbol{c}$ might be varied, such as pre-defined keywords and Constituent Parse Tree. To uniformly encode these conditions and investigate their effectiveness, we propose a general framework GCPG. GCPG contains a standard encoder-decoder paradigm, which allows any mainstream PLMs to adapt to this task rapidly. Meanwhile, GCPG can flexibly use the combinations of included conditions by concatenating them as one sequence with "[SEP]". As shown in Figure 2, the source sentence "No one's home ?" is concatenated with optional sequential conditions by the separator signal "[SEP]", then fed into the model. Afterward, the model auto-regressively generates "Is anyone home?" as the final result.

3.2 Conditions under GCPG

3.2.1 Syntactical Condition

Syntactically CPG requests a syntax exemplar to constrain the syntax structure of paraphrase. However, exemplars are only available in the testing set

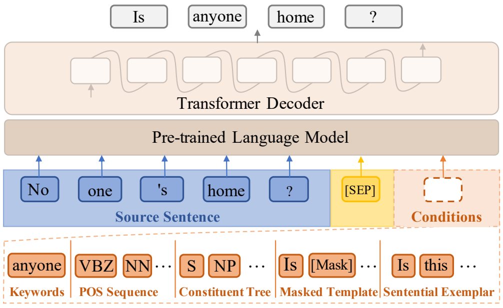

Figure 2: An overview of GCPG, the source sentence and separated condition (also being concatenated with "[SEP]") are concatenated as input.

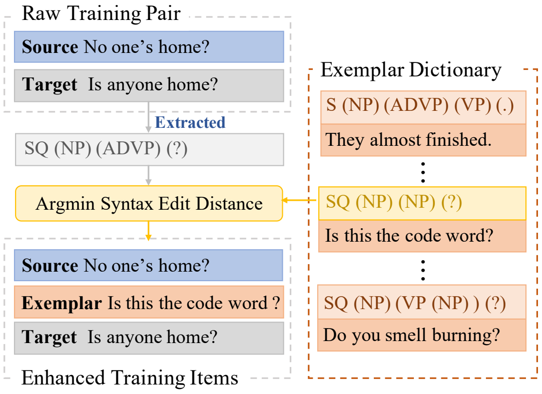

Figure 3: An overview of SSE. We take Truncated LCT as the sequential syntax structure here.

of existing paraphrasing datasets. To train a syntactically CPG model, we construct a syntactical condition based on the target sentences in the training set. During inference, we apply the same strategy to obtain the corresponding syntactical conditions from exemplars in the testing set. We explore four syntactical conditions in this work, as follows:

POS Tagging is one of simplest solutions in modeling the syntax structure (Cutting et al., 1992), which could be effectively implemented and show promising performance in various NLP tasks (Yang et al., 2021). We investigate POS Tagging as an independent condition, which is rarely explored in CPG. In detail, we extract POS sequence of target sentence by CoreNLP as the condition.[3] To learn these POS signals with PLMs, we regard these POS tokens as special ones and add them into the word vocabulary of PLMs.

Constituent Tree is a widely used condition for syntax controlling while paraphrasing. Here, we explore two kinds of LCT, i.e., full-fledged LCT and Truncated LCT. For the full-fledged LCT condition, we extract the complete sequential Constituent Tree from the target sentence for training and exemplar for testing, based on the off-the-shelf tools of CoreNLP. We further explore the Truncated LCT condition, which is the sequence that removing POS-level tokens in full-fledged LCT. Compared with full-fledged LCT, Truncated LCT drastically shortens the input length.

Masked Template is first introduced in Liu et al. (2020c), which randomly masks words of the target sentence to form a syntax template as the condition. To verify the effectiveness of this method in GCPG circumstance, we follow the current SOTA (Bui et al., 2021) to construct a masked template by substituting all nouns, adjectives, adverbs, and verbs with a special token in the exemplar. Similarly, this strategy is applied to the target sentences during training and the given exemplars during inference.

Sentential Exemplar is the most straightforward way for syntactically CPG, which directly uses the sentential exemplar as the condition. In contrast to the above three syntactical conditions, Sentential Exemplar uses natural sentences to represent desirable syntax structure, without introducing any special token which does not appear during PLMs pretraining. We argue that this way can make better use of PLMs. However, the previous method (Chen et al., 2019) suffers from the exemplar-side words copying problem during testing, which might be caused by the noticeable words overlap with the target sentence in constructing sentential exemplar during training. To alleviate this problem, we propose **S**yntax-**S**imilarity based **E**xemplar (**SSE**) to enhance sentential exemplar condition.

An overview of our SSE method is demonstrated in Figure 3. To alleviate the exemplar-side words copying issue, the proposed SSE constructs Sentential Exemplar by retrieving a syntactically similar but lexically different sentence for each target sentence during training. To achieve that, we construct an exemplar dictionary that contains the syntactical key-value mapping from the syntax structure $\boldsymbol{k}$ to its corresponding natural sentence $\boldsymbol{v}$. Each syntactical key $\boldsymbol{k} \in \boldsymbol{K}$ is a Truncated LCT sequence, and its value is a randomly selected natural sentence that can be assigned to this Truncated LCT sequence. During training, given a data pair $\langle \boldsymbol{x}, \boldsymbol{y} \rangle$ and the Truncated LCT $\boldsymbol{s}$ of $\boldsymbol{y}$, we select a syntactical key $\boldsymbol{k}^*$ by calculating the syntax edit distance D_{syn} between $\boldsymbol{s}$ and each syntactical key in the

---

[3] `https://stanfordnlp.github.io/CoreNLP/index.html`

exemplar dictionary, which can be formulated as:

$$\begin{aligned} \boldsymbol{k}^* &= \arg\min(D_{\text{syn}}(\boldsymbol{s}, \boldsymbol{k})) \\ &= \arg\min_{\boldsymbol{k}\in\boldsymbol{K}}(\frac{\text{LevEdit}(\boldsymbol{s}, \boldsymbol{k})}{\max(|\boldsymbol{s}|, |\boldsymbol{k}|)}), \end{aligned} \tag{2}$$

where LevEdit$(\cdot)$ denotes the token-level Levenshtein edit distance between two sequences and $|\cdot|$ denotes the token-level length of the sequence. We assign the corresponding sentence $\boldsymbol{v}^*$, which is related to $\boldsymbol{k}^*$, as the training exemplar.

Lexical Condition Lexically CPG uses pre-specified keywords to constrain paraphrasing, which requires a paraphrasing dataset containing ⟨*sentence*, *keywords*, *paraphrase*⟩ triples. Because the original dataset is formatted as ⟨*sentence*, *paraphrase*⟩, we need to pre-specify keywords for each data item. Following Zeng et al. (2019), we automatically extract keywords from the target sentence as the condition in the training stage. Besides, as also lacking manual keywords for each testing pair, we carry out two strategies for inference. On the one hand, we directly extract keywords from references as conditions following Zeng et al. (2019). On another, a standard sequence-to-sequence model is used to predict target keywords only from source sentences as conditions while testing, as described in Liu et al.(2020b). Specifically, we investigate three representative keyword extraction methods to verify the effectiveness of GCPG, including rule-based TF-IDF, TextRank (Mihalcea and Tarau, 2004), and model-based KeyBERT (Grootendorst, 2020). Each method filters out the stop words and punctuation, and guarantees the extracted keywords do not appear in the corresponding source sentence. The maximum number of keywords is set to 3. Besides, we use a special token "[NONE]" when there are no keywords extracted.

4 Experiments

Datasets Following previous works (Kumar et al., 2020; Bui et al., 2021), we evaluate GCPG on two datasets: (1) **ParaNMT-small** (Chen et al., 2019) is a subset of ParaNMT-50M dataset (Wieting and Gimpel, 2018), which is collected via back-translation referring to English sentences. It contains 500K training pairs formatted as ⟨sentence, paraphrase⟩, and 1.3K manually labeled data triples formatted as ⟨*sentence*, *exemplar*, *paraphrase*⟩ (0.8K for testing and 0.5K for validation). In each triple, *exemplar* is a sentence that has the same syntax as *paraphrase* but is semantically different from *sentence*. (2) **QQP-Pos** (Kumar et al., 2020) is selected from Quora Question Pairs (QQP) dataset. It contains about 140K training pairs and 3K/3K data triples for testing/validation. The format of dataset is the same as ParaNMT-small.

4.1 Syntactically Controllable Paraphrasing

We explore four syntactical conditions reconstructed by GCPG on the ParaNMT-small dataset, then compare SSE with baselines on two datasets.

Baselines We first choose two direct return-input baselines as dataset quality indicators: (1) *Source-as-Output* copies inputs as outputs. (2) *Exemplar-as-Output* regards exemplars as outputs. Next, we compare GCPG with mainstream competitive models as follows. (3) *SCPN* (Iyyer et al., 2018) has two encoders to encode source sentence and LCT separately, then constrain generation with soft attention mechanism.[4] (4) *CGEN* (Chen et al., 2019) encodes exemplars into latent vector to guide paraphrasing.[5] (5) *SGCP* (Kumar et al., 2020) uses a graph encoder to process the exemplar Constituent Trees as the condition.[6] (6) *ParafraGPT* (Bui et al., 2021) masks words with certain POS types in the target sentence as condition, then builds a paraphrasing generator based on a pre-trained GPT2 (Radford et al., 2019).

Syntactical Conditions We first examine conditions with manufactured syntax features, including (7) *POS Sequence*, (8) *LCT-Truncated* is the *LCT* sequence without POS-level information, (9) *LCT* is the full-fledged Linearised Constituent Tree sequence, and (10) *Masked Template*. Then, two implementations of SSE are evaluated: (11) *SSE-POS Sequence* uses *POS Sequence* to measure syntax similarity, and (12) *SSE-LCT-Truncated* uses *LCT-Truncated* as measurement.

Implementation and Hyper-parameters All GCPG models are instantiated by ProphetNet-large (Qi et al., 2020)[7]. We employ the original hyper-parameter setting of ProphetNet-large to train GCPG. During inference, the beam size and length penalty(Wu et al., 2016) are set to 4 and 1.2 following Bui et al. (2021). As for the

Table 2: Results of different syntactical conditions and comparisons with baselines on ParaNMT-small and QQP-Pos datasets. B-R: BLEU-R. R-1: ROUGE-1. R-2: ROUGE-2. R-L: ROUGE-L. MTR: METEOR. BS: BERTScore. ↑ means higher score is better where ↓ is exactly the opposite. The highest numbers are in **bold**.

SSE dictionary size, the ParaNMT-small has 27530 truncated LCT (the average number of sentences for each LCT: 2.83) and QQP-Pos has 8561 (the average number of sentences for each LCT: 5.99).

Metrics Following previous works (Iyyer et al., 2018; Bui et al., 2021), we evaluate generating results on six metrics, including BLEU-4 (Papineni et al., 2002), ROUGE-1 (R-1), ROUGE-2 (R-2), ROUGE-L (R-L) (Lin, 2004), Meteor (MTR) (Denkowski and Lavie, 2014), and BERTScore (BS) (Zhang et al., 2020). Besides, *Source-as-Output* will also get a high BLEU score and BERTScore, we introduce iBLEU (Sun and Zhou, 2012) for more precise evaluation. As a variant of BLEU, iBLEU considers both fidelity to *reference* and diversification from *input*:

$$\begin{aligned} \text{iBLEU} &= \alpha\text{BLEU-R} - (1 - \alpha\text{BLEU-S})\,, \\ \text{BLEU-R} &= \text{BLEU-4}\,(\mathit{output}, \mathit{reference}), \\ \text{BLEU-S} &= \text{BLEU-4}\,(\mathit{output}, \mathit{input}), \end{aligned} \tag{3}$$

where the constant α is set to 0.7, as in the original paper. Finally, for syntactical condition evaluation, we follow Kumar et al. (2020) to calculate Tree-Edit Distance (TED)[8] between the Constituency Parse Trees of both *output* and *reference*.

Results As shown in Table 2, the main conclusions are: (1) SSE consistently and significantly outperforms conditions that constructed with manufactured syntax features (Rows 11-12 vs. Rows 7-10). (2) GCPG with SSE gets significant improvement over the previous SOTA (Row 12/19 vs. Row 6/18). (3) All syntactical conditions reconstructed in GCPG outperform baselines (Rows 7-12 vs. Rows 3-6), demonstrating the superiority of GCPG paradigm. However, the TED of GCPG is lower than CGEN on ParaNMT-small dataset. As the ParaNMT-small contains various noise data points, it is optimistic to assume that the corresponding constituency parse tree could be well aligned (Kumar et al., 2020), which may limit TED in evaluation. To address this issue, we also conduct a human evaluation (details in § 4.3). As shown in Table 4, GCPG with SSE (GCPG-S) performs better than CGEN on Syntax score.

4.2 Lexically Controllable Paraphrasing

As mentioned in § 3.2, we use three different keyword extraction methods to pre-specify keywords and comprehensively evaluate the GCPG: (1) *TF-IDF* (2) *TextRank* (Mihalcea and Tarau, 2004), and (3) *KeyBERT* (Grootendorst, 2020). Also, we compare GCPG with recent competitive method CTRL-

---

[8] We use the evaluation tool implemented by SGCP.

Condition	**iBLEU ↑**	**B-R ↑**	**R-1 / R-2 / R-L ↑**	**MTR ↑**	**BS ↑**	**TED ↓**
Keywords Extraction, GCPG instantiated by ProphetNet

(10) GCPG (KeyBERT* + Mask Template)	12.13	20.98	58.83 / 33.58 / 61.01	35.02	92.67	8.44
(11) GCPG (KeyBERT* + SSE-POS)	15.67	**31.02**	66.85 / 45.30 / 68.48	40.12	90.39	7.95
(12) GCPG (KeyBERT* + SSE-LCT-Truncated)	**15.73**	30.92	**68.40 / 46.73 / 69.93**	**41.98**	**94.34**	7.95

Table 3: Performance of different conditions and combinations under GCPG on ParaNMT-small. For fair comparison, we use CTRLsum instantiated by ProphetNet. Result with * means that we use a vanilla ProphetNet trained on the same dataset to predict keywords for GCPG while testing.

sum (He et al., 2020), which extracts entity words as keywords. We follow the settings in § 4.1.

Metrics For lexical condition, it should be noted that there is a lack of the explicit request of desirable keywords in the testing set. A generated paraphrase hinted by model predicted keywords might get a low score in BLEU, although humans consider it reasonable. This is because paraphrasing models might focus on keywords that are not consistent with the single reference. Therefore, we evaluate GCPG in three settings. First, following Liu et al.(2020b), we use a keywords prediction model to generate top-k groups of keywords, which are fed into GCPG to generate k paraphrases. Then the sentence that has the highest BLEU with the reference is selected as the final output (marked with *). k is set to 4 as well as beam size. Note that we use this setting to report the final results unless otherwise specified. Second, we further conduct human evaluations on the keyword condition based on *KeyBERT* (The details are in § 4.3). We denote it as "GCPG-L (k=1)". Here "k=1" means GCPG only produces one paraphrase for each input, constrained by the top-1 set of keywords produced by *KeyBERT*. Third, following Zeng et al. (2019), we directly extract keywords from references as the condition, marked with "(Upper Bound)".

Results As shown in the first five rows of Table 3, *KeyBERT* outperforms other two keyword extraction methods and CTRLsum on the iBLEU score. Also, GCPG with keyword condition significantly performs better than GCPG without it, which verifies the lexically controllable ability of GCPG.

4.3 Combinations

To facilitate the description, we define that "GCPG-L" denotes GCPG with the keyword condition extracted by *KeyBERT*, "GCPG-S" is GCPG with the *SSE-LCT-Truncated* condition, and "GCPG-LS" indicates the combination of conditions in "GCPG-L" and "GCPG-S". Meanwhile, GCPG is also instantiated by ProphetNet-large.

Metrics We follow the metrics in § 4.1, yet the automatic evaluations can not fully capture the fluency and the quality of the generation results on CPG. Therefore, we conduct human evaluation following Kumar et al.(2020). Specifically, we evaluate GCPG with different conditions on ParaNMT-small, then choose the best settings to compare GCPG with baselines on QQP-Pos. 100 test samples are randomly selected from each dataset. Then, 5 crowdsource evaluators are shown a source sentence and the corresponding reference, then asked to rate model results in three categories: whether the paraphrase remains **loyalty** to the source sentence, the **fluency** of paraphrase, and **syntax** similarity with gold reference.[9] Scores are ranged from 1 to 4, and the higher score is better.

Results As shown in Table 3, combinations of lexical and syntactical conditions get consistently further improvements compared with employing lexical condition individually (Rows 7-12 vs. Row 5). Then, we illustrate human evaluations in Table 4. GCPG with lexical condition (GCPG-L (k=1)) outperforms baselines in meaning and fluency, yet poor in syntax similarity. More impor-

---

[9] Details can be found in Appendix C.

Model	Loyalty	Fluency	Syntax	All
ParaNMT-small				
CGEN (2019)	1.47	2.13	1.81	5.41

Reference	3.30	16.80

Table 5: GCPG can significantly reduce BLEU-Exemplar score compared with previous SOTA.

tantly, the combination of lexical and syntactical conditions (GCPG-LS (k=1)) shows significantly improvements on all three scores.

4.4 Analyses and Discussions

We conduct discussions to shed light on other interesting properties of GCPG. Due to space constraints, we take discussions with GCPG instantiated by ProphetNet-large.

Exemplar-side Words Copying Problem We calculate BLEU-4 between model outputs and exemplars. As shown in Table 5, GCPG with SSE (i.e., GCPG-S) can significantly reduce BLEU-Exemplar comparing with ParafraGPT, gets 4.69 / 1.14 improvements on two datasets, demonstrating that SSE effectively alleviates this problem.

Lexical Condition Analyze further investigate GCPG with lexical condition from two aspects: 1) Generating novel expressions; 2) How frequently and correctly do the model incorporate the lexical condition in outputs? For the first one, following Dou et al.(2021), the number of novel n-grams is counted in the model output. Specifically, these n-grams appear in gold references but not in source sentences. After normalized by the total number of n-grams, we calculate the recall of novel n-grams. As shown in Figure 4, GCPG indeed generates novel expressions. Then, we explore the lexical condition accuracy of the settings in Table 3 (Row 2 vs Row 5), i.e., whether offered keywords appear in final outputs. Specifically, we ignore the model outputs that only use "[NONE]" as the keyword while paraphrasing for a fair comparison. As shown in Table 6, GCPG-L outperforms CTRLsum (He et al., 2020) with 9.8% improvement.

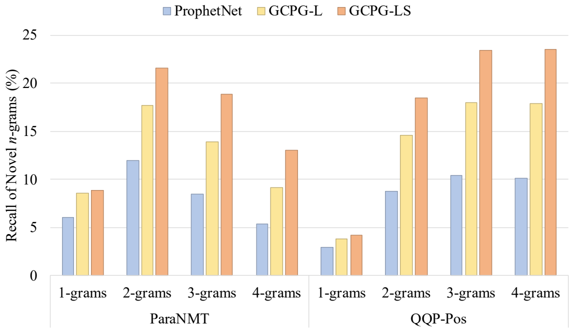

Figure 4: Recall of novel n-grams results.

Method	Accuracy (%)	iBLEU ↑
CTRLsum (2020)	89.45	10.06
GCPG-L	99.25	11.03

Table 6: Lexical condition accuracy on ParaNMT-small.

GCPG Backbone Analyze Whether the performance gain only from using strong PLMs is also of concern. As shown in Table 7, the results show that GCPG instantiated by vanilla Transformer gets comparable performance with ParafraGPT[10]. Also, we compare GCPG with ParafraGPT instantiated by the same backbone. GCPG still outperforms ParafraGPT with 2.8 iBLEU score.

Backbone	Method	iBLEU ↑
Transformer (2017)	-	4.72
BART (2020)	-	6.08
ProphetNet (2020)	-	4.67
GPT2 (2019)	ParafraGPT (2021)	8.61
ProphetNet (2020)	ParafraGPT‡	9.52
Transformer (2017)	GCPG-S	8.53
BART (2020)	GCPG-S	10.12
ProphetNet (2020)	GCPG-S	12.32

Table 7: Performance of GCPG-S with different backbones on ParaNMT-small. ‡: for fair comparisons, ParafraGPT is instantiated by ProphetNet.

5 Conclusions

In this paper, we propose a general framework GCPG, enabling flexibly combine lexical and syn-

---

[10] Due to space constraints, the results of all evaluations can be found in Appendix D.

tactical conditions and exploring their mutual effectiveness. Under GCPG, we provide SSE that allows GCPG to directly model syntax information from natural sentences and better utilize PLMs. As we tentatively give a successful implementation of leveraging two types of conditions in a unified circumstance, multilingual CPG and more types of conditions are barely being discussed. In the future, we will investigate to uniformly represent these conditions in a more superior way.

A GCPG Backbone Selection

We evaluate the following text generation models to select a backbone model for our GCPG. (1) *Transformer* (Vaswani et al., 2017), the conventional version in the original paper. (2) *BART* (Lewis et al., 2020)[11] has a denoising autoencoder for pre-training sequence-to-sequence models, and (3) ProphetNet-large (Qi et al., 2020)[12], which has shown its effectiveness in text generation (Liu et al., 2021). The results are shown in Table 8.

B GCPG with syntactical conditions on QQP-Pos dataset

The experimental results can be found in Table 9.

C Human Evaluation Details

For human evaluation, we first set a guideline for evaluating, which includes the task background, key points, detailed descriptions and examples of evaluation scores from 1 to 4. Then, we set an entry barrier for annotators. In detail, we organize a training program and a preliminary annotating examination (50 examples for each data set) to select appropriate annotators.

Score Definition We define three categories in human evaluation as follows:

Loyalty means whether the option is consistent with the meaning of the original sentence (whether the content is missing or omitted).

Fluency means whether the sentence corresponding to the option is fluent.

Syntax is the similarity of grammatical structure with reference answer, which means whether the sentence structure of this option similar to the reference answer.

Inter-annotator agreement We use Fleiss' kappa (Fleiss, 1971) to measure 5 annotator's reliability[13]. The results are : 1) Paranmt-small dataset (loyalty: 0.56, fluency: 0.42, syntax: 0.41); 2) QQP-Pos (loyalty: 0.55, fluency: 0.40, syntax: 0.37).

D GCPG Backbone Analyze

All kinds of scores in GCPG Backbone Analyze can be found in Table 10.

E Case Study

The qualitative effect of the lexical and syntactical conditions on the model output is also of interest. To intuitively display the effects of conditions, we show some paraphrasing results in Figure 5. In detail, GCPG-L can generate sentence "A powerful healing energy comes out of love." that contain prespecified keywords "[healing]". However, lexical condition provides less information about syntactical controlling. In comparison, GCPG-LS shows better performances on both controllability of lexical items and syntax.

ruoyu.hu18@imperial.ac.uk

Abstract

Task-oriented personal assistants enable people to interact with a host of devices and services using natural language. One of the challenges of making neural dialogue systems available to more users is the lack of training data for all but a few languages. Zero-shot methods try to solve this issue by acquiring task knowledge in a high-resource language such as English with the aim of transferring it to the low-resource language(s). To this end, we introduce **CrossAligner**, the principal method of a variety of effective approaches for zero-shot cross-lingual transfer based on learning alignment from unlabelled parallel data. We present a quantitative analysis of individual methods as well as their weighted combinations, several of which exceed state-of-the-art (SOTA) scores as evaluated across nine languages, fifteen test sets and three benchmark multilingual datasets. A detailed qualitative error analysis of the best methods shows that our fine-tuned language models can zero-shot transfer the task knowledge better than anticipated.

1 Introduction

Natural language understanding (NLU) refers to the ability of a system to 'comprehend' the meaning (semantics) and the structure (syntax) of human language (Wang et al., 2019) to enable the interaction with a system or device. Cross-lingual natural language understanding (XNLU) alludes to a system that is able to handle multiple languages simultaneously (Artetxe and Schwenk, 2019; Hu et al., 2020). We focus on task-oriented XNLU that comprises two correlated objectives: i) Intent Classification, which identifies the type of user command, e.g. 'edit_reminder', 'send_message' or 'play_music' and ii) Entity/Slot Recognition, which identifies relevant entities in the utterance including their types such as dates, messages, music tracks, locations, etc. In a modular dialogue system, this information is used by the dialogue manager to decide how to respond to the user (Casanueva et al., 2017; Gritta et al., 2021). For neural XNLU systems, the limited availability of annotated data is a significant barrier to scaling dialogue systems to more users (Razumovskaia et al., 2021). Therefore, we can use cross-lingual methods to zero-shot transfer the knowledge learnt in a high-resource language such as English to the target language of choice (Artetxe et al., 2020; Siddhant et al., 2020). To this end, we introduce a variety of alignment methods for zero-shot cross-lingual transfer, most notably **CrossAligner**. Our methods leverage unlabelled parallel data and can be easily integrated on top of a pretrained language model, referred to as **XLM**[1], such as XLM-RoBERTa (Conneau et al., 2020). Our methods help the XLM align its cross-lingual representations while optimising the primary XNLU tasks, which are learned only in the source language and transferred zero-shot to the target language. Finally, we also investigate the effectiveness of simple and weighted combinations of multiple alignment losses, which leads to further model improvements and insights. Our contributions are summarised as follows:

- We introduce CrossAligner, a cross-lingual transfer method that achieves SOTA performance on three benchmark XNLU datasets.
- We introduce Translate-Intent, a simple and effective baseline, which outperforms its commonly used counterpart 'Translate-Train'.
- We introduce Contrastive Alignment, an auxiliary loss that leverages contrastive learning at a much smaller scale than past work.
- We introduce weighted combinations of the above losses to further improve SOTA scores.
- Qualitative analysis aims to guide future research by examining the remaining errors.

2 Related Work

Several approaches to zero-shot cross-lingual transfer exist and can broadly be divided into: a) *Data-based Transfer*, which focuses on training data transformation and b) *Model-based Transfer* that centres around modifying models' training routine.

Data-based Transfer Translating utterances for the intent classification task is relatively straightforward so previous works focused on projecting and/or aligning the entity labels between translated utterances. This is followed by standard supervised training with those pseudo-labels and is commonly known as the *translate-train* method. One of the earliest works still being used for this purpose is *fastalign* (Dyer et al., 2013). It's an unsupervised word aligner trained on a parallel corpus to map each word (thus its entity label) in the source utterance to the word(s) in the target user utterance. Projecting the entity labels can also be done with word-by-word translation and source label copying (Yi and Cheng, 2021). A teacher model then weakly labels the target data, which is used to train the final student model. Sometimes, this type of label projection is complemented with an additional entity alignment step (Li et al., 2021a). Better performance can be achieved by using machine translation with entity matching and distributional statistics (Jain et al., 2019) though this can be a costly process for each language. A category of 'word substitution' methods such as code-switching (Qin et al., 2020; Kuwanto et al., 2021) or dictionary-enhanced pretraining (Chaudhary et al., 2020) have also been shown to improve cross-lingual transfer.

Model-based Transfer Prior to the adoption of multilingual transformers (Lample and Conneau, 2019), task-oriented XNLU methods employed a BiLSTM encoder combined with different multilingual embeddings (Schuster et al., 2019). Newer approaches usually involve a pretrained XLM and the addition of some new training component(s) with the inference routine remaining mostly unchanged. Xu et al. (2020) learn to jointly align and predict entity labels by fusing the source and target language embeddings with attention and using the resulting cross-lingual representation for entity prediction. Qi and Du (2020) include an adversarial language detector in training whose loss encourages the model to generate language-agnostic sentence representations for improved zero-shot transfer. Pan et al. (2020) and Chi et al. (2020) added a contrastive loss to pretraining that treats translated sentences as positive examples and unrelated sentences as negative samples. This training step helps the XLM produce similar embeddings in different languages. However, these methods require large annotated datasets and expensive model pretraining (Chi et al., 2020). Our proposed methods only use the English task data (which is relatively limited) and its translations for each language.

The most related prior works are Arivazhagan et al. (2019) for machine translation and Gritta and Iacobacci (2021) for task-oriented XNLU. Both of these are cross-lingual alignment methods that use translated training data to zero-shot transfer the source language model to the target language. We focus on the latter work, called XeroAlign, which reported the most recent SOTA scores on our evaluation datasets. XeroAlign works by generating a sentence embedding of the user utterance for each language, e.g. English (source) and Thai (target) using the CLS token of the XLM. A Mean Squared Error loss function minimises the difference between the multilingual sentence embeddings and is backpropagated along with the main task loss. XeroAlign aims to bring sentence embeddings in different languages closer together with a bias towards intent classification due to the CLS embedding, which is the standard input to the intent classifier. We reproduce this method for analysis and comparisons but add a small post-processing step that distinctly improves the reported scores.

3 Methodology

3.1 CrossAligner

Intuition We introduce CrossAligner, the most notable of our proposed cross-lingual alignment methods, outlined in Algorithm 1. CrossAligner enables effective zero-shot transfer by leveraging unlabelled parallel data for our new language-agnostic objective created through a transformation of the English entity labels. CrossAligner was borne out of early error analysis where we observed that the model incorrectly predicted entities that didn't occur in the input and failed to predict entities that did occur in the input. Using this insight as our main motivation, the essence of CrossAligner is being able to exploit information about the *presence of entities/slots in the user utterance*.

Algorithm We have used a proprietary service (Huawei Translate) to translate the English user utterances $\mathsf{X_{Eng}}$ into each target language $\mathsf{X_{Tar}}$, however, a publicly available translator can also be used. Note that we use the same translations for each of our alignment methods to compare them fairly. Our language-agnostic objective is created by transforming the English slot labels $\mathsf{y_{ec}}$ into a fixed binary vector $\mathsf{y_{ca}}$ indicating which entities are present in the input (lines 1-7 in Algorithm 1), irrespective of the frequency of their occurrence.

The standard XNLU training (lines 15-20) features an Intent Classifier (IC) and an Entity Classifier (EC). Each computes a cross-entropy loss (ce_loss) with a softmax activation using English labelled data (multi-class classification). This yields the standard losses $\mathcal{L}_{\mathsf{ic}}$ and $\mathcal{L}_{\mathsf{ec}}$. The CrossAligner (CA) classifier then pools the EC logits matrix by reshaping it into a long vector (lines 24 and 29) and predicts which entities are present in the user utterance (multi-label classification). We compute a Binary Cross-Entropy loss (bce_loss) with a sigmoid activation between the predicted labels $\mathsf{pred_{eng}}$ and $\mathsf{pred_{tar}}$ (for English and Target languages respectively) and our language-agnostic labels $\mathsf{y_{ca}}$ (lines 26 and 31). This yields the CrossAligner losses $\mathcal{L}_{\mathsf{eng}}$ and $\mathcal{L}_{\mathsf{tar}}$. The fact that these gradients are propagated through the EC to the XLM token embeddings ensures a good alignment for entity/slot recognition, as shown in the results section. Note that EC, IC and CA are shared between languages to aid zero-shot cross-lingual transfer.

BIO versus IO Using the BIO sequence tagging format (Sang and De Meulder, 2003) can introduce easily avoidable model errors, e.g. predicting a B-tag after an I-tag, two B-tags in succession or skipping the B-tag altogether. We have therefore simplified the training process by making it agnostic w.r.t. the entity's BI order. The B-tags were removed in preprocessing, meaning the entity classifier predicts only IO-tags. At inference, the B-tags get restored with a simple post-processing rule. Note that all our models use this IO-only training.

Architecture We use a common task-oriented XNLU model that employs a pretrained XLM, e.g. JointBERT (Chen et al., 2019). The IC, EC and CA each feature a single multi-layer perceptron of sizes: $[\mathsf{hidden\_size}, \mathsf{len(intent\_classes)}]$, $[\mathsf{hidden\_size}, \mathsf{len(entity\_classes)}]$ and $[\mathsf{seq\_len} \times \mathsf{len(entity\_classes)}, \mathsf{len(entity\_classes)}]$. Depending on the dataset, seq_len varies between 50-100 tokens. The model architecture is shown in Fig 1.

Algorithm 1 The CrossAligner alignment/loss.

```
 1: function TransformLabels($y_{ec}$)
 2:     $y_{ca} \leftarrow$ zeros(len(entity_classes))
 3:     for entity $\in y_{ec}$ do
 4:         $y_{ca}$[index_of(entity)] $\leftarrow 1$
 5:     end for
 6:     return $y_{ca}$
 7: end function

3.2 Contrastive Alignment for XNLU

Our contrastive alignment is based on InfoNCE (Oord et al., 2018). Previous work has employed a contrastive loss for cross-lingual alignment (Pan et al., 2020), however, the datasets were out-of-domain and orders of magnitude larger. We show that strong results can be obtained using only in-domain (fine-tuning) data. Similar to (Wu et al., 2021), if given a randomly sampled batch of N English sentences $\mathsf{X_{Eng}}$ and its parallel sentences

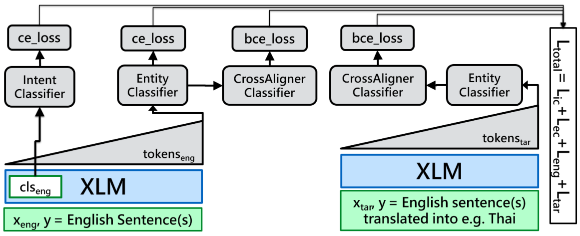

Figure 1: The architecture of CrossAligner. The parameters of the XLM model and all classifiers are shared between languages to enable cross-lingual transfer.

$\mathsf{X_{Tar}}$ in the target language, then the loss on the $\mathsf{i^{th}}$ sentence pair $\mathsf{x_{eng_i}} \in \mathsf{X_{Eng}}$ and $\mathsf{x_{tar_i}} \in \mathsf{X_{Tar}}$ equals:

$$\ell(\mathsf{x_{eng_i}}, \mathsf{x_{tar_i}}) = -\log \frac{\mathsf{e}^{\mathsf{sim}(\mathsf{x_{eng_i}}, \mathsf{x_{tar_i}})}}{\sum_{\mathsf{k}=1}^{\mathsf{N}} \mathsf{e}^{\mathsf{sim}(\mathsf{x_{eng_i}}, \mathsf{x_{tar_k}})}} \quad (1)$$

where $\mathsf{sim(u, v) = u \cdot v \;/\; ||u||_2 \cdot ||v||_2}$ is the cosine similarity between two sentence embeddings. A sentence $\mathsf{x_{eng_i}} \in \mathsf{X_{Eng}}$ symmetrically forms a positive pair with its translation $\mathsf{x_{tar_i}} \in \mathsf{X_{Tar}}$ while the other $\mathsf{N} - 1$ sentence embeddings are treated as negative samples. The batch loss is calculated as the average of all positive pair losses. Algorithm 2 below shows the steps that replace/complement the CrossAligner block (lines 21-32 in Algorithm 1).

Algorithm 2 The Contrastive Alignment loss.

```
$cls_{eng}, tokens_{eng} \leftarrow XLM(x_{eng})$
$cls_{tar}, tokens_{tar} \leftarrow XLM(x_{tar})$
$sim \leftarrow batch\_cosine\_sim(cls_{eng}, cls_{tar})$
$labels \leftarrow arange(batch\_size)$
$\mathcal{L}_{cl} \leftarrow ce\_loss(sim, labels)$
$\mathcal{L}_{total} \leftarrow \mathcal{L}_{ic} + \mathcal{L}_{ec} + \mathcal{L}_{cl}$
```

3.3 Translate-Intent

The translate-train method is used in multilingual NLP as a competitive baseline (Liang et al., 2020; Hu et al., 2020). After machine translation, the sequence tagging tasks require an additional transformation, i.e. entity label projection and/or word alignment (Schuster et al., 2019; Li et al., 2021b; Xu et al., 2020). This is followed by supervised fine-tuning with the new pseudo-labels. However, both label projection and word alignment are *sources of common errors*. We therefore introduce a simpler baseline called Translate-Intent, which to the best of our knowledge, has not been featured in task-oriented XNLU. We omit the entity/slot recognition for the target language (given the unreliable pseudo-labels) and only use the IC, which is trained with the parallel data $\mathsf{X_{Tar}}$ (labels copied from English). Algorithm 3 above shows the steps that either replace or complement (in case of a combination of multiple losses) the CrossAligner steps, shown in lines 21-32 in Algorithm 1.

Algorithm 3 The Translate-Intent loss.

```
$cls_{tar}, tokens_{tar} \leftarrow XLM(x_{tar})$
$pred_{ic} \leftarrow IC(cls_{tar})$
$\mathcal{L}_{ti} \leftarrow ce\_loss(pred_{ic}, y_{ic})$
$\mathcal{L}_{total} \leftarrow \mathcal{L}_{ic} + \mathcal{L}_{ec} + \mathcal{L}_{ti}$
```

3.4 Adaptive Weighting of Auxiliary Losses

In order to evaluate the benefits of combinations of two or more alignments, we employ the Multi-Loss Weighting with Coefficient of Variations (Groenendijk et al., 2021) technique (CoV) to calculate a weighted sum of auxiliary losses (Aux) that we add to the main XNLU losses $\mathcal{L}_{\mathsf{ic}}$ and $\mathcal{L}_{\mathsf{ec}}$ as follows:

$$\mathcal{L}_{\mathsf{total}} = \mathcal{L}_{\mathsf{ic}} + \mathcal{L}_{\mathsf{ec}} + \sum_{\mathsf{a} \in \mathsf{Aux}} \mathsf{w_a} \mathcal{L}_{\mathsf{a}} \quad (2)$$

The sole difference to CoV is that we opt to omit the loss weight normalisation step before application. The weights for an auxiliary loss $\mathcal{L}_{\mathsf{a,t}}$ for $\mathsf{a} \in \mathsf{Aux}$ at training step t are calculated as follows:

$$\mathsf{w_{a,t}} = \frac{\sigma_{\ell_{\mathsf{a,t}}}}{\mu_{\ell_{\mathsf{a,t}}}} \qquad \ell_{\mathsf{a,t}} = \frac{\mathcal{L}_{\mathsf{a,t}}}{\mu_{\mathcal{L}_{\mathsf{a,t-1}}}} \quad (3)$$

where $\ell_{\mathsf{a,t}}$ is the loss ratio of loss $\mathsf{a} \in \mathsf{Aux}$ at training step t, σ is the standard deviation over the history of loss ratios and $\mu_{\ell_{\mathsf{a,t-1}}}$ is the mean of the loss ratio ℓ_{a} up to and including step $\mathsf{t} - 1$. We also compare CoV to a simple sum of all losses i.e. equal weight for each loss, as shown in Algorithms 1, 2 and 3 (line beginning with $\mathcal{L}_{\mathsf{total}}$).

4 Experimental Setup

Datasets Three multilingual datasets are used to compare our methods with their most relevant counterparts. The datasets, which are used as standard benchmarks for the XNLU tasks, comprise nine unique languages (de, pt, zh, ja, hi, tr, fr, es, th) from 15 test sets (20,000+ instances in total) featuring diverse examples of users interacting with task-oriented personal assistants designed to test the XNLU capabilities of multilingual models. Two related tasks are being evaluated, Intent Classification and Entity/Slot Recognition.

Models	MTOP (5)	MTOD (2)	M-ATIS (8)	MEAN (15)	Overall
Zero-Shot	91.7/77.1	94.1/75.1	91.1/79.9	91.7/76.5	84.1
Target Language	95.7/88.7	98.4/91.8	92.5/88.9	94.3/89.2	91.8
Translate-Train SOTA	94.5/77.9	97.5/67.9	94.9/78.0	95.1/76.6	85.9
Translate-Intent (Ours)	95.2/77.1	98.1/76.5	95.9/80.0	95.9/78.5	87.2
Previous SOTA	**95.6**/80.3	**98.8**/72.9	96.0/81.2	96.1/79.8	88.0
$\text{XeroAlign}_{\text{IO}}$ (Ours)	95.3/81.3	98.5/75.1	96.4/82.3	96.3/81.1	88.7
CrossAligner (Ours)	94.4/81.6	95.3/78.8	94.8/**84.1**	94.7/**82.5**	88.6
Contrastive (Ours)	95.3/80.9	98.3/**79.6**	96.5/79.3	96.3/79.8	88.1
$\text{XeroAlign}_{\text{IO}}$ + CrossAligner (1+1)	95.3/81.5	98.6/78.2	96.2/81.6	96.2/81.1	88.7
$\text{XeroAlign}_{\text{IO}}$ + CrossAligner (CoV)	95.4/**82.2**	**98.8**/78.3	**96.6**/83.1	**96.5**/82.1	**89.3**

Table 1: Accuracy/F-Score for MTOP, MTOD, M-ATIS (number of non-English languages in brackets), MEAN over all datasets. Translate-Train SOTA is (Li et al., 2021b) for MTOP/MTOD and (Xu et al., 2020) for M-ATIS.

Multilingual Task-Oriented Parsing (MTOP) comprises 15K-22K utterances in each of 6 languages (en, de, fr, es, hi, th) spanning 11 domains (Li et al., 2021b). The **Multilingual Task-Oriented Dialogue** (MTOD) consists of 43K English, 8K Spanish and 5K Thai utterances covering 3 domains (Schuster et al., 2019). The **Multilingual ATIS++** (M-ATIS) contains up to 4.5K commands in each of 8 languages (en, es, pt, de, fr, zh, ja, hi, tr) featuring user interactions with a travel information system (Xu et al., 2020).

XLM Our pretrained language model of choice is XLM-RoBERTa (Conneau et al., 2020). We use the large (550M parameters) model from HuggingFace (Wolf et al., 2019) with a hidden_size = 1,024.

Training Setup We use a minimalist setup that features default settings and components to focus the results on the methods rather than hyperparameter tuning or custom architecture design. We implemented all models with PyTorch using fixed hyperparameters between experiments except for MTOD, where due to its size, we trained with fewer epochs and a lower learning rate (both 50% lower[2]).

5 Results

Terminology Henceforth, we refer to models trained with labelled data in each language as **Target Language**, the models trained only on English data as **Zero-Shot**, our translate-intent method as **Translate-Intent** (**TI**), the scores reported by Gritta and Iacobacci (2021) as **Previous SOTA**, our IO-only implementation of that model as $\textbf{XeroAlign}_{\text{IO}}$ ($\textbf{XA}_{\text{IO}}$), our contrastive alignment method as **Contrastive** (**CTR**) and our main method as **CrossAligner** (**CA**). Lastly, the simple sum of alignment losses is referred to as **1+1** and the weighted sum from 3.4 as **CoV**.

Metrics We use Accuracy for intent classification and F-Score for entity/slot recognition. In addition, we use an Overall score (the average of F-Score and Accuracy) for model ranking, similar to Hu et al. (2020); Wang et al. (2019, 2018). Results are shown as averages (MEAN) over all test sets and datasets, presented in Tables 1 and 2. Intent classification is thus evaluated on ∼20,000 diverse user commands and entity recognition on ∼60,000 individual slots from 100+ slot types. For a full breakdown, see Tables 4, 5 and 6 in Appendix A.2.

Statistical Significance For a robust comparison with the previous SOTA, we conduct a two-tailed z-test for the difference of proportions (Schumacker, 2017). Our most effective method is statistically significant for all datasets at $p < 0.01$. The margin of improvement for slot tagging is +2.3 (F-Score) over previous SOTA and significant at $p < 0.01$.

5.1 Individual Zero-Shot Transfer Methods

CrossAligner The focus of our primary method was to improve slot filling as the model must classify dozens of entity types in each dataset and to that end, it is an effective approach. CrossAligner exceeds the F-Score of the Previous SOTA by 2.7 points (82.5 versus 79.8). This is 1.4 points higher than $\text{XeroAlign}_{\text{IO}}$ and 6 points higher than Zero-Shot. Despite the intent accuracy being 1.4 points lower than Previous SOTA and 1.6 lower

4-Loss	x	x	x	x	96.3	79.7	88.0	96.4	79.7	88.1

Table 2: The Accuracy and F-Score for combinations of auxiliary losses with different weighting schemes. The number of non-English test languages is shown in brackets, MEAN is computed for all languages in the 3 XNLU datasets. More detailed breakdowns of each dataset and language are shown in Tables 4, 5 and 6 in Appendix A.2.

than $\text{XeroAlign}_{\text{IO}}$, 94.7 is still 0.4 higher than Target Language. CrossAligner's overall score is 0.6 higher than previous SOTA, which outperformed the common 'translate-train' models, including entity projection and word alignment. In order to demonstrate the necessity and specificity of the proposed architecture, we tested mean-pooled token embeddings as well as a CLS embedding as the input to CrossAligner instead of the entity classifier logits. The scores declined from 94.7/82.5 (88.6 Overall) to 92.3/80 (86.2 Overall) with a CLS sentence representation and 82.1/78.7 (80.4 Overall) for mean-pooled embeddings. Future applications of our method to other NLP tasks must note that CrossAligner is most effective for tasks with a *complex entity tag set* where the presence of entities in a sentence is informative, i.e. a higher complexity and slot density should lead to a higher performance. In addition, CrossAligner combines well with other losses as we show in Section 5.2.

Translate-Intent Our alternative to the common 'translate-train' baseline is not only conceptually simpler (no explicit slot recognition training), it also outperforms the previous Translate-Train SOTA scores (78.5 vs 76.6 F-Score, 95.9 vs 95.1 accuracy and 87.2 vs 85.9 Overall). Translate-Intent does not require error-prone preprocessing such as word/label alignment and can therefore be readily used as a default 'translate-train' baseline in future work. Note that using mean-pooled token embeddings as sentence representations is not recommended for Translate-Intent as this causes the F-Score to decline sharply (-25 points).

Contrastive Alignment Despite orders of magnitude less data than used in related work (Section 2), our Contrastive Alignment showed a marginal improvement over the previous SOTA on intent classification (96.3 vs 96.1) thus by 0.1 Overall. That said, even though the contrastive loss pushes negative sentence embeddings away from the positives, this does not seem to confer a strong advantage over the previous SOTA, which only used positive examples. We have also evaluated an implementation of Contrastive Alignment using mean-pooled token embeddings as sentence representations, however, the Overall score declined to 86.8 (versus 88.1 with a standard CLS embedding).

$\text{XeroAlign}_{\text{IO}}$ Our implementation of the previous SOTA with an additional post-processing step (described in 3.1) increased the F-Score by 1.3 points and accuracy by 0.2 (+0.7 Overall). For a comparison, training $\text{XeroAlign}_{\text{IO}}$ with the conventional BIO tags results in a drop of 1.8 points (81.1 to 79.3 F-Score) on entity recognition and 0.4 on intent classification (96.1 to 95.7). Mean-pooled tokens are not recommended for XeroAlign$_{\text{IO}}$ as this yields a 2-point decline (88.7 to 86.7 Overall). Other models also benefit from IO-only training, for example, the Zero-Shot model gains 2.6 points (73.9 up to 76.5 F-Score). One theoretical limitation of IO-only training is that given a sequence of ‘B-LOC I-LOC B-LOC’, the IO-only models would incorrectly classify this as a single entity. However, in practice, this is rare and not something we have seen during preprocessing or error analysis.

5.2 Combinations of Losses

As our alignment methods have different strengths and weaknesses, we have also evaluated their combinations (see Table 2) as either a simple sum of losses (**1+1**) or a weighted sum of losses (**CoV**) using the Coefficient of Variation. The highest overall score was achieved by a CoV-weighted combination of XeroAlign$_{\text{IO}}$ and CrossAligner, which considerably improved on the previous SOTA (96.5 vs 96.1 Accuracy, 82.1 vs 79.8 F-Score, 89.3 vs 88.0 Overall). In total, three individual and almost a dozen combinations of losses improve over the best previously reported scores. In the following paragraphs, we analyse and explain why the combinations that include CrossAligner consistently produce higher scores and why adding more losses can result in diminishing returns.

Compatibility of Losses We propose a hypothesis that can further help us interpret the numbers in Table 2. It states that combining losses which use dissimilar sentence representations may be more beneficial than combining losses using similar sentence embeddings. In order to test that assumption, we clustered our alignment methods into two groups based on how their sentence representations are obtained: 1) XeroAlign$_{\text{IO}}$, Translate-Intent and Contrastive Alignment, which all use the CLS *embedding* and 2) CrossAligner, which aligns through the *token embeddings* (used as the entity classifier input). In Figure 2, we note that for combinations of any two alignment losses using the CLS embedding (shown as blue squares), there is no difference in the overall scores when using CoV or 1+1. However, when combining losses with different sentence representations (orange with any blue square) using CoV weighting, we observe consistent increases over the 1+1 setup (on average 1+ point overall) as well as an increase over their highest individual score. Additionally, in a 3-loss combination, we note that adding CrossAligner to any two losses from the CLS-embedding group using CoV weighting yields an average improvement of 0.7 points compared to no improvement using 1+1.

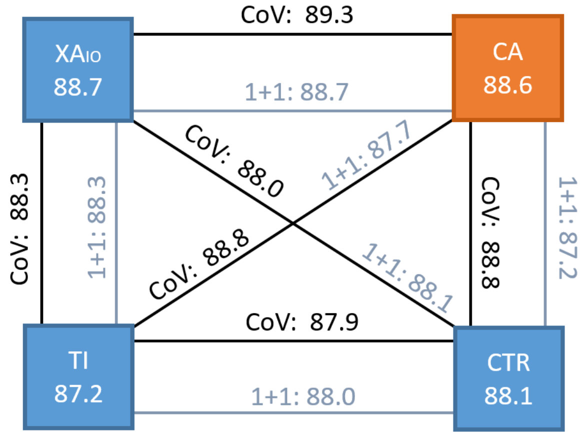

Figure 2: Overall scores for combinations of auxiliary losses weighted using either CoV or 1+1 (simple sum).

Oversaturation of Losses Another important observation harks back to our hypothesis stating that alignment methods with similar input embeddings do not lend themselves to being readily combined. We offer further evidence of this by testing combinations of CrossAligner with each of the CLS-embedding losses [XA$_{\text{IO}}$, TI and CTR], however, we use mean-pooled embeddings. The Overall scores decline in line with our hypothesis (XA$_{\text{IO}}$ by -1.2, TI by -4.9, CTR by -0.6) with CoV-weighted losses and even more with the 1+1 weighted combinations (XA$_{\text{IO}}$ by -2.1, TI by -7.6, CTR by -1.4). Similarly, combining multiple CLS-embedding losses leads to a gradually diminishing benefit relative to the individual scores. Once again, the CoV-weighted losses show a significantly lower decline than the 1+1 combinations (Table 2). Note that in our multi-loss scenario, intent classification remains unaffected by the choice of input embeddings as the accuracy remains stable at SOTA levels across experiments. We think this is due to the unequal task difficulty. In other words, sentence-level inference (intent recognition) is easier than token-level inference (entity recognition).

6 Error Analysis

In order to contextualise the numbers reported in Tables 1 and 2 in relevant linguistic insights, we have conducted a qualitative error analysis and

Categories	TH	HI	FR	DE	ZH	ES	PT	MEAN
Acceptable Transfer	28	51	53	40	37	38	23	38.6
Partial Transfer	34	15	13	30	34	47	58	33.0
Poor Transfer	38	34	34	30	29	15	19	28.4
Boundary Error	72	43	44	52	33	47	64	50.7
Semantics Error	38	40	37	38	59	30	32	39.1
Annotation Error	8	26	11	20	30	17	17	18.4

Table 3: The summary of our qualitative error analysis with native speakers (700 samples from 7 languages).

present the highlights in this section. Readers interested in language-specific analysis (including many more examples) are encouraged to read **Appendix A.1**. We focused on errors committed by CrossAligner and XeroAlign$_{\text{IO}}$, which achieved the best individual and combined scores. We sampled 100 random errors from each of the following settings: Hindi, French and German from MTOP, Portuguese, Chinese and Spanish from M-ATIS and Thai from MTOD for a diverse pool of errors. The authors adjudicated with native speakers to categorise mistakes into the following types.

Error Types We discovered two main sources of mistakes: A *boundary error* occurs when the model predicts more or fewer entity words/tokens than given in the gold annotation. A *semantics error* occurs when the wrong entity class/type is predicted. Models can therefore commit: 1) both errors resulting in *Poor Transfer*, 2) a boundary error without a semantic error and vice versa giving us a *Partial Transfer* or 3) neither error (a false negative), which we deemed an *Acceptable Transfer*. We report individual and average error occurrences as well as transfer type percentages in Table 3.

Poor Transfer indicates that the prediction error is too serious and unusable (even misleading) in a real-world personal assistant. This is typically due to both a boundary and a semantics error, however, some mistakes can be serious enough alone to result in poor transfer. For example, a boundary error can cause the retrieved name of a dish, person or a location to be incomplete and therefore invalid. A semantics error that classifies '10 secondes' (French) as 'date_time' instead of 'music_rewind_time' would elicit the wrong agent response thus is unusable. On average, $\sim$28% of mistakes fall into the 'Poor Transfer' category.

Partial Transfer is defined as either a boundary or a semantics error where neither is considered a serious problem. Such entities could be made usable in a personal assistant application with simple post-processing rules. Around 33 percent of errors were deemed to be partially correct. Often, this was due to including some adjacent punctuation or an article/preposition as part of the entity or a slightly shorter/longer news headline even though a search engine query with that string would have returned the relevant article. Entities such as '24 minat ka' (Hindi) versus '24 minat' (24 minutes) exemplify the fact that a disputed entity boundary is the most frequent source of error in this category. On the semantics side, we considered a location partially correct if 'state_name' instead of 'city_name' (for Washington D.C.) was predicted, a location was expected and the boundary was accurate.

Acceptable Transfer These examples are 'errors' we considered correct and usable 'as is' because neither the entity boundary nor its semantics were thought to be wrong. On average, we deemed almost 39% of entities acceptable for a real-world personal assistant application with around half of those being down to *annotation problems* (labels missing or incorrect). In other cases, we accepted predictions that offered a valid alternative e.g. when both 'me' (French) and 'je' (I/me) are present in the user utterance and both refer to the same 'person_reminded'. Valid alternatives were predicted but annotated somewhat differently. For example, when the entity boundary was slightly wider 'de ida e volta' (Portuguese) instead of 'ida e volta' (round trip) where both entities are correct. Similarly, classifying 'salmon' as an ingredient rather than a dish (when 'salmon' is an object of 'prepare') was considered an acceptable transfer.

6.1 Error Analysis Summary

While the intent classification task is transferred well in a cross-lingual setting, performing better than training on labelled data, our SOTA slot recognition F-Score is almost 7 points behind Target Language. We think there are several factors involved. Articles, some prepositions, conjunctions, determiners and/or possessives do not transfer easily and may largely be ignored by the XLM as they don't carry important sentence level (e.g. intent) semantics. English is not ideal as a cross-lingual pivot for many of the dozens of languages covered by the XLM as elements of culture and vernacular that may not have a direct English equivalent don't transfer easily in a zero-shot setting. Aligning on the most well-resourced language in the same family should help (Xia et al., 2021). The limits of machine translation, especially for low-resource languages (Mager et al., 2021), can further inhibit alignment methods that leverage parallel data. Inconsistency of annotation (intra-language and inter-language) is a source of errors when the key concepts are learnt in one language and evaluated (sometimes unreliably) in the target language. Finally, there were no substantial qualitative differences between XeroAlign$_{\text{IO}}$ and CrossAligner in our error analysis suggesting that the aforementioned error patterns may be a feature of the XLM model itself, the nature of the datasets or some as yet unknown confounding variable rather than the choice of the alignment method.

7 Conclusions

We have introduced a variety of cross-lingual methods for task-oriented XNLU to enable effective zero-shot transfer by learning alignment with unlabelled parallel data. The principal method, *CrossAligner*, transforms English train data into a new language-agnostic task used to align model predictions across languages, achieving SOTA on entity recognition. We then presented a *Contrastive Alignment* that optimises for a small cosine distance between translated sentences while increasing it between unrelated sentences, using orders of magnitude less data than previous works. We proposed *Translate-Intent*, a fast and simple baseline that beats previous Translate-Train SOTA approaches without error-prone data transformations such as slot label projection. The best overall performance across nine languages, fifteen tests sets and three task-oriented multilingual datasets was achieved by a *Coefficient of Variation* weighted combination of CrossAligner and XeroAlign$_{\text{IO}}$. Our quantitative analysis investigated which types of auxiliary losses yield the most effective combinations. This resulted in several proposed configurations also exceeding previous SOTA scores. Our detailed qualitative error analysis revealed that the best methods have the potential to approach target language performance as most errors were deemed to be of low to medium severity. We hope our contributions and resources will inspire exciting future work in this fascinating NLP research area.

Acknowledgements

We want to thank Philip John Gorinski, Guchun Zhang, Sushmit Bhattacharjee and Nicholas Aussel for providing the native speaker expertise for our qualitative error analysis. We are grateful to the ARR reviewers for their insightful comments and feedback. We also want to thank the MindSpore[3][4] team members for the technical support.

A Appendix

A.1 Error Analysis per Language

German examples of partial transfer are boundary errors such as tagging punctuation '-' as part of the entity (e.g. in a timer or alarm name) as well as *not* tagging some punctuation e.g. in '14. Mai' where '.' is equivalent to the English 'th' in '14th' and is expected in German dates. Such entities can be used with a basic post-processing rule as their classes and contents were sufficiently well predicted. Similarly, including 'die', 'den', 'das', 'mir', 'des', 'der' in the retrieved entity, particularly in *free-format entities* such as news headlines, text message contents and memos need not invalidate the prediction, e.g. '*die* hausschliessung' (house closure), '*des* Reiseverbots' (*of* travel ban) and '*den* Termin' (appointment). Just a few of such linguistic 'bad habits' can quickly accumulate to cause more than half of all errors.

Chinese cross-lingual transfer problems often include boundary issues featuring the 'of' preposition or the possessive ''s' (*de* in Chinese) e.g. 'Zuì piányí *de*' (cheapest), 'Jiāzhōu *de*' (California) or 'āndàlüè *de* hángbān' (flights to Ontario). Depending on context, we considered these at least partially correct rather than a failed transfer. More serious though less explicable errors were 'Gěi wǒ zhōu'èr' (*give me* Tuesday's), 'Liè chū zhōu liù' (*list* Saturday's) or 'Xiǎnshì zhōusān' (*show me* Wednesday's) where 'give me', 'list' and 'show me' were tagged as part of 'date_time' a total of 20 times. The most frequent semantic (partial) error was 'Washington D.C.', which was tagged as a state rather than a city no fewer than 16 times.

French instances of acceptable transfer include tagging 'Ankara' and 'Turquie' separately rather than as a single chunk 'Ankara, en Turquie' (possible annotation problem). Reminiscent of the patterns seen in other languages, articles tend to feature prominently in boundary errors, e.g. '*la* famille' (family), '*l'*arrosage' (watering), '*les* elections' (elections), '*le* chat Zoom' (Zoom chat) and '*la* mere de Kylie' (Kylie's mother), which we considered usable 'as is'. For an example of annotation inconsistency across languages, consider the entity 'gros titres' or 'top headlines' in English. The model correctly transferred the English tags for 'top' (news_reference) and 'headline' (news_type) although the French annotation was given as 'gros titres' (news_type), which is plausible but less coherent than the model's prediction.

Spanish Once again, articles, some prepositions and occasionally conjunctions e.g. 'de', 'las', 'y', 'la', 'por' (of, the, and, a, in/for) have caused the majority of boundary errors, most of which are partially acceptable. Examples include time '*las* 10 a.m.' (10 a.m.) and 'no mas tarde que *las*' (no later than), journey specifications '*de* ida' and 'ida *y* vuelta' (round trip), periods of day '*la* mañana' (morning) and '*la* noche' (night), dates 'seis *de* junio' (June 6th) as well as skipping '*en punto*' (o'clock) in 'antes de las 4 p.m. *en punto*' (before 4 p.m.). These minor errors show that the current SOTA in cross-lingual zero-shot transfer is close to solving these cases. Other errors such as 'conexión' instead of '*con* conexión' (*with* connection) and '*la* mañana' rather than '*por la* mañana' (*in* the morning) are more examples of disputed annotations.

Portuguese predictions closely follow Spanish error patterns and reflect the wider issues with articles and prepositions, e.g. 'terça-feira *de* manhã' (Tuesday morning), '*de* ida e volta' (round trip), 'cinco *de* abril' (April 5th) or '5 horas *da* tarde' (5 p.m.) with '*de*' and '*da*' (both *of*) being the unannotated parts that did not transfer optimally. Other boundary mistakes were caused by '*das*' (of) and '*as*' (the), for example, 'antes *das* 6 horas da tarde' and 'após *as* 6 horas da tarde' (before and after 6 p.m). Annotations that needlessly punished cross-lingual transfer included '*somente* de ida' (one way) where '*somente*' (only) was not annotated in the English dataset and 'econômica' (economy), which was annotated as 'class_type' in English, correctly transferred but flagged as wrong.

Hindi errors have a relatively high number (26) of problematic annotations although most mistakes are caused by the now familiar improper handling of prepositions, articles and/or possessives e.g. '*ke*', '*tak*', '*ka*' ('of', 'by', ''s') in phrases such as '30 minat *ka*' (30 minutes), 'kitanee der *tak*' (how long), 'kal *ke*' (yesterday's), 'aaj *ke*' (today's) or '1 baje *ka*' (1 p.m.). Transliterated entities i.e. English pronunciation written in Devanagari, is the second largest category of transfer problems in Hindi, e.g. 'pakrino romaano' (Pecorino Romano), 'goda cheez' (Goda cheese), 'braun aaid garl' (Brown Eyed Girl), 'paindora' (Pandora), 'pool leeg' (Pool League), 'daayanaasor jooniyar' (Dinosaur Junior) or 'da most byooteephul moment' (The Most Beautiful Moment). These are problematic because such entities are neither native to Hindi nor are they written in Latin alphabet hence may not have been observed in this form during XLM pretraining.

Thai errors were analysed with a translation service as we were unable to secure a native speaker. Even so, we observed boundary errors previously seen in other languages. Words such as '*nai*' ('of' or 'in', the most frequent cause) and '*bpai*' ('in', 'off' or 'to', no direct English translation) were the typical sources of boundary issues, e.g. '*nai* sùt sàp-daa née' (this weekend), '*nai* wan pút' (Wednesday), '*bpai* séu XYZ' (go buy XYZ) and '*nai* wan née' (today or on this day). Such patterns accounted for more than half of all mistakes. Machine translation can also be a source of errors. For example, the word 'reminder' is an entity in English (tag: reminder/noun). It was translated as 'kam dteuuan', however, 'reminder' appears in Thai data as 'dteuuan kwaam jam', which the model repeatedly missed, leading to 18 errors for what should be an easy case of zero-shot transfer.

Attention as Grounding: Exploring Textual and Cross-Modal Attention on Entities and Relations in Language-and-Vision Transformer

Nikolai Ilinykh and **Simon Dobnik**
Centre for Linguistic Theory and Studies in Probability (CLASP)
Department of Philosophy, Linguistics and Theory of Science (FLoV)
University of Gothenburg, Sweden
`{nikolai.ilinykh,simon.dobnik}@gu.se`

Abstract

We explore how a *multi-modal transformer* trained for generation of longer image descriptions learns syntactic and semantic representations about entities and relations grounded in objects at the level of masked self-attention (text generation) and cross-modal attention (information fusion). We observe that cross-attention learns the visual grounding of noun phrases into objects and high-level semantic information about spatial relations, while text-to-text attention captures low-level syntactic knowledge between words. This concludes that language models in a multi-modal task learn different semantic information about objects and relations cross-modally and uni-modally (text-only). Our code is available here: `https://github.com/GU-CLASP/attention-as-grounding`.

1 Introduction

In this paper, we examine what kind of knowledge is encoded in the multi-modal transformer. Existing work has mostly looked at the knowledge captured in models that operate with **a single modality** (text). For instance, previous research has shown that the attention weights in large-scale models, e.g. BERT (Devlin et al., 2019), implicitly encode knowledge of sentence structure (Raganato and Tiedemann, 2018; Ravishankar et al., 2021), part-of-speech tags, syntactic dependencies (Clark et al., 2019; Vig and Belinkov, 2019), subject-verb agreement between words (Goldberg, 2019), and even information about textual co-reference (Tenney et al., 2019). Only a few papers have inspected what is captured by **multi-modal architectures**. Cao et al. (2020) demonstrate that the attention heads in image-and-text transformers effectively encode linguistic and cross-modal knowledge. Ilinykh and Dobnik (2021) provide the analysis of how language representations are indirectly affected by visual information in language-and-vision model.

Here we inspect what the model learns about two types of words in the multi-modal setting: (i) words denoting objects in the scene (e.g. "a red chair"), (ii) words depicting spatial relations between objects (e.g. "a chair *next to* the table"). While it is relatively simple to associate nouns with specific image regions, words describing relations are much harder to ground (Lu et al., 2017), possibly because visual representations are typically designed to capture objects without any explicit knowledge of relations. Secondly, grounded relations depend on knowledge from *both* vision and language modalities which contains information about the objects and their mode of interaction (*what*) as well as their physical location (*where*) (Ghanimifard and Dobnik, 2019). Ideally, each relation (and also other types of words) should be grounded in both modalities, but to a different degree.[1] However, studies of language-and-vision models indicate that they are frequently biased towards one modality, most often to language (Goyal et al., 2017). Therefore, *the main research challenge* is to develop architectures that learn to utilise an appropriate ratio of visual and language knowledge for generation (or understanding) of each word in its context. Towards this goal we investigate grounding of different semantic types and answer the following questions:

- **Q1**: Does attention across two modalities learn visually grounded semantics of nouns?
- **Q2**: What syntactic knowledge is encoded in attention on text in the multi-modal set-up?
- **Q3**: What does cross-modal attention learn about grounded semantics of spatial relations?

We use a two-stream multi-modal transformer (Herdade et al., 2019), which first attends to each modality independently and then learns to attend cross-modally. This architecture uses rich relative

---

[1] Of course, in uni-modal word-embeddings the semantics of words are grounded in word-contexts only but such representations give us only common sense knowledge not linked to particular situations.

Findings of the Association for Computational Linguistics: ACL 2022, pages 4062 - 4073
May 22-27, 2022

geometry between objects, while many other two-stream models (Tan and Bansal, 2019; Lu et al., 2019) simply use either coordinates of bounding boxes or their spatial location. We train the model for *image paragraph generation* (Ilinykh et al., 2019; Krause et al., 2017), allowing examination of the knowledge of semantic types in extensive contexts. Our experiments show how language and vision are bridged in the multi-modal transformer. In addition, our work provides insights into how multi-modal representations are learned for different word types.

2 Experimental Set-Up

Model We train a multi-modal transformer for image paragraph generation. The model is based on the image captioning transformer proposed by Herdade et al. (2019)[2]. We use the object detector provided by Anderson et al. (2018a)[3]. This model comes pre-trained on object annotations from Visual Genome (Krishna et al., 2016). We extract features of N objects per image, resulting in the set $\mathbf{V} = \{v_1, \ldots, v_N\}$ with $v_n \in \mathbb{R}^{1\times D}$. We set $N = 36$ and $D = 2048$. The object extractor also provides us with labels ("table") and attributes ("round") for the objects, which will be used in our experiments. Following Herdade et al. (2019), we also extract geometry information about each object $\mathbf{G} = \langle x, y, w, h \rangle$ (centre coordinates, width, height) and use it as an additional input along with visual features. Figure 1 describes the architecture of the model. In this model, each attention mechanism consists of six layers with eight attention heads in them. The *image encoder* (orange box) learns to combine visual and geometric features[4] and passes them through the standard self-attention block, consisting of multi-head self-attention, feed-forward network, residual connections and layer-normalisation. Due to uni-directional nature of description generation, the *text decoder* (blue box) produces representation of the current token w_i, based on previously generated tokens $(w_1, \ldots, w_{i-1})$, while $(w_{i+1}, \ldots, w_W)$ are replaced with $[MASK]$. Finally, the *cross-attention* (red box) uses information from both textual and visual streams to output a probability of the next word in the sequence.

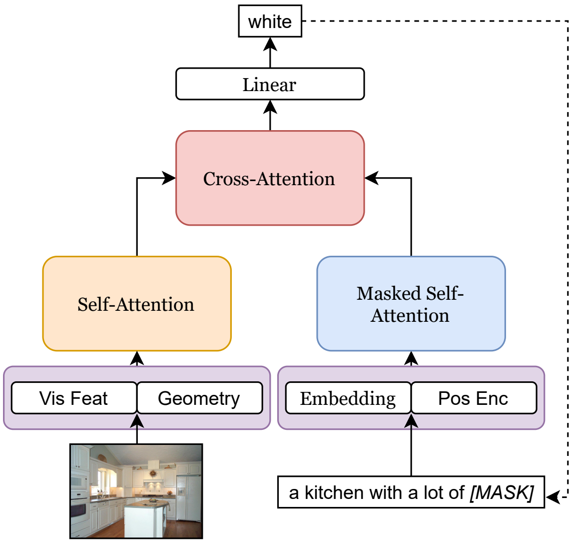

Figure 1: Multi-modal image description transformer. Every next generated word is concatenated with the previously generated words and passed to the model to output the next word prediction.

Figure 2: **Ground truth description of the image**: It's a room with a bar on the side. There is a pink couch in the center. There's a coffee table in front of the couch. It has a light purple rug. There are three chairs at the bar.
Generated description of the image: This appears to be a bonus room that is red and white. There is a wooden table in the center of the room. There is a red couch. There is a large plant in the corner.

Dataset We train our model on Tell-Me-More (Ilinykh et al., 2019), a dataset of natural multi-sentence descriptions of real-world images of rooms in the house setting (Zhou et al., 2017). The descriptions in this dataset are paragraphs produced by human describers in an image captioning task which are different from annotated relationships between object pairs in the Visual Genome (Krishna et al., 2016) which were examined in earlier work (Ghanimifard and Dobnik, 2019). Figure 2

Table 1: Automatic evaluation of image paragraphs generated by two different model architectures.

shows an example of the ground truth text and generated paragraph. For training, we use train and extra splits, providing us with 4820 image-sequence pairs, while for validation and testing we use 441 and 441 pairs respectively. We use beam search to generate sequences with beam width $bw = 2$. The model is trained with standard cross-entropy loss. The best model's checkpoint is chosen based on the highest CIDEr score (Vedantam et al., 2015) for the test set after training for 100 epochs. As Table 1 shows, our model achieves higher scores across most of the standard automatic metrics compared to the baseline architecture (CNN + LSTM + LSTM). Although our transformer performs slightly worse in terms of CIDEr score, note that different from previous work on multi-sentence image description generation (Krause et al., 2017; Chatterjee and Schwing, 2018; Ilinykh and Dobnik, 2020), we do not restrict the model to generate a specific number of sentences, instead stopping the generation when either the END token is encountered or the maximum number of words has been generated ($W = 150$). In addition, our dataset is much smaller than the Stanford image paragraph dataset (Krause et al., 2017), that the first model has been trained on.

3 Methods and Metrics

We extract the attention weights from both cross-modal attention and masked self-attention. Here, we could examine attention of the model while it is generating a new description or attention of the model receiving a ground truth description using teacher-forcing. Since our task is a validation task where we want to examine the behaviour of the model under fixed conditions we opted for ground truth descriptions. Using generated descriptions could produce identifiable attention patterns but the descriptions are not guaranteed to contain entities and relations that are in the image and we are interested in. If the model has approximated the training data well, then the unseen ground truth descriptions will not be far off from its predictions. Using ground truth descriptions that are not the model's predictions imposes more uncertainty for the model and therefore harsher conditions for evaluation of attention patterns. Identifying interpretable attention patterns under these conditions therefore makes the conclusions stronger.

For every generated word w_i, the attention weight α per head h in each layer ℓ is extracted. In transformers the attention weights are computed as the scaled dot-product of the query matrix Q with all the keys in K followed by a $\mathrm{softmax}$ operation. These weights are focusing on either previously generated words (masked self-attention *MSA*, Equation 1) or image objects (cross-attention *CA*, Equation 2).

$$\alpha_{\ell,h}(w_i \mid w_1, \ldots, w_{i-1}) = \mathrm{softmax}(\frac{Q_{MSA}K_{MSA}^T}{\sqrt{d_k}}) \quad (1)$$

$$\alpha_{\ell,h}(w_i \mid v_1, \ldots, v_N) = \mathrm{softmax}(\frac{Q_{CA}K_{CA}^T}{\sqrt{d_k}}) \quad (2)$$

We inspect how much attention is focused on specific parts of the input sequence when particular parts of the target sequence are generated. We refer to this measure as the **attention focus** or **attention proportion**. In our experiments, we calculate the proportion of total attention from a specific head that is focused on specific parts of the source sequence, e.g. previously generated words or image objects. Attention proportions are generally calculated as follows:

$$\boldsymbol{P}_{\ell,h}(\alpha \mid S, T) = \frac{\sum_{u \in \mathbf{U}} \sum_{i=1}^{|S|} \sum_{t=1}^{|T|} \alpha(s_i{,}S|t_j{,}T)}{\sum_{u \in \mathbf{U}} \sum_{i=1}^{|S|} \sum_{t=1}^{|T|} \alpha(s_i{,}t_j{,}T)}, \quad (3)$$

where $\boldsymbol{P}_{\ell,h}$ is the attention proportion for a specific head, S and T are the specific conditions imposed on the source and target sequences unique for every experiment (described below), $\mathbf{U}$ is the set of image descriptions sequences, t_j is the text span for either a noun phrase or relation from the target (generated) sequence T, s_i is the particular object or a text span from the source sequence S.

Conditions on $\boldsymbol{P}$ for Q1 For our experiments on visual grounding in cross-modal attention, T limits the target sequence to the text span of a noun phrase, while S defines the ground truth object that this noun phrase depicts. The attention proportion is calculated by computing the accumulated attention weight from the words in the noun phrase towards the corresponding object and then divided by the overall attention on all objects attended when this noun phrase is generated. We use spaCy (Honnibal et al., 2020) to extract noun phrases from image paragraphs which might introduce some errors, see Appendix A for examples. We skip any phrases which contain at least one word from the list specified in Appendix B. We keep determiners and adjectives in the noun phrases and any numerals if they occur. Some of the paragraphs might contain noun phrases that cannot be grounded in the bounding boxes in the image; either because the bounding boxes are not identified or because the noun phrases refer to abstract concepts. These phrases typically contain words such as "room", "image" or "photo" and are generally placed at the beginning of the description (e.g., "the image is of a kitchen with . . . "). In future experiments, we plan to investigate how the model grounds general descriptions of the scene ("the nursery room").

Conditions on P for Q2 For the experiments on word-to-word attention, T is set to the generated word at the specific time-step t_j, while S accumulates attention on words of specified part-of-speech tags when the target word t_j is generated. Ilinykh and Dobnik (2021) show that masked self-attention on text is indirectly affected by vision in the multi-modal set-up. Nouns that often describe objects are attended to a greater extent than some other words of specific part-of-speech tag (e.g., verbs) even though this model has never seen the image directly. Interestingly, the same phenomenon is not observed in text-only models such as `distilgpt-2`: its attention is much more local, focusing on the words that surround the target word instead of attending to more distant nouns. This finding suggests that a multi-modal transformer can learn *semantic* differences between words of various part-of-speech tags not just their structural arrangement which would be their syntax. Therefore, we construct two sets of part-of-speech tags, which reflect semantic differences between words in terms of the possibility of their grounding. The first set contains determiners, adjectives and nouns used in descriptions of objects, while the second set includes verbs and adpositions used in descriptions of relations between objects.

Conditions on P for Q3 To examine grounding of spatial relations, both S and T are determined based on the set of static spatial relations extracted from the texts. We extracted $target - relation - landmark$ triplets from each description (there are likely to be multiple relations mentioned in a single image description sequence), based on the annotation schema described in Kolomiyets et al. (2013) and publicly available tool[5]. We obtained 1015 relations of *region* type ("clothes on hangers"), 239 relations of *direction* type ("a gold chandelier above the table"), and 6 relations of *distance* type ("a large vase in the middle of the table"). Each of these relations consists of three spatial elements: a target (*a cup*), a landmark (*a table*) and a relation (*on*) in "a cup on the table". Given that the word order describing relations is typically a $target - relation - landmark$ sequence, the attention proportion for masked self-attention can be extracted only in following directions: $relation \rightarrow target$, $landmark \rightarrow relation$, $landmark \rightarrow target$, and $landmark \rightarrow target + relation$. For example, a possible T could restrict currently generated word to $relation$ (typically expressed with adpositions), while S could limit the calculation of the attention focus to $target$ (expressed as a noun phrase) in case of $relation \rightarrow target$ experiment.

4 Linking Nouns and Objects

To inspect attention heads for visual grounding, we require ground truth annotations of correct linking between image objects and noun phrases. We construct such links automatically using semantic similarity between noun phrases and object labels provided by the object feature extractor. First, we use spaCy (Honnibal et al., 2020) and extract noun phrases on different levels of nesting. For example, a noun chunk "a window with white lace curtains" and the nested chunk "white lace curtains" are identified as two different noun phrases. Potentially, this design choice allows for more accurate linking between noun phrases focusing on different objects ("window" and "curtains") and corresponding fine-grained object detections. In addition, noun phrases with specific details potentially disambiguate linking when multiple objects of the same type are in the image, e.g., several windows. As for object labels, for every detected object in every image, we take the predicted label and its attribute if the extractor's confidence for this attribute is higher

than 0.1. We determined this threshold manually allowing a lower degree of confidence to generate a sufficient number of adjectival attributes in order to disambiguate objects, e.g. "a brown chair" vs "a black chair".

Noun phrases and object descriptions typically include multiple words, Therefore, we compute semantic similarity between phrases. We examine several methods for linking noun phrases and object descriptions and compare them against the small subset of image paragraphs with manually annotated linking. Specifically, we randomly sample ten image-text pairs, consisting of 196 detected noun phrases. Then, 158 noun phrases were manually linked with image objects by the first author. The subset of the remaining 38 noun phrases included pronouns and abstract descriptions, too ambiguous to be linked with the specific object in the scene. In addition, we found that some noun phrases describe either a non-detected object or were extracted by mistake. A fraction of noun phrases that were not linked with any object is shown in Appendix A.

Table 2 shows the results of our search for the best linking method. We use GloVe embeddings (Pennington et al., 2014) to represent each word in a phrase and combine them by either element-wise multiplication (*GloVe Multiply*) or addition (*GloVe Add*), inspired by methods for phrase meaning representation (Mitchell and Lapata, 2008). The resulting vectors for a noun phrase and object description were compared based on cosine similarity. For *BERTScore* we follow Zhang et al. (2020) and use contextual word embeddings (Devlin et al., 2019) to represent every word. Words in a noun phrase and object description are then matched against each other by cosine similarity, and the F1 score can be used to examine the similarity. Finally, for *Sentence Transformer* we represent each word with the embedding from Sentence Transformer (Reimers and Gurevych, 2019). This model fine-tunes BERT embeddings for numerous NLI tasks and applies a mean pooling operation to get the fixed-size vector representing embedding of a whole phrase. We report accuracy *Acc* against manual annotations of ten image-text pairs. We also compute mean average precision *mAP@K*, a metric that allows us to see whether a particular combination method generally rates relevant object descriptions more similar to a noun phrase:

$$AP@K = \sum_{k=1}^{m} P_k(R_k - R_{k-1}), \tag{4}$$

where P_k and R_k are the precision and recall at cut-off k, m is the number of noun phrases detected in an image paragraph. K is set to the number of objects (36) since we inspect the linking of noun phrases with the whole set of objects. The final *mAP@K* score is the mean of average precisions for noun phrases in descriptions of images. Our search results for the linking method demonstrate that using embeddings from Sentence Transformer and comparing them for cosine similarity performs the best in terms of both metrics. Interestingly, simply using BERT embeddings and match them for similarity (*BERTScore*) is not enough to achieve a high *mAP@K* score, and this method also performs worse than a simple addition of non-contextualised embeddings (*GloVe Add*). A more complex fusion of information from different words is required to represent a phrase. When examining attention heads for visual grounding of nouns and relations, we thus use the best performing linking method (*Sentence Transformer*). Noun phrases might describe a group of objects in the scene ("six chairs"), corresponding to multiple object detections (several chairs). Labels of such objects are often identical, which makes their cosine similarity scores also identical. Therefore, we link a noun phrase with multiple objects on top of the similarity ranking if they have the same cosine score. Otherwise, a noun phrase is linked with the object that is ranked the highest.

5 Experiments and Results

Attention Entropy We compute entropy of the attention weights in both modules for each attention head. Specifically, the entropy E of an attention head h in layer ℓ is defined as follows:

$$E_{\ell,h}(t_j) = -\sum_{i=1}^{|S|} \alpha(s_i, t_j) \log(\alpha(s_i, t_j)) \tag{5}$$

where s_i and t_j are specific source and target sequence items and α is the attention weight between

(b) CA entropy

Figure 3: Normalised entropy of attention heads in different layers for masked-self attention (MSA) and cross-attention (CA). The darker the colour, the higher the entropy. All values were normalised by the maximum achievable entropy $-log_2(O)$. Note that the range of values is different between the graphs.

them. As Figure 3 shows, the entropy pattern is similar across both attention modules. Attention heads have lower entropy in deeper layers, focusing more on specific parts of the source sequence. In contrast, surface layers scatter attention across many items (either objects or previously generated words). Intuitively, such progressive increase of attention focus from surface to deeper levels indicate that both modules first learn to generalise over low-level features, gradually moving to capture more specialised, high-level conceptual knowledge (Ullman, 1984). Here, a fair question to ask is *what kind of low-level and high-level knowledge do masked and cross-modal attention learn in different layers with different entropy?*

As Ghader and Monz (2017) show for the task of machine translation, lower attention entropy is mainly observed when looking at nouns and adjectives, while higher entropy is witnessed when attending to adpositions and verbs. This finding demonstrates that attending to nouns in purely textual syntactic dependencies is less complex than focusing on verbs. In the context of our task, adpositions and verbs would be used when generating spatial relations, while objects are described with nouns and adjectives. Learning nouns in a multi-modal setting implies their visual grounding, a more complex task that requires knowledge of the scene. Similarly, in general, understanding spatial relations is a much more sophisticated task for the multi-modal transformer. It requires higher-level semantic knowledge and identification of objects and relations, compared to simple attention on verbs and adpositions as part-of-speech tags in a uni-modal setting. It has also been shown that attention on highly complex phenomena (named entities) would happen in deeper layers of the model, while low-level constructs (determiners) are attended much earlier in the layers of both uni-modal (Vig and Belinkov, 2019), and multi-modal (Ilinykh and Dobnik, 2021) architectures. Therefore, in our experiments, we examine how attention heads in different layers of masked and cross-modal attention capture either **syntactic knowledge** (nouns and relation phrases as words) or **semantic information** (visually grounded nouns and spatial relations).

Visual Grounding in Cross-Attention Here we investigate whether the high focus of cross-attention heads in deeper layers can be attributed to their specialisation in visual grounding of nouns. Specifically, *based on the linking method*, we compute the proportion of attention that radiates from words in a noun phrase towards **corresponding objects** described by this noun phrase. Figure 4 shows the results. We can see that attention heads

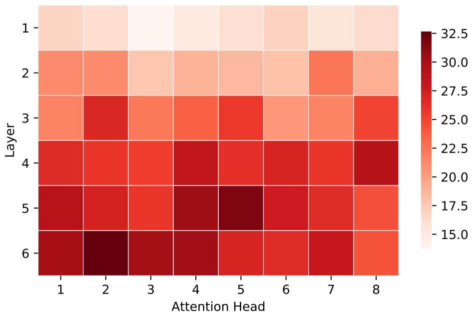

Figure 4: Attention proportions $\boldsymbol{P}$ on correct noun-object pairs (as determined by linking) for each attention head in the cross-modal attention. The darker the colour, the **bigger** the proportion. The proportions are averaged over the noun phrases in descriptions.

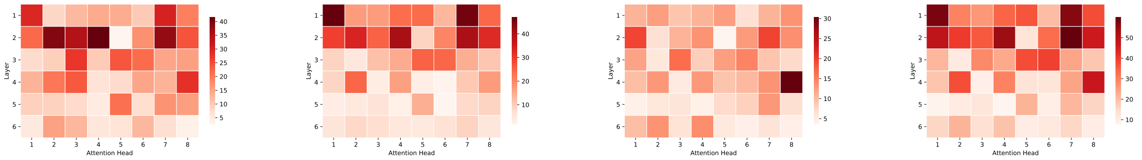
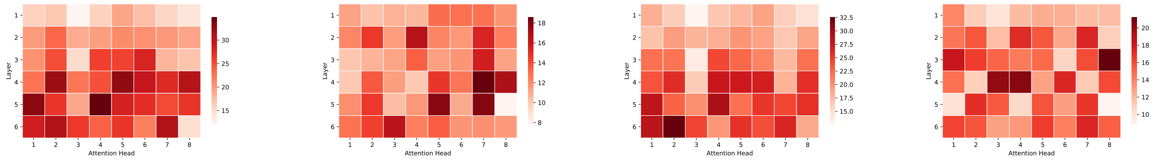
in deeper layers concentrate on linking bounding boxes of detected objects with noun phrases that describe them when these phrases are generated. Specifically, while in the first layer, attention heads pay on average 16% of their attention to the linked objects, in the deeper layers, the average attention focus reaches 29%. The most activated head is the second head in the sixth layer, which places 33% of its attention on connecting noun phrases with the bounding boxes of objects linked with this phrase. These findings show that the model captures complex visually grounded semantics of nouns in deeper layers of cross-attention. In addition, lower entropy observed in these layers (Figure 3b) also indicates that deeper heads are strongly focused and specialised in grounding of nouns.

Masked Self-Attention on Specific Part-of-Speech Tags Figure 5 demonstrates the attention focus on previously generated words of specific POS tags. We separate between tags which either describe objects $\langle$`DET, ADJ, NOUN`$\rangle$ or relations $\langle$`VERB, ADP`$\rangle$. Based on the heat-maps, we can see that previously generated determiners, adjectives and nouns are more attended in all layers except the first one, in which the focus is on relation part-of-speech tags. At the same time, according to Figure 3a, the attention in the first layer is more dispersed, which means that when attending to verbs and adpositions, attention is also looking at other words to a lesser degree, possibly such words which are involved in the action described by the verb. We calculated the Pearson correlation coefficient between both heat-maps in Figure 5. The test has shown a significant negative correlation ($r = -0.71, p = 1.7e-08$), indicating that there is a clear separation in attention focus on two types of words in masked self-attention. Overall, text-to-text attention is able to capture local and non-grounded syntactic knowledge of objects and relations between them.

Masked Self-Attention on Spatial Relations Figures 6a–6d show the attention focus in masked self-attention for several possible directions between parts of the phrase describing spatial relation. For example, $rel \rightarrow target$ shows the attention on the noun phrase describing the target object when a phrase describing relation is generated. Note that in masked self-attention, we are not able to look into the future; thus, we cannot inspect attention on $rel \rightarrow landmark$ or $target \rightarrow landmark$. The first important observation is a clear difference between attention on the word depicting the target object depending on where this attention is coming from. Numerous attention heads in the first layers focus on the target when relation is generated (Figure 6a), while only a few heads are looking at the target when landmark is generated. According to Figure 6b, relation is more important for landmark since it is widely attended by many heads, compared to only a few heads in Figure 6c and only a single head (head 8, layer 4) being highly active. In addition, there are three attention heads in the second layer (2, 3, 4) in Figure 6a, which are also highly activated in Figure 5a. This might indicate that these heads do not simply look at the words depicting objects but specialise in such words, which are playing the part of the "target" object in spatial relations. Therefore, we can identify particular heads that learn knowledge of syntactic dependencies between words describing spatial relations in the textual encoder. Also, based on Figure 6b, we can see that the focus on relation phrases is mostly captured in surface layers, which supports our statement that the model first needs to



(a) $rel \rightarrow target$ (b) $land \rightarrow rel$ (c) $land \rightarrow target$ (d) $land \rightarrow rel + target$



(e) $rel \rightarrow target$ (f) $rel \rightarrow land$ (g) $land \rightarrow target$ (h) $target \rightarrow land$

Figure 6: Heat-map visualisations of $\boldsymbol{P}$ for masked self-attention (**the top row**) and cross-attention (**the bottom row**) for different possible configurations of attention between words constituting spatial relations. All attention proportions are normalised by the number of spatial relations in the test set.

learn general knowledge about existing relations in the scene, later starting to exploit it for better focus on correct target and landmark nouns.

Cross-Attention on Spatial Relations Figures 6e–6h show how much each head looks at the specific object that corresponds to a target or a landmark in spatial relations. Similar to our experiment on visual grounding, we linked every noun phrase describing either a target or a landmark with a bounding box of the detected object by computing semantic similarity between the noun phrase and the label of every object. Note that here we look at how words of *semantic categories* describing relations between objects are grounded in *visual representations* (objects) rather than other words, as in the case of the masked self-attention. One noticeable difference between the top and bottom rows in the Figure 6 is that the attention focus in the cross-modal part of the architecture is much more distributed across heads.

Given that, according to Figure 4, while multimodal grounding of nouns into objects is clearly observed in the deeper parts of the model, grounding of relations in objects is much less interpretable. First, relations cannot be straightforwardly linked to the visual features of objects in a scene. When grounding relations the system needs to rely on several sources of knowledge, both linguistic and visual, and here systems tend to rely on linguistic knowledge more than on visual information (Ghanimifard and Dobnik, 2019). Learning is further complicated by the fusion of information in cross-attention. For example, the model needs to simultaneously rely on the semantic information from the language representations and identify objects that are targets and landmarks in spatial relations. Therefore, cross-modal attention activates several attention heads when trying to learn about spatial relations, which require attention on multiple sources of knowledge.

Interestingly, as Figure 6f and Figure 6h show that attention on landmark in cross-attention is distributed across multiple layers. However, the first layer of $rel \rightarrow land$, which generally has the highest entropy (cf. Figure 3b), is more activated compared to the first layer of the $target \rightarrow land$ attention map. This shows that certain attention heads in the first layer specialise to identify landmarks from relations (Figure 6f), whereas there are less such heads that identify landmarks from targets (Figure 6h). This can be attributed to the fact that the model learns to confidently attend targets only in the deeper layers of the network because targets require much more complex inference. Landmarks are intuitively semantically closer to relations as in descriptions they are used together to identify targets. For example, Dobnik et al. (2018) show that there is a strong asymmetry between knowledge about targets and landmarks. Landmarks are generally much easier to predict, and they contribute less to the perplexity of the model than targets. Intuitively, a speaker would like to describe the target, and they need to find a suitable contextually salient landmark, which then selects an appropriate relation and finally produce a full description including the target. Therefore, it might happen that the model first distributes its attention between heads in surface and deeper layers to identify landmarks in the context of particular relation, and then learns to strongly map this relation-landmark context with the specific target in deeper layers. This idea is also supported by strongly localised and focused attention on the target object in deeper layers when either a relation or a landmark are generated (Figure 6g and Figure 6e).

Note the differences between attention patterns in Figure 6a and Figure 6e for the $relation \rightarrow target$ direction. Surface layers in masked self-attention, as we have shown, seem to learn local syntactic dependencies between words in the source input (text). This is different from the multi-modal scenario, where deeper layers are much more activated for visual and language inputs. This indicates that spatial relations are much more sophisticated in the language-and-vision context: they need to capture semantic dependencies between words and objects in the scene. Also, the complexity of information might be the reason why $rel \rightarrow target$ attention is much more scattered across many heads in deeper layers in cross-modal attention, compared to more focused attention in specific heads in surface layers for masked self-attention.

6 Conclusion

We have shown that the language model in a multimodal task captures linguistic phenomena of different kind depending on the source knowledge (text or objects) and semantic type of the output words (noun phrases or spatial relations). Cross-modal attention visually grounds objects and, therefore, semantic dependencies in its deeper layers (addresses **Q1**). Text-only attention learns low-level linguistic phenomena, e.g. local syntactic dependencies (addresses **Q2**). This is also exemplified for target-relation-landmark descriptions which are attended in a sequential order that they appear in the text. We have also shown that there is a difference in a way objects and relations are grounded cross-modally and such grounding is particularly challenging for relations (addresses **Q3**). The grounding of landmarks depends on relations to a greater degree than on targets in both masked and cross-modal self-attentions. This could be attributed to the auto-regressive nature of the image paragraph generation task. However, there are important differences in terms of activations across attention layers for different semantic pairs. Deeper heads in the cross-modal attention tend to be activated more than the surface heads which is the opposite tendency compared to masked self-attention. Overall, our work demonstrates that attention on vision and language captures considerably more diverse linguistic knowledge, *both syntactic and semantic* which is not *linearly aligned*, compared to uni-modal (language only) architectures.

One possible follow-up experiment is to use attention as input to the probing classifier and identify a specific knowledge encoded by the weights. However, the performance of the probing model does not tell us whether the original model utilises acquired knowledge since it is *detached* from the original architecture (Belinkov, 2022). Although attention is not necessarily an explanation (Jain and Wallace, 2019), inferring linguistic properties from attention weights does not require learning a new set of parameters. Other methods include fine-grained analysis of features preferred by specific neurons in the model architecture by examining their maximum activation values (Rethmeier et al., 2020). This method would identify the neurons that are active at each step of generation, but would not straightforwardly tell us how words and objects are linked together, which is clearly expressed in attention. Our results indicate that the way relations are grounded in a transformer model is not completely transparent. Future research should focus on examining the effect of different feature representations that are relevant for spatial relations (e.g., RGB-D and different models of geometry, common sense knowledge about objects' affordances) as well as the models that can be built around them. In another follow-up study we could examine grounding of relations in a different task, for example in vision-and-language navigation (Anderson et al., 2018b) which is rich with descriptions of relations between objects and compare whether the same observations also hold for those models.

A Appendix A

Pronouns such as `it` and `his` were not linked with any object in the scene. Noun phrases depicting spatial descriptions or locations were also ignored, e.g. `the right`, `the background`, `the corner`. Some noun phrases are describing properties of objects in the scene (e.g., `color`, `the overall color of the room`) or positional arrangement (`a straight line` in `three paintings hang in a straight line`). Other noun phrases describe a general understanding of the image, and not a single bounding box could cover it (`a beachside hotel` in `a room that looks like inside a beachside hotel`). Some noun phrases were incorrect either due to an error made by spaCy or human producing the original description, e.g. `the walls floor sofa`.

B Appendix B

When extracting noun phrases for the experiment on visual grounding we ignore all pronouns and spatial phrases found on this list: `right`, `a right`, `the right`, `left`, `a left`, `the left`, `top`, `the top`, `bottom`, `the bottom`, `back`, `the back`, `front`, `the front`, `far`, `the far`, `close`, `the close`, `side`, `each side`, `background`, `the background`, `foreground`, `the foreground`, `middle`, `the middle`, `corner`, `a corner`, `the corner`.

Improving Zero-Shot Cross-lingual Transfer Between Closely Related Languages by Injecting Character-Level Noise

Noëmi Aepli[1] and **Rico Sennrich**[1,2]
[1]Department of Computational Linguistics, University of Zurich
[2]School of Informatics, University of Edinburgh
`{naepli,sennrich}@cl.uzh.ch`

Abstract

Cross-lingual transfer between a high-resource language and its dialects or closely related language varieties should be facilitated by their similarity. However, current approaches that operate in the embedding space do not take surface similarity into account. This work presents a simple yet effective strategy to improve cross-lingual transfer between closely related varieties. We propose to augment the data of the high-resource source language with character-level noise to make the model more robust towards spelling variations. Our strategy shows consistent improvements over several languages and tasks: Zero-shot transfer of POS tagging and topic identification between language varieties from the Finnic, West and North Germanic, and Western Romance language branches. Our work provides evidence for the usefulness of simple surface-level noise in improving transfer between language varieties.

1 Introduction

Recent research has achieved impressive results in zero-shot cross-lingual transfer based on multilingual pre-training (Devlin et al., 2019; Conneau and Lample, 2019) or monolingual transfer of embeddings (Artetxe et al., 2020). However, these methods require large amounts of unlabeled data in the target language (Lauscher et al., 2020) and do not take into account surface similarity between languages except for the sharing of subword units in multilingual models. For the transfer between closely related languages and dialects, we deem it desirable to exploit the similarity of surface representations. Specifically, we target orthographic variations that commonly result from pronunciation differences between closely related languages.[1]

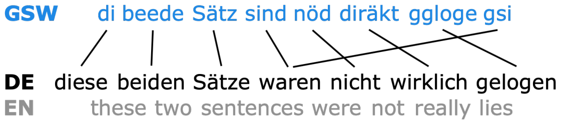

Figure 1: Swiss German (GSW) sentence with corresponding standard German (DE) and English (EN) translations. The sentence shows various spelling differences on the word level, and reordering occurs on the sentence level due to different past-tense formation.

In this paper, we propose to augment the training data of a high-resource language with character-level noise to simulate spelling variations and thus facilitate generalization to closely related[2] low-resource languages.

We test this strategy on two tasks and several language regions. The considered tasks are part-of-speech (POS) tagging on the word level and topic classification on the sentence level; the languages are from the Finnic, West and North Germanic, and Western Romance language branches. We observe that our baseline method for cross-lingual transfer learns undesirable heuristics, e.g., assigning unseen words to open word classes in POS tagging and that injecting noise reduces this bias. Our experiments show absolute accuracy improvements between 1.4 and 22 percentage points over the state of the art, providing evidence that a simple data-augmentation strategy can boost transfer learning for language varieties and dialects with a closely related high-resource language.

2 Related Work

Zero-shot cross-lingual transfer based on multilingual language models (Devlin et al., 2019; Conneau and Lample, 2019) or machine translation models (Siddhant et al., 2020) has turned out

---

[1] Note that there are also differences on different levels as described in Hollenstein and Aepli (2014) and partly observable in Figure 1 which illustrates a German example sentence with a closely related variant.

[2] Language relatedness is on a continuum, and the difference between dialects and distinct languages is often political. Hence we use a broader term to indicate that the method is not limited to dialects.

Findings of the Association for Computational Linguistics: ACL 2022, pages 4074 - 4083
May 22-27, 2022

to be surprisingly effective. Such representations proved themselves beneficial for a range of diverse tasks (Hu et al., 2020). However, they still require large-scale data sets to train, making them impractical for low-resource languages, to which dialects and language varieties typically belong.

Artetxe et al. (2020) introduce zero-shot cross-lingual transfer by mapping monolingual representations between languages. They also propose adding Gaussian noise to the embeddings during the fine-tuning step. Huang et al. (2021) also operate in the embedding space by constructing robust regions in the embedding space to tolerate noise in the contextual embedding. These are not ideal strategies for closely related languages because words with similar surface forms could still be far from each other in an embedding space.

Surface-level noise such as character substitutions, insertions, and deletions has been proposed as an effective data augmentation strategy for machine translation (Sperber et al., 2017; Heigold et al., 2018; Belinkov and Bisk, 2018; Karpukhin et al., 2019; Vaibhav et al., 2019; Anastasopoulos et al., 2019). Authors report improvements in system accuracy due to more robustness towards speech recognition errors, spelling mistakes, and other naturally occurring noise in text data. Even though cross-lingual transfer between closely related languages has received some attention (Muller et al., 2020; Sakaguchi et al., 2017; Zeman et al., 2017, 2018), it has not been investigated whether this transfer can be improved with character-level noise inserted at training time. We tackle this in our work by adding random character-level noise to the training data of a standard language and applying the model to closely related languages.

Exploiting orthographic similarity to improve cross-lingual transfer between closely related languages is currently an understudied area. Relevant previous work has been done by Sharoff (2018), who used orthographic similarity to refine bilingual dictionary induction.

Transliteration is another line of related work that focuses on improving the transfer between closely related languages with different alphabets (Durrani et al., 2014; Lin et al., 2016; Murikinati et al., 2020; Han and Eisenstein, 2019). On the other hand, our work focuses on languages using the same script. The recent report by Muller et al. (2021) investigating transfer between the same and different alphabets involves a zero-shot task transfer which is, however, preceded by a language model training on (unlabeled) target language data. To the best of our knowledge, we are the first to focus on zero-shot transfer learning techniques for closely related languages.

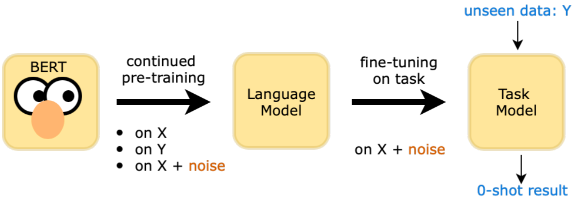

Figure 2: Methodology for zero-shot cross-lingual transfer: We first continue the pre-training of a language model (LM) on text. Then, we fine-tune the adapted LM to task T in high-resource language X. We augment the training data for continued pre-training or fine-tuning with character-level noise and apply the model to task T in a closely related low-resource language Y.

3 Method

Consider a high-resource language X and a closely related low-resource language Y. We perform zero-shot cross-lingual transfer by pre-training a model on unlabeled data from X (and optionally Y if available), then fine-tuning on task T in language X. The resulting model is applied to task T in language Y. This procedure is illustrated in Figure 2. Thus, our question is: How can we best make the model trained on X generalize to Y?

Ideally, such a model would take surface similarity of words into account for generalization. We hypothesize that in closely related languages, unknown words in the low-resource language are likely to correspond to similar known words in the high-resource language in function and meaning.[3] However, state-of-the-art language models represent words through subwords (Sennrich et al., 2016). This representation is sensitive to slight surface variations: minor changes to a string will lead to different segmentations and internal representations.

To account for this problem, we apply noise to the surface representation of words in language X. We implement this through character-level noise, i.e., we randomly[4] select $10\% - 15\%$ of the tokens

---

[3] Please refer to Table A1 for examples.

[4] We tested more linguistically motivated constraints on the character replacements but did not find it to have a big effect.

Noise	DE-BERT	DE-BERT + GSW	DE-BERT + DE	DE-BERT + DE + Noise
✗	50.66	**72.1**	52.08	53.88
✓	72.77	**82.11**	71.13	70.45

Table 1: POS tag accuracy for Swiss German (GSW) on different language models fine-tuned on German (DE) training data with and without noise.

of a sentence[5] excluding numbers and punctuation. One randomly selected character of the chosen token undergoes one of three possible operations: *delete*, *replace*, *insert*, each with equal probability. The latter two operations work with an additional randomly selected character of the (extended) Latin Alphabet for the source language. The following sentence *This is a short example.* will end up with some sort of a "typo", e.g., as *This* ***ius*** *a short example.* Noise can be applied during pre-training on X, and/or during fine-tuning on a task T for language X.

Another possibility to alleviate the subword representation problem is BPE-dropout (Provilkov et al., 2020), which applies different segmentations to words in a randomized fashion. BPE-dropout was originally motivated to increase robustness for morphological variance. We hypothesize that it is similarly effective for orthographic variance; see Table A1 for examples. Overall, both character-level noise and BPE-dropout encourage the model to learn generalizations across similar surface strings via shared subwords.

A second motivation for character-level noise is that we aim to imbue the model with different inductive biases. For example, a model for POS tagging might learn that only a small set of words can map to closed word classes such as articles, whereas unknown words are likely to belong to an open word class such as named entities. Training with character-level noise will reduce this bias.

4 Experiments

We design our experimental procedure[6] to answer the following question: Does character-level noise improve zero-shot transfer to closely related languages? Within three controlled experiments, we ablate the importance of the noise-augmentation strategy. We select two cross-lingual tasks: 1) POS tagging (15% noise) and 2) topic classification (10% noise). While the former task illustrates the strategy's potential on word level, the latter provides insight into how much it helps on text level.

4.1 POS Tagging for Swiss German Dialects

As base models, we use the German "dbmdz" BERT[7] (DE-BERT) and mBERT (Devlin et al., 2019). We continue pre-training on the *SwissCrawl* corpus (Linder et al., 2020) for the Swiss German (GSW) LM-adaptation and the DE part of *The Credit Suisse News Corpus* (Volk et al., 2018) for the German LM-adaptation. For task fine-tuning, we use a DE UD treebank and for the evaluation a part of *NOAH's Corpus* (Hollenstein and Aepli, 2014).

As shown in Table 1, all settings profit from fine-tuning with noise and bring about improvements of up to 22 percentage points (DE-BERT without pre-training). The best result with an accuracy of 82.11% for zero-shot GSW POS tagging is achieved with a GSW-adapted language model and task fine-tuning on a noised DE corpus. Considering the case where no GSW text data is available for language model adaptation, we still achieve an accuracy of 77.11% for zero-shot GSW POS tagging with mBERT fine-tuned on noised DE data (see Table 2).

4.2 POS Tagging with mBERT

We fine-tune mBERT on a UD corpus of a language already seen during mBERT pre-training: DE, Finnish (FI), Swedish (SV), French (FR), or Icelandic (IS, Arnardóttir et al. (2020)) and test on a closely related language variety absent from mBERT: GSW, Old French (OFR), Livvi (OLO, Pirinen (2019)), Karelian (KRL, Pirinen (2019)), or Faroese (FO, Tyers et al. (2018)). In addition to noise, we added experiments with a BPE-dropout of 0.1 (empirically selected) during the fine-tuning step.

Table 2 illustrates that the method works well for closely related language varieties (upper part) but less for other language pairs, which are more distant (lower part). We do see an occasional improvement for more distant language pairs, but they

---

[5] We relied on previous work by Vincent et al. (2008) where similar choices were made regarding the amount of noise.

[6] We work with code bases by Wolf et al. (2020) and Wang et al. (2021), multilingual BERT (mBERT), and the data sets' default splits. Most of the corpora we work with were provided by the Universal Dependency project (UD, Nivre et al. (2016)); refer to Appendix A.2 for details.

Table 2: Zero-shot POS tagging accuracy of different strategies for several languages (TRAIN→TEST). The training and test languages are closely related in the upper but not in the lower part of the table as indicated by the colors (Finnic, West Germanic, North Germanic, and Western Romance language branches.) Noise consistently adds additional accuracy points beyond BPE-dropout performance increase.

are generally smaller and less consistent than the improvements for the closely related languages we evaluated.

Furthermore, we have to consider the (much) lower baseline where an accuracy gain does not have the same impact. Hence, the two strategies BPE-dropout and noise improve the zero-shot performance for POS tagging over several closely related language pairs. While BPE-dropout shows some performance gain over the baseline, character-level noise adds additional accuracy points.

4.3 Cross-dialect Topic Identification

We work with mBERT and *MOROCO: The Moldavian and Romanian Dialectal Corpus* (Butnaru and Ionescu, 2019). The data set contains 33,564 news domain text samples, each belonging to one of six topics (culture, finance, politics, science, sports, tech). We fine-tune mBERT on topic identification on Moldavian (MD) and evaluate on Romanian (RO) and vice versa. We emphasize the difference between this sentence-level task and the previous word-level task. While POS tagging works on the word form and can benefit from transferring prior information about probable POS sequences, topic classification is mainly meaning-oriented, making a transfer more challenging.

Training	Noise	Test	Accuracy
MD	✗	RO	63.34
	✔		**68.48**
RO	✗	MD	81.65
	✔		**83.01**

Table 3: Results for Moldavian (MD) vs. Romanian (RO) cross-dialect topic identification. Training with noise improves the transfer by 5.1 (MD→RO) respectively 1.3 (RO→MD) percentage points.

Topic identification results in Table 3 show that fine-tuning with noise consistently improves the accuracy. However, noise-augmented training data appears to have a more substantial effect when transferring from MD to RO (5.1 percentage points) than vice-versa (1.4 percentage points). This is interesting given that RO represents the high-resource standard language in this context (being one of the languages used to train mBERT), while MD is its low-resource variety. We conjecture that this is caused by the fact that the model trained in MD struggles with word meaning and is, therefore, more sensitive to variations than its RO counterpart.

5 Analysis

Figure 3 illustrates the prediction differences of a model trained with and without noise. We observe that the models trained without noise have learned a tendency towards labeling unknown words as open-class words such as names (`NE`) or adjectives (`ADJD`), with the label for foreign words (`FM`) being massively overpredicted, while it tends to undergenerate closed-class tags such as articles (`ART`) or adverbs (`ADV`). In contrast, the model trained with noise comes much closer to the gold standard tag distribution. It has learned to rely more on probable POS tag sequences than on the surface form of a token. Consider e.g. the GSW article *d* (DE *die*; the). In the DE training corpus, the token appears only as a foreign word (`FM`) because it also happens to be a French word, but the model trained with noise is more likely to correctly tag it as an article, relying more on context than just strict mappings.[8]

Figure 4 depicts the per-type F1 change for the most frequent STTS (Schiller et al., 1999) tags. The past participles of the auxiliary verbs (`VAPP`) form another closed class which profits substantially from a model focusing on tag sequences given the compound structure of the perfect tense. As Swiss German does not have a simple past, the

---

[8] For more examples, please refer to the Appendix A.1.

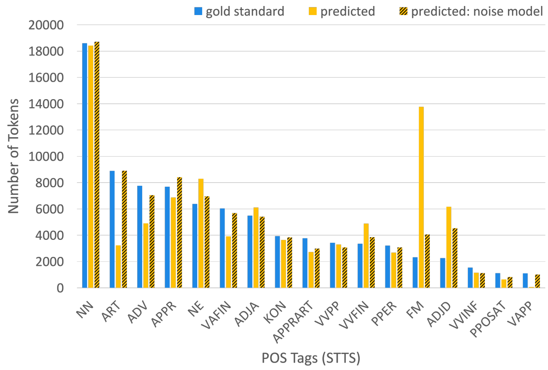

Figure 3: Number of tokens per POS tag in the gold standard vs. predictions of two models, fine-tuned with and without noise. Only the most frequent STTS tags are displayed.

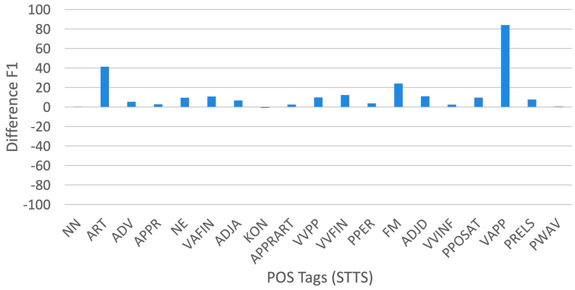

Figure 4: Per-type F1 change of the most frequent STTS tags illustrating which tags profit the most when the model is fine-tuned with noise.

perfect tense is much more frequent than it is in German.

5.1 Conditional Random Field

Given that one potential consequence of adding noise is that the model relies more on surrounding context and probable POS tag sequences (rather than strict word-level mappings), we compare our results to a method that explicitly models tag sequences, Bi-LSTMs+CRF (bidirectional long-short-term memory + conditional random field). This method was used to achieve state-of-the-art performance for POS tagging (Huang et al., 2015). For the implementation, we added a CRF layer on top of BERT.[9]

The added CRF layer did not improve the performance of the fine-tuned mBERT model for zero-shot POS tagging for Swiss German trained on German, as presented in Table 4. In contrast, noise injection has proven effective in both configurations.

Noise	mBERT	mBERT+CRF
✗	70.24	69.26
✔	**78.57**	76.90

Table 4: Zero-shot POS tag accuracy for Swiss German on mBERT & mBERT+CRF models trained on German with and without noise.

6 Discussion

Our investigation into cross-lingual zero-shot transfer between closely related languages demonstrates that simple data augmentation with character-level noise can successfully improve transfer, with absolute improvements ranging from 1.4 (RO→MO transfer of topic identification) to 22 (DE→GSW transfer of POS tagging in the case of DE-BERT without pre-training) percentage points.

The examination of prediction errors shows that a baseline BERT model has learned heuristics for unseen words that are undesirable for transfer between closely related languages. In contrast, a model trained with noise can combat this bias without substantial performance losses in the source languages.

We expect that the final effectiveness of using character-level noise for zero-shot cross-lingual transfer depends on the task and language characteristics. We plan to evaluate the effect of character-level noise in a broader range of settings in future work. More broadly, we encourage further research that exploits surface-level word similarity for cross-lingual transfer between related languages and dialects, rather than focusing purely on vector space representations.

Acknowledgments

We thank Yves Scherrer for input regarding data sets and the anonymous reviewers for their valuable comments. This project has received funding from the Swiss National Science Foundation (project nos. 191934 & 176727).

Ethical Considerations

Our work did not involve any new data collection or annotation and did not require in-house workers or introduce any new models and related risks. Instead, we examine how character-level noise can help the transfer between closely related languages, especially in low-resource zero-shot settings.

A Appendix

A.1 Analysis

Table A1 shows Swiss German (GSW) words (and their corresponding standard German (DE) form and English (EN) translation) that had the highest accuracy increase when using a part-of-speech (POS) tagging model trained with character-level noise compared to the model trained without noise. These words were wrongly tagged with open-class tags by the baseline model. However, the model trained with noise was able to reduce this bias and thus correctly tag them with their closed-class tag.

Furthermore, in most cases, one *substitution/insertion/deletion*-operation on the DE word would not suffice to get an exact match with the GSW word. This indicates that it is unnecessary to design a noise function that closely mirrors the linguistic differences between variants.

Structural Supervision for Word Alignment and Machine Translation

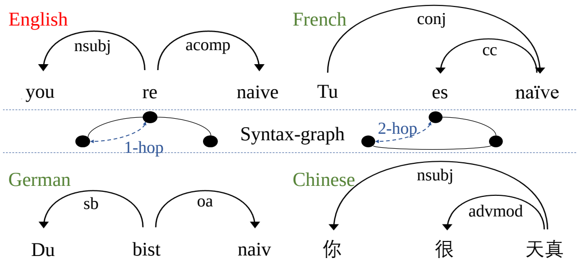
Abstract

Syntactic structure has long been argued to be potentially useful for enforcing accurate word alignment and improving generalization performance of machine translation. Unfortunately, existing wisdom demonstrates its significance by considering only the syntactic structure of source tokens, neglecting the rich structural information from target tokens and the structural similarity between the source and target sentences. In this work, we propose to incorporate the syntactic structure of both source and target tokens into the encoder-decoder framework, tightly correlating the internal logic of word alignment and machine translation for multi-task learning. Particularly, we won't leverage any annotated syntactic graph of the target side during training, so we introduce Dynamic Graph Convolution Networks (DGCN) on observed target tokens to sequentially and simultaneously generate the target tokens and the corresponding syntactic graphs, and further guide the word alignment. On this basis, Hierarchical Graph Random Walks (HGRW) are performed on the syntactic graphs of both source and target sides, for incorporating structured constraints on machine translation outputs. Experiments on four publicly available language pairs verify that our method is highly effective in capturing syntactic structure in different languages, consistently outperforming baselines in alignment accuracy and demonstrating promising results in translation quality.

1 Introduction

Word alignment (Brown et al., 1993) aims to find the correspondence between tokens in a sentence pair. Neural machine translation (NMT) (Bahdanau et al., 2015; Vaswani et al., 2017) works by taking an end-to-end approach to incrementally predict the target translation from a source sentence, where no explicit word alignment is required during model training or decoding. Recently, there has been an increasing interest (Zenkel et al., 2020; Chen et al., 2020, 2021; Zhang and van Genabith, 2021) in combining the two tasks through inducing accurate word alignment in neural translation models for improving translation quality.



Regardless of direction and type: (1) the dependencies between '**you**' and '**re**' and between '**re**' and '**naive**' in English match the dependencies between '**Du**' and '**bist**' and between '**bist**' and '**naiv**' in German.
(2) For English-French (Chinese) pairs, although there is no explicit dependency between '**Tu**'(**你**) and '**es**'(**很**), we can capture the implicit dependency by tracing the dependencies between '**Tu**'(**你**) and '**naïve**'(**天真**) and between '**naïve**'(**天真**) and '**es**'(**很**).

Figure 1: Similar dependencies of different languages.

Intuitively, word alignment is helpful to enforce the domain-specific terminology or improve the translations of low-frequency tokens (Song et al., 2019; Dinu et al., 2019). Also, word alignment provides supportive linguistic information on translation outputs, being useful in interactive translation with the human in the loop (Weng et al., 2019). Since the target-to-source attention in NMT models can infer rough word alignments but induce many errors with low accuracy, a number of recent works (Garg et al., 2019; Zenkel et al., 2019, 2020; Zhang and van Genabith, 2021) focus on NMT-based alignment methods which take alignments as a by-product of NMT systems.

Although NMT-based aligners have proven to be effective and achieved the State-of-the-Art alignment accuracy, they suffer from two major limitations. First, due to the autoregressive property (Sutskever et al., 2014), they (Dyer et al., 2013; Bahdanau et al., 2015; Vaswani et al., 2017; Chen et al., 2020) only leverage partial target context.

The latest works (Chen et al., 2021; Zhang and van Genabith, 2021) alleviate this deficiency to exploit both sides of the target content to compute better target-to-source attention (alignment), by abandoning autoregressive decoder and sacrificing the translation ability. In addition, there are also related works (Bastings et al., 2017; Marcheggiani et al., 2018) proposing syntax-aware NMT models without word alignment task. However, they simply utilize the syntactic structure of source tokens and ignore to capture the syntactic structure of target tokens. In summary, the syntactic structure of both source and target tokens has not been thoroughly explored to guide accurate alignments, while the similarity of dependencies across diverse languages has not been utilized for producing translation outputs with high-quality and favorable generalization capabilities. Second, they (Garg et al., 2019; Zenkel et al., 2020) typically use multi-task learning architecture to jointly learn the word alignment and translation with elaborately designed loss functions. However, this is computationally expensive for training and the internal logic between the two subtasks is not well correlated.

To alleviate mentioned problems, we propose to simultaneously consider the syntactic structure of both source and target tokens. According to the similar dependencies across language pairs, the syntactic graphs of target tokens are first sequentially inferred through introduced Dynamic Graph Convolution Networks. Hierarchical Graph Random Walks are then performed based on the built syntactic graphs at both ends, as well as the initialized multi-scale and trainable "hidden graphs" (Nikolentzos and Vazirgiannis, 2020). We found that by correlating cross-linguistic dependencies without any additional guided loss, word alignment and translation can be more effectively integrated into a unified learning framework, efficiently correlating the internal logic between subtasks while improving the interpretability of the model.

Our contributions are as follows: **(1)** We introduce Dynamic Graph Convolution Networks to sequentially infer the syntactic graphs of target tokens and further guide the word alignment learning. **(2)** Hierarchical Graph Random Walks are further performed to incorporate both local and global structural constraints for producing translation outputs. **(3)** Results on four language pairs demonstrate that our method is highly effective in such alignment- or translation-related NLP tasks, consistently outperforming baselines in alignment accuracy and translation quality.

2 Background

2.1 Word Alignment

A naive way to extract alignments from NMT models is to choose the source token with the maximum accumulated attention weight towards the current target token (Arthur et al., 2016; Hasler et al., 2018): $\gamma(t) = \underset{i \in \{1,\ldots,M\}}{\arg\max} \sum_{l=1}^{N} \alpha_{t,i}^{l}$, where i is the candidate aligned source-side position. For decoding step t in layer l, $\alpha_{t,i}^{l}$ is the attention weight of the i-th position in the source, produced by an average of all the attention heads in Transformer (Vaswani et al., 2017). Although simple to implement, this method fails to obtain satisfactory alignment results (Li et al., 2019; Ding et al., 2019; Chen et al., 2020). In this work, we sufficiently exploit the similarity of dependencies between language pairs, training a novel multi-task learning framework to jointly learn translation and word alignment.

2.2 Neural Machine Translation

Let $\mathbf{x} = x_1, ..., x_M$ and $\mathbf{y} = y_1, ..., y_N$ be the source and target sentence respectively, neural machine translation models the probability of the target sentence conditioned on the source sentence: $P(\mathbf{y}|\mathbf{x};\theta) = \prod_{i=1}^{N} P(y_i|\mathbf{y}_{<i}, \mathbf{x})$, where $\mathbf{y}_{<i}$ is a partial translation from the first to (i-1)-th target tokens. Existing NMT models are generally equipped with the encoder-decoder structure. The encoder encodes the source sentence, while the decoder generates the target sentence through a target-to-source attention mechanism and performs left-to-right autoregressive decoding. In this work, we adopt Transformer (Vaswani et al., 2017) as the baseline to build our method, which is also an encoder-decoder framework while each decoder layer attends to the encoder output with multi-head attention.

3 Approach

Our work is inspired by the fact that tokens in different languages have similar dependencies under the same semantics. As shown in Figure 1, the dependencies between tokens with the same semantics in the English-German pair are highly similar, while the similarity of dependencies between English and French (Chinese) can also be implicitly captured.

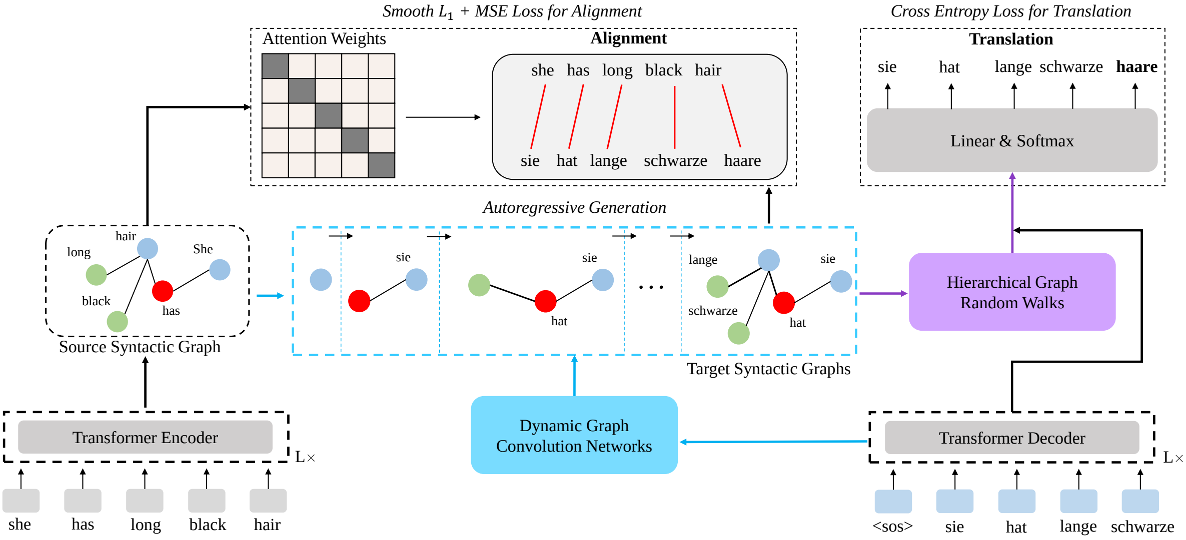

Figure 2: The architecture of proposed multi-task learning framework. **Supervised learning tasks**: word alignment and machine translation. **Unsupervised learning task**: generation of the target syntactic graph.

We regard each token as a node, and build the edges according to the corresponding dependencies between each node to form the syntactic graphs of different languages. For instance, there is a dependency between ’you’ and ’re’, and the node ’you’ is the 1-hop neighbor of ’re’ in the built English (syntactic) graph. While there is no explicit dependency between ’Tu’ and ’es’ and we have to pass through ’naïve’ to reach ’es’ from ’Tu’, so the node ’Tu’ is treated as the 2-hop neighbor of ’es’ in the French (syntactic) graph.

3.1 Multi-task Learning

Figure 2 shows the overall architecture of proposed multi-task learning framework. We model the joint distribution of the target tokens and the target syntactic graphs by factorizing it into the product of a series conditional distributions.

$$\begin{aligned}P(\mathbf{y},\mathbf{y}^s|\mathbf{x}^s,\mathbf{x}) = \prod_{i=1}^{N} & P(y_i|\mathbf{y}^s_{\leq i},\mathbf{x}^s,\mathbf{y}_{<i},\mathbf{x}) \\ & \times P(y^s_i|\mathbf{y}^s_{<i},\mathbf{x}^s,\mathbf{y}_{<i},\mathbf{x}),\end{aligned}$$

where $\mathbf{y}_{<i},\mathbf{y}^s_{<i}$ are partially generated target sentence and syntactic graph, and $(\mathbf{x},\mathbf{x}^s)$ indicates the entire information from the source side. For the tokens $\mathbf{y}$, we can directly optimize translation loss. However, since we mainly focus on the word alignment dataset, we do not leverage the ground-truth of the target syntactic graph to maximize the likelihood. In order to use the supervised signal of word alignment, we propose a proxy to construct the word alignment α with graph convolution networks:

$$\alpha = \text{proxy}(\mathbf{y}^s),$$

where the proxy construction will be elaborated in the next section. Then we optimize the word alignment loss as a surrogate.

In summary, we learn three tasks simultaneously, machine translation and word alignment via supervised signals while inferring syntactic graph of the target side as a byproduct in an unsupervised way.

Specifically, our approach first build the syntactic graph of source tokens, on which basis we introduce Dynamic Graph Convolution Networks to sequentially infer the syntactic structure of observed target tokens, efficiently generating accurate alignment results which derived from the structural attention weights between both sides. To better encourage the correlation of the internal logic between word alignment and translation, Hierarchical Graph Random Walks are then performed to incorporate structural constraints for producing high-quality translation outputs.

3.2 Dynamic Graph Convolution Networks

We can first build the source syntax graph with the output representations H_e from Transformer encoder, where each node corresponds to one token representation. In particular, the adjacency matrix A_s is generated from the parsed syntactic structure, where $a_{(i,j)} = 1$ indicates there is a dependency between node i and j. Meanwhile, we initialize the rough adjacency matrix $\bar{A}_t$ containing only self-connections for each target token. Afterwards, Dynamic Graph Convolution Networks are leveraged to adaptively adjust the graph topology for obtaining refined adjacent structures. Significantly, both masking and attention mechanisms are introduced to distinguish and re-weight observed target nodes through the captured multi-hops neighbor.

For each decoding step, masking mechanism is first built for the observed set of target nodes. For each observed token (or node), we predict a soft mask M to indicate its dependency with other observed tokens. It treats any of the observed tokens as the central node alternately, to reward its significant dependencies from multi-hops neighbor and penalize leftovers. A light-weight two-layer pooling network is used to learn the mask which could be formulated as:

$$M = f_M(A_s, \bar{H}_d, H_e),$$

where $\bar{H}_d \in R^{\bar{N} \times D}$ denotes the D-dimension features of $\bar{N}$ observed target nodes generated from Transformer decoder. The detailed network architecture of f_M can refer to the Appendix. The obtained $M \in R^{\bar{N} \times \bar{N}}$ serves as an information gatekeeper, retaining the nodes that are optimal for local aggregation with a global perspective, capturing linguistic dependencies discriminatively without compromising the topology of the syntactic graph. We will then process a graph-based information aggregation (Kipf and Welling, 2016) and proceed with a linear transformation, i.e.,

$$\bar{H}_m = W_m \cdot \left[(\bar{A}_t + M) \cdot \bar{H}_d \right] + b_m,$$

where $\cdot$ denotes the matrix multiplication and the formula in square bracket means information aggregation. In this way, the set of observed nodes and their edge connections at target side change dynamically in successive decoding steps.

In addition, an attention mechanism is introduced to re-weight and balance the captured multi-hops neighbor of each observed token. In particular, we aggregate context information by attending over the multi-hops neighbor of each node, while its updated representation is calculated by the weighted average of the connected nodes:

$$\bar{H}_a^i = \text{ReLU}\left(\sum_{y_j \in \mathcal{N}^+(y_i)} a_{ij}^{(h)} \cdot (W_a \bar{H}_m^j) \right),$$

where $j = 1, ..., \bar{N}$ and $\mathcal{N}^+(y_i)$ includes the node y_i and the nodes directly connected to y_i, W_a is a learnable parameter. Note that the attention coefficient a_{ij} is the normalized similarity between two nodes (Veličković et al., 2017) of $\bar{H}_a$ in previous decoding step, and h-hop $a_{ij}^{(h)}$ is the corresponding element of h-th power of matrix $[a_{ij}]$.

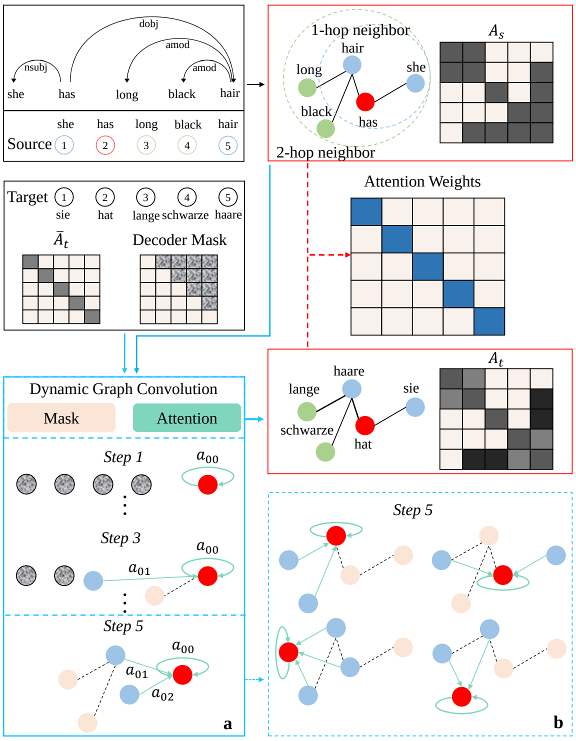

Figure 3: Structural attention based on Dynamic Graph Convolution Networks. (a) Masking and attention mechanisms during sequence decoding. (b) In each decoding step, we perform discriminative dynamic graph convolutions by treating each observed token as a central node.

Figure 3 illustrates the detailed process of introduced DGCN. The masking and attention mechanisms are iterated until the decoding process is terminated. Then we average the attention coefficients a_{ij} over all decoding steps, and normalize them to obtain the refined adjacency matrix $\tilde{A}_t$. Considering our initial intuition of the similarity for the syntactic structure at both ends, we calculate the final syntactic structure of the target sentence as follows:

$$A_t = \text{Sigmoid}\left(W_s \left(A_s + \tilde{A}_t \right) + b_s \right),$$

where W_s and b_s are learnable parameters.

Structural Attention for Word Alignment We adopt A_s and the inferred A_t to update the representation of language pairs, with the target-to-source attention in (Chen et al., 2021). The learned representation simultaneously contains the content and

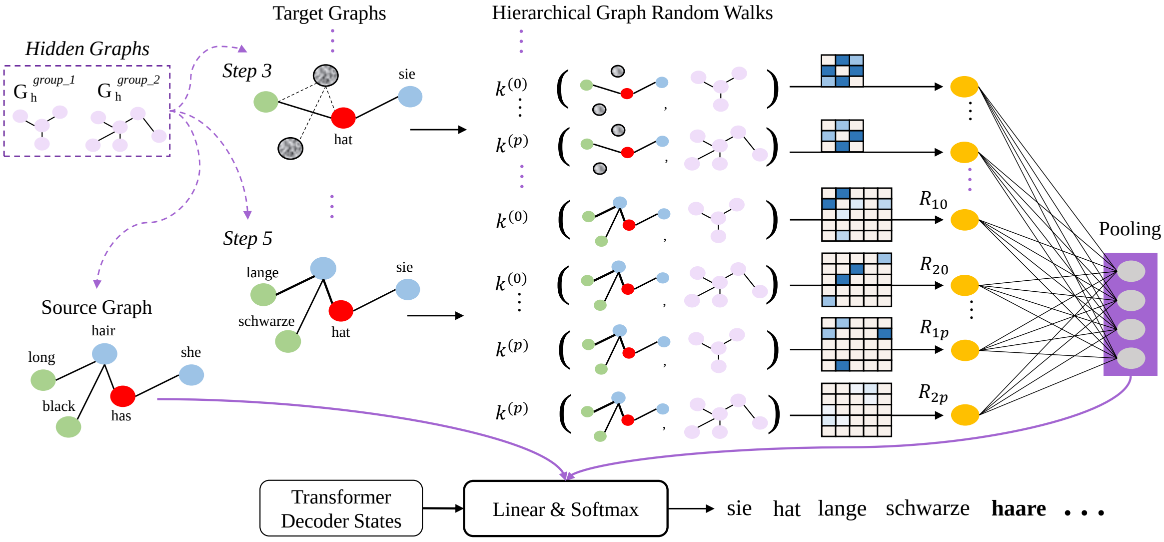

Figure 4: Overview of the introduced Hierarchical Graph Random Walks for translation.

structure information of the context for accurate word alignment. Finally, we choose the source token with the maximum attention weight towards the current target token:

$$\alpha = \text{attention}\left(A_t \cdot H_d,\ A_s \cdot H_e\right),$$
$$\gamma(t) = \underset{i \in \{1,\ldots,M\}}{\arg\max}\, \alpha_{t,i}.$$

IMPORTANT Note that even during training, we only use the ground-truth syntactic graph of source side. The syntactic graph of target side is inferred during training and its derived attention weights subsequently participate the loss calculation of word alignment task.

3.3 Hierarchical Graph Random Walks

In order to incorporate structural constraints for producing high-quality translation, we borrow the idea of (Nikolentzos and Vazirgiannis, 2020) to use a random walk kernel to capture the hierarchical representation of syntactic graphs. The random walk kernel can quantify the similarity of two graphs based on the number of common walks, adopted to effectively capture structures of the input graphs when compared against a number of trainable "hidden graphs"[1]. The adopted "hidden graphs" can learn the graph structures during training with backpropagation so that the translation outputs are highly interpretable, while the employed random walk kernel is differentiable and therefore the whole framework is end-to-end trainable. The whole process is illustrated in Figure 4.

In this work, we initialize two groups of trainable "hidden graphs" with differentiated scales, which compare the inputs using a random walk kernel to capture the structural representation of syntactic graphs both locally and globally. Consider the syntactic graph (denoted as G_d) in the decoder and a "hidden graph" G_h, their direct product $G_d^{\times}$ is a graph over pairs of nodes from G_d and G_h. We refer to the original paper (Nikolentzos and Vazirgiannis, 2020) for more details.

It has been shown that performing a random walk on the direct product $G_d^{\times}$ is equivalent to performing a simultaneous random walk on the two graphs G_d and G_h. We denote by $A_d^{\times}$ the adjacency matrix of $G_d^{\times}$, and assume a uniform distribution for the starting and stopping probabilities over the nodes of G_d and G_h. In this way, the random walk kernel will count all pairs of matching walks on G_d and G_h through the adjacency matrix $A_d^{\times}$. We then perform the P-step ($P \in \mathbb{N}$) random walk kernel which calculates the number of common walks of length p between two graphs:

$$k^{(p)}\left(G_d, G_h\right) = \sum_{i=1}^{\left|V_d^{\times}\right|} \sum_{j=1}^{\left|V_d^{\times}\right|} \left[A_d^{\times(p)}\right]_{ij}.$$

For each $p \in \{0, 1, \ldots, P\}$, a different kernel value is calculated which can be thought of as the structural representation of graph G_d. Therefore, given the two sets $\mathcal{P} = \{0, 1, \ldots, P\}$ and $\mathcal{G}_h = \left\{G_h^1, G_h^2, \ldots, G_h^K\right\}$ where G_h^1, G_h^2, ..., G_h^K denote the K "hidden graphs", we can compute one feature for each element of the Cartesian product $\mathcal{P} \times \mathcal{G}_h$, and further build a matrix $R \in \mathbb{R}^{K \times (P+1)}$

---

[1] Similar to the trainable "kernel" in convolution.

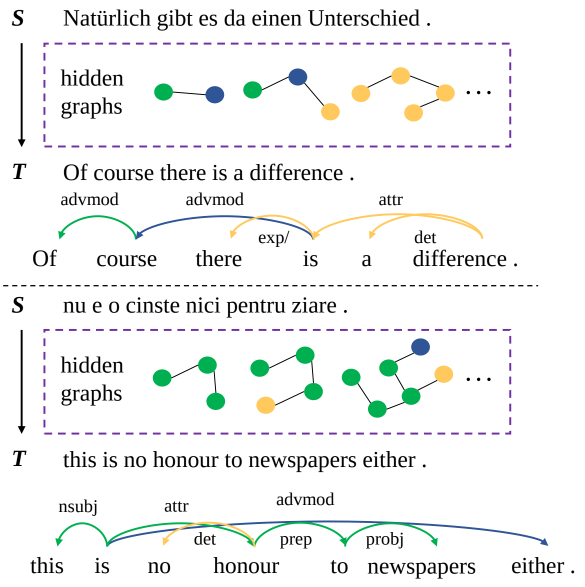

Figure 5: Visualizations of learned "hidden graphs". S: Source sentence, T: Translation output. (The ground-truth syntactic structure parsed by tools are given.)

for G_d where $R_{ij} = k^j\left(G_d, G_h^i\right)$. Finally, the matrix R is flattened as supplementary representation to incorporate structural constraints into the decoder outputs from Transformer for guiding translation outputs.

In order to capture both local and global structural information, we assign two differentiated scales (with node sizes 4 and 6) of "hidden graphs" to compare against the syntactic graphs at both ends. In the meantime, the syntactic information from both encoder and decoder are considered to access the robust and high-quality translation system. We also provide case studies of the experiments in Figure 5, demonstrating the learned "hidden graphs" can capture both the local and global dependencies of target sentences, leading to more discriminative features which are further adopted to guide the translation outputs.

4 Experiments

4.1 Datasets

We conducted our experiments on four publicly available datasets. For German-English (de-en)[2], Romanian-English (ro-en) and French-English (fr-en)[3], we followed the experimental setup in (Zenkel et al., 2020) and used the preprocessing scripts from (Zenkel et al., 2019). We also followed (Ding et al., 2019) to set the last 1K sentences of the training data before preprocessing as validation set. The Chinese-English training set is from the NIST corpora while the test set is from the v1-testset released by TsinghuaAligner (Liu and Sun, 2015). We learned a joint source and target Byte Pair Encoding (BPE) (Sennrich et al., 2016) with 10K merge operations.

4.2 Settings

We adopted parsing tools[4] to construct syntactic graphs for the language of the encoder. Both the encoder and the decoder of Transformer have 4 layers of attentions with 4 attention heads each. The embedding size and hidden states are set to 512, while the feed-forward layer has 2,048 cells. The training token-level batch size is 36K. All models were trained in both translation directions and symmetrized with *grow-diag* (Koehn et al., 2005) using the script from (Zenkel et al., 2019)[5]. We aggregated the 1- and 2-hop neighbor of each target token in proposed dynamic graph convolutions for alignment, and performed $\mathcal{P} = \{0, 1\}$-steps random walk with beam size to 4 in the decoding process of translation. Alignment error rate (AER) (Och and Ney, 2000) and BLEU (Papineni et al., 2002) are used for measuring word alignment accuracy and translation quality, respectively.

4.3 Baselines

We compare our method with two statistical baselines FAST-ALIGN (Dyer et al., 2013) and GIZA++ (Brown et al., 1993). Besides, our proposal (structure-based) is compared to several neural baselines (content-based), and all the baselines induce alignments from attention weights of content-based representation: NAIVE-ATT (Garg et al., 2019), NAIVE-ATT-LA (Garg et al., 2019), NAIVE-ATT-LA (Garg et al., 2019), SD-SMOOTHGRAD (Ding et al., 2019), ADDSGD (Zenkel et al., 2019), SHIFT-ATT (Chen et al., 2020), SHIFT-AET (Chen et al., 2020), BTBA (Zhang and van Genabith, 2021) and MASK-ALIGN (Chen et al., 2021).

NAIVE-ATT (Garg et al., 2019) induces alignments from cross-attention weights of the best penultimate layer in a vanilla Transformer.

NAIVE-ATT-LA (Garg et al., 2019) without layer selection induces alignments from attention weights averaged across all layers.

Table 1: AER on the test set. The column Full denotes whether full target sentence is used to extract alignments at test time. *avg.* are the averaged AER scores of both language directions for each language pair, and *bidir.* are symmetrized alignment results. The lower AER, the better. We mark best results among all with boldface.

SD-SMOOTHGRAD (Ding et al., 2019) induces alignments from token saliency.

ADDSGD (Zenkel et al., 2019) explicitly adds an extra attention layer on top of Transformer to predict the to-be-aligned target token.

SHIFT-ATT (Chen et al., 2020) induces alignments when the to-be-aligned target token is the decoder input instead of the output.

SHIFT-AET (Chen et al., 2020) extracts alignments from an additional module with supervision from symmetrized SHIFT-ATT alignments.

BTBA (Zhang and van Genabith, 2021) predicts the current target token by paying attention to the source context and both left-side and right-side target context to produce target-to-source alignment.

MASK-ALIGN (Chen et al., 2021) extracts alignments from introduced *leaky attention* and trains with the masked language model fashion.

4.4 Alignment Results

Comparison with Baselines Table 1 compares the alignment results of our method with all the baselines. Our approach significantly outperforms both statistical and neural baselines. Specifically, it improves over GIZA++ by 2.0-7.2 AER points across different language pairs, demonstrating that building a neural aligner is better than statistical aligners. When compared with neural baselines either using guided training or without guidance, we find our proposal still achieves substantial improvements over all methods. For instance, it improves over SHIFT-AET and MASK-ALIGN by 2.4 and 0.7 individually AER points on the Romanian-English pair, indicating that the incorporation of syntactic structure achieves superior alignment results compared to these that rely only on the content of inputs.

Method	zh→en	en→zh	*bidir.*
SHIFT-ATT	28.1	27.3	20.2
SHIFT-AET	20.1	22.0	17.2
MASK-ALIGN	-	-	13.8
Ours	**18.9**	**21.2**	**13.5**

Table 2: AER on the test set of zh-en.

Besides, we also evaluate our proposal on Chinese-English pair and compare other methods in Table 2. The experimental results are highly consistent with the observations on other language pairs, demonstrating the effectiveness of alignment based on modeling dependencies and capturing structural similarities for distant language pairs.

Ablation Study Table 3 shows the ablation results on two language pairs. Our approach achieves a gain of 23.8 and 14.6 AER points with fewer parameters compared to vanilla Transformer. When considering the introduced Dynamic Graph Convolution Networks, the aggregated 1-hop neighbor can only capture the local structure, and thus the alignment accuracy is limited. In contrast, aggregating all the 1-, 2-, and 3-hop neighbor for each target node, while better capturing the global dependency, brings with it an increase of parameters and the possible introduction of noisy nodes. We finally achieve the trade-off between performance and parameter size by aggregating both the 1- and 2-hop neighbor. Notably, the accuracy of alignment slightly decreases when we remove the translation task, showing the effectiveness of our multi-task learning framework.

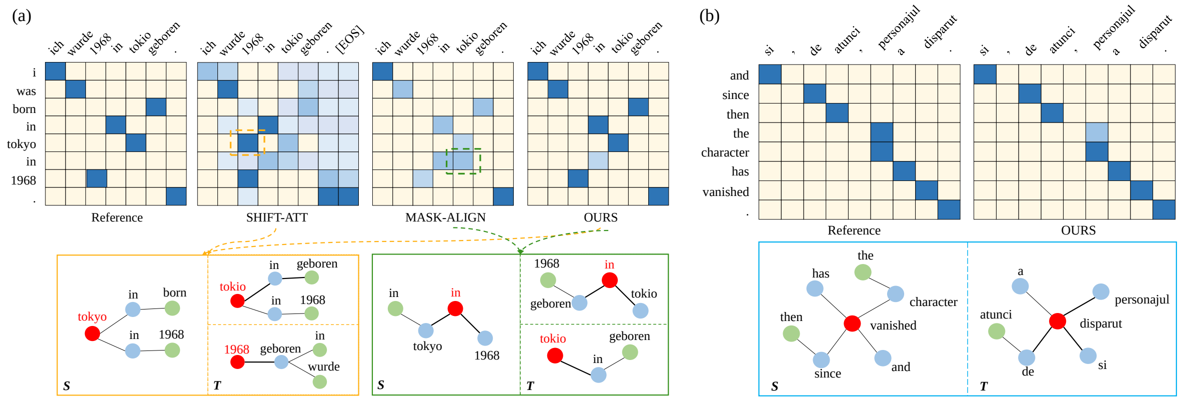

Figure 6: (a) Attention weights from different models, and visualizations of the local connection structure for important target tokens inferred by our method. Gold alignment is shown in Reference. S: Source tokens, T: Target tokens. (b) Attention weights for a symmetrized alignment example from ro-en test set. Besides, visualizations of syntactic graphs which built from the source sentence and inferred from the target sentence are given.

Method	fr-en	ro-en	# param.
Vanilla Transformer	27.9	33.4	36.8M
Ours$_{(1-hop)}$	7.6	25.8	31.9M
Ours$_{(1,2,3-hop)}$	4.4	19.3	33.2M
Ours (w/o translation)	4.3	19.5	28.5M
Ours$_{(1,2-hop)}$	**4.1**	**18.8**	32.7M

Table 3: We report the symmetrized AER on the test set. We treat vanilla Transformer (Vaswani et al., 2017) as the baseline, and Ours$_{(1,2,3-hop)}$ indicate that the introduced graph convolutions aggregate representation from all the 1-, 2-, and 3-hop neighbor. Ours (w/o translation) denotes that we remove the translation branch and only perform the training and test of word alignment.

Case Study Figure 6(a) shows the attention weights from three different models for a symmetrized alignment example from de-en test set. In this example, SHIFT-ATT puts high weights wrongly on "1968" when predicting the target token "tokyo", while MASK-ALIGN fails to resolve ambiguity when predicting the target token "in". In contrast, our approach produces the attention weights based on structural matching of source and target tokens, which are highly consistent with the gold alignment. Furthermore, we visualize the complete syntactic structure inferred by introduced DGCN in Figure 6(b), which could explicitly reflect the dependencies between each target token.

4.5 Translation Results

Comparison with Baselines Table 4 shows the comparison of translation quality and the corresponding decoding speed. Although this work has improved the performance of word alignment, our experiments show that the benefits from the representation of syntactic structure also extend to the translation task. Compared with (Marcheggiani et al., 2018) that only utilize syntactic structure at the encoder side, we substantially improve the performance by incorporating syntactic structure at the decoder side.

Ablation Study To investigate the effectiveness of introduced Hierarchical Graph Random Walks, we further conducted ablation experiments from two perspectives: the number of steps for random walk and the beam size for decoding. Table 4 shows the comparison results. It can be inferred that increasing the step length (e.g., $p = 2$) can improve the capability of "hidden graphs" to better capture the global structure. However, continuing to increase the step (e.g., $p = 3$) length will not always improve the performance, since it not only introduces more parameters, but also is likely to confuse the model by the complicated closed-loop structure which is prevalent in the graph network. Moreover, increasing the beam size does not bring sustainable gains, but it inevitably decreases the speed of decoding. Notably, the quality of translation significantly decreases when we remove the alignment branch, suggesting that the internal logic of both tasks are tightly correlated by exploiting the dependencies between language pairs for multi-task learning.

5 Related Works

Our work is closely related to unsupervised neural word alignment. While early unsupervised neural aligners failed to outperform their statistical counterparts such as FAST-ALIGN (Dyer et al.,

Method	de→en	en→de	fr→en	en→fr	ro→en	en→ro	$avg.speed$ (tokens/sec)
vanilla Transformer (Vaswani et al., 2017)	25.1	21.7	22.9	21.4	25.3	17.9	70.1
CNN + GCN (Marcheggiani et al., 2018)	23.4	20.3	20.7	20.1	23.8	16.4	86.5
BiRNN + GCN (Marcheggiani et al., 2018)	23.9	20.6	21.2	20.5	24.3	17.0	82.3

Ours$_{(p=1,beam=5)}$	25.7	22.5	24.0	22.2	**26.3**	18.3	66.5
Ours$_{(p=1,beam=4)}$ (w/o alignment)	25.5	22.1	23.4	21.7	25.5	18.3	76.7

Table 4: Comparison of BLEU scores and the averaged decoding speed tested on test sets of three language pairs. p refers that a p-step random walk is performed during the decoding process, while $beam$ is the beam size.

2013) and GIZA++ (Och and Ney, 2003), a lot of latest works (Li et al., 2019; Garg et al., 2019; Zenkel et al., 2019, 2020) have made significant progress by inducing unsupervised neural aligners from NMT to produce better word alignments. Significantly, BTBA (Zhang and van Genabith, 2021) and MASK-ALIGN (Chen et al., 2021) leverage the both side content information of the decoder, sacrificing the ability of translation.

Our work is also related to syntax-based or Transformer based neural machine translation models which have shown large advantages on a myriad of datasets. (Bastings et al., 2017) incorporated syntactic structure into the encoder of NMT model and proposed syntactic GCNs. (Marcheggiani et al., 2018) refined the above work to inject a semantic bias into sentence encoders. Transformer based NMT models (Vaswani et al., 2017; Hasler et al., 2018) attribute their superior performance to the multi-layer and multi-head self-attention architecture. (Garg et al., 2019) trained the Transformer to jointly learn word alignment and translation through multi-task learning based on existing token aligners such as GIZA++ (Och and Ney, 2003). Our work differs from prior studies in that we simultaneously incorporate the syntactic structure into both encoder and decoder to tightly correlate the internal logic of word alignment and machine translation for multi-task learning. To the best of our knowledge, this is the first work that incorporates syntactic structure based constraints into the decoder of NMT models.

6 Conclusion

We propose a multi-task learning framework that tightly correlates the internal logic of word alignment and machine translation, by fully exploits the syntactic structure of both source and target tokens and the similarity of dependencies at both ends. Experiments show that our proposal achieves the new State-of-the-Art results among all neural methods in word alignment, while producing high-quality translations. We leave it for future work to extend our study to more downstream tasks and systems in natural language processing.

A Detailed Network Architecture of f_M

For each observed token from the target side, we learn a soft mask M to predict its dependency with other observed tokens by a light-weight network:

$$\begin{aligned}
\bar{h}_d &= M_{ean}P_{ooling}(\bar{H}_d + A_s \cdot H_e), \\
\hat{M} &= (\bar{H}_d \cdot W_d) \otimes \bar{h}_d, \\
M &= \text{Sigmoid}\left(M_{ax}P_{ooling}(\hat{M})\right),
\end{aligned}$$

where $\otimes$ denotes the element-wise multiplication, and W_d is a trainable matrix.

B Translation Results

Case Study We provide the translation results among different variants of our proposal in Figure 7.

Focus on the Action: Learning to Highlight and Summarize Jointly for Email To-Do Items Summarization

Abstract

Automatic email to-do item generation is the task of generating to-do items from a given email to help people overview emails and schedule daily work. Different from prior research on email summarization, to-do item generation focuses on generating action mentions to provide more structured summaries of email text. Prior work either requires large amount of annotation for key sentences with potential actions or fails to pay attention to nuanced actions from these unstructured emails, and thus often lead to unfaithful summaries. To fill these gaps, we propose a simple and effective learning to highlight and summarize framework (LHS) to learn to identify the most salient text and actions, and incorporate these structured representations to generate more faithful to-do items. Experiments show that our LHS model outperforms the baselines and achieves the state-of-the-art performance in terms of both quantitative evaluation and human judgement. We also discussed specific challenges that current models faced with email to-do summarization.

1 Introduction

Automatic email to-do generation is the task of summarizing to-do items from given emails (Mukherjee et al., 2020) to help people overview overwhelming numbers of emails they receive every day (Radicati and Hoang, 2011) and schedule their daily work. Unlike prior research on emails such as generating email conversation summarization (Muresan et al., 2001; Nenkova and Bagga, 2003; Rambow et al., 2004), keyword extraction (Turney, 2000; Lahiri et al., 2016; Lin et al., 2017) and subject line generation (Zhang and Tetreault, 2019; Xue et al., 2020), to-do items generation focuses more on *action mentions* to provide more *structured* summaries from email communications, which requires identifying important tasks to be performed among all the action items and aligning them with the right users (Mukherjee et al., 2020).

To tackle these challenges in to-do item generation, a two-stage framework (Zhang and Tetreault, 2019; Mukherjee et al., 2020) is generally utilized to first extract the commitment sentence which is the most related to the to-do item and then generate to-do items based on those selected sentences. Despite the effectiveness, several limitations exist: (1) extra annotations are usually needed for the first stage (Mukherjee et al., 2020) to learn the classifiers which require extra cost/expertise and are often hard to obtain in low-resourced settings; (2) any information loss in the identification stage might lead to bigger noises in the to-do generation stage; (3) directly extracting actions from less-structured text usually leads to unfaithful summaries (Chen and Yang, 2021) that mismatch the relations between users and actions.

To fill in these gaps, in this work, we propose a learning to highlight and summarize model, where we learn the important sentence identification module and to-do summarization module concurrently in an end-to-end manner to focus on the most salient actions, as well as to incorporate structured action representations to generate more faithful to-dos. One example is shown in Figure 1. Specifically, we use an unsupervised approach to extract the salient sentences and actions by comparing them to the ground truth to-do. We extract action triplets from the text and construct an action graph to encode the structural information in the unstructured text. During training, the model learns to generate to-do items and identify highlights jointly. During prediction, the model utilizes the predicted highlights by modifying the attention distribution accordingly. Furthermore, as extrinsic hallucinations involving named entities are common in automatic summarization tasks (Maynez et al., 2020; Chen et al., 2021), we propose a perturbation technique based on person names to reduce the extrinsic hallucinations.

We conduct experiments on the SmartToDo cor-

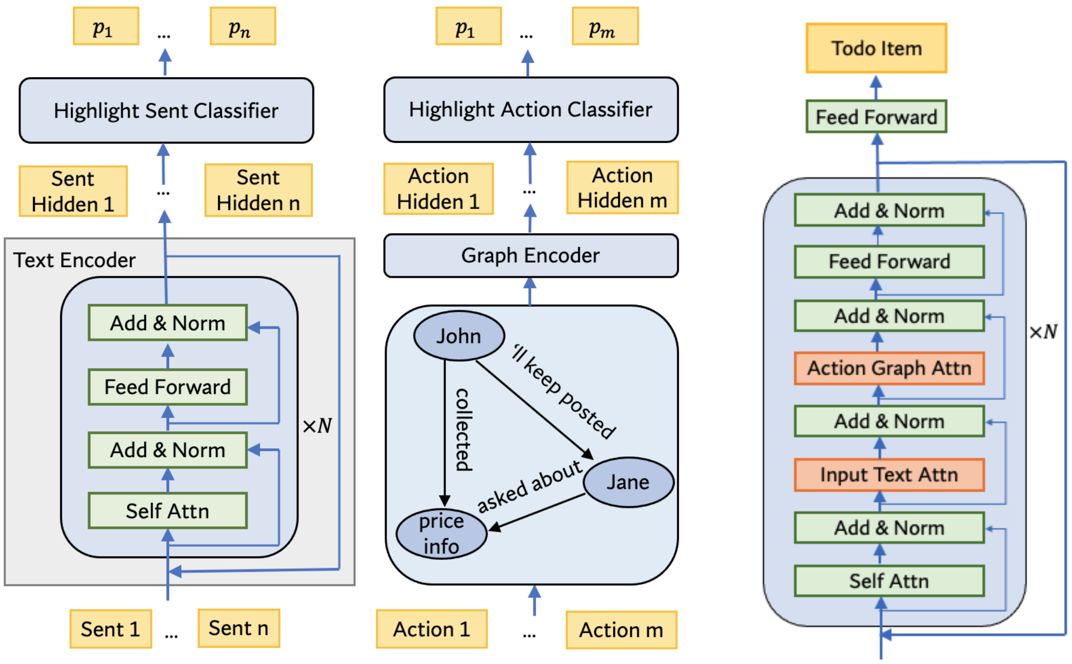
pus(Mukherjee et al., 2020) and show that our LHS model outperforms strong baselines on to-do item generation, demonstrating the effectiveness of this joint model on learning to highlight and summarize. By evaluating our LHS model on a different email corpus, we demonstrate that it generalizes well on a zero-shot condition.

2 Related Work

Document summarization Recent works on document summarization are usually extractive (Gupta and Lehal, 2010; Narayan et al., 2018; Liu and Lapata, 2019) and abstractive. Methods for abstractive document summarization include sequence-to-sequence models (Rush et al., 2015), pointer generators (See et al., 2017), reinforcement learning (Paulus et al., 2018; Huang et al., 2020) and methods based on pre-trained language models (Lewis et al., 2020; Zhang et al., 2019). To generate faithful abstractive document summaries (Maynez et al., 2020), recent works on abstractive summarization have incorporated different types of guidance signals extracted including key tokens (Gehrmann et al., 2018; Chen and Bansal, 2018; Li et al., 2018; Saito et al., 2020; Dou et al., 2021), highlight sentences (Liu et al., 2018; Dou et al., 2021; Saito et al., 2020) and relational triplets (Jin et al., 2020; Zhu et al., 2020a; Dou et al., 2021). However, these models are mainly designed to find important information from all parts of the document, while todo items are often associated with only several sentences in emails.

Conversation summarization Automatic to-do generation is also similar to the task of conversation summarization in the way that the input data contains both the current email in which the user promises to take an action and the previous email to which the user is replying. For extractive conversation summarization(Murray et al., 2005), statistical machine learning methods such as skip-chain CRFs (Galley, 2006), SVM with LDA models (Wang and Cardie, 2013), and multi-sentence compression algorithms (Shang et al., 2018) have been used. When key information is scattered in multiple sentences, such methods had trouble in succinctness, fluency and naturalness (Song et al., 2020). Abstractive conversation summarization methods are more effective in these circumstances. These methods design hierarchical models (Zhao et al., 2019; Zhu et al., 2020b), incorporate commonsense knowledge (Feng et al., 2020), or leverage conversational structures like dialogue acts (Goo and Chen, 2018), key point sequences (Liu et al., 2019a), topic segments (Liu et al., 2019b; Li et al., 2019) and stage developments (Chen and Yang, 2020). Some recent research has also utilized structural information to detect important content in conversations (Murray et al., 2006; Bui et al., 2009; Qin et al., 2017). However, recent methods that explicitly identify salient content has not been used jointly with conversation summarization models.

Summarization tasks on email Several summarization-like tasks have been proposed such as email text summarization (Muresan et al., 2001; Nenkova and Bagga, 2003; Rambow et al., 2004), keyword and action extraction (Turney, 2000; Lahiri et al., 2016; Lin et al., 2017; Corston-Oliver et al., 2004), subject line generation (Zhang and Tetreault, 2019; Xue et al., 2020) and to-do generation task (Mukherjee et al., 2020). These previous works often deploy a two-stage framework that first extracts salient sentences from the email and then generates summary based on extracted sentences. However, any information loss in the first stage might lead to bigger noises in the to-do



(a) Encoder (b) Decoder

Figure 2: Model Architecture. The sentences and actions are first encoded and then fed to the highlight classifiers. The hidden representations of sentences and actions, along with their probability of being highlights are then used in the cross-attention layer in the decoder. The email encoder has the same structure as BART encoder. The graph encoder utilizes graph attention networks to encode the action graph.

generation stage, and directly extracting actions from less-structured text might lead to unfaithful summaries (Chen and Yang, 2021). To fill these gaps, we propose to explicitly model actions within sentences in the email in a structured way, by using action graphs to model the actions, introducing an auxiliary classifier to identify the highlights, and further combining these with a decoder that attends to both the encoding of input tokens and extracted actions for to-do generation.

3 Methods

To generate faithful to-do items that correlate actions with correct users from emails[1], we propose to encode both text-level and action-level information as guidance signals. The architecture of LHS model is shown in Figure 2. We first extract the action mention ("WHO-DOING-WHAT" triples (Chen and Yang, 2021)) from the emails and construct an action graph (Section 3.1), then we encode text and actions separately (Section 3.2) and use a multi-scale decoder that attends to both email and action graphs to generate the to-do item (Section 3.4). Besides directly incorporating different levels of information, we further design an end-to-end framework to utilize guidance signals such as important sentences and actions to help summarization models focusing more on the key to-dos by jointly learning a highlight classifier (Section 3.3) with the summarization model and view the predicted results as priors to attention distributions in the decoder (Section 3.4).

3.1 Action Graph Construction

Unlike general summarization over emails, to-do item summarization is more action-focused, requiring identification of specific tasks to be performed (Mukherjee et al., 2020). As a result, we propose to explicitly inject structured action information into the to-do summarization model. To do so, we first extract actions triples from the emails in the form of subject-predicate-object triplets and then construct the action graphs to aid the to-do summarization.

Action extraction Following Chen and Yang (2021), we first pre-process the emails to a third-person point-of-view via (1) replacing first-person pronouns with the name of the sender of the email,

---

[1] Before generating to-do items for a given email, we must first tell whether it contains a to-do item. This problem is addressed by (Mukherjee et al., 2020) using an RNN-based classifier during the construction of the SmartToDo dataset, hence we focus on the generation problem in our paper.

(2) replacing second-person pronouns with the each of the names of the recipients of the email, (3) replacing the third-person pronouns with the coreference resolution algorithm provided by Stanford CoreNLP (Manning et al., 2014). Then we utilize OpenIE (Angeli et al., 2015) to extract subject-predicate-object triplets from the processed email.

Action graph construction With the extracted triples, we construct the action graph $G = (\mathbf{V}, \mathbf{E})$, where the nodes in $\mathbf{V}$ represent the subjects, predicates and objects in the action triplets, and $\mathbf{E}_{ij} = 1$ if nodes i and j appear in one same triplet. Note that we construct one action graph per email. One example is shown in Figure 1, where the subjects and objects of the actions triplets are 'John', 'Jane', 'developers' and 'price info', and the predicates of the actions include 'talked', 'talked with', 'will keep posted' and 'collected'.

3.2 Encoder

Our LHS model includes two encoders that encode the email text and the action graphs separately.

3.2.1 Email Encoder

We initialize the email text encoder E_T with a pre-trained transformer-based encoder (BART (Lewis et al., 2020)). For an input email with n sentences, $\{x_1, x_2, \ldots, x_n\}$, we concatenate and encode them together into hidden representations h_i: $\{h_1, h_2, \ldots, h_n\} = E_T(\{x_1, x_2, \ldots, x_n\})$

We truncate the email text if it exceeds the length limit of BART.

3.2.2 Action Graph Encoder

Inspired by Huang et al. (2020); Chen and Yang (2021), we utilize Graph Attention Network (Veličković et al., 2018) to encode the constructed action graph $G = (\mathbf{V}, \mathbf{E})$. Each node v with text $\{x_1^v, x_2^v, \ldots, x_k^v\}$ is initialized with the average of the hidden states from the text encoder E_T using the text of the node: $h_v = \frac{1}{k}\sum_{i=1}^{k} E_T(x_k)$.

In each layer of the graph attention network, the hidden state of every node v_i is represented by a weighted average of its neighbors' previous hidden states ($\mathbf{W}$ is a trainable parameter, $\mathcal{N}_i$ is the set of neighbors of i, and σ is the activation function):

$$\alpha_{ij} = \text{softmax}((\mathbf{W}v_i)^T(\mathbf{W}v_j))$$

$$h_i^a = \sigma(\sum_{j \in \mathcal{N}_i} \alpha_{ij}\mathbf{W}v_j)$$

3.3 Highlight Identification

Guiding an abstractive summarization model with extracted salient sentences has been used in previous works on document summarization (Gehrmann et al., 2018; Chen and Bansal, 2018). Compared to typical document summarization task which needs to consider information from all parts of the document, to-do generation usually needs to focus only on a few important sentences of the email. Thus, we jointly learn an auxiliary highlight classifier to indicate whether a sentence/action is important or not. The predicted probabilities are incorporated during the decoding stage to guide the decoder paying higher attentions to the important sentences/actions in the email.

Highlight label extraction For an email $X = \{x_1, \ldots, x_n\}$ with n sentence, and its ground truth to-do item y, we automatically extract the k most important sentences for classifier learning through oracle extraction using a greedy search algorithm: (1) Rank the sentences $\{x_1, \ldots, x_n\}$ based on ROUGE scores with the ground truth y. (2) For the sentences with the k largest ROUGE scores, we label the tokens in them as highlight tokens.

Similarly, we extract the highlight actions by concatenating the triplets and calculating ROUGE scores with regard to the ground truth action, which is extracted from the concatenation of the name of the sender and the to-do item (e.g. if the sender is 'John' and the to-do item is 'Keep Jane posted about price info', the ground truth actions are extracted from the sentence 'John keep Jane posted about price info'.) The extracted actions and sentences are used only as labels to train the highlight classifiers. During inference, the LHS model directly utilizes the predictions from highlight classifiers as guidance signal.

Highlight classifier There are two highlight classifiers in the model, one for highlighting sentences and the other for highlighting actions. We utilize the hidden representation of sentences and actions given by the encoder as the input for highlight classifiers. The hidden representations are fed to a multi-layer perceptron to be classified. The classification loss is calculated with respect to the labeled highlights using cross entropy loss, where h are the real highlights and $\hat{h}$ are the predictions:

$$L_{classification}(h, \hat{h}) = -\sum_i h_i \log(\hat{h}_i)$$

We train LHS model in a joint fashion. Here $L_{classification}$ is the sum of losses for both highlight classifiers, and $L_{generation}$ is the cross entropy loss for finetuning BART for generation tasks. We use α and β as the weights to control the learning speed for two modules:

$$L_{total} = \alpha \cdot L_{generation} + \beta \cdot L_{classification}$$

3.4 Decoder

We improve the decoder of BART (Lewis et al., 2020) with additional layers of cross attention on graphs and incorporating the guidance of highlights. Each decoder layer is composed of 3 attention layers: the self-attention layer that attends to the previously generated tokens, the cross-attention layer that attends to the hidden representation of each input token, and the cross-attention layer that attends to the hidden representation of each node in the action graph. When calculating encoder-decoder attention, we modify every attention distribution with the predictions from the highlight classifiers.

Specifically, for a sequence of length l, given the original attention weights of an attention head $\alpha_{1,...,l}$ and the probability sequence $p_{1,...,l}$ where p_i denotes the predicted probability for the i-th token being highlighted (we use the probability of one sentence being highlighted as the probability for all the tokens in that sentence being highlighted). We use the L1-normalization of the predictions as the weights of modification:

$$w_i = \frac{p_i}{\sum_{j=1}^{l} p_j}$$

We then modify the attention weights from cross attentions to obtain the new distribution: $\alpha_i' = w_i \alpha_i$. The re-weighting of attention probabilities puts more weight on the highlighted sentences and actions, which makes it easier for the model to focus on the text snippets related to the to-do item.

3.5 Perturbation

According to previous studies on hallucinations (Maynez et al., 2020), about 70% of hallucinations that happen in summarization tasks, regardless of the model used, are extrinsic (model generations that ignore the input document). Among these extrinsic hallucinations, a large fraction (35%) happen on named entities (Chen et al., 2021). Such finding is consistent with our observations on this email to-do item generation task.

To address the hallucinations on named entities and prevent the model from sampling a random name from the dataset, we use a simple yet effective perturbation approach by replacing the persons' names. For each data point, we first cluster the names so that the different forms of a same name are put in the same cluster. Since the email text is preprocessed with coreference resolution as mentioned in (Section 3.1), we do the clustering by assuming two names with at least one word in common are the same.

For each cluster of names, we replace the occurrences in the cluster with a new name taken from common American names for both email text and the labeled to-do item. During training, we use original data for the first 4 epochs of fine-tuning and we use perturbed data for the last 3 epochs.

4 Experiments

4.1 Datasets

We train our LHS model on the dataset SmartToDo (Mukherjee et al., 2020). The dataset consists of around 10,000 emails and their corresponding annotated todo items. The SmartToDo dataset is constructed based on the Avocado Email corpus [2]. We also randomly sample 50 emails from the Enron Email corpus [3] and annotate them manually, in order to examine the model's performances on out-of-domain generalization.

4.2 Baselines

We compare our methods with several baselines:

- **SmartToDo** (Mukherjee et al., 2020) is the first model to address the todo generation task. We take the evaluation metrics directly from SmartToDo (Mukherjee et al., 2020) since the setting of our experiments is similar to it.

- **Transformer** (Vaswani et al., 2017): We trained transformer using OpenNMT (Klein et al., 2017) with its default setting on summarization tasks.

- **BART** (Lewis et al., 2020) is a pre-trained model that shows great performance when being fine-tuned on summarization tasks.

Dataset	Model	ROUGE-1	ROUGE-2	ROUGE-L
SmartToDo	Transformer	0.373	0.156	0.387
	SmartToDo‡	0.600	0.410	0.630
	BART	0.635	0.431	0.669
SmartToDo	LHS without highlight actions and perturbation†	0.673	0.469	0.685
	LHS without perturbation†	0.681	**0.472**	**0.692**

Table 2: LHS † is our learning to highlight and summarize model that incorporates highlight sentences, highlight actions and perturbation. Average human evaluation of ground truth, baselines and LHS in terms of **Fac**tualness, **Succ**intness and **Inf**ormativeness.

4.3 In-Domain Results

Quantitative evaluation We evaluate all the models with the commonly used metric for text generation, ROUGE scores (Lin and Och, 2004). We report the F1 scores of all the models in Table 1. We found that: given the large corpus used for pretraining, finetuned BART (Lewis et al., 2020) is a strong baseline that already outperforms the original SmartToDo (Mukherjee et al., 2020) model. Generally, our method that incorporates highlight sentences, action graph and perturbation outperforms the baselines greatly. Compared to the baseline model, BART, the quantitative evaluation of our method is increased by 5.1% in ROUGE-1, 3.9% on ROUGE-2 and 6.2% on ROUGE-L.The model that utilizes both highlight sentences and structured information in the action graph outperforms the model with the highlight sentences only by 1.2% in ROUGE-1, 0.3% in ROUGE-2 and 0.7% in ROUGE-L, indicating that the effectiveness of action graph and highlight action classifier. We describe some randomly picked generation examples in the Appendix.

Human evaluation We also conducted human evaluation to further assess the generation results. We randomly sampled 50 emails from the test set of the models and asked human evaluators (undergraduate research assistants who are familiar with the task) to rate the ground truth, the predictions of BART and the predictions of the proposed LHS model using a scale from 1 to 5 in three aspects: **factualness** (e.g. selecting the correct objects of the to-do action), **succinctness** (e.g. does not contain redundant information) and **informativeness** (e.g. contains the necessary information in a to-do item for the sender of the email). The Fleiss' Kappa for the raters was 0.42, showing moderate agreement (Landis and Koch, 1977). We report the results of human evaluation in Table 2. The results show that our method outperforms the baseline BART in all aspects of qualitative measures. However, our method is still weaker than human, especially in terms of factualness and succinctness, suggesting that current models still struggle with to-do item generation.

4.4 Out-of-Domain Results

To evaluate the generalizability of the proposed LHS model, we train the models on the SmartToDo dataset and evaluate them on a small batch of the Enron Email corpus which we annotated manually. The results are shown in Table 1. Given that the Enron Corpus is constructed using the emails of an energy company while the Avocado Corpus is

from a technology company, the frequently mentioned entities and terms are different. Still, the LHS model achieves 0.592 in ROUGE-1, 0.418 in ROUGE-2 and 0.614 in ROUGE-L, indicating that LHS model generalizes well on a zero-shot condition. Furthermore, we observed that incorporating highlight sentences and actions increase ROUGE scores significantly by 7.5% in ROUGE-1, 6.1% in ROUGE-2 and 7.8% in ROUGE-L, indicating that learning to highlight and summarize jointly is also effective when generalized.

4.5 Ablation Studies

To verify the effectiveness of our proposed approaches comprehensively, we conducted a set of ablation studies as follows.

Effectiveness of highlight sentences We first examine the quality of the extracted highlight sentences and their influences on the LHS model for the to-do generation task in Table 3. We compared the ROUGE scores of the LHS model using the highlight sentences extracted by the algorithm in Section 3.3 and randomly sampled sentences. For each data point, we sample a score for each sentence from a normal distribution and select the sentences with the largest k scores as the substitute for highlight sentences, where k is the number of actual highlight sentences in that data point. The results showed that randomly sampled sentences did not improve the model's performance, and our extracted highlights were effective in guiding the model to focus on the to-do item related sentences.

Number of highlighted Sentences We also conducted experiments to show how the number of extracted highlight sentences effected the perfor-

Graph	R-2 DOINGs	R-2 WHATs
LHS w/o perturbation	**0.378**	0.562
LHS	0.370	**0.593**

Table 5: ROUGE-2 scores of LHS with and without perturbation on actions extracted from the subset of the test set that contains person names. DOINGs and WHATs are the second and third part of an action triplet. WHATs in this case contain the person names.

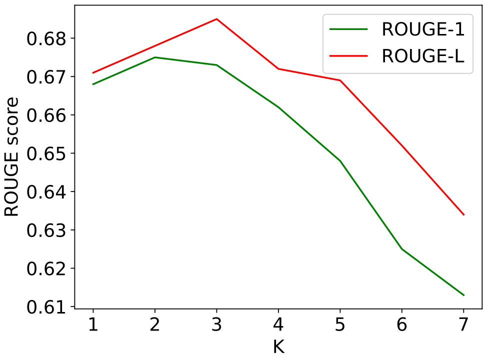

Figure 3: ROUGE scores when varying the value of k in the top k sentences extracted as highlights.

mance of the model. The results shown in Figure 3 indicates that increasing the number of highlighted sentences does not necessarily improve the model's performance. Specifically, when k increases from 1 to 3, ROUGE scores also increase; after k=3, adding more highlighted sentences seems to be associated with decreased performances. This trend makes a lot of sense as the to-do items are usually related to only 2 to 3 important sentences in the email. This pattern can also be observed in the samples shown in Table 6.

Effectiveness of action graph To show that the constructed action graph was giving guidance to the model, we conducted experiments with random graphs whose nodes are the same as action graphs but whose edges are randomly sampled. Table 4 indicates that random graphs without structural information did not guide the model to achieve better performance. When LHS uses random graphs instead of action graphs, the ROUGE scores are even lower than the BART baseline. This indicates that the structural information of the action graph, rather than the node entities is essential to the extraction of to-do items.

Effectiveness of perturbation The perturbation is intended to improve the model's performance in extracting the correct person names. To show

Type	Percentage	ROUGE-2	Ground Truth	Wrong Prediction	Email Text
multiple todos	26%	0	Check out the action.	Try to create a new account.	I'll check out the action. ... I'll also try to create a new account
incorrect action with correct objects	14%	0.36	Send the second item to Lewis.	Get the second item updated for Lewis.	To: Lewis, ... We have sent the second item to you. And we'll update it next week.
correct action with incorrect objects	8%	0.5	Look into the application of creating a new account.	Look into the new account.	You applied to create a new account. We'll look into it.
missing objects	26%	0.4	Get Darshan some mockups asap for intuit status.	Get some mockups asap.	As for intuit status, I'll get some mockups asap.
hallucination	12%	0.4	Keep Dan updated on the meeting.	Keep Darshan† updated on the schedule.	To Dan: .. I will keep you updated.

Table 6: Statistics for 50 samples with lowest ROUGE-2 scores in the validation set. † is a name in the corpus but not mentioned in the email.

its effectiveness, we evaluate its performance on person names independently from other parts of a to-do item by comparing the names in generated to-dos and reference to-dos. Such comparison can be done by extracting the action triplet from the prediction and the reference.

For a to-do item, the names in it correspond to the third part of the corresponding action triplet (the WHAT in WHO-DOING-WHAT), so we extract the mentioned names of a to-do item similarly to the method in Section 3.1. For a pair of action triplets WHO1-DOING1-WHAT1, WHO2-DOING2-WHAT2 extracted from the prediction and the reference, we compute ROUGE-2 score for DOING1, DOING2 and WHAT1, WHAT2 separately. The ROUGE-2 score for WHAT1 and WHAT2 indicates how well the model is able to capture the correct person names. The results are reported in Table 5. When perturbation is applied during training, the ROUGE-2 score for person names increase by 0.03, which indicates that our perturbation trick is effective in alleviating hallucinations about names.

4.6 Challenges and Error Analyses

To examine the challenges our models were faced with, we analyzed the errors made by our method on the test set. We manually examine 50 data points with the least ROUGE-2 scores and put them into different categories of challenges, as shown in Table 6. For each type of challenge we manually picked a sample that shows how the prediction is problematic. The major types include:

- **Multiple todos**: Instead of being a major challenge for models, this is more like a dataset annotation issue. Some data points in the SmartToDo (Mukherjee et al., 2020) dataset actually contain more than one todo items, but the ground-truth has only one item. The annotator and the model selected two different todo items to generate, though both belong to the *actual* ground-truths.
- **Missing objects:** The correct action related to the to-do item is extracted, but the information is not sufficient as the objects of such action are missing.
- **Correct action with incorrect objects:** The correct action has been extracted, but the objects of the action have been assigned to incorrect objects. This kind of error usually happens when the object of the action is not in the same sentence of the action.
- **Incorrect action with correct objects:** The correct objects are extracted, but they are associated with incorrect actions. This kind of error is usually related to multiple sentences or events expressed in the future tense.
- **Extrinsic hallucination:** The incorrect action problem and the incorrect object problem mentioned before belong to *intrinsic hallucinations* which extract information from the email but matches it in a wrong way. While in *extrinsic hallucinations*, the objects of the to-do item are not extracted from the email, but generated from similar entities in the corpus.

5 Conclusion

In this work, we propose a simple yet effective learning to highlight and summarize framework (LHS) to learn to identify salient text and actions from both email text and the constructed action graph, and generate faithful to-do items jointly. Experiments show that the proposed model outperforms the baselines significantly and achieves state-of-the-art performance in both quantitative evaluation and human judgement. We further demonstrated that our LHS framework generalized well to out-of-domain conditions. In the future, we plan to extend the email to-do item generations to other domains such as generating multiple to-do action items from conversation or meeting threads.

Ethical Discussion

The dataset used in this work is released by SmartToDo (Mukherjee et al., 2020), based on the Avocado dataset from the Linguistic Data Consortium, which mainly contains emails from an anonymous defunct technology company referred to as Avocado. The Avocado email dataset entered the public domain via the cooperation and consent of the legal owner of the corpus. Although we do not encounter any major ethical issues in training these models, we anticipate there might be key challenges when it comes to the deployment of email to-do item generation systems, given the highly sensitive and personal nature of emails. We strongly recommend any future use of email to-do generation models only do it in a secure and private manner, and call for a code of AI ethics that lays out how various issues will be handled around deploying these systems for real world uses.

Table 7: Four samples randomly picked from the predictions of the model, where the first two are from SmartToDo (the same corpus as the training set), and the second two are from Enron Email (a different email corpus).

B Implementation Details

Following the setting of SmartToDo (Mukherjee et al., 2020), we used 1000 email instances each for validation and testing. We initialize the token-level encoder and the decoder layer that attends to input tokens with pre-trained BART-base (Lewis et al., 2020) parameters and randomly initialize the newly added components. For the components initialized with BART, we employ an initial learning rate of 5e-5. For the newly added components, we employ an initial learning rate of 5e-4. We set the number of warm-up steps to 100. We set the α, the coefficient of $L_{classification}$ to be 1.7 and β, the coefficient of $L_{generation}$ to be 0.3. We fine-tune each model for 7 epochs on the training set.

Exploring the Capacity of a Large-scale Masked Language Model to Recognize Grammatical Errors

Abstract

In this paper, we explore the capacity of a language model-based method for grammatical error detection in detail. We first show that 5 to 10% of training data are enough for a BERT-based error detection method to achieve performance equivalent to what a non-language model-based method can achieve with the full training data; recall improves much faster with respect to training data size in the BERT-based method than in the non-language model method. This suggests that (i) the BERT-based method should have a good knowledge of the grammar required to recognize certain types of error and that (ii) it can transform the knowledge into error detection rules by fine-tuning with few training samples, which explains its high generalization ability in grammatical error detection. We further show with pseudo error data that it actually exhibits such nice properties in learning rules for recognizing various types of error. Finally, based on these findings, we discuss a cost-effective method for detecting grammatical errors with feedback comments explaining relevant grammatical rules to learners.

1 Introduction

Recent studies have shown that masked language models pre-trained on a large corpus (hereafter, simply language models) achieve tremendous improvements over a wide variety of natural language processing tasks with fine-tuning. These results suggest that they are also effective in recognizing erroneous words and phrases, the task known as grammatical error detection. There has been, however, much less work on this aspect of grammatical error detection than in other tasks. One can argue that since language models are trained on language data produced by native speakers of a language (specifically, English in this paper), they might not work well on the target language data produced by non-native speakers of that language. In other words, English language models do not know at all about grammatical errors made by non-native speakers. Even apart from grammatical errors, the target language is different from the canonical English, meaning that it contains unnatural phrases and characteristic language usages that native speakers do not normally use, as Nagata and Whittaker (2013) demonstrate. These differences might affect performance of language model-based methods in grammatical error detection.

Actually, researchers have reported on performance of language models on grammatical error detection and correction. Cheng and Duan (2020) and Kaneko and Komachi (2019) have shown that BERT (Devlin et al., 2019)-based methods improve grammatical error detection performance in Chinese and English, respectively. Kaneko et al. (2020) and Didenko and Shaptala (2019) have shown a similar tendency in grammatical error correction. While these studies empirically prove the effectiveness of language models in grammatical error detection and correction, the questions of why and where language models benefit error detection/correction methods are left unanswered.

In this paper, we explore this aspect of language models in grammatical error detection to better answer the research questions. We first show that a BERT-based method incredibly quickly learns to recognize various types of error as summarized in Figure 1; it achieves only with 5 to 10% of training data an $F_{1.0}$ that a non-language model-based method can achieve with the full training data (the details will be described in Sect. 4). This implies that the BERT-based method (i) should have a good knowledge of the grammar required to recognize certain types of error and (ii) can transform it into error detection rules by fine-tuning with very few

Findings of the Association for Computational Linguistics: ACL 2022, pages 4107 - 4118

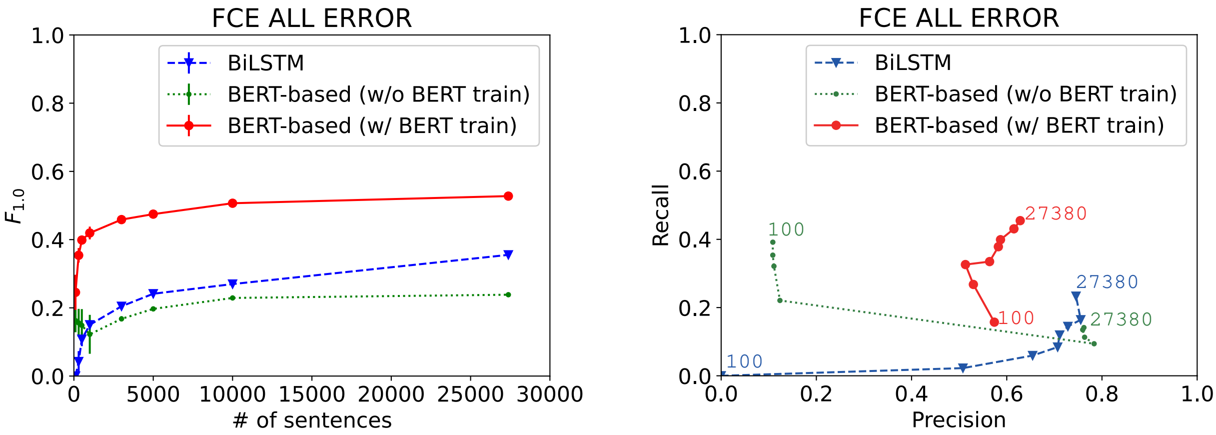

Figure 1: Detection Performance in Relation with Training Size (FCE).

training samples. Following this, we further show with real and pseudo error data why and where it gains in error detection, revealing the insights of language model-based methods. For instance, we show that the BERT-based method trained on few instances of a transitive verb with a preposition (e.g., **discuss about*) can detect the same type of error in other verbs (e.g., **approach to* and **attend in*). Finally, based on these findings, we discuss a cost-effective method for detecting grammatical errors with feedback comments explaining relevant grammatical rules to learners.

2 Related Work

Rei (2017) shows it is useful for neural error detection models to introduce a secondary language model objective together with the main error detection objective. Rei and Yannakoudakis (2017) compare several other auxiliary training objectives including Part-Of-Speech (POS) tagging and error type identification and find that the language model objective is the most effective. This line of work suggests that grammatical error detection benefits from language modeling, although these studies use BiLSTM-based language models instead of masked language models trained on a large corpus.

As mentioned in Sect. 1, several researchers have applied masked language models including BERT to grammatical error detection and correction. Cheng and Duan (2020) and Kaneko and Komachi (2019) show that error detection methods gain in recall and precision with the use of language models. Bell et al. (2019) use BERT-based contextual embeddings for grammatical error detection and compare it with other types of contextual embedding. They show the BERT-based contextual embeddings are effective in almost all error types provided by ERRANT (Bryant et al., 2017) although BERT is not fine-tuned in their study. Yuan et al. (2021) compare BERT, XLNet (Yang et al., 2019), ELECTRA (Clark et al., 2020) in grammatical error detection to show their effectiveness in grammatical error detection[1]. Kaneko et al. (2020) and Didenko and Shaptala (2019) also show performance improvements in grammatical error correction. To strengthen the findings of these previous studies, we will explore why and where error detection methods benefit from language models, revealing their generalization ability, in the following sections.

There has been a long history of studies that investigate the linguistic knowledge of language models including the work by Li et al. (2021); Ettinger (2020); Warstadt et al. (2020) to name a few. A popular approach is to test whether a language model assigns higher likelihood to the appropriate word than an inappropriate one, given context. The linguistic knowledge to be explored ranges from syntactic/semantic knowledge to common sense. These studies mostly use (i) synthetic test data: sentences that are generated synthetically by using a certain kind of template or (ii) perturbed test data: sentences that are generated by perturbing a natural corpus. Our work is different from these previous studies in two points: (i) to our best knowledge, we examine linguistic phenomena that have never been explored before in the conventional studies (e.g., subjects marked with a preposition and errors involving the usages of transitive and intransitive verbs); (ii) we use a real learner corpus with real

---

[1] ELECTRA is not a language model. It however contains an architecture similar to that of a language model.

errors as our test data.

Mita and Yanaka (2021) examine if an encoder-decoder neural network for grammatical error correction (not BERT-based) can learn the knowledge of grammar through the task of grammatical error correction. They target five error types: subject-verb agreement, verb form, word order, adjective/adverb comparison, noun number. They use both synthetic and real learner data. They report a negative answer to the research question except for word order errors. They also report that their model learns the knowledge to detect the target errors in their synthetic data. However, there is still room for debate in this argument because error positions tend to be rather obvious in their synthetic data (e.g., adjective forms erroneously used as adverbs almost always appear at the end of a sentence). Our study expands and deepens their findings for a wider variety of error types that are much more difficult to detect (in that it requires a much wider range of linguistic knowledge including POS, lexical, and syntactic knowledge).

3 Data and Methods

3.1 Real and Pseudo Error Data

In this paper, we use two kinds of data: real and pseudo data. Real data are error-annotated learner corpora while pseudo error data are automatically generated by perturbing a native English corpus.

For the real data, we use four English learner corpora: the First Certificate of English error detection dataset (FCE) (Yannakoudakis et al., 2011); NUS Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013); BEA-2019 shared task dataset (BEA) (Bryant et al., 2019); the International Corpus Network of Asian Learners of English with feedback comments (ICNALE) (Nagata et al., 2020). We use the data splits provided by the creator except for ICNALE where we randomly split the essays into training, development, and test sets in the ratios of 85%, 7.5%, and 7.5%, respectively. Table 1 shows their statistics[2].

ICNALE provides information about errors in preposition use and their corresponding feedback comments. We use it to investigate in detail why and where language model-based methods gain an advantage. Their essay topics are controlled; they are written on either (a) *It is important for college students to have a part-time job.* or (b) *Smoking should be completely banned at all the restaurants in the country.*, which hereafter will be referred to as *PART-TIME JOB* and *SMOKING*, respectively. Each essay is manually annotated with errors in preposition use and their corresponding feedback comments. For example, the major errors in the corpus include deverbal prepositions (e.g., **include → including*), intransitive verbs with a direct object (e.g., **agree it → agree with it*), a verb phrase used as a noun phrase (**Learn English is difficult. → To learn/Learning English is difficult.*), and comparison between a phrase and a clause (e.g., **because an error → because of an error*); see the work (Nagata et al., 2020) for the details.

To investigate the relationship between the number of training sentences and detection performance, we randomly sample 100, 300, 500, 1,000, 3,000, 5,000, 10,000, and all sentences, resulting in eight sets of training data for each corpus[3]. Note that these training, development, and test sets con-

Table 1: Statistics on Real Datasets.

---

[2] The data development is still ongoing in the work (Nagata, 2019). For this work, we used data that had not been open to the public yet from the developer.

[3] In the sub-corpora A and C in BEA, only seven sets are used because they consist of less than 10,000 sentences.

tain error-free sentences.

For the pseudo error data, we use the 1998-2000 New York Times in the AQUAINT Corpus of English News Text (Graff, 2002) as a base corpus. We automatically generate erroneous sentences by injecting errors into them (one error per sentence). We first obtain chunks and parses by using spaCy[4]. Here, we only use sentences whose lengths are longer than three tokens and shorter than 26 to obtain reliable chunks and parses. We then add, remove, or replace a word in the sentences based on the analyses.

While we target all errors labeled as errors in the real data, we only target the following five error types in the pseudo error data:

Prepositional infinitive: *to*-infinitive with other prepositions than *to*.
(e.g., *a book to read* → **a book for read*)

Subject verb: Verb phrases used as a subject
(e.g., **Learn English is difficult.*)

Preposition + subject: Subjects used with a preposition
(e.g., **In the restaurant serves good food.*)

Transitive verb + preposition: Transitive verbs used with a preposition
(e.g., **We discussed about it.*)

Intransitive verb + object: Intransitive verbs taking a direct object
(e.g., **We agree it.*)

These five error types are selected with the following two criteria: (i) they are major errors in ICNALE; (ii) we can write a software program to generate pseudo errors based on chunks and parses. For example, we can find the subject of a sentence from its parse and then can add a randomly-chosen preposition before the subject noun phrase (e.g., *The restaurant serves good food.* → **In the restaurant serves good food.*). We randomly choose one of the following five prepositions: *at*, *about*, *to*, *in*, and *with* for addition and replacement; an exception is that we only use *for* for "Prepositional infinitive" (e.g., *a book to read* → **a book for read*), which often appears in ICNALE. Similarly, we can extract pairs of a verb and its direct object from parses and then can add one of the prepositions before the direct object noun phrase as in *discuss the matter* → **discuss about the matter*. We select the following transitive verbs as our targets: in training/development data: *answer*, *attend*, *discuss*, *inhabit*, *mention*, *oppose*, and *resemble*; in test data: *approach*, *consider*, *enter*, *marry*, *obey*, *reach*, *visit*. Similarly, we select the following intransitive verbs: in training/development data: *agree*, *belong*, *disagree*, and *relate*; in test data: *apply*, *graduate*, *listen*, *specialize*, *worry*. It should be emphasized that there is no overlap of the target transitive/intransitive verbs in the training/development and test data.

From the resulting pseudo error data, we randomly sample $2^k (1 \leq k \leq 10)$ sentences for each error type, resulting in ten sets of training data (e.g., when $k = 1$, the set comprises two instances of each error type, ten instances in total). We use these training sets to estimate the relationship between the number of training sentences and detection performance. For a validation set, we randomly sample 200 sentences for each error type. Similarly, we use a test set consisting of 200 sentences randomly sampled for each error type plus another 200 error-free sentences. The validation and test sets are fixed regardless of the training data.

3.2 Grammatical Error Detection Methods

This subsection describes the three methods to be explored and compared. Before looking into them, let us define grammatical error detection formally. Grammar error detection can be solved as a token classification problem[5]. We will denote a sequence of words and its length by $w_1, \ldots, w_i \ldots, w_N$ and N, respectively. We will denote the corresponding sequence of labels by $l_1, \ldots, l_i, \ldots, l_N$ where l_i corresponds to the label of w_i. We assume two sets of labels: (i) either C or E denoting *correct* or *erroneous* in the real data, respectively; and (ii) K labels for K error types plus C for *correct* in the pseudo error data. Then, grammatical error detection is defined as a problem of predicting the optimal label sequence given $w_1, \ldots, w_i \ldots, w_N$.

We use neural networks to predict the optimal label sequence. In this paper, training is repeated five times with different (but fixed) random seeds. The reported performance values (i.e., recall, precision, and $F_{1.0}$) are averaged over the five runs. Training epochs are 50 for the real data or ten for the pseudo error data at the maximum and we adopt

---

[4] `https://spacy.io/`

[5] More generally, it can also be solved as a sequence labeling problem using for example CRF. However, Rei (2017) shows that the grammatical error detection task does not benefit from CRF. We observed the same tendency in our datasets. Accordingly, we solve it as a token classification problem (without CRF).

the epoch achieving the best $F_{1.0}$ on the development set. Other major hyper parameters are shown in Appendix A.

3.2.1 BERT-based Method

The BERT-based method takes as input a word sequence $w_1, \ldots, w_i \ldots, w_N$ and conducts the following procedures:

(1) Subword: convert all w_i into their corresponding subwords: $s_1, \ldots, s_j \ldots, s_M$. Note that the total number of all subwords are generally different from that of all words in the input word sequence.

(2) Encode: encode all s_j into BERT embeddings b_j by:

$$b_j = \mathrm{BERT}(s_j) \tag{1}$$

where $\mathrm{BERT}(\cdot)$ denotes BERT taking subwords as input and outputs their corresponding embedding vectors of h-dimension (specifically, $h = 768$ for 'bert-base') from the final layer. We use 'bert-base-uncased' for $\mathrm{BERT}(\cdot)$.

(3) Token classification: output the optimal labels by:

$$l_i = \arg\max \mathrm{softmax}(Wb_j) \tag{2}$$

where W is a $k \times h$ weight matrix where k is either 2 or $K + 1$ (the number of different labels). To take care of the difference in the lengths of the input word sequence and the corresponding subword sequence, only the first subword of each word is considered in prediction.

3.2.2 Methods to Be Compared

For comparison, we select a BiLSTM-based error detection method. Basically, it follows the above steps (1) to (3), but uses BiLSTM as an encoder in place of BERT. Also, the input word sequence is turned into a sequence of embedding vectors where each embedding vector consists of the concatenation of the conventional word embedding and a character-based embedding. The character-based embedding is obtained by another BiLSTM taking the characters of each word following the work (Akbik et al., 2018). The concatenated embeddings are put into the encoder BiLSTM to produce vectors for prediction in step (3). Specifically, we use the implementation FLAIR (Akbik et al., 2019). We will refer to this method for comparison as the BiLSTM-based method hereafter.

We also investigate how effective the fine-tuning of BERT is. Namely, the BERT part of the BERT-based method is fixed during training and only the output layer is adjusted by the training data. We will refer to this method as the BERT-based method without BERT training hereafter.

4 Performance on Real Data

Figure 1 (see the second page) to Figure 3 show the relationship between the number of training sentences and $F_{1.0}$ in FCE[6], NUCLE, and BEA with its corresponding precision-recall curves, respectively. All $F_{1.0}$ graphs show the high generalization ability of the BERT-based method. They also show that the BERT-based method exhibits a performance saturation at a very early stage (1,000-3,000 training sentences). It is worthwhile to point out the fact that the $F_{1.0}$ curves for all proficiency levels (A, B, and C)[7] in BEA (Figure 3) exhibit the same trend as the other corpora although the absolute performances differ depending on the levels. These results empirically confirm that the high generation ability of the BERT-based method holds in various writer populations.

Unlike the BERT-based method, the BiLSTM-based method improves steadily as the number of training sentences increases although even with the full training data, it only achieves an $F_{1.0}$ that the BERT-based method can achieve with only 500 or less training sentences. Also, the BERT-based method without BERT training does not perform well at all. This is probably because it requires much more degrees of freedom in terms of the network parameters to learn rules for detecting a wide variety of grammatical errors, which have a certain degree of complexity.

To investigate the results from a different point of view, let us now consider precision-recall curves

---

[6] The best performance of the BERT-based method in FCE is a recall and precision of 0.455 and 0.628, respectively. These numbers are considerably lower than those of the state-of-the-art Yuan et al. (2021) report; they show that the ELECTRA-based method achieves the best recall and precision of 0.505 and 0.821, respectively (c.f., recall: 0.480, precision: 0.757 for their BERT-based method). Note that they use the large models whereas we use the bert-base model, which should be part of the reason for the performance differences. While our results do not achieve the best results, they explain well why large-scale masked language models perform well in grammatical error detection.

[7] The proficiency levels A, B, and C in BEA, which corresponds to those in CEFR, becomes higher in this order.

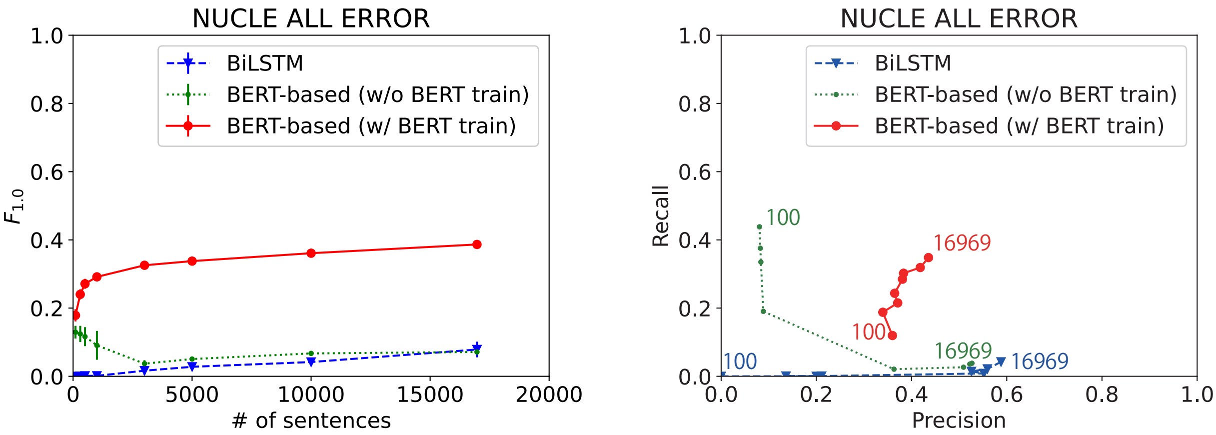

Figure 2: Detection Performance in Relation with Training Size (NUCLE).

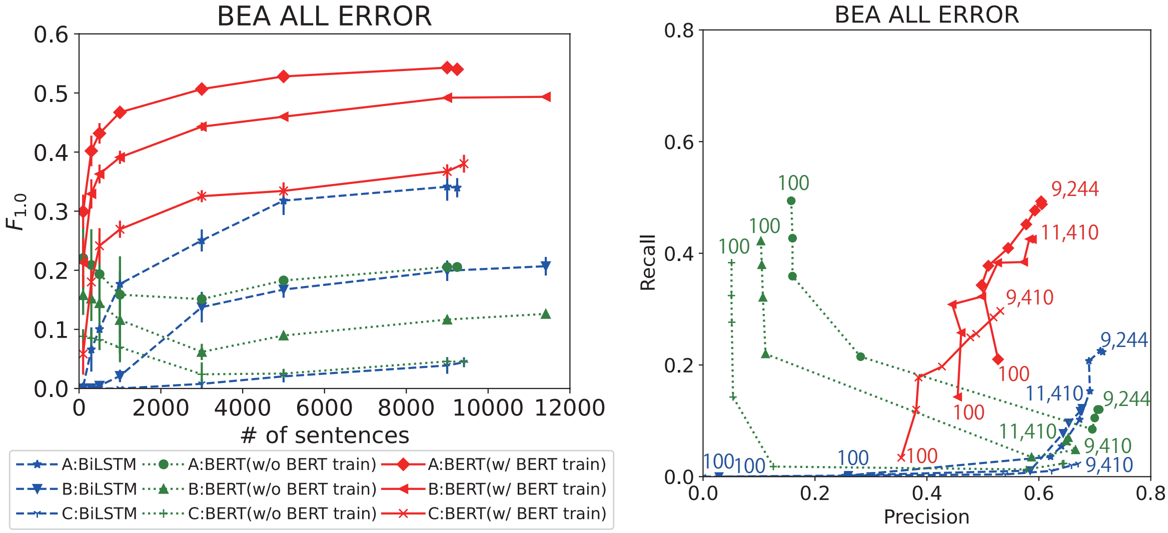

Figure 3: Detection Performance in Relation with Training Size (BEA). Essays in BEA are classified into three categories A, B, and C corresponding to the CEFR levels. The categories are referred to by the labels such as "A:BERT" and "B:BERT" in the legend.

(the right graphs; the numbers at the edges of each curve correspond to the numbers of minimum and maximum training sentences and the plots are lined in minimum to maximum order). All precision-recall curves show that only the BERT-based method quickly improves in recall as the number of training sentences increases while the BERT-based and BiLSTM-based methods both improve in precision. In other words, only the BERT-based method learns to recognize various error types with little exposure to error examples.

Figure 4 shows recalls per detailed error types in FCE[8] where error types are automatically obtained by using ERRANT. Figure 4 shows that the BERT-based method quickly achieves a good recall in SPELL (spelling errors) while the BiLSTM-based method shows a much milder rise. This is not surprising considering that BERT is trained on large native corpora. Namely, it virtually has a large vocabulary list and knows about English spellings well. More interestingly, it exhibits a performance saturation at a very early stage (500-3,000 training sentences) in all errors, resulting in log-like-shape curves while the BiLSTM-based method improves rather linearly (except for SPELL). Even more interestingly, it shows a sharp rise in recall in DET (determiner errors) and NOUN:NUM (errors in noun number). The notion of noun countability with POS plays an important role in detecting these two types of error as in **I am student/countable.* and *an evidence/uncountable*. This suggests that BERT contains some kind of knowledge corresponding to noun countability and POS (singular/plural nouns). More generally, from these, one

---

[8] PUNCT, OTHER and those whose frequency is less than 150 are excluded in Figure 4.

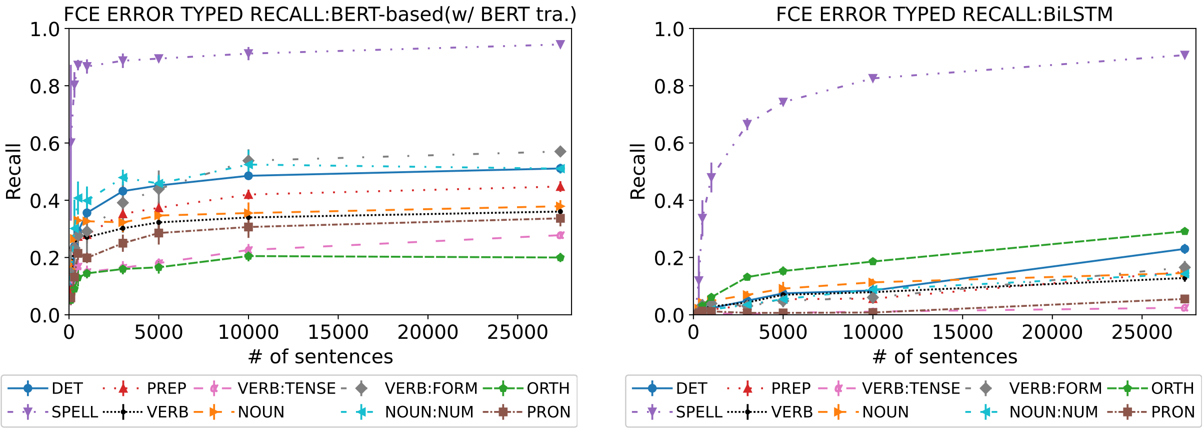

Figure 4: Detection Performance (Recall) per Error Type in Relation with Training Size (FCE).

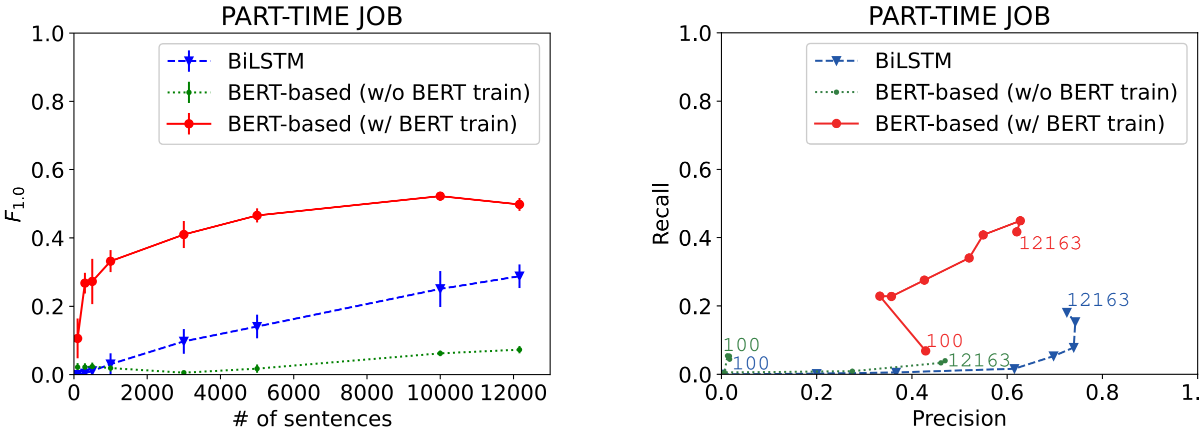

Figure 5: Detection Performance in Relation with Training Size (ICNALE, in-domain test data).

can expect that it has broad knowledge about linguistic properties, which we will observe presently in the experiments with ICNALE.

Let us then turn to ICNALE where we only target errors concerning preposition use (meaning that the other errors are unmarked and that if other errors are detected, they are treated as false positives). Here, we only present performance on PART-TIME JOB due to the space limitation; the results for SMOKING exhibit a very similar tendency, which can be found in Appendix B.

Figure 5 and Figure 6 show performance in PART-TIME JOB in ICNALE; in Figure 5, all models are trained on essays on PART-TIME JOB and tested on (test) essays on the same topic (in-domain setting) while in Figure 6, they are trained on SMOKING and tested on PART-TIME JOB (out-of-domain setting). In both settings, 300 to 500 training sentences are again enough for the BERT-based method to rival the BiLSTM-based method with the full training data, which exhibits again a linear improvement in $F_{1.0}$. Also, only the BERT-based method quickly improves in recall.

A closer look at the detection results reveals that many of the errors require linguistic knowledge including POS, syntactic relations, and lexical properties such as transitive/intransitive verbs. For example, "Preposition + subject" errors, which were introduced in Subsect. 3.1, require the notions of POS such as verbs and syntactic relations such as subjects. Similarly, the distinction between transitive and intransitive verbs play a crucial role in "transitive verb + preposition" and "intransitive verb + object". The fact that the BERT-based method can detect these types of errors with a few training instances suggest that it has an access to grammar-like knowledge and that it can turn the knowledge into error detection rules by fine-tuning. We will explore this in more detail in the following section.

These results also shed light on an important aspect of the BERT-based method in practice. Namely, a cost-effective way of developing an error detection system based on BERT would be to create a small amount of training sentences (e.g., 1,000) for each essay topic; according to the above

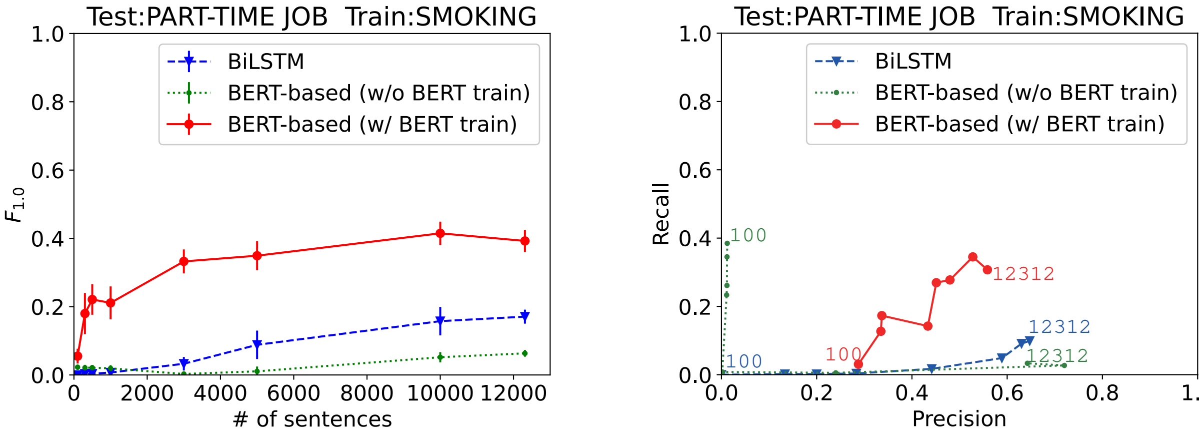

Figure 6: Detection Performance in Relation with Training Size: (ICNALE, out-of-domain test data).

figures, the gain would be much smaller after 1,000 training sentences. Of course, the results are only for a simple BERT-based method. No one knows how differently the performance curves grow with different architectures and/or with a much larger set of training instances. It will be interesting to investigate these points for future work.

5 Performance on Synthetic Data

In the previous section, we have seen that the BERT-based method has a much higher generalization ability in grammatical error detection. To analysis this phenomenon in detail, we now turn to detection performance of the BERT-based method on the pseudo error data. As described in Subsect. 3.1, we train it on the ten sets of training data (i.e., 2, 4, $\cdots$, 1024 training sentences for each error type) and test the trained models on the fixed test set. Doing so, we estimate the relationship between the number of training sentences and detection performance for each error type.

Figure 7 shows the relationship between the size of training data and $F_{1.0}$ for each error type where the size is measured by the number of sentences. Figure 7 reveals that the BERT-based method already recognizes some of the target errors at early stages (even with two or four training sentences). Performance goes much higher even with eight training sentences in most of the error types with an exception of the error type “Intransitive verb + object”. For instance, the BERT-based method recognizes more than half of the “Preposition + subject” errors with a precision of 0.800 only with eight training instances. This implies again that BERT has certain knowledge about the notions of POS such as verbs and syntactic relations such as subjects; otherwise, it would be difficult to achieve

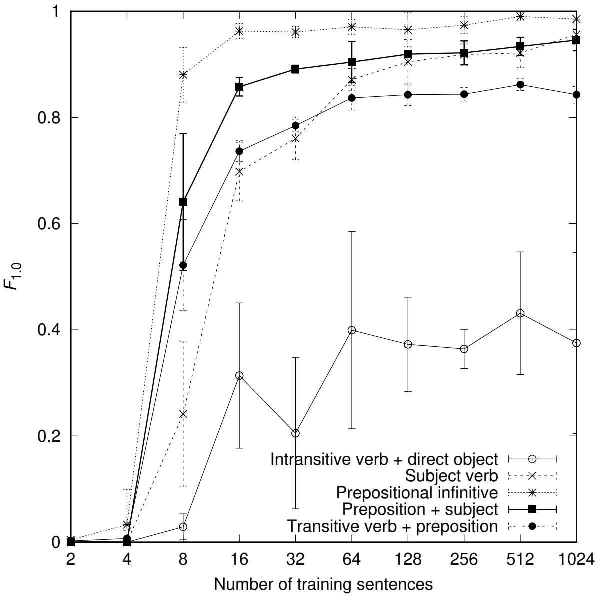

Figure 7: Detection Performance ($F_{1.0}$) per Error Type in Relation with Training Size: Synthetic Data.

a similar performance in this type of error considering that the noun phrase of a subject and its position in the sentence considerably vary depending on the target sentence.

The same argument applies to “transitive verb + preposition” and “intransitive verb + object”. It should be emphasized that the BERT-based method has to detect errors in verbs that never[9] appear in the training data; recall that there is no overlap of the target transitive/intransitive verbs in the training and test data. In other words, the BERT-based method can recognize unseen erroneous combinations, for example, **visited in Atlanta* (transitive verb + preposition type) and **specialized environ-*

---

[9] Strictly, some of the verbs may appear in the training sentences for the other error types. However, they never appear in the erroneous phrases. Also, they do not appear at all when the training size is small.

mental litigation (intransitive verb + direct object error type) after just seeing **mention in*, *discussed about* and **were related drugs* and *belongs Lon's grandmother*. These training and test sentences have almost nothing in common except that they are the combinations of transitive/intransitive verbs and prepositions/objects. Besides, the fact that correct combinations of other verbs and prepositions/objects often appear in the test data makes the task even more difficult without the knowledge of POS and syntactic relations. These findings support the hypotheses that BERT has linguistic knowledge and that it can turn the knowledge into error detection rules by fine-tuning.

6 Exploration for Cost-Effective Error Detection with Feedback Comments

The findings we have obtained so far bring out the possibility that one can implement with few training instances a system that accurately detects grammatical errors and recognizes their detailed error types. For example, manually or automatically, by creating few instances of the erroneous combination of transitive verbs and prepositions as we saw in the previous sections (e.g., **discuss about*), one can develop a system detecting the same type of error in other transitive verbs and prepositions (e.g., **attend in it*). With the detailed error types, the system can also output feedback comments to the user such as *Transitive verbs do not take a preposition. Instead, they take a direct object* instead of just indicating them as preposition errors.

As a pilot study, we trained the BERT-based method on the pseudo error data and tested it on the real (learner) data to examine the above possibility. To achieve it, we manually annotated the real data with the target five error types based on the feedback comments available in ICNALE.

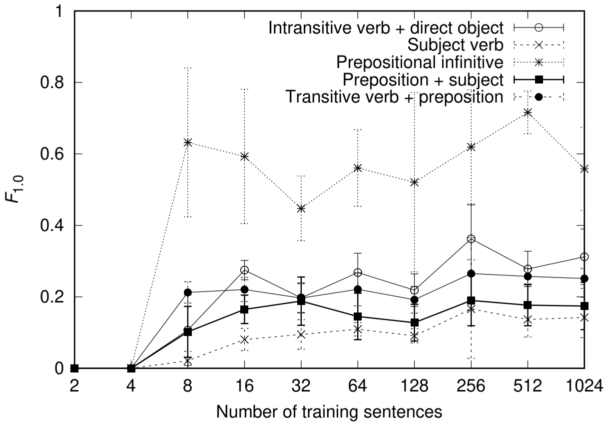

Figure 8: Detection Performance ($F_{1.0}$) on per Error Type in Relation with Training Size: Trained on Synthetic Data; Tested on Real Data (PART-TIME JOB and SMOKING merged).

Figure 8 shows the results. It reveals that the BERT-based method trained on the pseudo data does not perform on the real data as well as on the pseudo data. Performance growths stop at an early stage (around eight training sentences). A possible reason for this is that in the real data, multiple errors often appear in a sentence. Also, multiple errors in a sentence can range over multiple types of error. Besides, the error rate is much lower in the real data than in the pseudo error data where one error occurs per sentence except 200 error-free sentences (although multiple types of error appear in the whole data set). These conditions make the task much more difficult on the real data, as Flachs et al. (2019) demonstrate.

Having said that, the results shown in Figure 7 still encourage us to develop language model-based systems with a small amount of in-domain training data in order to detect grammatical errors with detailed error types. One possible way to achieve it is to sample sentences from unannotated essays written on the target topic, and then to annotate them with the specific error types that the developer wants to give feedbacks to learners. This will naturally mitigate the problems caused by the multiple-type multiple error situation and the error rate difference. One can also manually create sample error sentences (and their correct versions).

7 Conclusions

In this paper, we have explored the capacity of a large-scale masked language model to recognize grammatical errors. Our findings are summarized in the following three points: (1) Experiments with the real learner data show that a BERT-based error detection method has a much higher generalization ability in grammatical error detection than a non-language model-based method, and the first performance saturation comes at the point of around 1,000-3,000 training instances; (2) It starts to recognize the target errors involving a wide variety of grammatical knowledge with very few instances of them; (3) The high generalization ability brings out its potential for developing systems that detect and explain grammatical errors with very few training instances.

Abstract

We explore the notion of uncertainty in the context of modern abstractive summarization models, using the tools of Bayesian Deep Learning. Our approach approximates Bayesian inference by first extending state-of-the-art summarization models with Monte Carlo dropout and then using them to perform multiple stochastic forward passes. Based on Bayesian inference we are able to effectively quantify uncertainty at prediction time. Having a reliable uncertainty measure, we can improve the experience of the end user by filtering out generated summaries of high uncertainty. Furthermore, uncertainty estimation could be used as a criterion for selecting samples for annotation, and can be paired nicely with active learning and human-in-the-loop approaches. Finally, Bayesian inference enables us to find a Bayesian summary which performs better than a deterministic one and is more robust to uncertainty. In practice, we show that our Variational Bayesian equivalents of BART and PEGASUS can outperform their deterministic counterparts on multiple benchmark datasets.

1 Introduction

State-of-the-art text summarization methods have achieved remarkable performance in various benchmarks (Song et al., 2019; Dong et al., 2019; Lewis et al., 2019; Zhang et al., 2020). The majority of these methods use very large Transformer models pre-trained on language generation tasks.

Although such methods can generate high quality summaries for texts similar to their training set, they suffer from a couple of issues when the inputs lie far from the training data distribution. They are prone to generating particularly bad outputs (Xu et al., 2020; Kryściński et al., 2020) and are usually fairly confident about them (Gal and Ghahramani, 2016; Xiao et al., 2020). These shortcomings are bound to cause problems once a summarization model is deployed to solve a practical problem.

Since the output of automatic summarization models is usually expected to be consumed by humans, it is very important to know when such an output is of good enough quality to be served to users. In most cases, it is very much preferable to not serve an output at all, instead of serving a bad output. This will in turn increase users' trust to automated summarization systems.

Model uncertainty is one way of detecting when a model's output is likely to be poor on the grounds of predicting far away from it's training distribution. Recent summarization methods have focused heavily on improving the overall performance, but model uncertainty has been explored very little (Xu et al., 2020).

In addition to improving user experience, the development of uncertainty measures for summarization can pave the way for active learning approaches (Gal et al., 2017; Houlsby et al., 2011; Liu et al., 2020; Lyu et al., 2020). The value of active learning stems from the fact that obtaining labeled samples for training is hard, but it is relatively easy to obtain large amounts of unlabeled samples. Summarization is no different in this perspective, since creating good quality target summaries for training can be very costly.

This work explores uncertainty estimation for state-of-the-art text summarization models, from a Bayesian perspective. We extend the BART (Lewis et al., 2019) and PEGASUS (Zhang et al., 2020) summarization models with Monte Carlo dropout (Gal and Ghahramani, 2016), in order to create corresponding Variational Bayesian PEGASUS (VarPEGASUS) and BART (VarBART) models. Sampling multiple summaries from those models allows us to approximate Bayesian inference in a practical way, which in turn enables us to estimate summarization uncertainty. To the best of our knowledge this is the first attempt to apply Bayesian summary generation with large Transformer models.

Findings of the Association for Computational Linguistics: ACL 2022, pages 4119 - 4131
May 22-27, 2022

Based on Bayesian approximation, we adapt the Monte Carlo BLEU variance metric (Xiao et al., 2020) to the summarization task, and investigate its efficacy as a measure of summarization uncertainty. Our findings suggest that this uncertainty metric correlates well with the quality of the generated summaries and can be effective at identifying cases of questionable quality.

Finally, we take the summarization uncertainty study one step further, and select the summary with the lowest disagreement out of multiple summaries sampled from our Variational models. Experiments across multiple benchmark datasets show that this method consistently improves summarization performance (see Table 5), and by using it our VarPEGASUS and VarBART models achieve better ROUGE F-scores compared to their original deterministic counterparts.

The rest of this paper is structured as follows. Section 2 discusses related work on Bayesian deep learning and uncertainty estimation methods. Section 3 presents our approach. Section 4 describes our experimental setup, while Section 5 presents and discusses the results. Finally, Section 6 concludes our work and considers its broader impact.

2 Related work

Uncertainty estimation in deep learning is a topic that has been studied extensively. Bayesian deep learning includes a family of methods that attempt to capture the notion of uncertainty in deep neural networks. Such methods have gained increased popularity in the deep learning literature and there exist multiple applications in subfields such as Computer Vision (Kendall and Gal, 2017; Litjens et al., 2017; Gal et al., 2017) and Natural Language Processing (NLP) (Siddhant and Lipton, 2020; Liu et al., 2020; Lyu et al., 2020; Xiao et al., 2020).

Despite their obvious advantage of modeling uncertainty, the main problem with Bayesian deep learning methods is the computational cost of full Bayesian inference. To tackle this problem, Gal and Ghahramani (2016) propose using standard dropout (Srivastava et al., 2014) as a practical approximation of Bayesian inference in deep neural networks and call this method Monte Carlo dropout. Gal et al. (2017) use a convolutional neural network with Monte Carlo dropout in order to obtain an uncertainty estimate for active learning in the task of image classification. Houlsby et al. (2011) sample many networks with Monte Carlo simulation and propose an objective function that takes into account the disagreement and confidence of the predictions coming from these networks.

Similar methods have also been applied to NLP. In machine translation, Xiao et al. (2020) extend the Transformer architecture with MC dropout to get a Variational Transformer, and use it to sample multiple translations from the approximate posterior distribution. They also introduce BLEUVar, an uncertainty metric based on the BLEU score (Papineni et al., 2002) between pairs of the generated translations. Lyu et al. (2020) extend the work of Xiao et al. (2020) to question answering and propose an active learning approach based on a modified BLEUVar version. Similarly, Liu et al. (2020) use a conditional random field to obtain uncertainty estimates for active learning and apply their method to named entity recognition.

Although summarization is a prominent NLP task, summarization uncertainty has not been widely studied. Xu et al. (2020) is the only work that focuses on uncertainty for summarization, but their work does not make use of Bayesian methods. They define a generated summary's uncertainty based on the entropy of each token generated by the model during the decoding phase. Their study includes experiments on CNN/DM and XSum using the PEGASUS and BART summarization models. Their main focus is on understanding different properties of uncertainty during the decoding phase, and their work is not directly comparable to ours.

3 Methods

We first introduce Bayesian inference, in the context of deep neural networks and show how it can be used to measure uncertainty. Subsequently, we show how Bayesian inference can be applied to summarization in order to estimate the uncertainty of a summary generated for a given input. Finally, we show how Bayesian inference can be employed for producing better summaries.

3.1 Monte Carlo dropout

Contrary to standard neural networks, Bayesian probabilistic models capture the uncertainty notion explicitly. The goal of such models is to derive the entire *posterior* distribution of model parameters θ given training data X and Y (Equation 1).

$$P(\theta|X,Y) = \frac{P(Y|X,\theta)P(\theta)}{P(Y|X)} \qquad (1)$$

At test time, given some input x, a prediction $\hat{y}$ can be made by integrating over all possible θ values (Equation 2). The predictive distribution's variance can then be used as a measure of the model's uncertainty.

$$P(\hat{y}|x, X, Y) = \int P(\hat{y}|x, \theta)P(\theta|X, Y)d\theta \quad (2)$$

In practice, integrating over all possible parameter values for a deep neural network is intractable, and therefore Variational methods are used to approximate Bayesian inference. A neural network trained with dropout can be interpreted as a Variational Bayesian neural network (Gal and Ghahramani, 2016), and as a result making stochastic forward passes with dropout turned on at test time is equivalent to drawing from the model's predictive distribution. This Monte Carlo (MC) dropout method can be easily applied to any neural network that has been trained with dropout.

3.2 Summary uncertainty

MC dropout is a simple yet effective method that requires no adjustment to the underlying model. It is possible to convert any state-of-the-art summarization model to a *Variational Bayesian model*, with the use of MC dropout. For Transformer based models in particular, the Transformer blocks that make up the encoder and decoder are usually trained with dropout, and therefore the conversion is trivial by simply turning dropout on at test time.

In Variational models, the variance of the predictive distribution can be used to measure the model's uncertainty. For a text summarization model, we can approximate the variance of this distribution, by measuring the dissimilarity of N stochastic summaries $y_1, y_2 \dots y_N$, generated with MC dropout.

The BLEU metric (Papineni et al., 2002) is commonly used for measuring the similarity between a pair of texts. As in Xiao et al. (2020), we approximate the model's predictive variance with the BLEU Variance (BLEUVar) metric over the N summaries generated with MC dropout as shown in Equation 3. BLEUVar is computed by summing the squared complement of BLEU among all pairs of summaries (twice as BLEU is asymmetric) generated for the same input with different dropout masks.

$$\text{BLEUVar} = \sum_{i=1}^{N} \sum_{j \neq i}^{N} (1 - \text{BLEU}(y_i, y_j))^2 \quad (3)$$

Because we sum over all pairs of N samples twice, scores that are computed with different N values are not directly comparable. To alleviate this issue we propose a normalized version of the metric, BLEUVarN, where we divide BLEUVar by $N(N-1)$ (Equation 4). This allows for comparisons between scores computed with different N values.

$$\text{BLEUVarN} = \frac{\sum_{i=1}^{N} \sum_{j \neq i}^{N} (1 - \text{BLEU}(y_i, y_j))^2}{N(N-1)} \quad (4)$$

By running multiple stochastic forward passes for the same input, we essentially create an ensemble of models with different parameters. Making predictions with this ensemble has the following effects. For inputs close to the learned distribution the summaries generated by all models in the ensemble will be similar to one another, and as a result BLEUVarN will be low. On the other hand, for inputs lying away from the learned distribution, the generated summaries will differ wildly and BLEUVarN will be high, indicating high uncertainty.

3.3 Bayesian summary generation

Inspired by the fact that making multiple predictions with MC dropout is equivalent to ensembling multiple stochastic models, we propose a novel Bayesian approach to summary generation. Instead of generating a single deterministic summary without dropout, as is commonly the case with modern summarization approaches, we consider using the *predictive mean* of multiple predictions made with MC dropout. Because the predictions in our case are summaries their predictive mean is not well defined, so instead we opt for selecting one of the N summaries.

We assume that the *predictive mean* of the N summaries generated with MC dropout should be the one having the lowest *disagreement* with the rest of the $N - 1$ summaries. Since the pairwise complement of BLEU between all pairs of the sampled summaries has already been computed when estimating BLEUVarN uncertainty, it can be further used to help us find the lowest disagreement summary. In practice, we select the summary $\hat{\mu}$ that maximizes the sum of symmetric BLEU similarity with the rest of the summaries (Equation 5) (Xiao et al., 2020). This summary could be seen as the *median* of all the summaries generated with MC dropout, although this is not a mathematically correct expression.

$$\hat{\mu} = \underset{y_i}{\operatorname{argmax}} \sum_{j \neq i}^{N} [\text{BLEU}(y_i, y_j) + \text{BLEU}(y_j, y_i)] \quad (5)$$

The intuition behind this approach is based on the following assumption. We expect the *median* summary to integrate the key concepts that all individual summaries agree on. Consequently, for inputs close to the model's learned distribution, the individual summaries will be similar to one another and as a result the *median summary* will be the best choice. On the other hand, for out-of-distribution inputs, the *median* out of a number of very different summaries will result in a more robust and overall better final summary. In practice, even for well trained models, we expect to have a fairly large number of inputs that are not close to the models' learned distribution, and therefore we expect to benefit from the positive effects of ensembling multiple outputs.

4 Experimental Setup

We first present the three datasets that are involved in our experiments, their main statistics and the reasons for including them in our empirical study. Then we present the two summarization models that we employed, along with their parameters and details on stochastic summary generation.

4.1 Datasets

In order to verify the effectiveness of our Bayesian abstractive summarization approach, we conducted a series of experiments on three well-known summarization benchmarks:

- **XSum** (Narayan et al., 2018) is a dataset of 227k BBC articles on a wide variety of topics. Each article is accompanied by a human written, single-sentence summary.
- **CNN/DailyMail** (Hermann et al., 2015) is a dataset containing a total of 93k articles from the CNN, and 220k articles from the Daily Mail newspapers. All articles are paired with bullet point summaries. The version used is the non-anonymized variant similar to (See et al., 2017).
- **AESLC** (Zhang and Tetreault, 2020) is a dataset of 18k emails from the Enron corpus (Klimt and Yang, 2004). The body of each email is used as source text and the subject as summary.

Table 1: Basic statistics for each one the datasets used in our experiments. The document and summary length are measured in words.

	Size		**Length**	
Dataset	**Val.**	**Test**	**Doc.**	**Sum.**
XSum	11,332	11,334	431	23
CNN/DM	13,368	11,490	760	46
AESLC	1,960	1,906	75	4

The main criteria for selecting these datasets are the availability of recent, open source models trained on them and their relatively short texts that would allow us to run a number of different experiments quickly. Since our methods do not involve training, we will only focus on the validation and test set of each dataset. All datasets are obtained from the Hugging Face datasets repository[1]. Table 1 presents some basic statistics for these datasets.

4.2 Models

BART (Lewis et al., 2019) and PEGASUS (Zhang et al., 2020) are Transformer based sequence-to-sequence models, pre-trained on massive corpora of unsupervised data (Web and news articles). Since our experiments do not involve training, we utilize open-source models fine-tuned on the training set of each dataset. These models can be found in the Hugging Face models repository[2].

Our BART models follow the BART$_{\text{LARGE}}$ architecture with 12 Transformer blocks for the encoder and the decoder. BART is pre-trained as a denoising autoencoder, where the text is corrupted and the model learns to reconstruct the original text. Open-source fine-tuned BART models are only available for XSum and CNN/DM. Our PEGASUS models follow the PEGASUS$_{\text{LARGE}}$ architecture and have 16 Transformer blocks for the encoder and the decoder. PEGASUS is pre-trained on the C4 and HugeNews datasets, on a sentence infilling task. Open-source fine-tuned PEGASUS models exist for all three datasets considered in our experiments.

In order to convert BART and PEGASUS to Variational models, we enable dropout for all Transformer blocks of the encoder and decoder. For each sample, we generate N summaries using beam

---

[1] https://huggingface.co/datasets

[2] https://huggingface.co/models

search decoding with 8 beams. We experimented with N equal to 10 (MC-10) and 20 (MC-20). The rest of the hyper-parameters used were identical to the original papers.

5 Results

Our main experiment evaluates BLEUVarN's effectiveness in quantifying uncertainty for summarization models. A second experiment investigates the potential of the Bayesian summarization method proposed in Section 3.3 as a way of improving summarization performance at test time.

5.1 Evaluating Bayesian uncertainty

We here evaluate the effectiveness of BLEUVarN in measuring the model's uncertainty. The performance versus data retention curve (Filos et al., 2019) measures how well a model would perform if we completely removed the $k\%$ most uncertain outputs from the test set. In the x-axis we have the fraction of data from the test set that are removed, while in the y-axis we have the performance metrics. An effective uncertainty measure should show a consistent improvement in performance as we discard more samples based on high uncertainty. In this experiment, we arrange samples by decreasing BLEUVarN score and gradually remove the samples with the highest score.

Figure 1 shows, for each dataset, the performance of our Variational models in terms of ROUGE-1 F-score versus the fraction of data discarded based on BLEUVarN. ROUGE-2 and ROUGE-L F-scores follow similar patterns and can be found in the Appendix A. For reference, we are also plotting the performance of the deterministic models using all data as straight lines. Also, in Table 2 we quantify the percentage increase in ROUGE F-scores as we discard different fractions of the full test datasets based on BLEUVarN.

All ROUGE F-scores improve as we gradually discard samples with high BLEUVarN, an observation that is consistent across all test datasets and models. More specifically, we notice that the increase is linear for the first 80% of the data, but then becomes almost exponential. From these observations we can draw two conclusions. First, models indeed perform significantly worse on samples with high uncertainty. Second, BLEUVarN is effective at quantifying uncertainty and can be used to identify high uncertainty samples.

Furthermore, we notice that the performance increase is significantly higher in the XSum and AESLC datasets compared to CNN/DM. In particular, VarPEGASUS-20 shows a staggering 58 point increase in ROUGE-1 score. We think that this difference might be related to the more extractive nature of CNN/DM summaries as opposed to the other two datasets. Such a finding would mean that Bayesian uncertainty filtering is more beneficial in abstractive rather than extractive setups.

Table 2: Percentage increase in ROUGE F-scores when discarding 25%, 50% and 75% of the data based on the highest BLEUVarN.

	25%	**50%**	**75%**
Model	**R-1/R-2/R-L**	**R-1/R-2/R-L**	**R-1/R-2/R-L**
		XSum	
VarBart-10	6.4/13.8/8.3	12.2/25.2/15.4	22.1/41.9/26.1
VarBart-20	6.5/14.1/8.3	13.2/26.7/16.5	22.5/42.6/27.2
VarPegasus-10	7.5/15.8/9.6	14.9/29.4/18.6	25.2/4.9/29.9
VarPegasus-20	8.0/16.8/10.3	15.8/31.2/19.6	26.3/48.1/31.2
		CNN/DM	
VarBart-10	2.9/7.2/4.8	5.4/13.1/8.5	8.8/20.4/13.3
VarBart-20	3.2/7.8/5.1	5.3/12.8/8.5	8.3/19.4/12.6
VarPegasus-10	4.1/9.9/6.1	7.8/17.4/10.9	12.6/26.1/16.8
VarPegasus-20	4.6/10.7/6.8	8.5/19.0/11.9	14.7/29.6/18.7
		AESLC	
VarPegasus-10	17.5/33.5/17.7	30.6/51.9/31.1	54.4/75.0/54.7
VarPegasus-20	18.7/36.3/18.9	36.0/59.7/36.6	58.4/78.0/58.8

To further illustrate how BLEUVarN behaves across different parts of the data, Figure 2 shows the decrease in the average BLEUVarN of all Variational models as we gradually discard samples with low ROUGE-1 scores from each dataset. We observe that for the samples with the highest ROUGE performance BLEUVarN becomes almost zero. This observation further supports our argument that model uncertainty has a significant impact on model performance.

5.1.1 MC-10 vs MC-20

From Figure 1 we can see that MC dropout with 20 samples performs better than 10 samples, resulting in higher performance. In more detail, for highly uncertain data, both MC-10 and MC-20 converge to similar BLEUVarN values (Figure 2) as well as ROUGE scores (Figure 1). On the other side of the spectrum, for low uncertainty data, using 20 samples leads to bigger performance increase along with a little higher BLEUVarN scores.

Based on these observations, we conclude that MC dropout with 20 samples is generally better in terms of performance. This comes at the cost of increased computational overhead because it requires running twice as many stochastic passes with

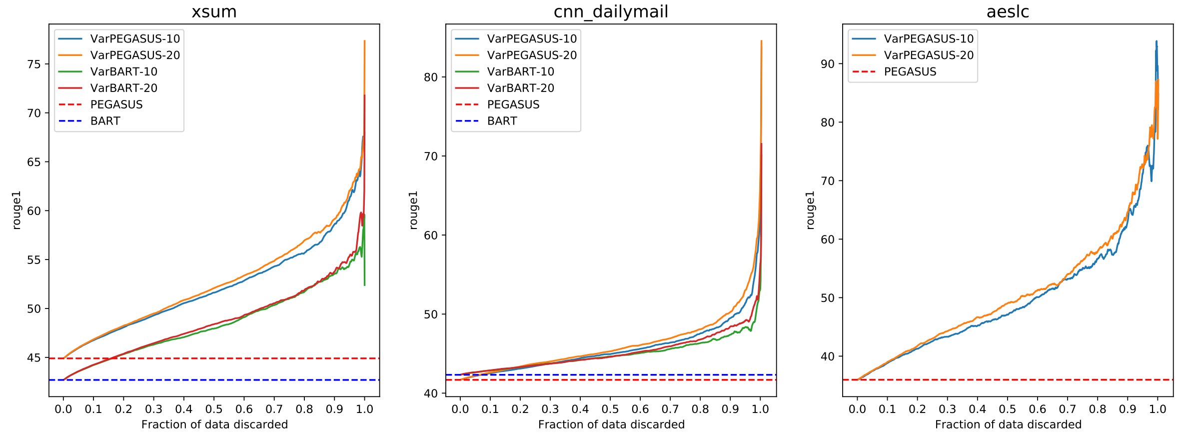

Figure 1: ROUGE-1 scores vs fraction of data discarded due to high BLEUVarN. The straight dashed lines indicate the performance level of the deterministic PEGASUS and BART models.

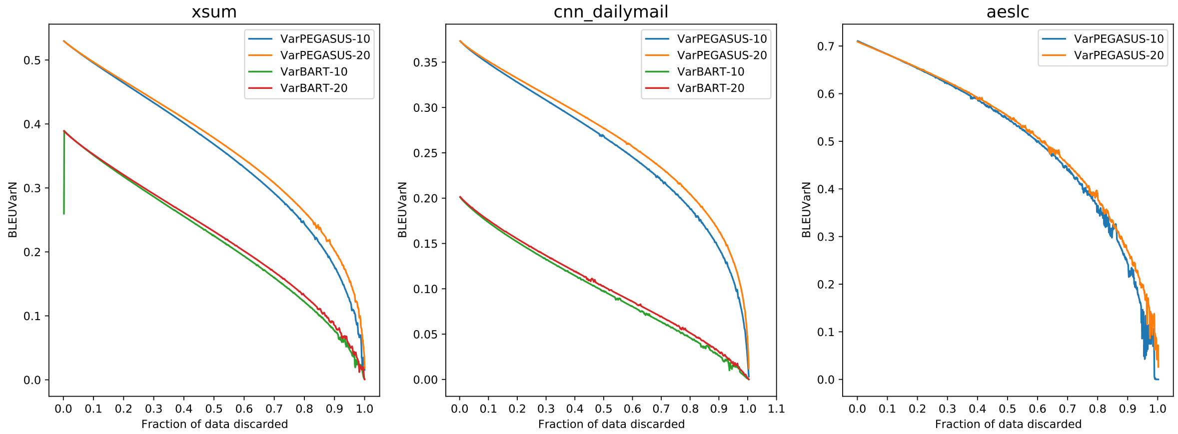

Figure 2: BLEUVarN curves as a function of data discarded due to low ROUGE-1 scores.

MC dropout. However, this computation is embarrassingly parallelizable in modern hardware, and can be easily optimized by batching MC dropout generations with different dropout masks for each sample within the batch.

Although we have shown that MC dropout with 20 samples performs better than 10 samples, we observed that further increasing this number, for example to 30 or 50 samples, was beginning to bring diminishing returns. Furthermore, the performance increase we got by using 10 and 20 samples was substantial enough while the runtimes for MC dropout with more samples were becoming a lot longer. For these reasons we refrained from increasing it even further in order to keep computational capacity manageable.

5.1.2 VarBART vs VarPEGASUS

Out of the two models, VarPEGASUS is consistently showing the biggest increase in performance as more uncertain samples are dropped from the dataset. It should be noted here, that the decline in performance as data uncertainty increases, is much steeper for VarBART than it is for VarPEGASUS on both the XSum and the CNN/DM dataset. This coincides with the fact that VarPEGASUS also has much higher BLEUVarN uncertainty as shown in Figure 2, which hints us that the PEGASUS model is in general less confident about the outputs it generates. Anecdotally, we can say here that PEGASUS is more aware of the things it does not know, and as a result it seems to benefit more from the uncertainty estimates.

5.2 Bayesian vs deterministic summarization

The next experiment focuses on the Bayesian summarization method proposed in Section 3.3. We compare the performance of Bayesian summarization using the VarBART and VarPEGASUS models against the standard summarization paradigm using the deterministic BART and PEGASUS models. Our goal is to verify the efficacy of Bayesian summarization as a post-hoc way of improving summarization performance.

Table 3 reports the ROUGE-1, ROUGE-2 and ROUGE-L F-scores of our VarBART and VarPEGASUS models along with the deterministic BART and PEGASUS models on all benchmark datasets, re-evaluated for consistency. The results show that Bayesian summarization is effective, with both VarBART and VarPEGASUS outperforming their deterministic counterparts on all datasets. Furthermore, increasing the number, N, of samples generated during the Bayesian inference, improves performance for all datasets except for AESLC, at the cost of increased computational complexity as discussed in Section 5.1.

Note that our goal in this work was not to compete with other state-of-the-art models. What we want to show is that relying on the agreement between multiple Bayesian summaries for the same input, is an effective way to boost the summarization performance of deterministic models. Also, this is a post-hoc method and does not involve training new models, which makes it easily applicable to many different scenarios.

Figure 3 plots the difference in ROUGE-1 of each Variational model with its deterministic counterpart versus the fraction of the data discarded due to high uncertainty. Similar plots for ROUGE-2 and ROUGE-L can be found in Appendix A. Positive values indicate that the Variational model achieves a higher score than the deterministic one. These plots give us a better view of how the Variational models fare against the deterministic ones for different levels of uncertainty. As far as we know, this is the first study to directly compare Variational and deterministic models on data with varying levels of uncertainty.

Looking at the curves, we clearly see that the differences are positive for most uncertainty levels but start decreasing as more data with high uncertainty are discarded. For the top $10\% - 20\%$ most certain samples we start seeing a fluctuation between positive and negative values. This pattern is in line with the observations made in Figure 1, and leads us to believe that there is a significant gap between the deterministic model's performance on the 20% most certain samples and the rest of the data.

These observations lead us to the following conclusions. For samples of very low uncertainty, we can expect both Variational and deterministic models to converge to equally good outputs. In contrast, as uncertainty becomes higher, we observe a clear advantage of the Variational summaries over the deterministic ones. This pattern is consistent across all models and datasets, and underpins our case that Bayesian summarization is beneficial for the majority of inputs.

5.3 Qualitative analysis

In order to better illustrate our findings in this work, we present a couple of real examples from VarPEGASUS-10 on XSum. For each example, we show the 10 sample summaries generated with MC dropout for the same input, as well as the corresponding BLEUVarN score. We have highlighted the median summary in bold typeface and for the sake of comparison we also show the summary generated by the deterministic PEGASUS model.

The first example (Table 4) is a case of high uncertainty from the XSum dataset. We can see that all 10 samples are considerably different from one another, which leads to a high BLEUVarN score. In contrast, the second example (Table 5) has much lower uncertainty. In this case all 10 samples seem to mostly agree on the main points and as a result BLEUVarN is fairly low. Here, the median summary is the one that represents better this agreement.

Looking at the ROUGE-1 score for both examples we can see there's a rather drastic difference as well. For the sample in Table 4 we can see that neither the deterministic nor the Bayesian summary show a strong performance, yet even in that case the median Bayesian summary scores a bit higher. On the other hand, the sample in Table 5 showcases a solid performance from both the deterministic and the Bayesian summary. Here it is evident that the median Bayesian summary is close but slightly better than the deterministic summary in terms of ROUGE.

6 Conclusions and future work

This work explored Bayesian methods in the context of text summarization. We extended state-of-

Table 3: A comparison of our VarBART and VarPEGASUS models against the deterministic BART and PEGASUS.

the-art summarization models with MC dropout to approximate Bayesian inference, and demonstrated how BLEUVarN can be used to quantify model uncertainty. This allows us to effectively identify high uncertainty summaries at prediction time, which can be a significant advantage.

Furthermore, we show that ensembling multiple stochastic summaries generated by Variational Bayesian models can lead to improved performance compared to similar deterministic models. This finding is verified by experiments for two different models and across 3 benchmark datasets.

It should be noted here that the proposed methods are directly applicable to other abstractive summarization datasets as well. We acknowledge that some of the more interesting summarization problems involve much longer summaries, for example scientific abstracts. In this work we focused on datasets of short summaries in order to be more resource efficient and conduct more experiments. There's a lot of interesting work that focuses on the summarization of longer documents (Gidiotis and Tsoumakas, 2020; Zaheer et al., 2020) that could potentially be applied in combination with the methods we propose here.

Our work can have a broader impact in several ways. To the research community, being the first work to study Bayesian uncertainty for abstractive summarization and paving the way for other similar methods. To the industry, because it improves automatic summarization systems and can be paired nicely with active learning and human-in-the-loop approaches. Finally, to the end users, improving their experience and building up confidence towards automatic summarization systems.

Abstract

As large and powerful neural language models are developed, researchers have been increasingly interested in developing diagnostic tools to probe them. There are many papers with conclusions of the form "observation X is found in model Y", using their own datasets with varying sizes. Larger probing datasets bring more reliability, but are also expensive to collect. There is yet to be a quantitative method for estimating reasonable probing dataset sizes. We tackle this omission in the context of comparing two probing configurations: after we have collected a small dataset from a pilot study, how many additional data samples are sufficient to distinguish two different configurations? We present a novel method to estimate the required number of data samples in such experiments and, across several case studies, we verify that our estimations have sufficient statistical power. Our framework helps to systematically construct probing datasets to diagnose neural NLP models.

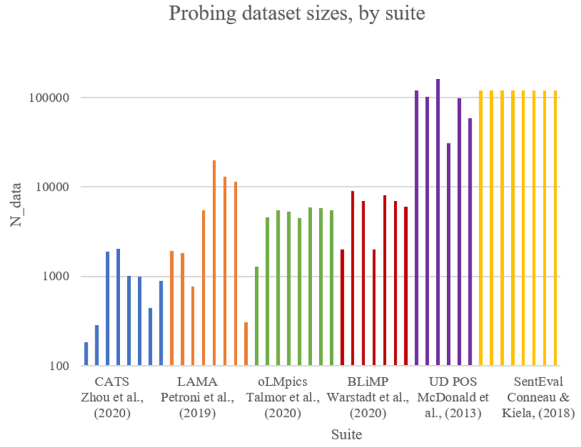

Figure 1: Sizes of the datasets in some common probing suites. Depending on the tasks, they vary from hundreds to larger than 10^5.

1 Introduction

While modern deep neural language models achieve impressive performance on various benchmarking datasets, the question of *how* this is achieved is gaining increased attention. This line of inquiry includes a new avenue of research: probing.

There are many methods to probe a neural network. Among these, diagnostic classification is by far the most common. To probe a neural network in a classification configuration, we specify a classification task that examines an ability (e.g., detecting verb tense). We encode the texts with a deep neural network and apply a post-hoc classifier to the encoded representations. If the classifier can easily predict an attribute, we consider this deep neural network capable of encoding the specified ability. Researchers have expanded the targets of probing classifications to a wide range of abilities including syntax and semantics (Jawahar et al., 2019; Tenney et al., 2019a; Kulmizev et al., 2020; Vulić et al., 2020), discourse (Koto et al., 2021; Zhu et al., 2020; Chen et al., 2019) and commonsense reasoning (Petroni et al., 2019; Lin et al., 2020). These probing papers are associated with datasets of varying sizes, as shown in Figure 1.

What is a suitable size for probing datasets? Larger training datasets lead to tighter generalization bounds. With other conditions fixed, larger testing datasets allow for higher statistical power in comparing probing models and classifiers. That said, it is neither realistic nor desirable to increase the probing dataset sizes arbitrarily. It is therefore essential to find a balanced size for probing classifications.

We propose a framework to formally estimate the data requirements of probing configurations (§3). Our framework considers the scenario of comparing probing configurations given some data. How many additional data samples may be necessary to reliably reproduce this comparison effect? We propose a novel method to estimate the required data samples by adapting a generalization bound.

Findings of the Association for Computational Linguistics: ACL 2022, pages 4132 - 4147
May 22-27, 2022

We evaluate our framework on various probing tasks. First, we verify that the choice of generalization bound agrees with the probing results (§4.2). On a case study recognizing synthetic Gaussian noise, we verify that larger datasets provide higher statistical power (§4.3). We evaluate the utility of our framework on a collection of comparison problems (§4.4 - §4.5), where the probing data sizes recommended by the theoretical framework always supports power larger than 0.8. This paper helps to formalize probing experiments. Our framework can be used by the research community in collecting probing datasets.

2 Related Work

Understanding the datasets There is increased research attention paid to the datasets used for deep learning models. One way to study the dataset is to visualize each of the dataset samples in a map. Swayamdipta et al. (2020) mapped the data samples in NLP datasets to regions such as "hard-to-learn" and "easy-to-learn" using signals observed during the training process. Yauney and Mimno (2021) mapped the difficulty of data samples by the data-dependent complexity (Arora et al., 2019). Vania et al. (2021) used Item Response Theory (Baker and Kim, 2004), a statistical framework from psychometrics to describe various attributes related to the difficulty of test set items. Similarly, researchers also describe the effects of datasets as a whole. Several papers attempted through information theory (Pimentel and Cotterell, 2021; Zhu et al., 2021). Le Scao and Rush (2021) compared the effectiveness of prompts to those of classification samples. When collecting datasets for probing, showing the effect of data is an important goal. Our framework considers the classification data samples, but we do not impose restrictions on the signal to probe in the classification tasks.

Probing methods The probing literature has proposed numerous diagnostic methods. This paper focuses on diagnostic classifiers, where post-hoc classifiers predict labels from representation vectors. These vectors can be a unified representation of a sequence (Conneau and Kiela, 2018; Tenney et al., 2019b), a collection of vectors from different tokens in a sequence (Hewitt and Manning, 2019), or a pair of carefully set-up vectors that contrast between the "control" and the "treatment" (Hewitt and Liang, 2019; Elazar et al., 2021). We defer to Belinkov (2021) for a systematic overview.

Note that there are also many probing papers without post-hoc classifiers (Zhou and Srikumar, 2021; Torroba Hennigen et al., 2020; Li et al., 2021). While many of these do not mention the term "probing", they nevertheless probe the intrinsics of deep neural models. In this paper, we consider only classification-based probing methods. Our framework can generalize to unsupervised probing methods in future work.

Reliability of tests When all data samples follow i.i.d assumptions, larger datasets allow higher reliability. The reliability of testing is essential in quantitative studies, including medical, societal, and educational contexts (Kraemer, 1992; Drost, 2011; Golafshani, 2003). *Reliability* describes how possible the test results can be reproduced. Depending on the forms of these tests, there are many ways to measure reliability. The test-retest reliability (usually quantified by Pearson correlations between the test and the retest results) measures the consistency of the results across time. The internal consistency reliability (usually quantified by Cronbach's α (Cronbach, 1951)) measures the consistency of participants responding to a set of items. The inter-rater reliability (quantified by Cohen's κ (Cohen, 1960) or Krippendorff's α (Krippendorff, 2018)) measures the extent of agreements between the annotators.

To our knowledge, existing works reflecting on the reliability of model diagnostics rely on repeating the tests on a variety of controlled conditions (Aribandi et al., 2021; Novikova, 2021). A larger variance in results indicates lower test reliability. The reliability is related to two other attributes – validity and robustness. *Validity* measures how well the test measures what it intends to measure. In a valid test, the result is right for the right reasons (McCoy et al., 2019; Ravichander et al., 2021). *Robustness* measures how well the results of a test can generalize from the experimental setting to real-world settings (Xing et al., 2020; Niu et al., 2020).

3 Methodology

3.1 Problem statement

Much of probing research considers some form of comparison problem. For example:

- Which deep neural language model encodes certain linguistic signal in an easier-to-extract manner?
- For a neural model, does pretraining with set-

ting A support higher probing classification performances than models pretrained on setting B?

- Is the accuracy of a simple probing classifier (e.g., logistic regressor) higher than a more complicated one (e.g., MLP with hidden layers)?

These problems are instances of comparison problems, where we compare two probing configurations. We formalize them as follows.

Definition 1 (Probing configuration)**.** A *probing configuration* $\mathcal{C}$ consists of $\{T, E, f\}$, where T specifies the probing task (e.g., past-vs-present from the SentEval suite), E is the encoder that encodes the text specified by T into representation vectors (e.g., the output from the 11^{th} layer of BERT_base), and f is the probing classifier.

Remark. Task T can be a text-based classification dataset, with either word inputs or sequential inputs. Here we only consider the classification problems with fixed number of classes. For more complex problems (e.g., generalization problems), the generalization bounds need to be adapted.

Definition 2 (Comparison problem)**.** A *comparison problem* consists of a pair of probing configurations, $\mathcal{C}_A = \{T, E_A, f_A\}$ and $\mathcal{C}_B = \{T, E_B, f_B\}$.

Remark. Usually, the two configurations of a comparison problem, $\mathcal{C}_A$ and $\mathcal{C}_B$ differ by only one of $\{E, f\}$ to avoid confounds. A comparison problem can *collapse* if the two configurations are identical. Recommending the required number of data samples for a collapsed comparison problem is not meaningful.

3.2 An overview of the framework

For researchers collecting a probing dataset, we recommend the following procedure to estimate the probing dataset sizes:

1. Identify a comparison problem by specifying two probing configurations, and collect a small set of data in a pilot study. Using the existing data, run the two probing classifications. Let R_1 and R_2 denote the probing performances, respectively.
2. When $|R_1 - R_2|$ is small, it is likely that the comparison problem collapses – §3.6 describes some heuristics to verify.
3. When the comparison problem has a difference in the performances $|R_1 - R_2|$, our framework can recommend the data requirements: Plug in $\frac{|R_1 - R_2|}{2}$ to the generalization bounds to retrospectively solve for a recommendation of train data size N_{train}. §3.3 elaborates the generalization bounds in probing classifiers. §3.4 presents numerical examples.
4. Without loss of generality, we assume that the train, validation, and test data have relative sizes of $\eta : 1 : 1$. Then $(1 + \frac{2}{\eta})N_{\text{train}}$ is the total data requirement.

3.3 Generalization bounds

Machine learning theory literature provides many generalization bounds. These bounds usually occur in the following form:

$$\mathbb{P}\left(|R(\hat{f}) - R(f_*)| > B(n, \delta)\right) < \delta, \qquad (1)$$

where f is the classifier, $R(\cdot)$ is the risk, n is the number of training data points, and δ is a hyperparameter. Given n, a generalization bound states that, with a probability of at least $1 - \delta$, the risk of the empirically optimal classifier $R(\hat{f})$ differs from the risk of the globally optimal classifier $R(f_*)$ by at most $B(n; \delta)$. The risk is usually assumed to refer to the cross entropy loss. We show that several metrics used in probing have bounds with the form as well.

Accuracy The most widely used scores to measure the probing performance include accuracy, precision, recall, and F1 score. If we substitute the risk with accuracy, the bounds can apply without loss of generality, modulo two differences: accuracy (etc.) is bounded by $B = 1$ (whereas the upper bounds for loss could be larger), and is the highest with f_* (whereas the loss is the lowest with f_*).

Note that most behavioural probes[1] use evaluation metrics in this category. Many structural probes use additional evaluation metrics. We discuss them below.

Control tasks It is possible that the probes, as diagnostic classifiers, rely on some irrelevant dataset statistics to boost the performance. To factor out this effect, Hewitt and Manning (2019) proposed to use control tasks. In a control task setting, we need to set up an auxiliary diagnostic classification task, and take the difference of the two classifications. Note that the difference is related to information theoretic terms (Pimentel et al., 2020b; Zhu and Rudzicz, 2020). Regardless, their formulations

---

[1] as described in Belinkov et al. (2020)

involve some intractable terms that have to be empirically ignored.

Dependent on the goal of the tasks, there are different ways to set up the auxiliary task. In the part-of-speech (PoS) probing task, for example, Hewitt and Manning (2019) associated each word type to a fixed PoS label. Another example is amnesic probing (Elazar et al., 2021), which uses iterative null-space projection (Ravfogel et al., 2020) to remove the probing task information from the representations.

Theorem 1. *The probing results for control tasks are subject to the generalization bounds in the following form:*

$$\mathbb{P}\left(|R(\hat{f}) - R(f_*)| > 2B(n, \delta)\right) < \delta \quad (2)$$

Proof. The proofs of all theorems are listed in Appendix B.

Minimum description length Recently, Voita and Titov (2020) presented an alternative viewpoint of structural probing based on the minimum description length (MDL). The MDL of a probe or classifier is defined by the sum of (a) the code length required to transmit the data, and (b) the code length required to transmit the model for compressing the data. Voita and Titov (2020) gives two ways to approximate the MDL values: variational and prequential.

The *variational MDL* consists of two terms: the cross entropy loss $L(\hat{f})$, and the KL divergence between the posterior (β) and prior distribution (α) of the model parameters θ.

$$MDL_{\text{var}} = L(\hat{f}) + KL(\beta_\theta \parallel \alpha_\theta)$$

Theorem 2. *The probing results of variational MDLs subject to the identical bounds as Eq. 1.*

The *prequential MDL* computes the code length required in this "transmission protocol". First, transmit the first t_1 data points using random coding. Then, optimize the model with the transmitted data, and transmit the next portion with the new model. The first portion t_1 constitutes of as few as 0.1% of the dataset.

$$\begin{aligned} MDL_{\text{pre}} &= t_1 \text{log} K - \\ &\sum_{i=1}^{S-1} \text{log} p_{f_i}(y_{t_i+1..t_{i+1}} | x_{t_i+1..t_{i+1}}) \\ &= t_1 \text{log} K + \sum_{i=1}^{S-1} R(f_i; n_i) \end{aligned}$$

Theorem 3. *The generalization bound for prequential MDL takes the following form:*

$$\mathbb{P}\left(|R(\hat{f}) - R(f_*)| > \frac{Cn}{t_1} B(n, \delta)\right) < \delta, \quad (3)$$

where C is a constant.

3.4 From generalization bounds to training data requirement

To estimate the required number of training data samples n, we can fix δ and enforce an upper bound on the excess risk $|R(\hat{f}) - R(f_*))|$. Then the corresponding n would be the required number of training data samples. Following is a numerical example where we consider the textbook finite function space bound[2]:

$$\mathbb{P}\left(|R(\hat{f}) - R(f_*)| > B\sqrt{\frac{2\text{log}\frac{2|\mathcal{F}|}{\delta}}{n}}\right) < \delta.$$

Here, we set $\delta = 10^{-8}$. In a probing classification configuration $\mathcal{C} = \{T, E, f\}$, the encoder E produces vectors with $D = 768$ dimensions and f is a logistic regressor. Additionally, we assume that the $D + 1$ weight parameters in f are stored in 32-bit floating point numbers[3], so each weight parameter takes 2^{32} possible values. Then the probing classifier constitutes a finite space with cardinality $|\mathcal{F}| = 2^{32} \times (D + 1)$.

When there are $n = 65,536$ training data points, with probability of at least $1 - 10^{-8}$, the empirically optimal accuracy is different from the global minimum by at most 0.039 for $D = 4,096$ (InferSent) classifications.

More importantly, we can also plug in an expectation on the generalization bound to retrospectively solve for the training data requirement. For example, a bound of 0.05 requires $N = 40$k i.i.d data samples at $D = 4,096$.

If the datasets for both probing configurations in a probing classification are sufficiently large, the generalization bounds would be sufficiently small, so that the result of the comparison problem is reliable. As a heuristic, we let the bound be $\frac{|R_1 - R_2|}{2}$, where R_1 and R_2 are the probing performances from the existing datasets.

A tighter bound (e.g., $\frac{|R_1 - R_2|}{10}$) requires more data samples (hence larger statistical power) as well

---

[2] This bound assumes that classifiers f come from a finite space $\mathcal{F}$. We defer to Theorem 7 of Liang (2016) for details. In the rest of this paper, we use this finite function class bound.

[3] Following PyTorch's default for `FloatTensor`.

as higher expectation for budgets. We consider $\frac{|R_1-R_2|}{2}$ to be a balanced choice. Following are some justifications.

In the most ideal case, both R_1 and R_2 are the true global minima $R(f_*)_1$ and $R(f_*)_2$, then the comparison results will remain consistent regardless of the number of data samples.

In the less ideal case, both R_1 and R_2 are the empirical minima $R(\hat{f})_1$ and $R(\hat{f})_2$, then a generalization bound of $\frac{|R_1-R_2|}{2}$ guarantees that the relative preference in the comparison will remain consistent (yet the scale of the comparison may fluctuate). We expect that most probing classifiers resemble this scenario, since they reach almost perfect training accuracies.

In the most unfortunate case, R_1 and R_2 deviate from the empirical minima. The extent they differ contributes to the randomness. While the scales of the empirical imperfectness remain unknown, one can consider some heuristics reduce this imperfectness. First, a probing classifier with higher accuracy tend to have smaller empirical imperfectness, hence smaller unknown instability. Second, identifying the collapsed comparisons helps reduce the uncertainties introduced by the classifier imperfectness.

3.5 Power analysis

We use power analysis to evaluate the reliability of our data recommendations. For a statistical test, the power is the probability of correctly rejecting the null hypothesis. In the context of this paper, we compare the reliability of the prediction results provided by two probing configurations, $\mathcal{C}_A$ and $\mathcal{C}_B$. The hypothesis is stated as follows.

H_0: On a test set $\{x_i\}_{i=1}^{M}$, the results f_A and f_B are not significantly different.

To accept or reject H_0 on the two probing classifiers, one can apply the McNemar's test (McNemar, 1947), which checks if the χ^2 statistic is significant. The χ^2 can be computed as $\chi^2 = \frac{(p_{01}-p_{10})^2}{p_{01}+p_{10}}$, where $p_{00}, p_{01}, p_{10}, p_{11}$ are the probabilities specified by the contingency table (Table 1).

	f_B incorrect	f_B correct
f_A incorrect	p_{00}	p_{01}
f_A correct	p_{10}	p_{11}

Table 1: Contingency table between two probing results, f_A and f_B.

Card et al. (2020) described a framework that estimates the power by simulation. One repetitively samples a portion of test data and computes χ^2. The portion of simulations with significant χ^2 is taken as the estimated power. Empirically, one runs multiple classifications with distinct random seeds to increase robustness. To account for multiple classifications, we run the simulations of Card et al. (2020) for each random seed, and then count the total number of significant simulations to compute the power. Usually, we expect that a reliable decision to reject the null hypothesis should have a statistical power of at least 0.8.

3.6 Detecting collapsed comparison problems

When we have data for a comparison problem from a "pilot study" and observe very small classification performance differences (e.g., of 0.5%), we might fall back to the null hypothesis – that the comparison problem collapses – in this case, increasing the data size does not "uncollapse" this comparison problem. Here we describe some heuristics to increase the confidence of detecting a collapse.

In our experiments, our data are subsampled from a larger dataset, so we can test if a probing configuration collapses by repeatedly subsampling the data, and run statistical tests. In the real-world, this is similar to running multiple "pilot studies" and collecting small-scale probing data, repeatedly. If the probing configurations output almost indistinguishable results, one can infer that the probing configuration collapses.

Alternatively, one can consider this augmentation method based on cross validation folds. For each dataset in a comparison problem, we divide it into, e.g., 6 folds. For each of $i = 1..6$ runs, take Fold i as the validation split, Fold $(i+1)$ mod 6 as the test split, and the rest as the train split. Considering the probing classification results of all 6 runs can lead to higher confidence.

4 Experiments

4.1 Data and Models

Probing task We run probing classifiers on several classification tasks in one of the largest existing probing suites, SentEval (Conneau and Kiela, 2018): Past_present (tense prediction), bigram_shift (whether two words are flipped in a sentence), and coordination_inversion (whether two sentences are flipped) are binary classification tasks with 120k samples per class. Sentence_length contains 6 classes with 12k samples per class. To test the data requirements, we stratify sample subsets with $\{2^7, 2^9, 2^{11}, 2^{13}, 2^{15}\}$ training data samples per class, where applicable[4].

Encoders

- BERT (Devlin et al., 2019) is a contextualized language model. We take the multilingual $\text{BERT}_{\text{base}}$ model.
- SBERT (Reimers and Gurevych, 2019) encouraged semantically similar sentences to be mapped to nearby vectors in the representation space.
- GloVe (Pennington et al., 2014) is a static word embedding model. It maps each token to a fixed, 300-dimensional vector. We average all embedding vectors of a SentEval sequence as the input representation.
- InferSent (Conneau et al., 2017) is a contextualized language model. It processes the GloVe embeddings with a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) with 2,048 hidden dimensions.

Probing classifiers We use a logistic regressor and a multilayer perceptron (MLP) with 20 hidden units (§4.6) as probing classifiers. In addition, we run several MDL probes, whose results are described in Appendix C.5.

4.2 Verifying the theoretical bounds

We run probing classifications using a collection of subsets. Each subset is subsampled in a stratified manner from the dataset. We run 5 probing classifications with different random seeds on each subset.

To qualitatively examine the extent that the generalization bounds agree with the probing classifications, we plot both the empirical and the theoretical margins. Figure 2 shows an example. Appendix C.1 contains additional plots. The empirical classification results reside within the theoretical margins, except for an outlier classification trial – this is the classification suboptimality, and we extend the discussion in Appendix D.1.

4.3 Larger datasets support higher power

Intuitively, adding noise into the representation vectors makes it harder to decode the referential attribute. In this case study, we add Gaussian noise drawn from $\mathcal{N}(0, \sigma^2)$, where $\sigma^2 \in \{.01, .03, .1, .3, 1, 3\}$, and compare against the probing classification with the original representations. Figure 3 shows the effect of noise on a configuration. Appendix C.2 contains additional figures. Adding noise with a larger scale results in a configuration that is easier to distinguish. In addition, a larger training dataset usually leads to a higher power to distinguish the configurations.

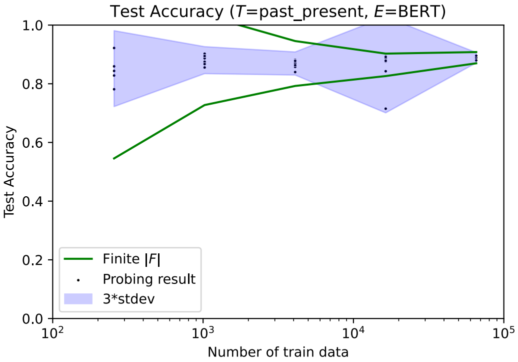

Figure 2: Theoretical bounds vs. empirical results on $T = \text{past\_present}$, $E = \text{BERT}$, and $f = \text{LogReg}$. The purple regions represent the empirical margin (mean ± stdev), while the green lines are the empirical mean ± margins computed by the learning theory bound.

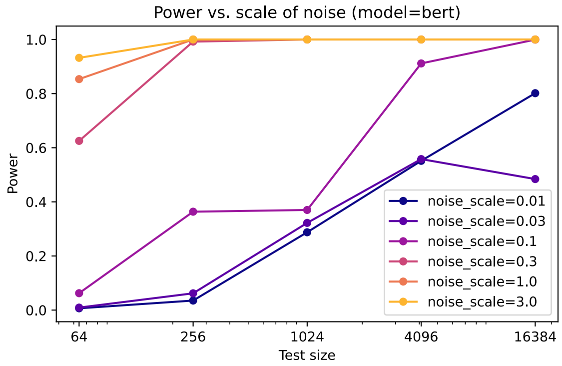

Figure 3: The powers to distinguish the representations with Gaussian noise from the original representations, for $T = \text{past\_present}$, $f = \text{LogReg}$, and $E = \text{BERT}$.

This case study shows that we can verify the data requirement by incrementally collecting larger datasets for comparisons until we have sufficient power. For example, on the tense prediction task, distinguishing GloVe embeddings from its counterpart with $\mathcal{N}(0, 0.1)$ noise, $1,024$ testing data samples is sufficient to lead to 0.8 power. However, the same comparison with $\mathcal{N}(0, 0.03)$ noise

---

[4] When there are 2^7 train sample per class, the subset consists of 256 train samples, 64 dev and 64 test samples, all with evenly distributed labels. i.e., $\eta = 4$. In this paper, we keep this ratio consistent.

requires up to $16,384$ testing data points.

The scale of Gaussian noise constitutes a spectrum. When we keep reducing the Gaussian scale, the comparison problem becomes more data-hungry. This leads to a question: where, on the "min-max" spectrum, do some other comparison settings (e.g., comparing between encoders) reside? In subsequent case studies, we verify that the numbers predicted by learning theory bounds have sufficient power.

4.4 Comparing to corrupted encoders

In this case study, we finetune the BERT models on WikiText[5] sentences with scrambled tokens for 200 steps.

Table 2 shows the recommended N_{train} values in the probing comparisons with corresponding "pilot data" (subsampled) sizes. As shown in Figure 4, the probing datasets with sizes no fewer than $N_{\text{test}} = 256$ (i.e., $N_{\text{train}} = 1024$) have sufficient power, and all recommended values fall within the "sufficient-power" range.

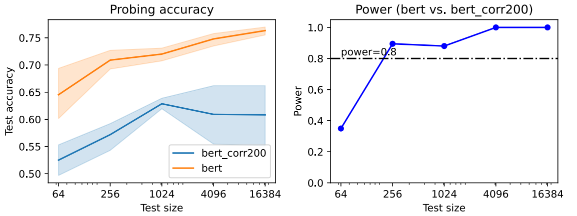

Figure 4: Left: the probing accuracies of BERT (orange) and BERT "corrupted" by 200 steps (blue). $T =$ bigram_shift, $f =$ LogReg. Right: the power to compare between them.

Subsampled N_{test}	Mean $\lvert R_1 - R_2 \rvert$	Recommended N_{train}
64	.1313	22,263
256	.1281	23,362
1,024	.0879	49,647
4,096	.1331	21,662
16,384	.1488	17,331

Table 2: The recommended N_{train} values in the comparison problem in Figure 4 given different subsample sizes.

4.5 Comparing between encoders

In this case study, we compare pairs of configurations containing the same task, data, and probing classifier but different encoders. Figure 5 shows an example. A test set of size $N_{\text{test}} = 1,024$ does not have sufficient power to compare the probing accuracy of BERT vs. GloVe, but $N_{\text{test}} = 4,096$ does. This corresponds to $N_{\text{train}=16,384}$, indicating that the recommendations in Table 3 are sufficient. Appendix C.3 contains two other examples supporting the same finding.

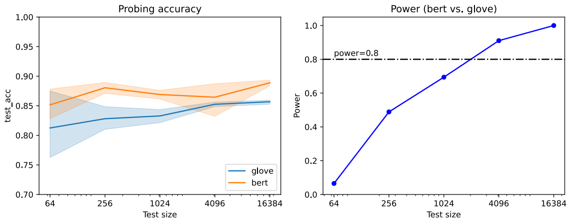

Figure 5: Left: the comparison of accuracies between BERT (orange) and GloVe (blue). $T =$ past_present, $f =$ LogReg. Right: the power of this comparison. The probing classification accuracy of BERT is higher than that of GloVe, but we do not have enough power to identify that until the testing dataset size is increased to $N_{\text{test}} = 4,096$.

Subsampled N_{test}	Mean $\lvert R_1 - R_2 \rvert$	Recommended N_{train}
64	.0344	324,563
256	.0492	158,315
1,024	.0355	303,516
4,096	.0091	4,600,037
16,384	.0320	373,513

Table 3: The recommended N_{train} values in the comparison problem in Figure 5 given different subsample sizes.

4.6 Comparing between classifiers

Here, we compare two probing configurations with different classifiers: LogReg vs. MLP with one hidden layer of $H = 20$ neurons. Although the two configurations involve the same task, they have different training data requirements[6]. We take the larger one as the recommendation. Table 4 recommends N_{train} that are larger than the SentEval dataset sizes. These numbers are actually not necessary – Figure 6 shows that $N_{\text{test}} = 16.4$k (corresponding to $N_{\text{train}} = 65.6$k) is still insufficient to distinguish the results of the two probing classifier configurations on the bigram_shift task. There is insufficient evidence to reject the null hypothesis.

---

[5] `wikitext-2-v1` from huggingface datasets (Lhoest et al., 2021).

[6] The LogReg has $D + 1 = 799$ parameters, while the MLP has $(D + 1)H + H + 1 = 15,401$, leading to a larger data requirement.

In other words, the comparison problem between LogReg vs. MLP on $T =$ bigram_shift collapses[7]. The exceedingly large data recommendations are meaningless.

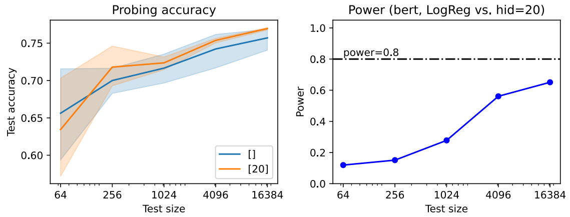

Figure 6: A comparison between probing classifiers. $T =$ bigram_shift, $E =$ BERT, $f = \{$LogReg (blue) vs. MLP (orange)$\}$.

Subsampled N_{test}	Mean $\lvert R_1 - R_2 \rvert$	Recommended N_{train}
64	.022	801,472
256	.018	1,187,812
1,024	.007	7,757,460
4,096	.012	2,912,787
16,384	.013	2,444,949

Table 4: The recommended N_{train} values in the comparison problem in Figure 6 given different subsample sizes.

5 Discussion

What does a high accuracy entail? Our framework implicitly considers the probing classification performances, but the causal relationship between, e.g., the accuracy, the data requirements, and the reliability can be explored further in future frameworks. A high probing accuracy indicates a small empirical risk $R(f)$. This could result from a small $|R(f) - R(\hat{f})|$ (the probe "learns the task"), or a small $R(\hat{f}) - R(f_*)$ (the distribution of the data samples represent the "true distribution" well). The two possibilities resemble the dichotomy raised by Hewitt and Liang (2019), but do they describe the same phenomenon? We leave this as an open question to future researchers.

On the stability of theoretical recommendations How stable are our theoretical recommendations? For those comparisons with sufficient evidence to reject the null hypotheses, the recommended N_{train} sometimes varies (e.g., at $N_{\text{test}} = 4096$ in Table 3). This is brought in by the suboptimality of several probing classifications. We extend the discussions about how to interpret and reduce classifier suboptimality in Appendix D.1. Future methods to estimate data requirement may improve the stability.

Cross-task comparison problems Our framework does not consider cross-task comparison, i.e., when comparing $\mathcal{C}_A = \{T_A, E_A, f_A\}$ vs. $\mathcal{C}_B = \{T_B, E_B, f_B\}$ where $T_A \neq T_B$, because McNemar's test requires pairwise data. Alternative power tests would be necessary to consider cross-task comparison problems. We leave this to an open problem for future research.

Why not just collect as much data as possible? We argue in favor of knowing how many data samples we need, instead of directly collecting as many samples that budgets allow. The two views resemble the "top-down" vs. "bottom-up" research approaches mentioned in Bender and Koller (2020). Practically, our experiments show that many comparison problems do not need as many data samples as the sizes of some existing large probing datasets.

A "recipe" for probing datasets To systematically probe the linguistic abilities of neural networks, many more datasets need to be collected. To make the probing dataset collection procedure systematic, a complete "recipe" would be beneficial. Several recent papers called for this goal (Ethayarajh and Jurafsky, 2020; Rodriguez et al., 2021). Our framework is one component of such a recipe, by quantifying questions of dataset sizes. Additional components for future work include quantifying the label distributions and the inherent 'difficulties' of samples.

6 Conclusion

This paper presents a novel framework to estimate the data requirements for probing experiments. This framework uses generalization bounds from formal learning theory to determine minimum training set sizes. In a series of comparison problems, we verify that our recommendations provide sufficient power. Our framework describes an actionable procedure to double check if an experiment needs additional data samples to be scientifically meaningful. Additionally, this paper calls for further attention to complete a systematic methodology in evaluating probing datasets and methods.

---

[7] Note that LogReg vs. MLP on other tasks e.g., $T =$ sentence_length do not collapse. We include the results in Appendix C.3.

.

A Probing is a unique classification problem

The learning theory literature provides a rich collection of theories for classification. One might consider that these theories can directly apply to probing classifiers, but we argue for the alternative. Compared to conventional classifiers, the probing classifiers differ in many aspects. Following are some of them.

Goals. Conventional classifiers try to reach high performance on both the experimental and the real-world data distribution. Probing classifiers, while also maximize the probing performance, aim at quantifying the "easiness to decode" from the input representations (Belinkov, 2021). Therefore, some papers (e.g., Hewitt and Liang (2019)) argued in favor of selectivity. A highly selective probe should output results that differ a lot between hard-to-decode and easy-to-decode representations.

Models. In general, conventional classifiers use models with many more parameters than probing classifiers. Researchers have raised several concerns for larger probing classifiers. First, larger probing classifiers may "learn the task", introducing a confounding factor in the result interpretation: a high probing classification performance could result from the probe itself "learns the task". Hewitt and Liang (2019) raised this hypothesis, and Zhu and Rudzicz (2020) confirmed from an information-theoretic perspective. Second, larger probing classifiers require more data to train, which slows down the diagnosis procedure. Ideally, the computation effort spent in diagnosis should be much smaller than training the neural models.

Datasets. The data to train a conventional classifier should be abundant, so the classifier could learn sufficient inductive bias that can generalize beyond the experimental conditions. The data to train a probing classifier, however, should contain a collection of specific "test cases", covering the "corner cases" of the deep neural models, akin to the diagnostic suites in software engineering (Ribeiro et al., 2020).

Considering the differences, it is necessary to formulate a framework to study the validity of probing rigorously. Adapting the tools in machine learning theory can be a good start.

B Proofs of theorems

Theorem 1. *The probing results for control tasks are subject to the generalization bounds in the following form:*

$$\mathbb{P}\left(|R(\hat{f}) - R(f_*)| > 2B(n, \delta)\right) < \delta \quad (2)$$

Proof. Let us use A_o and A_c to denote the original and the control task performance, and $\hat{f}$ and f_* (and $\hat{f}_c$ and $\hat{f}_{c*}$ for control task) to denote the empirical and the optimal classifier, respectively.

Since both A_o and A_c are count-based metrics, the aforementioned analysis gives us $|A_o(\hat{f}) - A_o(f_*)| \leq B_o$, and $|A_c(\hat{f}_c) - A_c(f_{c*})| \leq B_c$ with probabilities $1 - \delta_o$ and $1 - \delta_c$ respectively.

Then, with probability $(1 - \delta_o)(1 - \delta_c)$, we have $|A_o(\hat{f}) - A_c(\hat{f}_c) - (A_o(f_*) - A_c(f_{c*}))| \leq B_o + B_c$. In other words, a bound with the same form, hence the same convergence rate, as the count-based metrics still applies to the results of control tasks. □

Theorem 2. *The probing results of variational MDLs subject to the identical bounds as Eq. 1.*

Proof. The generalization error of variational MDL is bounded by that of $R(\cdot)$, plus the estimation uncertainty of $\text{KL}(\beta_\theta \parallel \alpha_\theta)$. In a Bayesian network implementation, the $\text{KL}(\beta_\theta \parallel \alpha_\theta)$ can be acquired with less than 2e-3 variance (Molchanov et al., 2017), bringing in a negligible additional uncertainty. In short, the generalization of variational MDL is bounded by the cross entropy term. □

Theorem 3. *The generalization bound for prequential MDL takes the following form:*

$$\mathbb{P}\left(|R(\hat{f}) - R(f_*)| > \frac{Cn}{t_1} B(n, \delta)\right) < \delta, \quad (3)$$

where C is a constant.

Proof. Following likewise analysis, the generalization error of individual loss term is bounded by $\epsilon(n_i) = R(f_i; n_i) - R(f_{i*}) \leq B(n_i, \delta)$ with probability of at least $1 - \delta$.

Using a union bound, the error of summing up all these terms is bounded by the sum of all individual bound. The error bound of prequential MDL is dominated by the first a few terms (i.e., the cross entropy losses with $n = \{0.1\%, 0.2\%, ...\}N$). □

Remark. Naturally, the theoretical bounds for prequential MDL appear "looser" than the bounds of previous metrics.

C Additional experiment details

C.1 Theory bounds vs experiment plots

We include additional theory vs. experiment plots in Figure 7. The purple regions represent the em-

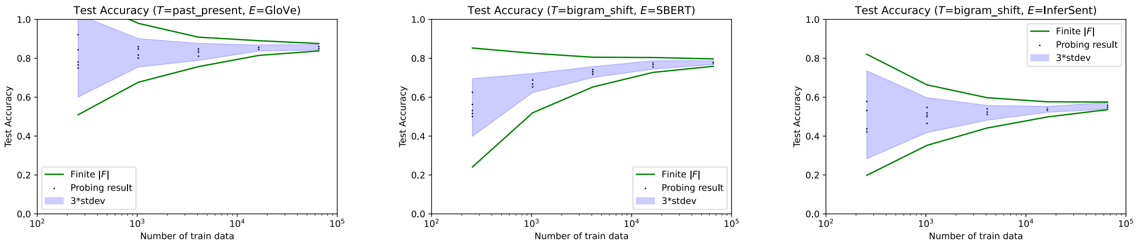

Figure 7: Theoretical bounds vs. empirical results, with f = LogReg. Left: T = past_present, E = GloVe. Middle: T = bigram_shift, E = SBERT. Right: T = bigram_shift, E = InferSent.

pirical margin (mean ± stdev), while the lines represent the margins predicted by the empirical mean ± the learning theory bound.

C.2 Power vs scale of noise plots

We include additional power vs. scale of noise plots in Figure 8.

C.3 Results on additional tasks

We list some results of additional tasks here:

- Table 5 and Figure 9 for T=sentence_length, BERT vs InferSent, f=LogReg.
- Table 6 and Figure 10 for T=coordination_inversion, BERT vs InferSent, f=LogReg.
- Table 7 and Figure 11 for T=sentence_length, E=BERT, LogReg vs MLP.

Subsampled N_{test}	Mean $\lvert R_1 - R_2 \rvert$	Recommended N_{train}
192	0.065	95,156
768	0.128	24,375
3,072	0.178	12,481
12,288	0.196	10,285

Table 5: The recommended N_{train} values in the comparison problem in Figure 9. Given different subsample sizes, the recommended N_{train} are greater than $3,072$ (i.e., $N_{\text{test}} > 768$). Their statistical powers are greater than 0.8.

Subsampled N_{test}	Mean $\lvert R_1 - R_2 \rvert$	Recommended N_{train}
64	0.025	635,040
256	0.019	1,128,961
1,024	0.041	231,499
4,096	0.051	151,861
16,384	0.063	100,153

Table 6: The recommended N_{train} values in the comparison problem of Figure 10. These values correspond to $N_{\text{train}} > 4096$, indicating statistical powers of greater than 0.8.

Subsampled N_{test}	Mean $\lvert R_1 - R_2 \rvert$	Recommended N_{train}
192	0.049	40,001
768	0.030	105,979
3,072	0.029	114,746
12,288	0.025	148,437

Table 7: The recommended N_{train} values in the comparison problem of Figure 11. The accuracies from MLP are higher than that of LogReg, but we do not have sufficient power until $N_{test} = 3,072$. This corresponds to $N_{train} = 12,288$, which the recommended N_{train} satisfy.

C.4 Hyperparameter configurations

We use Ray Tune to find the optimal hyperparameters for training. The search space include:

- Learning rate: 1e-4, 5e-4, 1e-3, 5e-3, 1e-2
- Batch size: 8, 16, 32, 64
- Number of epochs: we set it to 50. We stop running when the validation loss reaches a plateau for 5 epochs. Then, we report the result from the epoch with the highest validation accuracy.

We use pytorch to implement the models, and Adam (Kingma and Ba, 2014) to optimize. To reduce the training time, we cache the representation vectors. The runtime is about one minute per 200 training data points. Our analysis scripts are available at `https://github.com/SPOClab-ca/probing_dataset`.

C.5 Other probing methods

To show the generalizability of our framework, we extend the experiments to two probing classifiers motivated by minimum description lengths: variational and prequential MDL probes (Voita and Titov, 2020). For the variational MDL probe, its results are affected by the arbitrary choice of prior (Pimentel et al., 2020a). Empirically, when we apply a uniform prior, the variational MDL usually

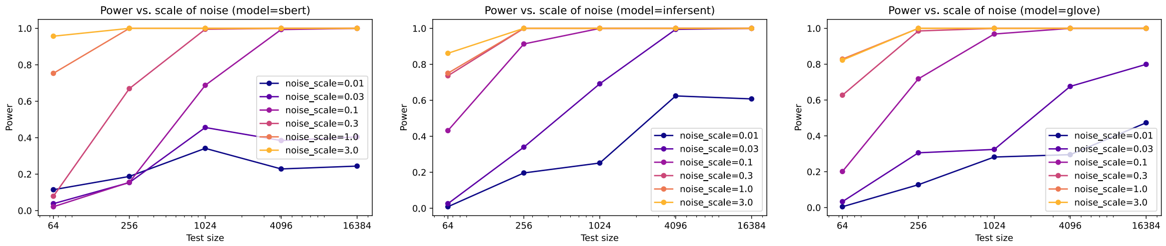

Figure 8: Additional power vs. scale of noise plots, on T = past_present, f = LogReg. Left: E = SBERT. Middle: E = InferSent. Right: E = GloVe.

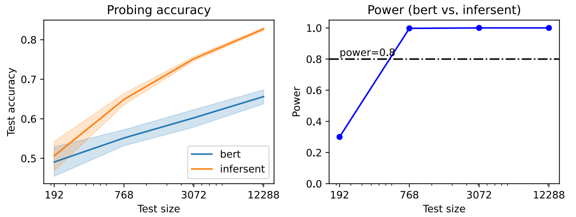

Figure 9: An example for T = sentence_length. Left: the probing performance of BERT (blue) and InferSent (orange). Right: the statistical power in this comparison.

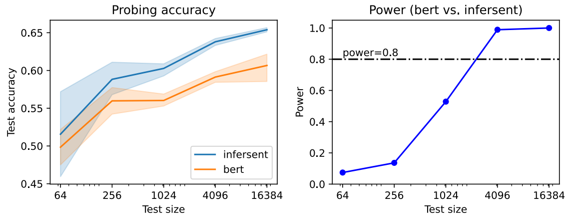

Figure 10: An example for T = coordination_inversion. Left: the probing performance of BERT (orange) vs. InferSent (blue). Right: the statistical power in this comparison.

degenerates[8], resulting in 0.5 accuracy. To alleviate this problem, varying of hidden layers and neurons in the probing classifiers is beneficial. For the prequential MDL probes, the results depend on the input sequence of data. Lovering et al. (2021) mentioned that the early steps sometimes produce cross-entropy losses that are larger than the uniform coding codelength. We also observe this effect, especially when the early steps contain imbalanced data.

D Additional discussions

D.1 The suboptimality of probing classifier results

The probing classifiers are usually imperfect. Due to the presence of, e.g., degenerative runs and local minima, the empirical result $R(f)$ may be different from the empirical optimum $R(\hat{f})$. While $R(f_*)$ describes the probing classification goal, the "easiness to extract", only $R(f)$ is empirically visible. As illustrated in Figure 12, the difference between the measured values $R(f)$ and the true global minimum $R(f_*)$ can be decomposed into two parts: $R(\hat{f}) - R(f_*)$, which is bounded by the generalization bounds, and $R(f) - R(\hat{f})$, which is the the empirical imperfectness.

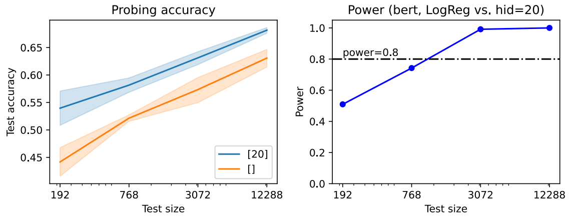

Figure 11: An example for T = sentence_length. Left: the probing performance of f=LogReg (orange) vs. f=MLP (blue). Right: the statistical power in this comparison.

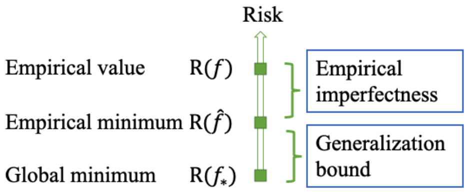

Figure 12: An illustration of the risk values.

E Current sizes of some probing datasets

This section surveys some commonly used probing datasets, as well as their sizes. Table 8 lists the number of classes and the total number of samples. As listed in the table, most probing classification tasks contain more than enough data for, e.g., comparing BERT vs. InferSent. Regardless, we recommend that future researchers to consider the

data requirements for reliability when collecting probing datasets.

Here is how we count the numbers of data samples: For SentEval (Conneau and Kiela, 2018), each data sample contains a text sequence and a label. Universal Dependencies (McDonald et al., 2013) contains rich annotations, and have been used as, e.g., the part-of-speech tagging probing task (Pimentel et al., 2020b). Here we count the number of words in the train, validation, and the test set respectively. For BLiMP (Warstadt et al., 2020), there are multiple "phenomenon" categories for each task, with 1,000 pairs in each phenomenon. The oLMpics (Talmor et al., 2020) suite splits the task datasets train and test divisions, and we list the numbers of both.

Abstract

Recent Quality Estimation (QE) models based on multilingual pre-trained representations have achieved very competitive results in predicting the overall quality of translated sentences. However, detecting specifically which translated words are incorrect is a more challenging task, especially when dealing with limited amounts of training data. We hypothesize that, not unlike humans, successful QE models rely on translation errors to predict overall sentence quality. By exploring a set of feature attribution methods that assign relevance scores to the inputs to explain model predictions, we study the behaviour of state-of-the-art sentence-level QE models and show that explanations (i.e. rationales) extracted from these models can indeed be used to detect translation errors. We therefore (i) introduce a novel semi-supervised method for word-level QE; and (ii) propose to use the QE task as a new benchmark for evaluating the plausibility of feature attribution, i.e. how interpretable model explanations are to humans.

1 Introduction

Quality Estimation (QE) is the task of predicting Machine Translation (MT) quality at inference time, when no gold standard human translation is available (Blatz et al., 2004; Specia et al., 2009). QE can be framed as a word-level or a sentence-level task. Both tasks have numerous practical applications, such as deciding whether a given MT output can be published without editing, highlighting potential critical errors. Current QE approaches fine-tune powerful representations from pre-trained multilingual encoders such as BERT (Devlin et al., 2018) or XLM-R (Conneau et al., 2019). In the recent Shared Task on QE at WMT2020 (Specia et al., 2020) these approaches have achieved very high performance at predicting sentence-level translation quality (up to 0.9 Pearson correlation with human judgements for some language pairs). However, as evidenced by these results, the accuracy of word-level prediction still leaves room for improvement. This is partly due to the limited amount of training data. Word-level error annotation is especially time-consuming and expensive, as it requires work from bilingual experts. In this work we introduce a new semi-supervised approach to word-level QE that removes the need of training data at word level. To achieve this, we propose addressing QE as a rationale extraction task (Lei et al., 2016).

Explainability is a broad area aimed at explaining predictions of machine learning models (Lipton, 2016). Rationale extraction methods achieve this by selecting a portion of the input that justifies model output for a given data point. In translation, human perception of quality is guided by the presence of translation errors (Freitag et al., 2021). We hypothesize that sentence-level QE models also rely on translation errors to make predictions. If that is the case, explanations for sentence-level predictions can be used to detect translation errors, thus removing the need for word-level labeled training data. To extract model explanations, we use *post hoc* rationale extraction methods (Sundararajan et al., 2017) which try to explain the predictions of a given model (as opposed to modifying its architecture or introducing constraints during training), since one of our goals is to study to what extent existing QE models rely on the same information as humans to make predictions.

At the same time, by using word-level errors as explanations for sentence-level QE scores, we introduce a new benchmark for evaluating explainability methods. Recent work has introduced various datasets for measuring the agreement between rationales extracted from NLP models and those provided by humans (DeYoung et al., 2019). QE is different from these datasets in various important aspects. First, it is a regression task, as opposed to binary or multiclass text classification mainly explored in previous work. Second, it is a multi-

Findings of the Association for Computational Linguistics: ACL 2022, pages 4148 - 4159
May 22-27, 2022

lingual task where the output score captures the relationship between source and target sentences. Finally, manual annotation of translation errors is a practical task with a long tradition in MT research and translation studies (Lommel et al., 2014), and thus offers an interesting alternative to human explanations collected specifically for evaluating rationale extraction methods.

Our **main contributions** are:

- We introduce a novel semi-supervised approach for word-level QE. We provide practical recipes on how feature attribution methods can be used to derive information on translation errors from sentence-level models.
- We provide insights into the behaviour of state-of-the-art (SOTA) QE models by analysing attributions to different parts of the input sequence (source vs. target sentence, correct words vs. errors) at different hidden layers.
- We propose to use the QE task as a new benchmark for evaluating the plausibility of feature attribution explanations, i.e. how interpretable model explanations are to humans (Jacovi and Goldberg, 2020).

2 Background and Related Work

Quality Estimation Current SOTA models in *sentence-level* QE, which is typically framed as a regression task, mainly use multilingual representations from pre-trained transformers (Devlin et al., 2018), notably XLM-R (Conneau et al., 2019). The input to a sentence-level QE model is a concatenation of the source and translated sentences, separated by the [SEP] token. The sequence is encoded by the pre-trained Transformer model, and the [CLS] token is passed through a multilayer perceptron (MLP) layer to obtain a sentence-level score. During fine-tuning both the parameters of the pre-trained model and the parameters corresponding to the MLP layer are updated.

Word-level QE is typically addressed as a binary classification task, where the QE model needs to predict a binary label indicating whether a word is correct or wrong for each word in the MT output (Lee, 2020). As illustrated in Figure 1 (left), some supervised approaches use both sentence-level and word-level objectives in a multi-task setting, which results in superior performance (Kim et al., 2017; Lee, 2020). Methods that do not require word-level training data either need access to the MT model (Rikters and Fishel, 2017; Fomicheva et al., 2020b), or still treat the problem as a supervised task but use synthetically generated data for supervision (Tuan et al., 2021).

Rationale Extraction for NLP SOTA NLP models based on deep neural networks achieve high performance in a variety of tasks, often at the cost of interpretability (Lipton, 2016). Recent work aims to address this issue by focusing on two different goals. On the one hand, the aim is to produce justifications for model predictions that are *plausible* to the users, in order to increase users' trust (Ribeiro et al., 2016). On the other hand, the aim is to reveal the inner workings of the model and *faithfully* explain its predictions, so the explanation can be useful to model developers (Jacovi and Goldberg, 2020).

Typically, explainability methods operate by selecting a portion of the input that justifies model prediction for a single data point. This can be done either by modifying the model architecture, or by trying to explain the predictions of a given model. The first type of approaches (a.k.a. rationalization by construction) involves imposing restrictions on the generated rationales to satisfy certain constraints, e.g. compactness (Yu et al., 2019; Chalkidis et al., 2021). Note that such restrictions often result in lower performance and indeed are not guaranteed to explain the behaviour of an unconstrained model (Jain et al., 2020). The second type of approaches (the so called *post hoc*) usually rely on feature attribution methods, which assign an importance value to each input feature of a network (Sundararajan et al., 2017; Schulz et al., 2020). These methods do not allow for introducing useful biases during training, but focus on faithfully explaining model behaviour.

Feature attribution has a long tradition in image recognition tasks (Simonyan et al., 2013) and only recently have been applied to some NLP tasks, most commonly text classification (DeYoung et al., 2019). QE is fundamentally different from text classification where clues are typically separate words or phrases (Zaidan et al., 2007) which often can be considered independently of the rest of the text. This independence assumption does not hold for the task of evaluating translation quality where a word cannot be identified as a clue (e.g. translation error) without considering the surrounding context.

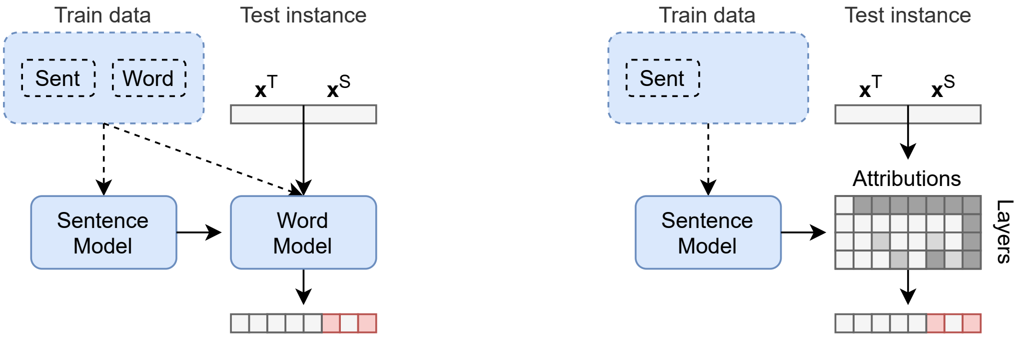

Figure 1: Fully supervised word-level QE (left) and semi-supervised word-level QE as rationale extraction (right). Dashed and solid lines represent training and test time, respectively.

Furthermore, SOTA NLP models based on contextualized representations for input words make rationale extraction especially challenging, as the representation for a given word can encode not only the word identity but also its interactions with other words in the text. Recent work has revealed various interesting properties that characterize the information flow through hidden layers in deep transformer models (Voita et al., 2019; De Cao et al., 2020; Yun et al., 2021). We provide additional insights on this topic in Section 5.2.

3 Translation Error Prediction as Rationale Extraction

We propose framing semi-supervised word-level QE as rationale extraction from sentence-level QE models. Instead of training a dedicated supervised model for word-level prediction, we propose deriving word-level scores from a strong sentence-level QE model by extracting explanations for model predictions (see Figure 1 (right)). Given a trained sentence-level QE model and the test data, rationale extraction methods detect the parts of the input that are relevant for model predictions on a sample-by-sample basis. We hypothesize that words with the highest relevance scores should correspond to actual translation errors on word-level.

3.1 Approach

More formally, given the source sequence $\mathbf{x}^S = x^S_1,...,x^S_{|S|}$, the target sequence $\mathbf{x}^T = x^T_1,...,x^T_{|T|}$ and the QE model $M(\mathbf{x}^S,\mathbf{x}^T) = \hat{y}$ that predicts sentence MT quality, a feature attribution method produces a vector of attribution scores $\mathbf{a} = a_1,...,a_{|S+T|}$, which represent the contribution of each source and target word to the prediction $\hat{y}$.

Crucially, no word-level labels are required for training. For evaluation, the attribution scores are compared against binary gold labels $\mathbf{w} = w_1,...,w_{|T|} \in \{0,1\}$ indicating whether each given word in the target sequence is an error or correct.

The predictive models for QE explored in our experiments are built by fine-tuning multilingual representations from pre-trained transformers. Transformer model starts from context-agnostic representations consisting of positional and token embeddings. These representations are passed through a set of hidden layers where at each layer the representations are iteratively updated via multi-head attention. This allows the hidden representation for each token to encode information on other words in the sentence.

We note that attribution to the input tokens or to the embedding layer can hardly succeed in detecting translation errors, as those cannot be identified independently from the context given by the source and target sentence. In this work, we perform feature attribution to hidden states at different layers and analyse which layer results in attribution scores that best correspond to translation errors.

3.2 Feature Attribution Methods

Feature attribution methods can be divided into those providing explanations by simplification, such as LIME (Ribeiro et al., 2016); gradient-based explanations (Sundararajan et al., 2017); and perturbation-based explanations (Schulz et al., 2020).

We select three popular methods for rationale extraction, which (i) do not require modifying the model architecture or re-training the model and (ii) allow attribution to hidden states. For comparison, we also use LIME which operates directly on the input text. We note that this set is not exhaustive of SOTA rationale extraction methods. Our main goal is not to conduct a comparative study of feature attribution methods but rather testing whether it is possible to address word-level QE as a rationale extraction task without any word-level supervision.

LIME (Ribeiro et al., 2016) is a simplification-based explanation technique, which fits a sparse linear model in the vicinity of each test instance, to approximate the decision boundary of the complex model.[1] The data for fitting the linear model is produced by perturbing the given instance and computing model predictions. Linear model coefficients are then used as attribution scores for each input feature. For NLP tasks features correspond to input tokens and perturbation is achieved by randomly removing words from the sequence.

Information Bottleneck is a perturbation-based method originally proposed by Schulz et al. (2020) for the task of image recognition. The method applies the idea of information bottleneck (Tishby and Zaslavsky, 2015) for feature attribution. Specifically, it injects noise into an intermediate layer representation. The amount of noise injected at the position corresponding to each input feature is optimized to minimize the loss of the main task while at the same time maximizing the overall amount of injected noise.

Integrated Gradients (Sundararajan et al., 2017) is a gradient-based method similar to the traditional salience and input$*$gradients approaches (Simonyan et al., 2013). The latter takes the signed partial derivatives of the output with respect to the input and multiply them by the input itself. Intuitively, this is analogous to inspecting the products of model coefficients and feature values in linear models (Sundararajan et al., 2017). Integrated gradients improves on that by defining a baseline input and computing the average gradient while the input varies along a linear path from baseline input to the actual input. The baseline is defined by the user depending on the task. For image recognition, black image is used as baseline. It is not clear what such baseline representation should be in the case of language tasks. Here, we select a zero baseline for simplicity. Better results can be achieved with a more informed choice of a baseline and we leave this to future work.[2]

Attention Finally, we test attention as an attribution method. Self-attention mechanisms have been widely studied in the context of explainability (Jain and Wallace, 2019; Serrano and Smith, 2019; Bujel et al., 2021). To compute a single attention score for a transformer-based model with multi-head attention, we average the weights across the different attention heads.

4 Experimental Setup

4.1 Evaluation Metrics

Given a test set with both sentence-level and word-level gold labels, we want to measure to what extent the words with the highest attributions according to the QE model correspond to human annotations for MT errors. Note that we cannot use the evaluation metrics traditionally employed for assessing the performance of word-level QE, such as F1 score and Matthews correlation coefficient (Specia et al., 2020), as they require binary predictions while feature attribution methods return continuous scores. Instead, we rely on metrics based on class probabilities (Atanasova et al., 2020). Since attribution methods proceed on instance-by-instance basis and the scores produced for different instances are not necessarily comparable, we compute the evaluation metrics for each instance separately and average the results across all instances in the test set.

AUC score For each instance, we compute the area under the receiver operating characteristic curve (AUC score) to compare the continuous attribution scores $\mathbf{a}$ against binary gold labels $\mathbf{w}$. For a test set with N instances:

$$AUC = \frac{1}{N}\sum_{n} AUC_n(\mathbf{w}_n, \mathbf{a}_n^{\mathbf{x}^T}) \tag{1}$$

Average Precision AUC score can be overly optimistic for imbalanced data. Therefore, we also use Average Precision (AP).

Recall at Top-K In addition, we report the Recall-at-Top-K commonly used in information retrieval. Applied to our setting, this metric computes the proportion of words with the highest attribution that correspond to translation errors against the total number of errors in the MT output. Thus, for a given instance (we omit the instance index n here for simplicity):

$$\text{Rec@TopK} = \frac{1}{k}\sum_{j\in \mathbf{e}_{1:k}} \mathbf{w}_j \tag{2}$$

---

[1] We use the implementation available at https://github.com/marcotcr/lime

[2] For both information bottleneck and integrated gradients method we adapt the implementation available at https://github.com/nicola-decao/diffmask for our QE scenario. Our code will be made available upon acceptance.

	Ro-En	Et-En	Ne-En
Pearson r	0.84	0.66	0.66
Average DA	68.9	55.2	36.6
Num. sentences (all data)	1,000	1,000	1,000
Num. sentences (DA < 70)	438	640	935
Error rate (all data)	0.21	0.28	0.65
Error rate (DA < 70)	0.35	0.36	0.66

Table 1: General statistics for MLQE-PE test sets: performance of sentence-level QE models (Pearson r), average DA score, total number of sentences in the test set, number of sentences with DA < 70, as well as error rate in the full test set and in the subset of selected sentences.

Where $\mathbf{e}{=}argsort(\mathbf{a}^{\mathbf{x}^T})$ is a sequence of indices corresponding to target words sorted by attribution score from highest to lowest and k is the number of errors in the sentence. We then average the result across all instances in the test set.

Accuracy at Top-1 Finally, we report the proportion of sentences where the word with the highest attribution in the target corresponds to a translation error.

$$\text{Acc@Top1}{=}\frac{1}{N}\sum I[\mathbf{a}_{\mathbf{e}_1}{=}1] \tag{3}$$

We note that the above metrics are not defined for sentences where all words are labelled as errors or correct. We exclude such sentences from evaluation.

4.2 Sentence-level QE

For sentence-level QE, we rely on TransQuest (Ranasinghe et al., 2020b), which was one of the top submissions to the WMT20 QE Shared Task (Specia et al., 2020). To facilitate the use of feature attribution methods described above, we use our own implementation of the approach proposed by (Ranasinghe et al., 2020b,a). It achieves comparable results to the ones reported by the authors. Due to limited computational resources we use the XLM-R-base as the underlying pre-trained Transformer model. We expect that using a more powerful sentence-level model would result in higher performance.

4.3 Data

We use the MLQE-PE (Multilingual Quality Estimation and Post-Editing) dataset described in Fomicheva et al. (2020a).[3] MLQE-PE provides various types of manual MT evaluation for multiple language pairs. The MT outputs were assigned a sentence-level score inspired by the Direct Assessment (DA) annotation (Graham et al., 2015; Guzmán et al., 2019) on a continuous [0, 100] scale capturing overall translation quality. In addition, the MT outputs were independently post-edited by professional translators. MT outputs and their corresponding post-edited versions were automatically aligned in order to derive word-level binary labels ("BAD" if the word was corrected, and "OK" otherwise), as well as their HTER score that corresponds to the average number of "BAD" labels in a sentence (Snover et al., 2006). We use these labels to evaluate the performance of different feature attribution approaches. We treat "BAD" labels as the positive class and "OK" labels as negative class in all of our experiments.[4] We do not evaluate attribution to source words.

It is worth noting that word-level labels derived from post-editing do not capture error severity and do not always correspond to translation errors. However, due to the costs of collecting detailed error annotations for the substantially large amounts of data required to train SOTA models, this is a standard way of approximating error annotation in QE (Specia et al., 2020).[5]

To circumvent the above limitation, we leverage both types of sentence-level annotation (DA and HTER scores) in our experiments. We train sentence-level QE models with (i) DA scores and (ii) HTER scores. We evaluate both types of models using the word-labels derived from post-editing as described above. We then conduct evaluation as follows:

1. We first evaluate explanations for DA-based models on the sentences with a sentence-level DA score lower than 70.[6]

---

[3] https://github.com/sheffieldnlp/mlqe-pe

[4] The tokenization used internally by XLM-R model is different from the tokenization used for producing word-level error labels. To map the attribution scores to the word labels we take their maximum value.

[5] Despite the limitations, we have chosen this dataset because it provides (i) sufficient amount of word-level training data, which allows us to compare our approach to a SOTA supervised approach; and (ii) access to the neural MT models that were used to produce the translations, thus enabling a comparison to an unsupervised glass-box approach.

[6] This threshold is selected based on the annotation guidelines described in Fomicheva et al. (2020a), as the sentences assigned a score lower than 70 are guaranteed to have translation errors.

	Romanian-English				Estonian-English				Nepalese-English			
Method	AUC	AP	A@1	R@K	AUC	AP	A@1	R@K	AUC	AP	A@1	R@K

Info. Bottleneck	0.65	0.62	0.71	0.50	0.58	0.55	0.56	0.46	0.64	0.78	0.80	0.71
Attention	**0.79**	**0.73**	0.80	**0.63**	0.65	0.57	0.52	0.49	**0.69**	**0.82**	0.88	**0.74**
LIME	0.54	0.48	0.40	0.39	0.56	0.56	0.65	0.46	0.52	0.75	0.76	0.68
Random	0.50	0.43	0.36	0.33	0.50	0.47	0.38	0.37	0.50	0.70	0.62	0.65
Glass-box	0.74	0.66	0.66	0.55	0.69	0.63	0.65	0.54	0.64	0.79	0.78	0.73
MicroTransQuest	0.88	0.81	0.88	0.70	0.84	0.80	0.89	0.70	0.82	0.89	0.96	0.82

Table 2: AUC/AP scores, as well as accuracy at top-1 (A@1) and recall at top-K (R@K) for different rationale extraction methods on the test partition of MLQE-PE dataset. Best rationale extraction results are highlighted in bold. Attributions are computed with respect to the hidden states at layer 10.

2. We also evaluate explanations for DA-based sentence-level models on the full subset of sentences that contain at least one word-level error.

3. Finally, we evaluate explanations for HTER-based sentence-level models on the full subset of sentences that contain at least one word-level error.

Interestingly, despite the discrepancy between DA training objective and word labels derived from post-editing, explanations for DA-based models achieve better accuracy. We report the results for (1) in the main body of the paper, while (2) and (3) are reported in Appendix B.

We select three language pairs for our experiments: Estonian-English (Et-En), Romanian-English (Ro-En) and Nepali-English (Ne-En) with the best performance at sentence level achieved at WMT2020 Shared Task. Table 1 shows statistics for the respective test sets. These three language pairs present very different conditions for the task. Sentence-level model for Ro-En has much stronger performance in terms of Pearson correlation with human judgements. Ne-En has substantially lower translation quality where "BAD" words actually represent the majority class.

4.4 QE Benchmarks

We consider two benchmarks for word-level QE. On the one hand, we report the results for a strong supervised model based on pre-trained representations from XLM-R adapted to predict word-level binary labels derived from post-editing. To report the metrics presented in 4.1, we use the probability of the positive class as attribution scores. On the other hand, we consider a fully unsupervised approach, which however, requires access to the neural MT model, that was used to generate the translations.

Black-box Supervised QE We use the word-level architecture available as part of the TransQuest toolkit (Ranasinghe et al., 2020b).[7] Similarly to the sentence-level TransQuest model, it relies on XLM-Roberta-base pre-trained model fine-tuned for token classification task. We use XLM-Roberta-base to be consistent with the sentence-level settings.

Glass-box Unsupervised QE Fomicheva et al. (2020b) propose to extract information from the MT system to predict translation quality in a fully unsupervised way. Following their work, we use log-probabilities from the neural MT model as attribution scores. The lower the log-probability corresponding to each word, the higher the chance that this word constitutes an error.

5 Results

5.1 QE as Rationale Extraction

Table 2 shows the performance of our approach with different rationale extraction methods, as well as SOTA word-level QE methods for the MLQE-PE dataset. For the first three methods we compute the attributions to the hidden states at each layer on the dev set and report the results for this layer on the test set. First, our semi-supervised approach with all explanation methods substantially outperforms the random baseline.[8] Among the different expla-

---

[7] https://tharindudr.github.io/TransQuest/architectures/word_level_architecture

[8] The smallest gap with respect to the random baseline is observed for Ne-En. The overall quality of the translation for this language pair is low. This setting might be less suitable

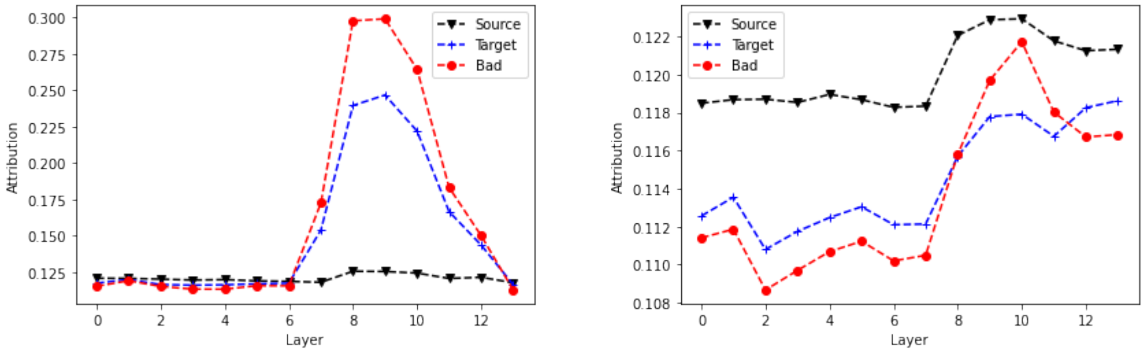

Figure 2: Average attribution at each hidden layer on the toy task (left) and MLQE-PE Et-En dataset (right). Attributions are computed with the information bottleneck attribution method (Schulz et al., 2020).

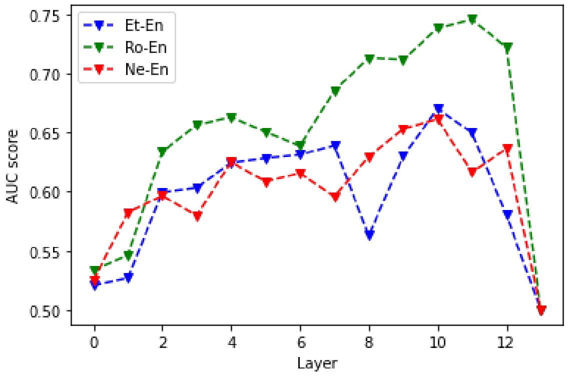

Figure 3: AUC score at each hidden layer for integrated gradients method.

nation methods, attention and integrated gradients achieve the best results. Second, the performance is comparable or better than the glass-box QE benchmark (MicroTransQuest) without requiring access to the neural MT model. For example, for Ro-En the AP scores achieved by the attention-based explanations and the glass-box word-level QE are 0.73 and 0.66, respectively. Third, the gap between the best-performing semi-supervised method and the supervised QE benchmark is the smallest for Ro-En, where the sentence-level QE model from which explanations are extracted is the strongest (see Table 1). Finally, on average, LIME-based explanations are substantially outperformed by the feature attribution methods. This agrees with our intuition that for the translation task where context plays a fundamental role, attribution to hidden states achieves much better performance than direct perturbation of input words.

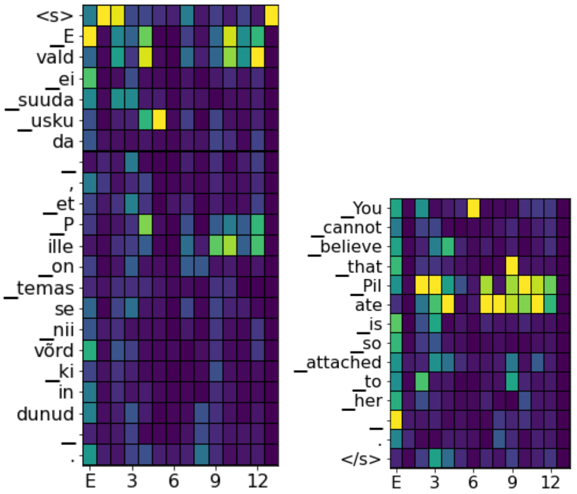

Figure 4: Example of Estonian-English translation with attributions to the source (left) and target (right) sentences computed using integrated gradients method for each hidden layer. The correct post-edited version of this translation is: ***Evald*** *cannot believe that* ***Pille*** *is so attached to her.*

5.2 Analysis

Feature Attribution per Layer Figure 2 shows attributions to tokens of different types across hidden layers. On the left, we show the results for a toy task, where we artificially introduced easy-to-detect errors in human translations and trained a QE model with near-perfect performance to predict whether a given sentence contain errors (see Appendix A). On the right, we show the results for the the MLQE-PE Et-En test set. Similarly to the toy task, we observe that in the later layers the tokens corresponding to translation errors receive higher attribution scores. However, in the toy dataset, the source tokens have very low attributions. Here, in

---

for the proposed error detection methods as most of the words in the data correspond to errors, as shown in Table 1.

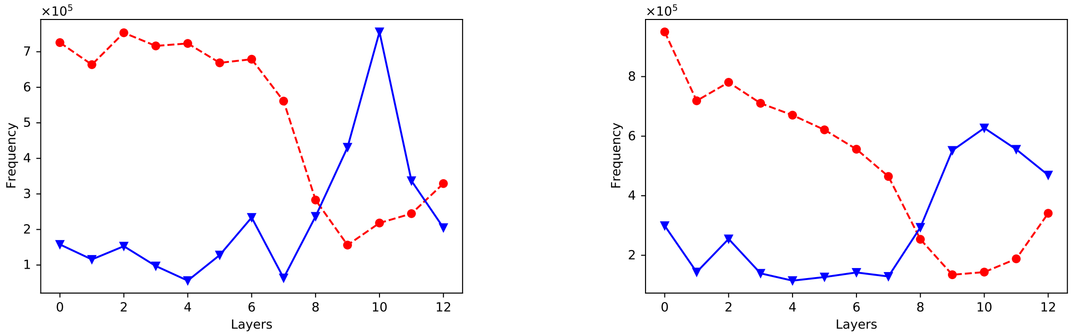

Figure 5: Frequency of the tokens with highest attribution in the neural MT training corpus. Y-axis shows the frequency of the source (left) and target (right) tokens with the highest attribution scores in low-quality MT sentences (red) and high-quality MT sentences (blue). X-axis corresponds to the hidden layers.

contrast, the model appears to be relying on the source as well as the target. This aligns very well with human evaluation where both source and target sentences need to be considered in order to correctly determine translation quality.

Figure 3 shows performance across layers for the integrated gradients method. As expected, the same layers that assign the highest attribution to the bad tokens (layers 9-11) are the ones that achieve the best performance. This finding is consistent across language pairs and attribution methods. Interestingly, this is also consistent with the findings reported in Voita et al. (2019), where they show that models trained with MLM objective encode context information in intermediate layers partially discarding the information on the identity of the input tokens which is recovered at the latest layers.

So far we have studied the behavior of the QE models on the sentences that contain errors. We now look at the pattern in the attributions scores for sentences which were assigned high quality by the model. We hypothesize that higher scores will be assigned to the words that are "easy" to translate. To test this, we select high-quality and low-quality sentences (sentences with predicted scores lower than 0.25 percentile and higher then 0.75 percentile, respectively). Figure 5 shows the average frequency with which the words occur in the neural MT training dataset. Red line corresponds to the words with the highest attribution for *high-quality* MT sentences. Blue line corresponds to the words with the highest attribution for the *low-quality* MT sentences. The first plot corresponds to the source tokens and the second plot corresponds to the target tokens. As shown in the plots, when the model predicts high quality the most frequent words receive the highest attribution as the information progresses through the network. By contrast when low quality is predicted by the sentence-level model, the least frequent words receive the highest attribution.

Qualitative Analysis Figure 4 shows an example. Attributions are shown for sentencepiece tokens, which is the representation used internally by XLM-R. Interestingly, both translation errors ("You" and "Pilate") and the corresponding words in the source ("Evald" and "Pille") receive higher attribution scores.

6 Conclusion

In this work, we propose a new semi-supervised approach for word-level QE by exploring feature attribution methods. We show that for well performing models our results approach performance of supervised methods. We also consider the QE as rationale extraction task as a new benchmark for plausibility-based evaluation of explainability methods. We hope this work will encourage further research on improving the efficiency of word-level QE models with lightly supervised methods. This work opens many directions for future research: from improving the achieved results by tuning linear weights to combine attributions to hidden states at different layers, to exploring different underlying architectures and sentence-level training objectives.

A Toy dataset

We devise a toy task to test feature attribution performance for word-level QE. We artificially introduce easy-to-detect errors in human translations and train a QE model with near-perfect performance to predict the presence/absence of such errors in a sentence. Specifically, we sample 10K/1K/1K sentence pairs from Es-En News-Commentary dataset (train/dev/test). Next, we artificially inject errors to half of the sentences at a rate of 0.1 using the following operations: insert, delete or replace random word, or swap two words selected at random.

We fine-tune an XLM-R-base model for a sentence-level binary classification task where sentences that contain errors are considered as positive class, and sentences that do not contain errors are considered as negative class. The F1-score of this sentence-level classifier is 0.97. This is expected as the task is very easy.

B Performance of Rationale Extraction Methods on HTER Data

Tables 4 and 5 show the performance of the proposed methods on the full subset of sentences that contain at least one word-level error for sentence-level QE models trained with HTER and DA ground truth scores. Pearson correlation for both types of models is shown in Table 3. Interestingly, even though for Ro-En and Et-En the performance of sentence-level models is near identical, extracted rationales are more accurate for the model trained with DA judgements.

	Ro-En	**Et-En**	**Ne-En**
Pearson r (DA)	0.84	0.66	0.66
Pearson r (HTER)	0.82	0.62	0.51
Num. sentences (all data)	1,000	1,000	1,000
Num. sentences (with errors)	714	889	945
Error rate (all data)	0.21	0.28	0.65
Error rate (with errors)	0.28	0.31	0.65

Table 3: Statistics for MLQE-PE test sets: performance of sentence-level QE models (Pearson r), total number of sentences with at least one translation error, and the error rate in the full test set and in the subset of sentences with at least one error.

Abstract

Recent work in task-independent graph semantic parsing has shifted from grammar-based symbolic approaches to neural models, showing strong performance on different types of meaning representations. However, it is still unclear that what are the limitations of these neural parsers, and whether these limitations can be compensated by incorporating symbolic knowledge into model inference. In this paper, we address these questions by taking English Resource Grammar (ERG) parsing as a case study. Specifically, we first develop a state-of-the-art, T5-based neural ERG parser, and conduct detail analyses of parser performance within fine-grained linguistic categories. The neural parser attains superior performance on in-distribution test set, but degrades significantly on long-tail situations, while the symbolic parser performs more robustly. To address this, we further propose a simple yet principled collaborative framework for neural-symbolic semantic parsing, by designing a decision criterion for beam search that incorporates the prior knowledge from a symbolic parser and accounts for model uncertainty. Experimental results show that the proposed framework yields comprehensive improvement over neural baseline across long-tail categories, yielding the best known SMATCH score (97.01) on the well-studied DeepBank benchmark.

1 Introduction

Semantic parsing is the task of mapping natural language to machine interpretable meaning representations, and *graph-structured* semantic representations, which encode rich semantic information in the form of semantic graphs, have played an important role in natural language processing (Oepen et al., 2019).

Parsing natural language sentences into the semantic-graph representation (e.g., Figure 1) has been extensively studied in the recent decade. Work in this area has shifted from the symbolic (grammar-based) approach to the neural approach. Thanks to the flourishing of deep learning technologies, sequence-to-sequence (seq2seq) models have shown great performance on data sampled from the training distribution. These neural semantic parsers reduce the need for domain-specific grammar and feature engineering, but comes at a cost of lacking interpretability, as the model directly outputs a (linearized) graph without revealing the underlying meaning-composition process. Moreover, these neural models often generalize poorly to tail and out-of-distribution (OOD) examples, and previous work has shown that combining high-precision symbolic approaches with neural models can address this issue for task-oriented semantic parsing (Shaw et al., 2021; Kim, 2021; Cheng et al., 2019). However, this type of approach requires complex architecture engineering to incorporate the grammar formalism. The grammar formalism being utilized is usually primitive, and was not tested beyond simple datasets such as SCAN (Lake and Baroni, 2018) or GEOQUERY (Zelle and Mooney, 1996). Therefore they are likely not sufficient for handling complex graph-based meaning representations derived from realistic corpora.

In this work, we aim to develop a simple yet principled neural-symbolic approach for graph semantic parsing to address long-tail generalization, which leverages the information from an *a priori* grammar parser while maintaining the convenience of neural seq2seq training built on top of massively pre-trained embeddings (Raffel et al., 2020). We take graph semantic parsing for English Resource Grammar (ERG) as our case study (Adolphs et al., 2008). ERG is a compositional semantic representation explicitly coupled with the syntactic structure. Compared to other graph-based meaning representations, ERG has high coverage of English text and strong transferability across do-

mains (Flickinger et al., 2010, 2012; Copestake and Flickinger, 2000; Ivanova et al., 2013), rendering itself has an attractive target formalism for automated semantic parsing. The classic ERG literature has focused on developing grammar-based ERG parser. However, they can suffer from issues such as incomplete categorization of lexical items and multi-word expression, and yields low coverage for realistic corpus such as Wikipedia (Baldwin et al., 2004). On the other hand, multiple neural ERG parsers have also been proposed (Buys and Blunsom, 2017; Chen et al., 2018, 2019; Cao et al., 2021). However, they are commonly structured as a pipelined system and often rely on external tools (e.g, aligners, part-of-speech taggers, and named entity recognizers), with the performance of the upstream component significantly impacting the final performance. This motivates us to build a pure end-to-end neural parser for ERG parsing that directly maps the input sentences to target graphs.

First, we present an end-to-end seq2seq model based on T5 (Raffel et al., 2020) that achieves the state-of-the-art results for ERG parsing. This model goes beyond the conventional multi-step predictions for node and edge in previous work, and does not require specialized architecture that explicitly incorporate the ERG rules or the synaptic structure as part of inductive bias. Despite the complicated syntax and semantic structures encoded in semantic graphs, we have shown that by devising proper linearization and tokenization, we can successfully transfer ERG parsing problem to translation problem (Section 3.1).

Second, we conduct a comprehensive study of the generalization behavior of the neural parser, interrogating its performance within fine-grained linguistic categories. Comparing with a state-of-the-art symbolic parser ACE, the neural parser exhibits complementary strengths. Particularly, the neural model yields much higher coverage than the symbolic parser, generating valid parses for a wider range of examples. However, the quality of the top-1 parse degrades severely in the long-tail situation. Perhaps remarkably, we also observed that the neural model's top-k parses in fact often contain candidate that generalizes well on long-tail, but the vanilla MLE-based inference fell short in selecting them (Section 4 and 5).

The above observation motivates our third contribution: to develop a practical framework for collaborative neural-symbolic parsing. The key lies in designing a principled decision making strategy for this neural-symbolic collaboration that performs optimally during inference time. To this end, we design a new decision criterion for neural model inference (e.g., beam search) that incorporates both model uncertainty and the prior knowledge from a symbolic parser, leveraging the theoretical framework of optimal decision-making under the incomplete knowledge of the world (Ulansky and Raza, 2021; Giang, 2015; Hurwicz, 1951). The basic idea is to utilize uncertainty estimates of the neural parser as a switch between the optimistic, MLE-based inference and the conservative, prior-based inference, such that the neural parser seeks the guidance from a symbolic parser during its decoding stage when encountering low-confident examples. This proposed approach achieves comprehensive improvement compared to the original neural parser, across almost all linguistic categories. Our result suggests that sometimes the limitation of the neural approach lies not necessarily in the model architecture or the training method, but in a sub-optimal inference procedure that naively maximize the *a posteriori* likelihood (e.g., the beam search) without questioning the reliability of the prediction (Section 3.2).

In summary, our contribution are three-fold:

- We propose the first end-to-end model that achieves the state-of-the-art results for ERG parsing on the DeepBank WSJ benchmark. Specifically, we get 30.1% error rate reduction in SMATCH score over the existing state-of-the-art.
- We conduct a thorough analysis of the neural parser in terms of generalization. Specifically, we compared the predictive performance of neural parser with the state-of-the-art symbolic parser in various important linguistic categories, showing that both parsers exhibit complementary strengths, validating the potential to build a neural-symbolic parsing framework.
- We propose a simple, yet principled framework for neural-symbolic parsing utilizing model uncertainty. The resulting framework not only comprehensively improved the model performance in tail linguistic categories, but further boosted the performance of the neural model on the standard in-domain test set (an extra 9.5% error rate reduction), establishing a new state-of-the-art SMATCH 97.01. [1]

---

[1] The code is available at `https://github.com/`

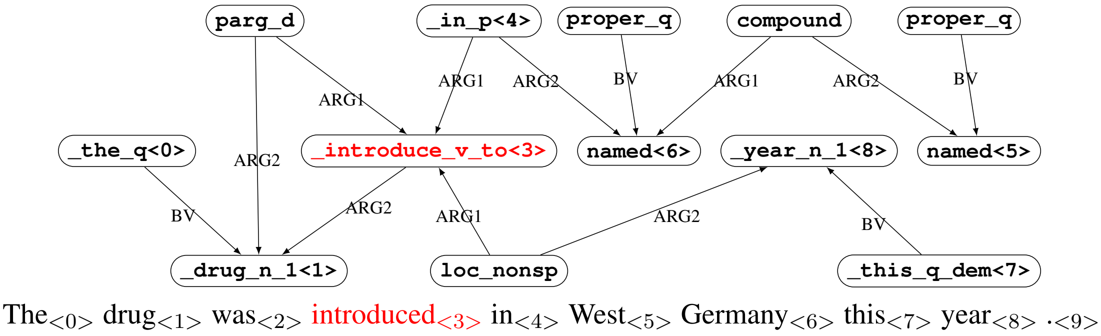

Figure 1: An example of semantic graph for English Resource Grammar (ERG). Some nodes are surface concepts, meaning that they are related to a single lexical unit, e.g. `_introduce_v_to` (the number in the angle brackets indicates their token alignments in the sentence), while others are abstract concepts representing grammatical meanings, e.g. `compound` (multiword expression), `parg_d` (passive) and `loc_nonsp` (temporal). Color red indicates the root of this semantic graph. It also supports light-weight named entity recognition (e.g., "West Germany" is labeled as two `named` in the graph).

2 Background and Related Work

2.1 Graph-based Meaning Representation

Considerable NLP research has been devoted to the transformation of natural language utterances into a desired linguistically motivated semantic representation. Such a representation can be understood as a class of discrete structures that describe lexical, syntactic, semantic, pragmatic, as well as many other aspects of the phenomenon of human language. In this domain, graph-based representations provide a light-weight yet effective way to encode rich semantic information of natural language sentences and have been receiving heightened attention in recent years. Popular frameworks under this umbrella includes Bi-lexical Semantic Dependency Graphs (SDG; Bos et al., 2004; Ivanova et al., 2012; Oepen et al., 2015), Abstract Meaning Representation (AMR; Banarescu et al., 2013), Graph-based Representations for English Resource Grammar (ERG; Oepen and Lønning, 2006; Copestake, 2009), and Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013).

2.2 English Resource Grammar (ERG)

In this paper, we take the representations from English Resource Grammar (ERG; Flickinger et al., 2014) as our target meaning representations. ERG is an open-source, domain-independent, linguistically precise, and broad-coverage grammar of English, which is rooted in the general linguistic theory of Head-driven Phrase Structure Grammar (HPSG; Pollard and Sag, 1994). ERG can be presented into different types of annotation formalism (Copestake et al., 2005). In this work, we consider the Elementary Dependency Structure (EDS; Oepen and Lønning, 2006) which converts ERG into variable-free dependency graphs, and is more compact and interpretable when compared to other types of annotation schemes, e.g., DMRS (Buys and Blunsom, 2017; Chen et al., 2018).

Figure 1 shows an example graph. The semantic structure is a directed graph $G = \langle N, E \rangle$, where N denotes nodes labeled with semantic predicates/relations (e.g., `_drug_n_1, compound`), and E denotes edges labeled with semantic argument roles (e.g., `ARG1, ARG2`).

There are different parsing technologies for graph-based meaning representations, which can be roughly divided into grammar- and neural-based approaches.

2.3 Parsing to Semantic Graphs

In this section, we present a summary of different parsing technologies for graph-based meaning representations, with a focus on English Resource Grammar (ERG).

Grammar-based approach In this type of approach, a semantic graph is derived according to a set of lexical and syntactico-semantic rules. For ERG parsing, sentences are parsed to HPSG derivations consistent with ERG. The nodes in the derivation trees are feature structures, from which MRS is extracted through unification. However, this approach fails to parse sentences for which no valid derivation is found. It is implemented in the PET

`google/uncertainty-baselines/tree/main/baselines/t5`

(Callmeier, 2000) and ACE[2] parser. Chen et al. (2018) also proposed a Synchronous Hyperedge Replace Grammar (SHRG) based parser by relating synchronous production rules to the syntacto-semantic composition process.

Factorization-based approach This type of approach is inspired by graph-based dependency tree parsing (McDonald, 2006). A factorization-based parser explicitly models the target semantic structures by defining a score function that can evaluate the probability of any candidate graph. For ERG parsing, Cao et al. (2021) implemented a two-step pipeline architecture that identifies the concept nodes and dependencies by solving two optimization problems, where prediction of the first step is utilized as the input for the second step. Chen et al. (2019) presented a four-stage pipeline to incrementally construct an ERG graph, whose core idea is similar to previous work.

Transition-based approach In these parsing systems, the meaning representations graph is generated via a series of actions, in a process that is very similar to dependency tree parsing (Yamada and Matsumoto, 2003; Nivre, 2008), with the difference being that the actions for graph parsing need to allow reentrancies. For ERG parsing, Buys and Blunsom (2017) proposed a neural encoder-decoder transition-based parser, which uses stack-based embedding features to predict graphs jointly with unlexicalized predicates and their token alignments.

Composition-based approach Following a principle of compositionality, a semantic graph can be viewed as the result of a derivation process, in which a set of lexical and syntactico-semantic rules are iteratively applied and evaluated. For ERG parsing, based on Chen et al. (2018), Chen et al. (2019) proposed a composition-based parser whose core engine is a graph rewriting system that explicitly explores the syntactico-semantic recursive derivations that are governed by a synchronous SHRG.

Translation-based approach This type of approach is inspired by the success of seq2seq models which are the heart of modern Neural Machine Translation. A translation-based parser encodes and views a target semantic graph as a string from another language. In a broader context of graph semantic parsing, simply applying seq2seq models is not successful, in part because effective linearization (encoding graphs as linear sequences) and data sparsity were thought to pose significant challenges (Konstas et al., 2017). Alternatively, some specifically designed preprocessing procedures for vocabulary and entities can help to address these issues (Konstas et al., 2017; Peng et al., 2017). These preprocessing procedures are very specific to a certain type of meaning representation and are difficult to transfer to others. However, we show that by devising proper linearization and tokenization (Section 3.1), we can successfully transfer the ERG parsing problem into a translation problem, which can be solved by a state-of-the-art seq2seq model T5 (Raffel et al., 2020). This linearization and tokenization can be applied to any meaning representations.

2.4 Neural-Symbolic Semantic Parsing

While seq2seq models excel at handling natural language variation, they have been shown to struggle with out-of-distribution compositional generalization (Lake and Baroni, 2018; Shaw et al., 2021). This has motivated new specialized architectures with stronger inductive biases for the compositional generalization, especially for task-oriented semantic parsing like SCAN (Lake and Baroni, 2018) and GEOQUERY. Some examples include NQG-T5 (Shaw et al., 2021), a hybrid model combining a high-precision grammar-based approach with a pretrained seq2seq model; seq2seq learning with latent neural grammars (Kim, 2021); a neural semantic parser combining a generic tree-generation algorithm with domain-general grammar defined by the logical language (Cheng et al., 2019).

However, there are not so much progress regarding neural-symbolic parsing for graph meaning representations. Previous work has shown that the utility of context-free grammar for graph semantic parsing was somewhat disappointing (Peng et al., 2015; Peng and Gildea, 2016). This is mainly because the syntax-semantics interface encoded in those graph meaning representations is much more complicated than pure syntactic rules or logical formalism, and is difficult to be exploited in data-driven parsing architecture.

3 A Collaborative Neural-Symbolic Parsing Framework

In this section, we design and implement a new collaborative neural-symbolic parsing framework for ERG parsing. The framework takes the neural

---

[2] http://sweaglesw.org/linguistics/ace/

parser's uncertainty as a trigger to the collaborative process with the symbolic parser. This requires the neural parser to model uncertainty based on the optimization problem given observed sentence s:

$$\arg\max_{N,E} p(G = \langle N, E \rangle | s)$$

Previous data-driven work on ERG parsing either requires pipeline settings (predict nodes N and edges E separately) or external tools such as aligners, part-of-speech taggers and named entity recognizers. In contrast, we aim to build an end-to-end seq2seq parser that directly maps the input sentences to the target strings of (linearized) ERG graphs. However, due to the complexity of the semantic graph representation, care needs to be taken to parametrize the output space of the graph strings, so that the seq2seq model can learn efficiently in finite data. Specifically, we show that by devising proper linearization and tokenization (Section 3.1), we can successfully transfer the ERG parsing problem into a translation problem that can be solved by a state-of-the-art seq2seq model T5 (Raffel et al., 2020). The proposed linearization and tokenization are essential to model performance, and can be applied to any meaning representations. The experimental results show that our model improves significantly in comparison with the previously reported results (Table 1).

3.1 Linearization and Tokenization

Variable-free top-down linearization A popular linearization approach is to linearize a directed graph as the pre-order traversal of its spanning tree. Variants of this approach have been proposed for neural constituency parsing (Vinyals et al., 2015) and AMR parsing (Barzdins and Gosko, 2016; Peng et al., 2017). AMR (Banarescu et al., 2013) uses the PENMAN notation (Kasper, 1989), which is a serialization format for the directed, rooted graphs used to encode semantic dependencies. It uses parentheses to indicate nested structures. Since nodes in the graph get identifiers (initialized randomly) in PENMAN notation that can be referred to later to establish a reentrancy, e.g., `_drug_n_1` in Figure 1, and will confuse the model to learn the real meaningful mappings, we remove the identifiers and use star markers instead to indicate reentrancies. For example, our variable-free linearization for graphs in Figure 1 can be written as:

```
( _introduced_v_to
  :ARG2 ( _drug_n_1 *
    :BV-of ( _the_q ) )
  :ARG1-of ( parg_d
    :ARG2 ( _drug_n_1 * ) )
  :ARG1-of ( loc_nonsp
    :ARG2 ( _year_n_1
      :BV-of ( _this_d_dem ) ) )
  :ARG1-of ( _in_p
    :ARG2 ( named
      :BV-of ( proper_q )
      :ARG1-of ( compound
        :ARG2 ( named
          :BV-of ( proper_q ) ) ) ) ) )
```

The rewriting process can be done by Algorithm 1. It is noted that there can be more than one reentrancy in the graph, and we use different numbers of star marks to indicate this (line 10 in Algorithm 1). More details about the implementation of linearization can be found in Appendix A.

Algorithm 1 Variable-free PENMAN rewriting

Input: $G = \langle N, E \rangle$ is the EDS graph
Output: Variable-free PENMAN notations of G

```
1:  $R \leftarrow \emptyset$                                   ▷ reenrancy set
2:  $n_R \leftarrow 0$                                  ▷ number of of reenrancies
3:  for $n \in N$ do
4:      if $\mathrm{child}(n) \cap \mathrm{child}(\mathrm{parent}(n)) \neq \emptyset$ then
5:          $R' \leftarrow \mathrm{child}(n) \cap \mathrm{child}(\mathrm{parent}(n))$
6:          $R \leftarrow R \cup R'$
7:      end if
8:  end for
9:  for $r \in R$ do
10:     $G \leftarrow \mathrm{rewrite}(G, r, r +' *' \times (n_R + 1))$
11:     $n_R \leftarrow n_R + 1$
12: end for
13: return $\mathrm{PENMAN}(G)$
```

Compositionality-aware tokenization Tokenization has always been seen as a non-trivial problem in Natural Language Processing (Liu et al., 2019). In the case of graph semantic parsing, it is still a controversial issue which unit is the most basic one that triggers conceptual meaning and semantic construction (Chen et al., 2019). While previous work can customize some off-the-shelf tokenizers to correspond closely to the ERG tokenization, there are still some discrepancies between the tokenization used by the system and ERG (Buys and Blunsom, 2017). Moreover, using customized tokenization means we need to pretrain our model from scratch, and this will cost lots of time and computation.

We address this issue by replacing the non-compositional part of ERG graphs with some non-tokenizable units in the T5 vocabulary. This will let the model learn the compositionality of ERG units by giving the signal of which type of units are tokenizable. More details can be found in Appendix B. This process is crucial since it not only reflects the original design of ERG vocabulary, but also dramatically reduces the sequence length of the output (around 16%). Additionally, it can be applied to any meaning representations by simply identifying the set of non-compositional, atomic units in the semantic graphs.

3.2 A Decision-theoretic Framework for Collaborative Neural-Symbolic Parsing

It is known that the performance of a neural model tends to suffer on examples that are under-represented in the training data, e.g., tail categories or OOD examples. Indeed, when analyzing our neural parser, we find the naive T5 parser's performance degrades significantly in the tail linguistic categories, while the symbolic parser performs more robustly (Section 5). This motivates us to explore principled strategies to exploit the complementary strengths of both parsers. Specifically, we cast neural model inference (e.g., beam search) as a decision-making problem under partial uncertainty of the world (Ulansky and Raza, 2021; Giang, 2015; Hurwicz, 1951), and design a new decision criterion incorporates both the model uncertainty about the testing data distribution and the prior information from a symbolic parser, thereby concretely improving the model performance beyond the i.i.d. regime.

Formally, consider a sequence prediction problem where the input and target sequences $(\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{X} \times \mathcal{Y}$ are generated from an underlying distribution $\mathcal{D} = p^*(\boldsymbol{y}|\boldsymbol{x})p^*(\boldsymbol{x})$. We denote $p(\boldsymbol{y}|\boldsymbol{x})$ the neural parser trained on the in-domain examples $\boldsymbol{x} \in \mathcal{X}_{ind}$, and $p_0(\boldsymbol{y}|\boldsymbol{x})$ a symbolic prior that encodes *a priori* linguistic knowledge from a grammar parser (e.g., ACE). Under a decision-theoretic formulation, the model inference can be understood as a decision-making game under uncertainty (Hurwicz, 1951). Specifically, given a world state (i.e., input utterance) $\boldsymbol{x}$, the goal of the model is to select the optimal parse $\boldsymbol{y}$ among the beam candidates $\{\boldsymbol{y}_b\}_{b=1}^{B}$ according to the decision criteria $\mathcal{R}(\boldsymbol{y}|\boldsymbol{x})$. Crucially, due to the imperfect distribution of the training data $\mathcal{X}_{ind} \subset \mathcal{X}$, the neural model does not have full familiarity of all the possible utterances $\boldsymbol{x} \in \mathcal{X}$, and the decision criteria based on neural likelihood alone may be a poor guide for the optimal decision $y|\mathbf{x}$.

To this end, the goal of neural-symbolic inference is to identify a improved criteria $\mathcal{R}(\boldsymbol{y}|\boldsymbol{x})$ that leverages knowledge from a symbolic prior p_0 and accounts for model uncertainty. Specifically, we find a solution in the well-known Hurwicz pessimism-optimism criteria from game theory (Hurwicz, 1951), which suggests an optimal criteria of the form

$$\mathcal{R}(\boldsymbol{y}|\boldsymbol{x}) = \alpha * \mathcal{R}_p(\boldsymbol{y}|\boldsymbol{x}) + (1-\alpha) * \mathcal{R}_0(\boldsymbol{y}|\boldsymbol{x}),$$

where $\mathcal{R}_p(\boldsymbol{y}|\boldsymbol{x})$ is an optimistic policy for the familiar states $\boldsymbol{x} \in \mathcal{X}_{ind}$, $\mathcal{R}_0(\boldsymbol{y}|\boldsymbol{x})$ a conservative policy in case of high uncertainty, and $\alpha \in [0,1]$ a trade-off parameter.

In the context of beam search, the optimistic crieria $\mathcal{R}_p(\boldsymbol{y}|\boldsymbol{x}) = -log\, p(\boldsymbol{y}|\boldsymbol{x})$ is the MLE-based strategy induced by the neural likelihood, which is known generalize well for the in-domain situations $\boldsymbol{x} \in \mathcal{X}_{ind}$. On the other hand, the pessimistic criteria $\mathcal{R}_0(\boldsymbol{y}|\boldsymbol{x}) = -log\, p_0(\boldsymbol{y}|\boldsymbol{x})$ is the log likelihood of tge symbolic prior $-log\, p_0$. In this work, we define $p_0(\boldsymbol{y}|\boldsymbol{x}) \propto exp(-\frac{d(\boldsymbol{y},\boldsymbol{y}_0)}{\lambda})$ to be the generalized Boltzmann distribution centered around the output of the symbolic parser $\boldsymbol{y}_0$. Here λ is the temperature parameter, and $d(y, y')$ is a suitable divergence metric for the space of ERG graphs, which we choose to be the SMATCH metric (Cai and Knight, 2013). This leads to the below criteria:

$$\mathcal{R}_p(\boldsymbol{y}|\boldsymbol{x}) = \alpha * -log\, p(\boldsymbol{y}|\boldsymbol{x}) + (1-\alpha) * \frac{\textsc{Smatch}(\boldsymbol{y}, \boldsymbol{y}_0)}{\lambda}, \quad (1)$$

where we have omitted the normalizing constant of p_0 since it does not impact optimization.

A caveat of (1) is α is fixed regardless of whether $\boldsymbol{x}$ is in-domain ($\mathcal{X}_{ind}$) or out-of-domain ($\mathcal{X}/\mathcal{X}_{ind}$). As a result, when $\boldsymbol{x}$ is in-domain, a fixed α can be too conservative since minimizing the beam score $-log\, p(\boldsymbol{y}|\boldsymbol{x})$ alone is known to generalize well. When $\boldsymbol{x}$ is OOD, however, (1) can be overly optimistic since the neural model $p(\boldsymbol{y}|\boldsymbol{x})$ may generalize poorly in the under-represented regions, and a more prudent strategy is to revert to the prior by focusing on minimizing $p_0(\boldsymbol{y}|\boldsymbol{x})$. To handle this challenge, we consider an improved criteria that accounts for model uncertainty:

$$\mathcal{R}(\boldsymbol{y}|\boldsymbol{x}) = \alpha(\boldsymbol{x}) * -log\, p(\boldsymbol{y}|\boldsymbol{x}) + (1-\alpha(\boldsymbol{x})) * \frac{\textsc{Smatch}(\boldsymbol{y}, \boldsymbol{y}_0)}{\lambda} \quad (2)$$

where $\alpha(\boldsymbol{x}) = \text{sigmoid}(-\frac{1}{T} * (\mathcal{H}(\boldsymbol{x}) - b))$ is a monotonic transformation of model uncertainty $\mathcal{H}(\boldsymbol{x})$ which is known as the Platt calibration (Platt et al., 1999), whose parameters (T, b) can be estimated using a small amount of validation data. As shown, depending on the value of $\mathcal{H}(x)$, the proposed criteria (2) approaches the original beam score $-log\, p(\boldsymbol{y}|\boldsymbol{x})$ when the model is confident, and reverts to the prior likelihood $-log\, p_0(\boldsymbol{y}|\boldsymbol{x})$ when the model is uncertain and $\mathcal{H}$ is high.

For the proposed criteria (2) to perform robustly in practice, the uncertainty estimator $\mathcal{H}(\boldsymbol{x})$ should be *well calibrated*, i.e., the magnitude of $\mathcal{H}$ is indicative of the model's predictive error. In this work, we choose $\mathcal{H}$ to be the margin probability, i.e., the difference in probability of the top 1 prediction minus the likelihood of the top 2 prediction based on the beam score:

$$\mathcal{H}_{\text{margin}}(p(\boldsymbol{y}|\boldsymbol{x}, \mathcal{D})) = p(\boldsymbol{y}^{(1)}|\boldsymbol{x}, \mathcal{D}) - p(\boldsymbol{y}^{(2)}|\boldsymbol{x}, \mathcal{D}),$$

due to its strong calibration performance on the graph semantic parsing tasks. Appendix D discusses alternative choices of $\mathcal{H}$ and investigates their respective efficacy in improving the collaborative parsing system's predictive performance.

4 Experiments

Dataset We conduct model training on DeepBank v1.1 that correspond to ERG version 1214, and adopt the standard data split. The Pydelphin[3] library is leveraged to extract EDS graphs and transfer them into PENMAN format.

Implementation Details T5 (Raffel et al., 2020) is a pre-trained sequence-to-sequence Transformer model that has been widely used in many NLP applications. We use the open-sourced T5X [4], which is a new and improved implementation of T5 codebase in JAX and Flax. Specifically, we use the official pretrained T5-Large (770 million parameters) and finetuned it on DeepBank in-domain training set. Despite the general fact that larger model size will lead to better performance on finetuning for some tasks, our empirical results show that adopting model sizes larger than T5-Large will not lead to further gain for ERG parsing.

For the collaborative neural-symbolic parsing, we set the beam size to 5, i.e., our combined predictions will be selected from the top 5 predictions produced by the model. For the monotonic transformation $\alpha(\boldsymbol{x})$ in (2), we set We set $\lambda = 0.1$ and $T = 0.1$.

Evaluation Metrics For evaluation, following previous work, we adopt the SMATCH metric (Cai and Knight, 2013), which was originally proposed for evaluating AMR graphs. It measures graph overlap, but does not rely on sentence alignments to determine the correspondences between graph nodes. Specifically, SMATCH is computed by performing inference over graph alignments to estimate the maximum F1-score obtainable from a one-to-one matching between the predicted and gold graph nodes. This is also ideal for measuring the divergence between predicted and prior graphs in our collaborative framework.

	Node			Edge			Graph
	P	R	F	P	R	F	SMATCH
w/o preprocess	96.29	91.72	93.95	93.86	88.66	91.19	92.57
w/ preprocess	97.67	96.93	97.30	97.71	96.85	95.81	96.54

Table 1: Comparision of precision, recall, and F1-score for node and edge prediction and SMATCH scores on the test set under the settings of with/without tokenization preprocessing.

Impact of Tokenization To validate the effectiveness of our proposed tokenization process, we report the performance of node and edge prediction and the SMATCH scores with and without the process on the test set in Table 1, which indicates that after this process, the SMATCH score is improved by 4.29% on the test set. We can find that the recall score for node prediction has significant improvement, and this is because that the sequence without tokenization preprocessing will lead to longer sequence length, and many output graphs have reached the max decoding sequence length and thus are incomplete.

Model	Node	Edge	SMATCH
ACE[5]	93.18	88.76	90.94
Transition-based (Buys and Blunsom, 2017)	89.06	84.96	87.00
SHRG-based (Chen et al., 2018)	94.51	87.29	90.86
Composition-based (Chen et al., 2019)	95.63	91.43	93.56
Factorization-based (Chen et al., 2019)	97.28	94.03	95.67
Factorization-based (Cao et al., 2021)	96.42	93.73	95.05
ACE-T5 (following Shaw et al. (2021))	93.46	89.19	91.30

Comparison with Existing Parsers We compared our parser with the grammar-based ACE parser and other data-driven parsers in Table 2. The baseline models also include a similar practice with Shaw et al. (2021), which takes T5 as a backup for grammar-based parser. Our model outperforms all previous work, and achieves a SMATCH score of 96.54 (a 30.1% error reduction), which is a significant improvement over existing parsers on this well-studies benchmark. After applying the collaborative parsing framework, we further improve the parser's performance to 97.01 (a 39.6% error reduction).

We notice that using the simple margin probability as the uncertainty estimator performs better than weighted entropy. We then conduct an investigation on the calibration quality of model uncertainty using different estimators. Specifically, we find predictive margin exhibits a surprisingly strong correlation with the model's test SMATCH score, while some more well-known uncertainty metrics (e.g., predictive entropy) are poorly calibrated. More details can be found in Appendix D.

5 Fine-grained Linguistic Evaluation

Though performs better than symbolic parser, we find that actually neural and symbolic parsers yield different distributions on the test set (see Appendix C for details). This has motivated us to dive deeply into more fine-grained evaluation for our models.

ERG provides different levels of linguistic information that is beneficial to many NLP tasks, e.g., named entity recognition, semantic role labeling, and coreference. This rich linguistic annotation can help us quantify different types of errors the model makes. We reported the detailed evaluation results in Table 3. Specifically, we consider:

Lexical construction ERG uses the abstract node `compound` to denote compound words. The edge labeled with `ARG1` refers to the root of the compound word, and thus can help to further distinguish the type of the compound into (1) nominal with normalization, e.g., "flag burning"; (2) nominal with noun, e.g., "pilot union"; (3) verbal, e.g., "state-owned"; (4) named entities, e.g., "West Germany".

Argument structure In ERG, there are different types of core predicates in argument structures, specifically, verbs, nouns and adjectives. We also categorize verb in to basic verb (e.g., `_look_v_1`) and verb particle constructions (e.g., `_look_v_up`). The verb particle construction is handled semantically by having the verb contribute a relation particular to the combination.

Coreference ERG resolves sentence-level coreference, i.e., if the sentence referring to the same entity, the entity will be an argument for all the nodes that it is an argument of, e.g., in the sentence, "What we want to do is take a more aggressive stance", the predicates "want" (`_want_v_1`) and "take" (`_take_v_1`) share the same agent "we" (`pron`). As discussed before, this can be presented as reentrancies in the ERG graph, we notice that one important type of reentrancies is the passive construction (e.g., `parg_d` in Figure 1), so we also report evaluation on passive construction in Table 3.

Type	#	ACE	T5	Collab.
Compound	2,266	80.58	**90.46**	90.36
Nominal *w/ nominalization*	22	85.71	**89.66**	82.76
Nominal *w/ noun*	1,044	85.28	90.96	**91.42**
Verbal	23	75.00	77.27	**81.82**
Named entity	1,153	82.92	**91.36**	90.40
Argument structure	7,108	86.98	90.68	**91.66**
Total verb	4,176	85.34	89.75	**90.50**
Basic verb	2,356	85.79	89.97	**90.90**
ARG1	1,683	90.25	93.40	**93.94**
ARG2	1,995	90.48	92.95	**93.79**
ARG3	195	**85.63**	83.08	84.62
Verb-particle	1,761	84.69	89.47	**90.00**
ARG1	1,545	89.57	93.50	**94.05**
ARG2	923	86.27	91.10	**91.26**
ARG3	122	87.88	86.75	**88.08**
Total noun	394	92.41	91.84	**92.63**
Total adjective	2,538	89.05	92.09	**93.25**
Reentrancy	2,343	77.29	87.88	**88.43**
passive	522	84.89	91.54	**92.72**

Table 3: Comparing ACE, T5 parsers and collaborative parsing (Collab.) on fine-grained linguistic categories. All scores are reported in accuracy. The underlined denotes the best in ACE and T5, and the bold denotes the best in ACE, T5 and Collab.

As shown, the T5 parser performs much better than ACE, especially for compound recognition.

---

[5] The results for ACE are lower than those reported in previous work, which are originally from Buys and Blunsom (2017). We use the same ACE parser and we have confirmed with other authors that those higher results are not reproducible. As the ACE parser fails to parse some of the sentences (more than 1%), we only evaluate sentences that are successfully parsed by ACE.

This indicates that local semantic information such as compound constructions or named entities can be easily captured by those pretrained embedding-based models. For argument structure, though performs better than ACE in most cases, the T5 parser still has relatively low accuracy for `ARG3` and noun structure recognition. This is mainly due to their relatively low frequency in the training set (1.94% for `ARG3` and 5.54% for noun argument structures).

Our analysis in this section is consistent with previous work: the T5 parser, similar to many other neural parsers, is fragile to tail instances that do not have sufficient representation in the training data. We also further report the evaluation results for our collaborative neural-semantic parsing framework (Collab.), where we can see that it brings improvement for the issues above, which validates the effectiveness of the collaborative framework.

6 Conclusions and Future Work

In this paper, we present a simple, uncertainty-based approach to collaborative neural-symbolic parsing for graph-based meaning representations. In contrary to the prior neural-symbolic approaches, we maintain the simplicity of the seq2seq training, and design a decision-theoretic inference criteria for beam candidate selection, incorporating model uncertainty and prior knowledge from an existing symbolic parser.

Remarkably, despite the simplicity of the method, our approach strongly outperform all the previously-known approach on the DeepBank benchmark (Table 2), and attains strong performance even in the tail linguistic categories (Table 3). Our study revealed that the commonly observed weakness of the neural model may root from a sub-optimal inference procedure. Therefore, developing a more calibrated neural semantic parser and developing principled inference procedure may be a fruitful avenue for addressing the generalization issues of neural parsers.

In the future, we plan to apply this approach to a broader range of graph meaning representations, e.g., AMR (Banarescu et al., 2013) and UCCA (Abend and Rappoport, 2013), and build a more advanced uncertainty estimation approach to quantify model uncertainty about sub-components of the graph, thereby allowing more fine-grained integration between neural prediction and symbolic derivations.

Ethical Consideration

This paper focused on collaborative neural-symbolic semantic parsing for the English Resource Grammar (ERG). Our architecture are built based on open-source models and datasets (all available online). We do not anticipate any major ethical concerns.

Appendix

A Detailed Implementation of Linearization

The original PENMAN styled linearization for graph in Figure 1 can be written as:

```
(x0 / _introduced_v_to
  :ARG2 (x1 / _drug_n_1
    :BV-of (x2 / _the_q))
  :ARG1-of (e0 / parg_d
    :ARG2 x1)
  :ARG1-of (e1 / loc_nonsp
    :ARG2 (x3 / _year_n_1
      :BV-of (x4 / _this_d_dem)))
  :ARG1-of (x5 / _in_p
    :ARG2 (e2 / named
      :BV-of (e3 / proper_q)
      :ARG1-of (e4 / compound
        :ARG2 (e5 / named
          :BV-of (e6 / proper_q))))))
```

The term `-of` is used for reversing the edge direction for graph traversing. Nodes in the graph get identifiers (e.g., `x0`, `e0`), which can be referred to later to establish a reentrancy, e.g., the node `_drug_n_1` serves as `ARG2` of `_introduced_v_to` and `ARG2` of `parg_d` at the same time, so the identifier `x_1` appears twice in the notation. However, in our settings, these identifiers can be randomly set to any unique symbols, which will confuse the model to learn the real meaningful mappings. To tackle this issue and create a variable-free version of the PENMAN notation, we replace these identifiers with star markers to indicate reentrancy, e.g., replacing `x1` with `_drug_n_1 *`.

To illustrate more about reentrancies, we consider two different types of cases:

(1) For cases where the second reentrancy still points back to the first `_drug_n_1`, e.g., in the sentence "the drug was introduced and used this year", the node will still be marked as `_drug_n_1 *`.

(2) For cases where the second reentrancy refers to another token span in the sentences, e.g., in the sentence "The drug was introduced this year, and another drug will be introduced next year", the second node reentrancy will be marked as `_drug_n_1 **`.

In other words, the max number of star markers $\star$ indicates the total number of different reentrancies in the sentences. This will not confuse the model to do the reentrancy prediction as it can always refer to how many reentrancies have been predicted in the previous sequences.

B Details about Tokenization

ERG makes an explicit distinction between nodes with surface relations (prefixed by an underscore), and with grammatical meanings. The former, called the surface node, consists of a lemma followed by a coarse part-of-speech tag and an optional sense label. For example, for the node `_drug_n_1` in Figure 1, the surface lemma is drug (`_drug`), the part-of-speech is noun (`_n`), and `_1` here specifies that it is the first sense under the noun "drug". The later, called the abstract node, is used to represent the semantic contribution of grammatical constructions or more specialized lexical entries, e.g., `parg_d` (for passive), `proper_q` (for quantification of proper words), `compound` (for compound words), and `named` (for named entities).

It is noted that the set of abstract concepts and edges are fixed and relatively small (88 for abstract nodes and 11 for edges in the training set), while the surface nodes have high productivity, i.e., many different lemmas can fit into some fixed patterns such as `_n_1` and `_v_to`. Therefore, we rewrite those fixed abstract, concepts surface patterns and edges into some non-tokenizable tokens in the T5 vocabulary to inform the model that these units are non-compositional in ERG graphs.

C Distributions of the T5 and ACE Parsers

D Uncertainty Estimates and Calibration Performance

There has been some work exploring the model uncertainty for seq2seq parser or some other non seq2seq models (Dong et al., 2018; Kamath et al., 2020). In this section, we are also interested in investigating the calibration quality of model uncertainty of a seq2seq neural parser. For the proposed criteria (2) to perform robustly in practice, the uncertainty estimator $\mathcal{H}(\boldsymbol{x})$ should be *well calibrated*, i.e., the magnitude of $\mathcal{H}$ is indicative of the model's predictive error. To this end, we notice that a reliable uncertainty measure for sequence prediction tasks is still an open research challenge (Malinin and Gales, 2020). In this work, we experiment with several well-known estimators of model uncertainty:

Margin probability. The simplest estimator for model uncertainty is the predictive margin, i.e., the difference in probability of the top 1 prediction minus the likelihood of the top 2 prediction based on the beam score:

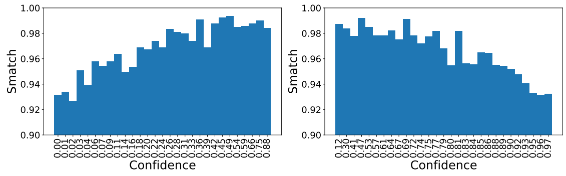
$$\mathcal{H}_{\text{margin}}(p(\boldsymbol{y}|\boldsymbol{x},\mathcal{D})) = p(\boldsymbol{y}^{(1)}|\boldsymbol{x},\mathcal{D}) - p(\boldsymbol{y}^{(2)}|\boldsymbol{x},\mathcal{D})$$

Weighted entropy. Considering that our model uses beam-search for inference, and with regards to the Monte-Carlo estimators, beam-search can be interpreted as a form of importance-sampling which yields hypotheses from high-probability regions of the hypothesis space. We can estimate uncertainty which is importance-weighted in proportion to $p(\boldsymbol{y}^{(b)}|\boldsymbol{x},\mathcal{D})$ such that

$$\mathcal{H}_{\text{entropy}}(p(\boldsymbol{y}|\boldsymbol{x},\mathcal{D})) = -\sum_{b=1}^{B} \frac{\pi_b}{L^{(b)}} \ln p(\boldsymbol{y}^{(b)}|\boldsymbol{x},\mathcal{D}),$$

where $\pi_b = \frac{p(\boldsymbol{y}^{(b)}|\boldsymbol{x},\mathcal{D})}{\sum_k^B p(\boldsymbol{y}^{(k)}|\boldsymbol{x},\mathcal{D})}$ is the estimated importance weight for each beam candidate (Malinin and Gales, 2020).

In our experiment, we investigate the calibration of the above uncertainty estimations (see below), and experiment with their respective efficacy in improving the collaborative parsing system's predictive performance (Table 4).



(a) Margin Probability (b) Weighted Entropy

Figure 3: Diagrams for the model's confidence verses SMATCH scores on the test set. Each bin contains 50 examples.

A common approach to evaluate a model's uncertainty quality is to measure its *calibration* performance, i.e., whether the model's predictive uncertainty is indicative of the predictive error (Guo et al., 2017). To understand how well the T5 parser's neural uncertainty correlates with its prediction reliability, we plot the diagrams for the model's confidence verses SMATCH scores on the test set in Figure 3. As shown, comparing to the weighted entropy, margin probability is qualitatively much better calibrated. [6] Correspondingly, Table 4 shows that the collaborative result using margin probability yields much strongly performance, confirming the connection between a uncertainty model's calibration quality and its effectiveness is collaborative prediction (Kivlichan et al., 2021).

Model	Node	Edge	SMATCH
ACE	93.18	88.76	90.94
Transition-based (Buys and Blunsom, 2017)	89.06	84.96	87.00
SHRG-based (Chen et al., 2018)	94.51	87.29	90.86
Composition-based (Chen et al., 2019)	95.63	91.43	93.56
Factorization-based (Chen et al., 2019)	97.28	94.03	95.67
Factorization-based (Cao et al., 2021)	96.42	93.73	95.05
ACE-T5 (following Shaw et al. (2021))	93.46	89.19	91.30
T5 (Ours)	97.30	95.81	96.54
Collaborative w/ margin probability	**97.64**	**96.41**	**97.01**
Collaborative w/ weighted entropy	97.27	96.14	96.70

Table 4: F1 score for node and edge predictions and the SMATCH scores on the test set.

---

[6] We hypothesize that the inferior performance of entropy is due to the well-known "length bias" (Yang et al., 2018), i.e., shorter predictions tend to have higher beam score, which also tend to have lower SMATCH score

Towards Few-shot Entity Recognition in Document Images: A Label-aware Sequence-to-Sequence Framework

Zilong Wang
University of California, San Diego

Jingbo Shang*
University of California, San Diego
`jshang@ucsd.edu`

Abstract

Entity recognition is a fundamental task in understanding document images. Traditional sequence labeling frameworks treat the entity types as class IDs and rely on extensive data and high-quality annotations to learn semantics which are typically expensive in practice. In this paper, we aim to build an entity recognition model requiring only a few shots of annotated document images. To overcome the data limitation, we propose to leverage the label surface names to better inform the model of the target entity type semantics and also embed the labels into the spatial embedding space to capture the spatial correspondence between regions and labels. Specifically, we go beyond sequence labeling and develop a novel label-aware seq2seq framework, LASER. The proposed model follows a new labeling scheme that generates the label surface names word-by-word explicitly after generating the entities. During training, LASER refines the label semantics by updating the label surface name representations and also strengthens the label-region correlation. In this way, LASER recognizes the entities from document images through both semantic and layout correspondence. Extensive experiments on two benchmark datasets demonstrate the superiority of LASER under the few-shot setting.

1 Introduction

Entity recognition lies in the foundation of document image understandings, which aims at extracting word spans that perform certain roles from the document images, such as *header*, *question*. Distinct from the text-only named entity recognition task, the document images, such as forms, tables, receipts, and multi-columns, provide a perfect scenario to apply multi-modal techniques into practice where the rich layout formats in such document images serve as the new, complementary signals for entity recognition performance in addition to the existing textual data.

Recent methods (Xu et al., 2020; Hong et al., 2020; Garncarek et al., 2021) follow the traditional sequence labeling framework to extract the word spans using the standard `IOBES` tagging schemes (Marquez et al., 2005; Ratinov and Roth, 2009) in named entity recognition tasks. Entity types are treated as class IDs and the semantics of the label surface names are ignored. These methods also largely extend the label space by including combinations of the boundary identifiers (`B`, `I`, `E`, `S`) and entity types. For instance, when there are 3 target entity types, the extended label space would have 13 (i.e., $4\times3+1$) dimensions. As a result, they fail to learn from the data efficiently and require extensive datasets and high-quality annotations to create the connection between entities and their entity types. Meanwhile, document images typically include various formats and have a high diversity of entities within each page. It is expensive or almost impossible to enumerate all required entity types and obtain enough annotated data for them. Moreover, ethical concerns would arise when it comes to the receipts or consent forms, which makes it even harder to collect enough data.

Due to the inefficiency of traditional methods and the data limitation in real application scenarios, it is necessary to resort to few-shot learning for entity recognition in document images. We aim at exploiting the potential of a limited number of training pages and try to generalize our model on the much larger number of new pages for testing. In our method, we go beyond the sequence labeling framework and reformulate the entity recognition as a sequence-to-sequence task. Specifically, we propose a new generative labeling scheme for entity recognition — the label surface name is explicitly generated right after each entity as a part of the target sequence. In this way, different entity types are no longer independent dimensions in the label space and models can leverage the semantic connect between the entities and entity types.

---

Findings of the Association for Computational Linguistics: ACL 2022, pages 4174 - 4186
May 22-27, 2022

To this end, we propose a label-aware sequence-to-sequence framework for entity recognition, LASER. Our implementation is based on pre-trained language model LayoutReader [1] (Wang et al., 2021), which is a layout-aware pre-trained sequence-to-sequence model.

As shown in Figure 1, LASER extends the architecture of LayoutReader for our proposed generative labeling scheme to better solve the few-shot entity recognition task for document images. Specifically, after generating certain word spans, the model can choose to generate either the following words in the source sequence or label surface names. The entity labels are explicitly inserted in the generated sequence so that the probability of the entity types conditioned on the entity, $P(\text{type}|\text{entity})$, can be maximized not only by the signals from the training data but also by the knowledge from the pre-training of the language models. We also embed the label surface names into the spatial embedding space, so the generation of labels is also aware of the correlation between labels and the regions in the page.

Benefit from the novel generative labeling scheme and the semantics of labels, LASER is able to effectively recognize entities in document images with only a limited number of training samples. In contrast, the sequence labeling models use less efficient tagging scheme, thus requiring more data and failing in the few-shot settings.

We validate LASER using two benchmarks, FUNSD (Guillaume Jaume, 2019) and CORD-Lv1 (Park et al., 2019). Both datasets are from real scenarios and fully-annotated with textual contents and bounding boxes. We compare our model with strong baselines and study the label-entity semantic and spatial correlations. We summarize our contribution as follows.

- We reformulate the entity recognition task and propose a new generative labeling scheme that embeds the label surface names into the target sequence to explicitly inform the model of the label semantics.
- We propose a novel label-aware sequence-to-sequence framework LASER to better handle few-shot entity recognition tasks for document images than the traditional sequence labeling framework using both label semantics and layout format learning.
- Extensive experiments on two benchmark datasets demonstrate the effectiveness of LASER under few-shot settings.

Reproducibility. We will release the code and datasets on Github[2].

2 Problem Formulation

The few-shot entity recognition in the document images is to take the text and layout inputs from a limited number of training samples to predict the boundary of each entity and classify the entity into categories. Given a document image page $\mathcal{P}$, the words within the page are annotated with their textual contents w and the bounding boxes $B = (x_0, y_0, x_1, y_1)$ (top-left and bottom-right corners) by human annotators or the OCR engines, and all the words and bounding boxes are listed in a sequence serving as the inputs from textual and layout modalities. In this way, the entities are spans of these words referring to precise concepts, which makes it possible to conduct entity recognition using sequence labeling or generative labeling scheme. We randomly select a small subset of training samples and evaluate the performance under the k-shot training, where k denotes the number of the training samples.

3 Our Generative Labeling Scheme

We propose our labeling scheme of entity recognition in the generative manner which generates the entity boundaries and the label surface names explicitly. Specifically, given an entity $e = [w_i, w_{i+1}..., w_j]$, we use the `[B]` and `[E]` to denote the boundary of the entity and append the label surface name afterwards. Overall, the generative formulation is to generate:

$$w_{i-1}, \texttt{[B]}, w_i, ..., w_j, \texttt{[E]}, \tau_1, ..., \tau_k, \texttt{[T]}, w_{j+1}$$

where `[B]` and `[E]` denote the start and end of the entity; $\tau_1 ... \tau_k$ are the words in the label surface name; `[T]` denotes the end of the label surface name. For example, "*Sender*" and "*Charles Duggan*" are a pair of *question* and *answer* from a document image. According to the generative labeling scheme, the corresponding generated sequence is that: `[B]` *Sender* `[E]` *question* `[T]` `[B]` *Charles Duggan* `[E]` *answer* `[T]`.

4 Our LASER Framework

In this section, we introduce our label-aware sequence-to-sequence framework for entity recog-

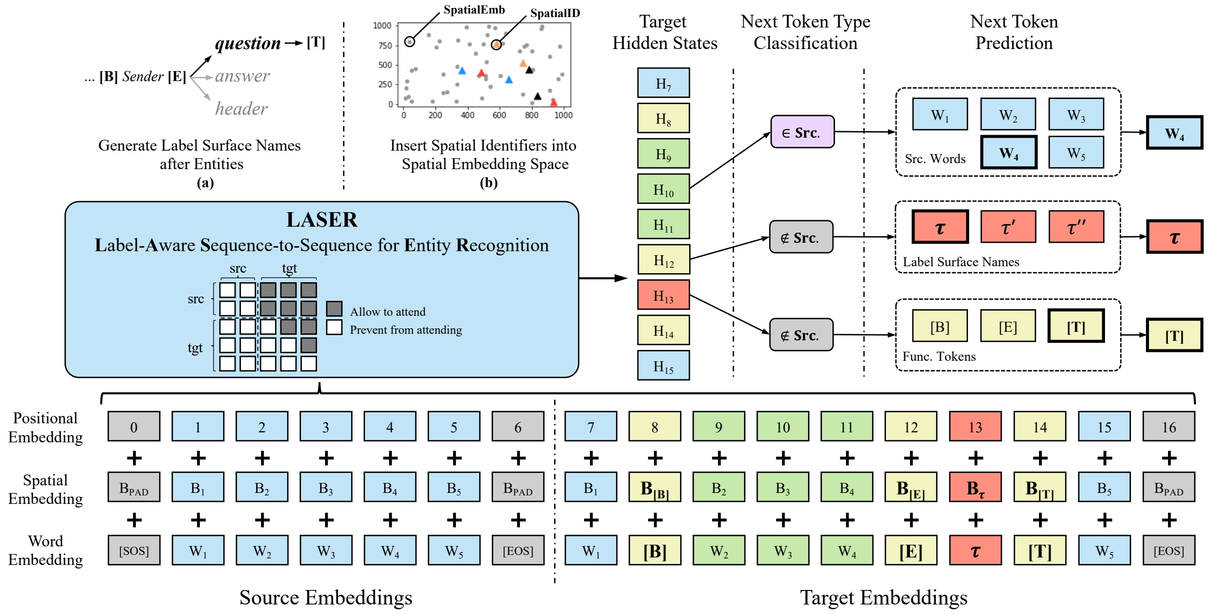

Figure 1: The Framework of LASER: `[B]`, `[E]`, `[T]` denote the boundaries; τ, τ', τ'' are the label surface names; (a) is the process of generative labeling scheme; (b) shows the alignment of the spatial identifiers and embeddings.

nition in document images. First, we introduce our method in a bird's eye view. Then we dive into the details of each part including the multi-modal prefix language model, the label-aware generation.

4.1 Overview

Our proposed LASER is a label-aware sequence-to-sequence model for entity recognition in document images. The framework is shown in Figure 1. The model follows the prefix language model paradigm (Raffel et al., 2019; Dong et al., 2019a; Bao et al., 2020) and is built upon the pre-trained language model, LayoutReader (Wang et al., 2021). With extensive knowledge learned in pre-training stage, the model leverages the semantic meaning of label surface names during generation.

Since the functional tokens (e.g. `[B]`, `[E]`) and the label surface names are foreign words in the given page, their layout features are nonexistent. We use trainable vectors as special layout identifiers for these extra tokens and these vectors are well aligned into the spatial embedding space. In this way, the spatial correspondence between layout formats and labels can be learned.

To reinforce the model to distinguish the functional tokens (e.g. `[B]`, `[E]`) and ordinary words, an extra binary classification module is added, and the probability is used in the next token prediction.

Equipped with all the components, our proposed model is able to conduct entity recognition efficiently and effectively under the few-shot setting.

4.2 Multi-modal Prefix LM

LASER is built on the layout-aware prefix language model, LayoutReader (Wang et al., 2021). Prefix language model refers to a multi-layered Transformer where the source sequence and target sequence are packed together and a "partially-triangle" mask is used to control the attention between tokens in the two sequences. In LASER, the source sequence has full self-attention and the target sequence only attends to the previous tokens so the conditional generative probability is learned.

Input Embedding The input embedding layer of LASER includes the word embedding, spatial embedding, and positional embedding. We normalize and round the bounding box coordinates to integers ranging from 0 to 1000, and embed them as trainable vectors as spatial embeddings (Xu et al., 2020, 2021a,b; Wang et al., 2021). So the input embeddings of the ordinary words are as follows:

$$e_{w_i} = \text{WordEmb}(w_i) + \text{SpatialEmb}(B_i) + \text{PosEmb}(i)$$

where WordEmb, SpatialEmb, PosEmb are the word embedding, the spatial embedding, and the positional embedding lookup tables, respectively; i is the index of the word in the packed sequence.

The functional tokens and label surface names are new tokens in the given page. We cannot extract the layout features from the bounding boxes of them because their bounding boxes are nonexistent. Instead of the actual bounding boxes, we design unique embedding vectors for each new tokens as their layout identifiers. These identifiers can perform in the same way as real bounding boxes during training to embed the functional tokens and label surface names into the spatial embedding space. The input embedding replaces the spatial embedding with the spatial identifiers:

$$e_\lambda = \text{WordEmb}(\lambda) + \text{SpatialID}(\lambda) + \text{PosEmb}(i)$$

where SpatialID is the spatial identifier lookup table; i is the index of the word in the packed sequence; $\lambda \in \{\texttt{[B]}, \texttt{[E]}, \texttt{[T]}, \tau_1, ..., \tau_t\}$.

Within the input embedding layer, the pre-trained model learns the semantic and layout formats from word embeddings or spatial features. The spatial embeddings are already pre-trained and further fine-tuned in the downstream tasks, and the spatial identifiers are new to the model and completely trained in the downstream tasks.

Attention Mask As mentioned, LASER depends on a "partially-triangle" mask to realize sequence-to-sequence training within one encoder. To be more specific, the "partially-triangle" attention mask has two parts, the source part and the target part. In the source part, the tokens can attend to each other, which enables the model to be aware of the entire sequence. In the target part, to predict the next token in a sequence-to-sequence way, we design the "triangle" mask which prevents the tokens from attending to the tokens after them. Therefore, the generative probability conditioned on the previous tokens can be computed.

Output Hidden States To learn the conditional generative probability of the next token, we take the output hidden states corresponding to the target sequence which is denoted as $\mathbf{h}_{n+1}, \mathbf{h}_{n+2}, ..., \mathbf{h}_{n+m}$, where $n+1$ is the beginning of the target sequence in the packed sequence. According to the "partially-triangle" attention mask, $\mathbf{h}_{n+k}$ is produced with the attention to the source tokens and the previous target tokens, i.e., the input embeddings whose index ranges from 1 to $n+k$. Therefore, $\mathbf{h}_{n+k}$ is used to predict the $(k+1)$-th token in the target sequence.

4.3 Label-aware Generation

In the sequence-to-sequence setting, LASER estimates the probability of next token conditioned on the previous context, i.e. $P(x_k|x_{<k})$ and $x_k \in \mathcal{C}$, where $\mathcal{C} = \{w_1...w_n\} \cup \{\tau_1...\tau_t\} \cup \{\texttt{[B]}, \texttt{[E]}, \texttt{[T]}\}$ is the set of all candidate words. Following LayoutReader, we restrain the candidates within the source words instead of the whole dictionary, and we go beyond it and extend the candidate set to include the functional tokens and label surface names. Moreover, to distinguish whether the next word belongs to the source or not, we design an extra binary classification module.

Specifically, we take the hidden states h_k to predict whether the next token is from the source or not. We denote the probability $P(x_{k+1} \in \text{src}) = p_{k+1}$. Then we use p_{k+1} to weight the next token prediction. The probability that the next token is the i-th word in the source is computed as follows:

$$P(x_{k+1} = w_i | x_{\leq k}) = \frac{p_{k+1} \exp\left(\mathbf{e}_{w_i}^T \mathbf{h}_k + b_k\right)}{\sum_j \exp\left(\mathbf{e}_{w_j}^T \mathbf{h}_k + b_k\right)}$$

where w_i is the i-th word in the source; $\mathbf{e}_{w_i}$ is the input embedding of w_i; $\mathbf{b}_k$ is the bias.

Similarly, the probability that the next token is one of the functional tokens or label surface names is computed as follows:

$$P(x_{k+1} = \lambda | x_{\leq k}) = \frac{(1 - p_{k+1}) \exp\left(\mathbf{e}_{\lambda}^T \mathbf{h}_k + b'_k\right)}{\sum_{\lambda'} \exp\left(\mathbf{e}_{\lambda'}^T \mathbf{h}_k + b'_k\right)}$$

where λ is a functional token or label surface name, i.e. $\lambda \in \{\texttt{[B]}, \texttt{[E]}, \texttt{[T]}, \tau_1, ..., \tau_t\}$; $1 - p_{k+1}$ is the probability that $(k+1)$-th token is a functional token or label surface name; $\mathbf{b}'_k$ is the bias.

Label Semantics Learning With the log likelihood loss of generative language modeling, the model maximize the dot production between the hidden states $\mathbf{h}$ and the input embeddings e. The semantic correlation is learned considering that the input embeddings of the labels surface names are encoded in the word embeddings.

Spatial Identifier Learning From the layout format perspective, the input embedding of the label surface names also includes the spatial identifiers. When predicting the next token, the log likelihood also strengthens the relation between the spatial identifiers and the layout context. In this way, LASER inserts the spatial identifiers into the hyperspace of the spatial embeddings. In other words, LASER predicts where a certain label is more likely to be. Similar to the joint probability of language modeling, LASER maximizes the joint probability of a mixture of spatial identifiers and spatial embeddings: $P(..., B_{k-1}, B_k, \tau, B_{k+1}, ...)$ where B_k is the bounding boxes of the words in the page and the τ is the label to predict. Further visualization is conducted in Section 5.7.

4.4 Sequential Decoding

After training, LASER follows the prefix language modeling paradigm and generates the target sequence sequentially. We input the source sequence into the model and take the last hidden states to predict the first token in the target. Then we append the result to the end of input and repeatedly run the generation. We cache the states of the model and achieve generation in linear time.

5 Experiments

In this section, we conduct experiments and ablation study on FUNSD (Guillaume Jaume, 2019) and CORD-Lv1 (Park et al., 2019) under few-shot settings. We replace the original label surface names with other tokens to study the importance of semantic meaning. We also plot the heatmaps of the similarity between the spatial identifiers and the spatial embeddings to interpret the spatial correspondence. Case studies are also conducted.

5.1 Experimental Setups

All the experiments are under few-shot settings using 1, 2, 3, 4, 5, 6, 7 shots. We use 6 different random seeds to select the few-shot training samples and the data augmentation is conducted to solve the data sparsity. We train all the models using the same data and compute the average performance and the standard deviation. We only report the result of 1, 3, 5, 7 shots for space limitation. To evaluate our model, we first convert our results into `IOBES` tagging style and compute the word-level precision, recall, and F-1 score using the APIs from Nakayama (2018) so that all comparisons with sequence labeling methods are under the same metrics. We believe such experiment settings guarantee the results are representative.

5.2 Datasets

Our experiments are conducted on two real-world data collections: FUNSD and CORD-Lv1. Both datasets provide rich annotations for the document image understandings includes the words and the word-level bounding boxes. The details and statistics of these two datasets are as follows.

Table 1: Dataset Statistics.

Dataset	# Train Pages	# Test Pages	# Entities / Page
FUNSD	149	50	42.86
CORD-Lv1	800	100	13.82

- **FUNSD:** FUNSD consists of 199 fully-annotated, noisy-scanned forms with various appearance and format which makes the form understanding task more challenging. The word spans in this datasets are annotated with three different labels: `header`, `question` and `answer`, and the rest words are annotated as `other`. We use the original label names.
- **CORD-Lv1:** CORD consists of about 1000 receipts with annotations of bounding boxes and textual contents. The entities have multi-level labels. We select the first level and denote the dataset as CORD-Lv1. The first level includes `menu`, `void-menu`, `subtotal` and `total`. We simplify `subtotal` as `sub` and `void-menu` as `void`.

5.3 Compared Methods

We evaluate LASER against several strong sequence labeling methods as follows.

- **BERT** (Devlin et al., 2018) is a text-only auto-encoding pre-trained language model using the large-scale mask language modeling. We fine-tune the pre-trained BERT-base model with the few-shot training samples on each datasets.
- **RoBERTa** (Liu et al., 2019) extends the capacity of BERT and achieves better performance in multiple natural language understanding tasks. We also conduct the fine-tuning with few-shot training samples.
- **LayoutLM** (Xu et al., 2020) is a multi-modal language model which includes the layout and text information. It is built upon BERT and adds the extra spatial embeddings into the BERT embedding layer. Following LayoutLM, LayoutLMv2 (Xu et al., 2021a) leverages extra computer vision features and improves the performance, which are strong signals but absent in our settings. For a fair comparison, we do not include LayoutLMv2 in our comparative experiments.
- **LayoutReader** (Wang et al., 2021) is a layout-aware sequence-to-sequence model for reading order detection. We append a linear layer upon the hidden states to conduct sequence labeling.

These compared methods are in their base version and follow the `IOBES` tagging scheme.

(a) FUNSD (b) CORD-Lv1

Figure 2: F-1 Curves with Different Sizes of Few-shot Training Samples.

5.4 Implementation Details

We build LASER on the base of LayoutReader. We use the Transformers (Wolf et al., 2019) and the s2s-ft toolkits from the repository of Dong et al. (2019a). We use one NVIDIA A6000 to finetune with batch size of 8. We optimize the model with AdamW optimizer and the learning rate is 5×10^{-5}.

5.5 Experimental Results

From Table 2 and Figure 2, the results show that, under few-shot settings, our proposed model, LASER, achieves the SOTA overall performance compared with sequence labeling models. We conclude that the gain of performance comes mostly from the generative labeling scheme since LASER largely outperforms LayoutReader although both of them share the same backbone.

Specifically, compared with the second-best baseline, LASER improves the F-1 scores by 8.59% on FUNSD and by 3.32% on CORD-Lv1 on average across the different shots and LASER (IRLVT) also surpasses the baselines under most settings.

Moreover, the improvement on precision is remarkable. LASER improves the precision by 12.35% on FUNSD and by 10.62% on CORD-Lv1 on average across the different shots. Especially, under 1-shot setting, it surpasses the best sequence labeling model on FUNSD by 19.01% on precision, 10.47% on recall and 17.18% on F-1 score.

We can also observe a drop in the improvement with the increasing number of training samples. We conclude that, with enough training samples, the sequence labeling learns the meaning of each label and the semantics of each label surface names no longer provides extra useful information.

Based on these comparison, we safely come to the conclusion that our proposed generative labeling scheme is superior to the traditional sequence labeling scheme in few shot settings.

5.6 Ablation Study

In the ablation study, we aim at study the role of the label surface names. We introduce an ablation version, LASER (IRLVT), by replacing the label surface names with irrelevant tokens. We also design more different sets of words as substitutes denoted Sub1 and Sub2. The detailed substitutes

Table 3: Ablation Study of Different Label Surface Names in LASER. IRLVT uses the irrelevant tokens as labels; ORIG uses the original label surface names; Sub1 and Sub2 use some reasonable alternative label surface names. as substitutes. **Bold** denotes the best model; Underline denotes the second-best model.

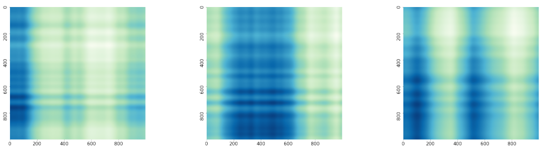
are introduced in Table 3.

To implement the ablation study, we simply replace the word embedding of label surface names. For example, in LASER (Sub1) on FUNSD, we use the wording embedding of *title* instead of the original *header*.

From Table 3, we compare the performance of all the ablation models. We observe that LASER performs differently with distinct label semantics. In most cases, the human-designed labels can provide stronger semantic correlation with the entities than the irrelevant labels so they can further improve the performance. However, there are also drops due to improper labels. Overall, we conclude that the semantic meanings of the label surface names are useful to bridge the gap between the labels and entities.

5.7 Spatial Correspondence Interpretation

In this section, we study the ability of LASER to capture the spatial correspondence between certain areas and the labels. The experiment is based on the results of LASER on FUNSD with 7 shots. As mentioned in Section 4.2, we design unique spatial identifiers for the label surface names. The identifiers are in the same form as the spatial embeddings and LASER inserts the identifiers into the original spatial embedding space during sequence-to-sequence training. Ideally, the model can learn where a certain label is more likely to appear. To visualize such patterns, we compute the cosine similarity matrix M of identifiers and the spatial embeddings as $M_{ij} = \cos(\text{SpatialID}(\tau), \text{SpatialEmb}(\text{(i, j)}))$ where (i, j) is the normalized coordinate pair; $\tau \in \{\tau_1, ..., \tau_t\}$. Then we plot the heatmap of the similarity matrix, where the highlight areas mean the higher similarities.



(a) Header (b) Question (c) Answer

Figure 3: Spatial correspondence visualization on FUNSD for different entity types.

From Figure 3, we observe that the label `header` is more likely to be in the middle column of the page and may appear in the bottom part as well when there are multiple paragraphs. Intuitively, the label `question` and `answer` should appear in pairs and it is observed in Figure 3 that their heatmaps are almost complementary to each other. Several examples from FUNSD are selected to demonstrate the visualization results in 4. Comparing the examples and the visualization results, we conclude that the spatial identifiers of labels capture the formats of pages and LASER leverages these features to better extract the entities under few shot settings.

5.8 Case Study

We visualize cases from the 5-shot setting. From Figure 5, we observe LASER can extract the enti-

Dataset	# Train	# Test	# Entity Type
OntoNotes	60.0k	8.3k	18
Mit Movie	7.8k	2.0k	12

ties correctly, and the errors of LayoutLM comes from the failure to extract the entities or wrong entity type predictions. Since the sequence labeling groups the words into spans through `IOBES` tagging, which creates great uncertainty. Meanwhile, LASER also learns `questions` and `answers` appear in pairs (see Figure 5(b)). It also properly predicts a numerical string as `menu` even if numbers are likely to be `total` (see Figure 5(e)).

5.9 Text-only Entity Recognition

LASER is designed for the entity recognition task in document images where both text and layout

Table 5: Results of 10-way-5-shot Experiments

Model	OntoNotes	MIT Movie
	F-1	F-1
BERT	60.79±0.97	47.88±0.97
RoBERTa (Huang et al., 2020)	57.70	51.30
UniLM	60.82±1.26	51.09±1.40
LASER	**61.11±1.08**	**51.88±1.27**

can be leveraged to acquire essential information. However, the generative labeling scheme is not constrained in the scenario of document images. We briefly explore the potential of the generative labeling scheme in text-only scenario. We initialize LASER with a text-only language model, UniLM (Dong et al., 2019b), based on the experiments in Wang et al. (2021), and apply it onto text-only entity recognition task. Following Huang et al. (2020), we conduct 10-way-5-shot experiments on two datasets, OntoNotes (Weischedel et al., 2013) and MIT Movie (Liu et al., 2013), which cover general domains and review domains, respectively. The dataset statistics are shown in Table 4 and the results are as shown in Table 5. We observe that our method can also surpass the sequence labeling methods in these two datasets, showing the great potential of the generative labeling scheme in the entity recognition tasks.

6 Related Work

Layout-aware LMs. Since the post-OCR processing has great application prospects, existing works propose to adapt the language pre-training to the layout formats learning. LayoutLM (Xu et al., 2020) is the pioneer in this area, which successfully uses the coordinates to represent the layout information in the embedding layer of BERT (Devlin et al., 2018). Following LayoutLM, the upgraded version, LayoutLMv2 (Xu et al., 2021a), is further proposed to leverage the visual features and benefits from the alignment between words and the regions in the page. LAMBERT (Garncarek et al., 2021) and BROS (Hong et al., 2020) continue studying the layout representation which uses the sinusoidal function or apply the relative positional biases from T5 (Raffel et al., 2019). LayoutReader (Wang et al., 2021) aims to predict the reading order of words from the OCR results. ReadingBank (Wang et al., 2021) is proposed to facilitate the pre-training of reading order detection, which annotates the reading order of millions of pages.

Generalized Seq2Seq. Sequence-to-sequence architecture is basic in natural language processing and is originally designed for machine translation. With the rise of large pre-trained models, sequence-to-sequence models are increasingly used with new problem formulation. Existing works exploit the potential latent knowledge and stronger representation ability of sequence-to-sequence modeling. GENRE (De Cao et al., 2020) creatively reformulates the entity retrieval task into the sequence-to-sequence settings. It inferences the lined entities using the generation of BART. Recent works on prompt learning also leverage the pre-trained sequence-to-sequence language models to conduct few shot learning (Liu et al., 2021; Puri and Catanzaro, 2019; Hambardzumyan et al., 2021).

7 Conclusions and Future Work

In this paper, we present LASER, a label-aware sequence-to-sequence framework for entity recognition in document images under few-shot settings. It benefits from the generative labeling scheme which reformulates the entity recognition task into the sequence-to-sequence setting. The label surface names are embedded into the generated sequence. Compared with the sequence labeling methods, LASER leverages the rich semantics of the label surface names and overcome the limitation of training data. Moreover, we design spatial identifiers for each label and well insert them into the spatial embedding hyperspace. In this way, LASER can inference the entity labels from the layout formats perspective and empirical experiments demonstrate our method can learn the layout formats though limited number of training samples.

For further research, we will investigate the selection of label surface names and how to better leverage the semantics from the pre-trained sequence-to-sequence models. We also notice that such labeling scheme can cope with unknown categories. We will focus on the generalization of our method.

Ethical Consideration

This paper focuses on the entity recognition in document images under few-shot setting. Our architecture are built upon open-source models and all the datasets are available online. We will release the code and datasets on `https://github.com/zlwang-cs/LASER-release`. Therefore, we do not anticipate any major ethical concerns.

Abstract

Despite the remarkable success deep models have achieved in Textual Matching (TM) tasks, it still remains unclear whether they truly understand language or measure the semantic similarity of texts by exploiting statistical bias in datasets. In this work, we provide a new perspective to study this issue — via the length divergence bias. We find the length divergence heuristic widely exists in prevalent TM datasets, providing direct cues for prediction. To determine whether TM models have adopted such heuristic, we introduce an adversarial evaluation scheme which invalidates the heuristic. In this adversarial setting, all TM models perform worse, indicating they have indeed adopted this heuristic. Through a well-designed probing experiment, we empirically validate that the bias of TM models can be attributed in part to extracting the text length information during training. To alleviate the length divergence bias, we propose an adversarial training method. The results demonstrate we successfully improve the robustness and generalization ability of models at the same time.

1 Introduction

Textual matching is a crucial component in various NLP applications, such as information retrieval (Li and Xu, 2014), question answering (Shen and Lapata, 2007) and duplicate detection (Bilenko and Mooney, 2003). Given a pair of texts, the goal is to determine the semantic similarity between them. A lot of deep models (Chen et al., 2017; Wang et al., 2017; Pang et al., 2016; Guo et al., 2019; Wan et al., 2016) have achieved excellent performance on various TM benchmarks.

However, recent work has found that current models are prone to adopting shallow heuristics in the datasets, rather than learning the underlying linguistics that they are intended to capture. This issue has been documented across tasks in natural language understanding. In natural language arguments, for example, Niven and Kao (2019) showed that model performance is inflated by spurious statistical cues. Similar heuristics arise in natural language inference (McCoy et al., 2019; Naik et al., 2018) and reading comprehension (Jia and Liang, 2017).

Table 1: Examples for length divergence bias, originally from Twitter-URL. "Output" is the output label by ESIM trained on the original training set. Numbers in bold are the number of words each text consists of. Model is misled by the length divergence of two texts.

In this paper, we address this issue in the domain of textual matching. The focus of our work is on the length divergence bias — models tend to classify examples with high length divergence as negative and vice versa. Table 1 shows a single set of instances from Twitter-URL that demonstrates the length divergence bias.

We analyze current TM datasets and find that all of them follow specific length divergence distribution by labels. To determine whether TM models have employed this spurious pattern to facilitate their performance, we construct adversarial test sets which invalidate this heuristic and re-evaluate TM models. There is a performance drop on 14 out of total 16 combinations of models and tasks,

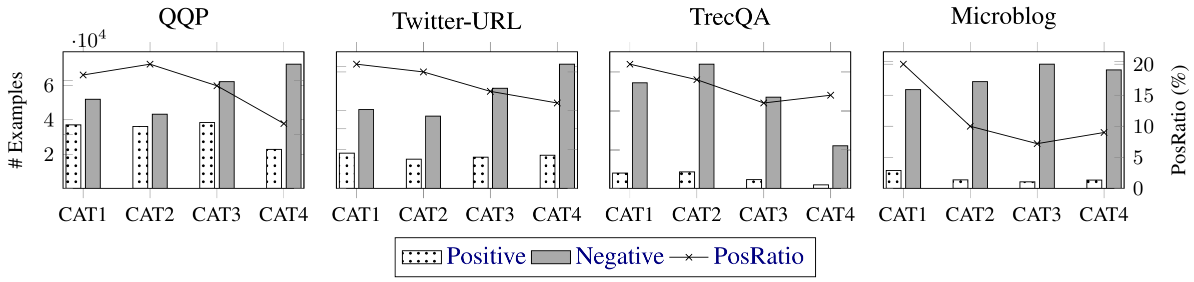

Figure 1: Length divergence distribution by labels across datasets. Bars represent the number of examples, corresponding to the left axis; polylines represent the ratio of positive examples, corresponding to the right axis.

suggesting their reliance on this heuristic.

Despite demonstrating the existence of length divergence bias, the underlying reason has not been well explained. By conducting the *SentLen* probing experiment (Conneau et al., 2018), we bridge this gap through revealing the text length information TM models have learned during training.

We finally explore a simple yet effective adversarial training method to correct the length divergence bias. The results show our approach not only reduces the bias but also improves the generalization ability of TM models. To encourage the development of TM models that understand semantics more precisely, we will release our code.

2 Datasets and Models

We select four well-known NLP and IR datasets as follows: **Quora Question Pairs (QQP)** (Wang et al., 2018), **Twitter-URL** (Lan et al., 2017), **TrecQA** (Wang et al., 2007), and **TREC Microblog 2013 (Microblog)** (Lin and Efron, 2013).

We study four models for textual matching tasks: **MatchPyramid** (Pang et al., 2016), **BiMPM** (Wang et al., 2017), **ESIM** (Chen et al., 2017) and **BERT** (Devlin et al., 2019). The four models above are representative in terms of neural architectures.

The detailed explanation for each dataset and model can be found in Appendix A.1 and A.2.

3 Length Divergence Heuristic in Current Datasets

In this section, we characterize existing datasets from the perspective of the length divergence between text pairs. We first formulate pairwise length divergence for NLP tasks and listwise length divergence for IR tasks, respectively.

Pairwise. Given two texts T_1 and T_2, their relative length divergence is defined as:

$$\Delta_{\text{rel}}\mathcal{L}(T_1, T_2) := \frac{|\mathcal{L}_{T_1} - \mathcal{L}_{T_2}|}{\min(\mathcal{L}_{T_1}, \mathcal{L}_{T_2})}, \tag{1}$$

where

$$\mathcal{L}_T := \#(\text{words in } T). \tag{2}$$

Listwise. In IR tasks, each example consists of a query Q and a list of documents $\boldsymbol{D}$ associated with it. We define the listwise relative length divergence with respect to Q as:

$$\Delta_{\text{rel}}\mathcal{L}(Q, \boldsymbol{D}) := \frac{|\overline{\Delta_{\text{rel}}\mathcal{L}}(Q,\boldsymbol{D}^+) - \overline{\Delta_{\text{rel}}\mathcal{L}}(Q,\boldsymbol{D}^-)|}{\min(\overline{\Delta_{\text{rel}}\mathcal{L}}(Q,\boldsymbol{D}^+), \overline{\Delta_{\text{rel}}\mathcal{L}}(Q,\boldsymbol{D}^-))}, \tag{3}$$

$$\overline{\Delta_{\text{rel}}\mathcal{L}}(Q, \boldsymbol{D}^{+/-}) = \frac{\sum_{d^{+/-} \in \boldsymbol{D}^{+/-}} \Delta_{\text{rel}}\mathcal{L}(Q, d^{+/-})}{|\boldsymbol{D}^{+/-}|}, \tag{4}$$

where $\boldsymbol{D}^+$ is the set of relevant documents while $\boldsymbol{D}^-$ is irrelevant. For instances whose $\overline{\Delta_{\text{rel}}\mathcal{L}}(Q, \boldsymbol{D}^{+/-})$ does not exist or is equal to zero, we set $\Delta_{\text{rel}}\mathcal{L}(Q, \boldsymbol{D})$ to be a large number.

Based on the length divergence definition, we sort and split the training sets into quarters, namely `CAT1-4`, and examine length divergence distribution by labels for each dataset. Statistics are shown in Figure 1. We can see that all datasets suffer from the same problem: as the length divergence increases, the ratio of positive examples decreases. Overall, negative examples tend to have higher length divergence than positive ones, providing direct cues for label assignment.

4 Length Divergence Bias in TM Models

In this section, we demonstrate that existing TM models indeed employ the length divergence heuristic in datasets. Existing test sets are drawn from the same distribution as the training sets, which are overly lenient on models that rely on superficial cues. To provide a more robust assessment of TM models, we construct adversarial test sets by eliminating such heuristic.

4.1 Adversarial Test Sets

For two NLP datasets, adversarial test sets are built by the following steps: First, examples are sorted and split into four categories according to their

	Original					Adversarial				
	CAT1	CAT2	CAT3	CAT4	ALL	CAT1	CAT2	CAT3	CAT4	ALL
# Positive	4,055	3,967	4,280	2,583	14,885	3,385	2,882	4,013	2,583	12,863
# Negative	5,781	4,923	6,853	7,988	25,545	5,781	4,923	6,853	4,410	21,967
# Total	9,836	8,890	11,133	10,571	40,430	9,166	7,805	10,866	6,993	34,830
PosRatio	0.41	0.45	0.38	0.24	0.37	0.37	0.37	0.37	0.37	0.37

Table 2: Statistics of the original and adversarial test set on QQP task. Each category in the original test set is down-sampled to align with the average PosRatio.

length divergence. Second, we down-sample each category to align with the average PosRatio of the whole test set, i.e., the adversarial datasets we construct are subsets of theoriginal ones. Table 2 gives the details of the adversarial test set we build on QQP task, with a comparison of the original one.

The construction of IR datasets follows the same first step as NLP datasets. Considering random down-sampling may break the completion of query and its associated documents, in the second step, we discard the fourth category directly instead of down-sampling across all categories.

4.2 Re-evaluating TM Models

To examine whether TM models exploit the length divergence heuristic of existing datasets, models trained on the original training sets are evaluated on the original and adversarial test sets, respectively. We provide further details to facilitate reproducibility in Appendix A.3.

Results. The results are shown in Table 3. Overall, almost all models have a performance drop on all datasets (14 out of total 16 combinations). It seems that MatchPyramid captures the richest length divergence cues, as its performance drops most dramatically. BiMPM and ESIM both perform worse on the adversarial test sets except for one task. Although BERT outperforms other models, it cannot maintain its performance under adversarial evaluation either.

Moreover, we explore how the recall varies with the length divergence of examples. We report the recall for four length divergence categories of all models on QQP adversarial test set. Figure 2 shows that the recall declines across four categories, which indicates that TM models are more inclined to determine examples with high length divergence as negative, and vice versa.

We address that the adversarial evaluation scheme, which invalidates the length divergence heuristic, provides a more robust assessment for TM models. The above results are well apt with our intuitions about the length divergence bias: models

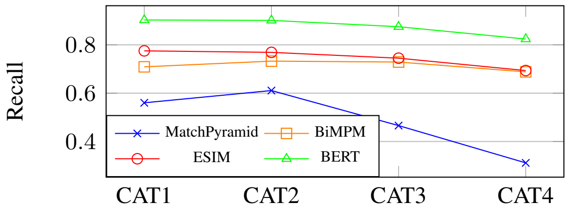

Figure 2: Recall of all models on the QQP adversarial test set. `CAT1` is the category with the lowest length divergence. Recall decreases across four categories, indicating TM models tend to determine examples with high length divergence as negative and vice versa.

do exploit some superficial cues about length divergence, instead of truly understanding the meaning of texts despite their good performance.

4.3 Probing Experiment

The adversarial evaluation has revealed the length divergence bias of TM models, but reason for this phenomenon is still unclear. In this section, we dig deeper into this problem.

Despite the variations of the architectures of TM models, all of them need to extract representation of texts first. The linguistic properties TM models capture have a direct effect on the downstream tasks. To explore what kind of information TM models have learned, we introduce a probing experiment using representations produced by TM models to predict the length of texts. We conduct the *SentLen* task in SentEval (Conneau et al., 2018), which is a 6-way classification task performed by a simple MLP with Sigmoid activation. As MatchPyramid cannot produce representation of a single text, we do not include it in this probing experiment. BiMPM and ESIM model both employ a BiLSTM encoder. We select the maximum value over each dimension of the hidden units as text representations, and use untrained encoders with random weights as the baseline. As BERT uses the output of the first token (`[CLS]` token) to make classification, we report the classification result using `[CLS]` token representations. We use the pre-trained model without fine-tuning as baseline.

Results. From Table 4 we can see that BiLSTM

Datasets	Metrics	MatchPyramid		BiMPM		ESIM		BERT	
		Original	Adversarial	Original	Adversarial	Original	Adversarial	Original	Adversarial
QQP	Acc	70.18 (+6.29)	68.66 (+7.31)	81.52 (-0.08)	80.91 (+0.15)	82.15 (-0.50)	81.38 (-0.15)	83.51 (+1.34)	82.57 (+1.67)
	BA	66.00 (+8.41)	64.60 (+9.44)	79.43 (+0.63)	78.97 (+0.81)	80.62 (-1.23)	80.01 (-0.96)	84.46 (+0.77)	83.65 (+1.04)

Table 3: Performances of four TM models on the original and adversarial test sets for four tasks. Models are first trained on the original training sets. Performances of all systems drop on the adversarial test sets compared to on the original test sets. Models are then re-trained on the adversarial training sets. Numbers in parentheses indicate absolute gains from adversarial training.

Models	QQP	Twitter-URL	TrecQA	Microblog
BiMPM				
Untrained	56.18	54.47	56.23	57.03
BiLSTM-max	63.85	64.66	57.35	57.64
ESIM				
Untrained	58.28	56.99	55.81	56.89
BiLSTM-max	65.83	65.43	66.59	66.06
BERT				
Untrained	72.63			
BERT-`[CLS]`	70.66	72.10	81.33	75.08

Table 4: Probing task accuracies. Classifier takes text representation produced by TM models as input.

encoder has a severe performance boost across all datasets after training, which indicates that BiMPM and ESIM extract rich text length information during training. Compared to untrained BiLSTM encoder, BERT achieves a substantially better performance without fine-tuning. Interestingly, while BERT model suffers bias too, they are less pronounced, perhaps a benefit of the exposure to large corpus where the spurious patterns may not have held. It seems that pre-training enables BERT to extract relatively deeper linguistic properties and forget about superficial information.

The *SentLen* probing experiment reveals that TM models learn rich text length information during training, indicating the intrinsic reason why TM models suffer from the length divergence bias.

5 Length Divergence Bias Correction

In this section, we propose to correct the length divergence bias. As the model modification method usually has a significant cost and is inefficient, we apply adversarial training with bias-free training data. Our method is much more practical, lower cost, and easier to be implemented and adopted. We first construct the adversarial training sets in the same way as the adversarial test sets. We next re-train each model on the adversarial training sets and report their performance on two test sets.

Results. As presented in Table 3, performances improve for almost all models across four datasets except for one combination (ESIM on QQP). It is a little inspiring that adversarial training brings tremendous benefits to some models on IR tasks (MatchPyramid and ESIM on TrecQA dataset, BiMPM and ESIM on Microblog dataset). One possible explanation for this phenomenon is that, in IR tasks, the length divergence and class-imbalance are more severe than NLP tasks. While alleviating the length divergence bias of TM models, our method also makes models achieve better performances on the original test sets. Overall, the adversarial training not only successfully corrects the length divergence bias in TM models but also improves their generalization ability.

6 Conclusion

The inspiring success of deep models is accounted for by employment spurious heuristics in datasets, instead of truly understanding the language. In this work, we investigate the length divergence heuristic that textual matching models are prone to learn. We characterize current TM datasets and find that examples with high length divergence tend to have negative labels and vice versa. To provide a more robust assessment, we construct adversarial test sets, on which models using this heuristic are guaranteed to fail. Experiments show that almost all TM models perform worse on adversarial test sets, indicating they indeed exploit the length divergence cues. We then provide a deeper insight by conducting the *SentLen* probing experiment. TM models are shown to learn rich text length information during training, which accounts for the length divergence bias. Finally, we propose a simple yet effective adversarial training method to alleviate the length divergence bias in TM models. It's a little inspiring that our approach improves models' robustness and generalization ability at the same time. Overall, our results indicate that, there is still substantial room towards TM models which understand language more precisely.

A Appendix

A.1 Datasets Details

Here, we provide details for the datasets we use.

Quora Question Pairs (QQP) (Wang et al., 2018) is a widely used benchmark in semantic matching. Each pair is annotated with a binary label indicating whether the two texts are paraphrases or not. We use split QQP from GLUE (Wang et al., 2018) benchmark with 363,849 examples for training and 40,430 for testing. We report accuracy (Acc) and balanced accuracy (BA).

Twitter-URL (Lan et al., 2017) is a sentence-level paraphrases dataset collected from tweets with 42,200 examples for training and 9334 for testing. For each pair, there are 6 raw annotations given by human raters. We perform the data preprocessing followed the author's notes.[1] We report macro-F1 and micro-F1.

TrecQA (Wang et al., 2007) is a widely used benchmark for question answering. According to Rao et al. (2016), there are two versions of TrecQA: both have the same training set, but their test sets are different. We use the clean version (Wang and Ittycheriah, 2015) with 53,417 examples for training and 1117 for testing. We report mean average precision (MAP) and mean reciprocal rank (MRR).

TREC Microblog 2013 (Microblog)(Lin and Efron, 2013) is a task to rank candidate tweets by relevance to a short query. We use the version prepared by Rao et al. (2019) with 39,378 examples for training and 6814 for testing. We report MAP.

Despite the fact that these datasets differ in tasks (similarity scoring vs. paraphrase detection vs. answer selection vs. tweet search), we regard all of them as a binary classification task to predict the textual similarity between two texts.

A.2 Models Details

Here, we provide details for the models we use.

MatchPyramid (Pang et al., 2016) views the matching matrix between two texts as an image, and a CNN is employed to learn hierarchical matching patterns.

BiMPM (Wang et al., 2017) matches encoded text pairs in two directions with four matching strategies. To accelerate the training procedure, we discard the character-composed embedding of the original BiMPM.

ESIM (Chen et al., 2017) is a sequential inference model based on chain LSTMs. We use the base ESIM without ensembling with a TreeLSTM.

BERT (Devlin et al., 2019) is a transformer-based (Vaswani et al., 2017) pre-trained language model. Due to the limitation of computational resources, we use BERT$_{\text{TINY}}$, which is a compact BERT model with 2 layers and 128 hidden units.

MatchPyramid is based on CNN, BiMPM and ESIM on RNN, and BERT$_{\text{TINY}}$ on Transformers.

---

A.3 Training Details

We provide further details about the evaluation in Section 4 to facilitate reproducibility. We implement baselines based on open-source reproduction.[2]

Parameters setting. For MatchPyramid, BiMPM and ESIM, we use 300-dimension GloVe word embeddings (Pennington et al., 2014), and keep the pre-trained embeddings fixed during training. Words not present in the set of pre-trained words are initialized randomly. The kernel size of MatchPyramid is set to be 5×5 and 3×3. The dimension of hidden states of ESIM and BiMPM is set to be 128 and 100, respectively. They are trained using Adam (Kingma and Ba, 2015) with initial learning rate of $1e^{-4}$ and batch size of 64. For BERT, we use the implementation provided by the authors[3] and apply their default fine-tuning configuration.

Number of parameters in each model. The number of parameters in MatchPyramid is $15{,}053{,}562$, of which $52{,}962$ are trainable. The number of parameters in BiMPM is $15{,}890{,}202$, of which $889{,}602$ are trainable. The number of parameters in ESIM is $16{,}695{,}410$, of which $1{,}694{,}810$ are trainable. The number of parameters in BERT$_{\text{TINY}}$ is $4{,}386{,}178$, and all of them are trainable.

Abstract

Accurate automatic evaluation metrics for open-domain dialogs are in high demand. Existing model-based metrics for system response evaluation are trained on human annotated data, which is cumbersome to collect. In this work, we propose to use information that can be automatically extracted from the next user utterance, such as its sentiment or whether the user explicitly ends the conversation, as a proxy to measure the quality of the previous system response. This allows us to train on a massive set of dialogs with weak supervision, without requiring manual system turn quality annotations. Experiments show that our model is comparable to models trained on human annotated data. Furthermore, our model generalizes across both spoken and written open-domain dialog corpora collected from real and paid users.

1 Introduction

Relying on human evaluation to determine the quality of open-domain dialog systems is not an efficient approach in terms of time and cost. Automatic evaluation can be a good replacement for human annotations and can increase the pace of open-domain dialog system development. However, standard word-overlap metrics (BLEU, ROUGE, Perplexity) do not correlate well with human judgements of open-domain dialog systems (Deriu et al., 2020; Liu et al., 2016) because of the diverse set of outputs that can be relevant given a dialog context.

A solution for better automatic evaluation methods is to train reference-free evaluators that learn how to assess the generated responses given dialog contexts from different aspects such as relevancy (Tao et al., 2018; Ghazarian et al., 2019; Lan et al., 2020), engagement (Ghazarian et al., 2020), fluency (Zhang et al., 2021b; Pang et al., 2020), contradiction (Pang et al., 2020; Nie et al., 2021) amongst others. It is also important to get some holistic evaluation at the dialog level in order to assess the dialogs as a whole (Zhang et al., 2021a; Li et al., 2021; Mehri and Eskenazi, 2020; Finch et al., 2021).

Recently, Mehri and Eskenazi (2020); Eskenazi et al. (2019) have shown the effectiveness of looking into the next user utterance as a proxy to measure the quality of the chatbot's generated responses. See and Manning (2021) have shown that predicting next user satisfaction helps to select more relevant system utterances. Inspired by works in this area, we propose to automatically extract features from the next user utterance, such as sentiment, to use as a proxy to evaluate system responses. The advantage of our method is that we do not need to train on data with human annotations for turn level quality, and instead can rely on available large datasets with automatically extracted annotations.

Most existing automatic evaluators focus purely on open-domain text-based dialog systems. In addition to textual interactions, we perform experiments on voice-based interactions that were collected via paid and real users. Furthermore, we compute correlations with a real user's own (referred to as first party, 1P) rating when available, in addition to annotations by third party (3P) annotators. Our contributions include:

1. training an automatic evaluator on the sentiment of the next user utterance in a weakly supervised fashion to evaluate system responses,
2. outperforming existing automatic evaluation metrics on both text and voice-based open-domain dialog datasets,
3. a turn-level annotated open-domain text-based dialog dataset that we will release.[1]

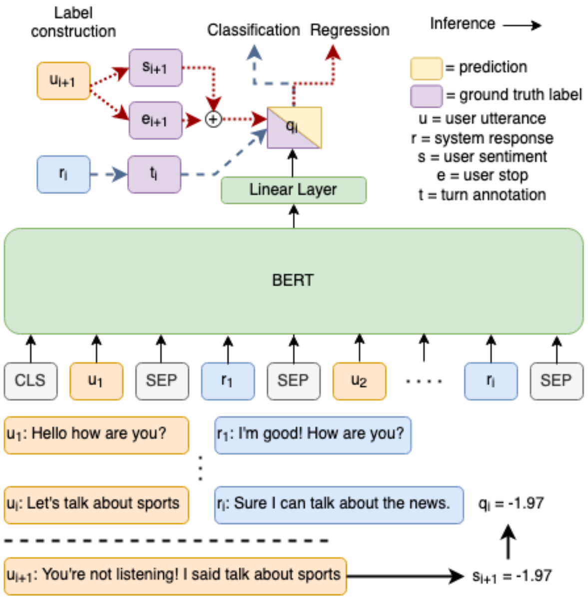
Findings of the Association for Computational Linguistics: ACL 2022, pages 4194 - 4204
May 22-27, 2022



u_1: Hello how are you?

r_1: I'm good! How are you?

u_i: Let's talk about sports

r_i: Sure I can talk about the news.

u_{i+1}: You're not listening! I said talk about sports

Figure 1: Training/Inference for turn quality estimation. The dotted arrows show how q_i, which represents the system turn quality for system response r_i, is constructed for training. For our regression model indicated by the red arrow, s_{i+1} (user sentiment) and e_{i+1} (user stop) are summed together to create q_i. For our classification model indicated by the blue arrow, q_i is equal to t_i. In the example dialog, the user expresses negative sentiment in u_{i+1}. The sentiment score -1.97 is used as the reference label q_i, indicating the quality of response r_i.

2 Methods for Automatic Evaluation

For turn quality estimation, the task is defined as follows: given a dialog context and a system response in the last turn, $D = [u_1, r_1 \ldots u_i, r_i]$ (where u_i and r_i are the user utterance and system response respectively for the i^{th} turn in a dialog), determine if r_i is an appropriate response. q_i indicates the quality of response r_i and will be used as our reference label when training the model. Figure 1 shows our model architecture. We train a BERT-base (Devlin et al., 2019) model that encodes the dialog context and the latest system response. We use the pooled representation output by the BERT model and pass it through a linear layer to determine the quality of the response. Depending on the reference label used to train this model, we adopt a classification or regression setup, described below.

- **Classification model trained using turn level annotations.** When annotations for system responses are available in our training data (a binary label t_i as shown in Figure 1 for response r_i, indicating if the system response is appropriate), we train a classification model using such reference labels.
- **Regression model trained using next user sentiment.** Obtaining turn level annotations for dialogs is costly. In this work, we explore using weak supervision to approximate response quality. Eskenazi et al. (2019) stated that given a system response, the follow up user's utterance should be used to evaluate the quality of the system response as it increased agreement amongst human annotators. Motivated by this, we propose to use the sentiment of the next user utterance as a proxy to estimate the quality of the previous system response. In Figure 1, s_{i+1} is the sentiment score for the next user utterance u_{i+1}. Note that this information is automatically generated from the user utterance, and thus allows us to leverage data without a turn level annotation. Since such sentiment scores are often continuous, we use a regression model for these target labels.
- **Next user stop signal.** We also examine if the next user utterance stops a dialog (e_{i+1} in Figure 1). e_{i+1} is 0 if the user stops the dialog and 1 if they continue the dialog. We use this as an additional signal by summing it with the sentiment information above as target labels for model training.

For dialog level evaluation, we follow previous work and use mean aggregation techniques to estimate dialog level ratings from turn level scores (Lowe et al., 2017; Ghazarian et al., 2019, 2020; Lan et al., 2020; Yeh et al., 2021). In our experiments, we show how aggregated turn level quality and user sentiment scores correlate with dialog level ratings.

3 Dialog Datasets

As described earlier, most previous work in automatic evaluation focuses on text-based open-domain dialog systems (Yeh et al., 2021; Lan et al., 2020; Sinha et al., 2020; Huang et al., 2020; Ghazarian et al., 2020). Additionally most dialog datasets are collected via crowdworkers. While we also evaluate on written (text-based) dialogs, the primary dataset in our work consists of spoken (voice-based) interactions between a dialog system and a real user.

3.1 Open Domain Dialog System

We first describe the open-domain dialog system used for our spoken dialog data collection. The

Dialog Split	Number of Interactions (Train/Dev/Test)	Avg. Number of Turns (Train/Dev/Test)	3P turn quality	3P rating	1P rating
PUI	-/-/87	- / - / 14.5	✓	✓	
RUI-1P	6215 / 690 / -	10.3 / 10.8 / -			✓
RUI-3P	500 / 55 / 132	11.1 / 10.7 / 14.3	✓	✓	✓
ConTurE	- / - / 119	- / - / 8.95	✓	✓	

Table 1: Dataset Statistics for Spoken and Written dialog datasets. RUI (Real User Interactions)

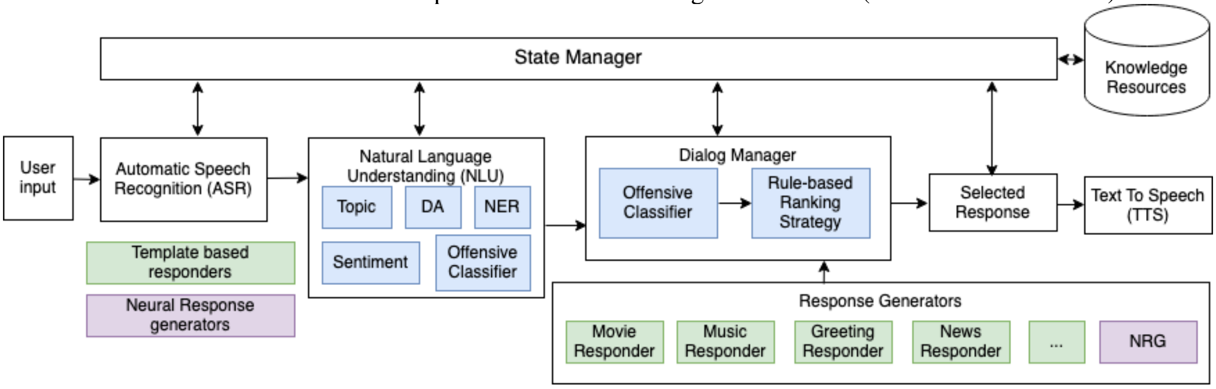


Figure 2: Architecture of our open-domain dialog system. NER = Named Entity Recognition, DA = Dialog Act

architecture of our dialog system is shown in Figure 2. Every user utterance in the dialog is sent into an ASR system whose output goes through a series of NLU modules that classifies topics, dialog acts, sentiment, extracts entities, and detects if the user utterance is offensive. Our system then calls multiple response generators (called responders) for the given dialog context and logs all the generated response candidates within the State Manager. The final response is selected based on a rule-based ranking strategy, and then sent to the TTS module whose output is presented to the user.

For popular topics in open domain dialogs, such as movies, music, recent news, we develop template-based responders (highlighted in green in Figure 2) for the given dialog state. An example state and response for the movie domain is: when the user turn mentions a movie name (based on the NER result), we respond with information about the actor, the rating, or the plot of this certain movie. In addition to topic-specific template-based responders, our system includes other template-based responders for some special dialog contexts, such as greetings, topic switches, etc.

For every user turn, we also apply a neural network-based response generation (NRG) model to produce a response, highlighted in purple in Figure 2. Our *NRG Responder* is a GPT2-XL (Radford et al., 2019) based model trained on real user-system interactions described in Section 3.2.

The rule-based response ranker uses predefined logic and selects a template-based responder when it is available and the user topic matches that responder, otherwise it uses the NRG response as a fall back. In our system since we have just a few template-based responders, the system uses NRG responses most of the time.

3.2 Spoken Dialogs

We deploy the dialog system described above within the Alexa Prize Socialbot framework (Ram et al., 2018) to interact with real users. A user initiates an interaction with our dialog system and consents to have their data collected. A turn within an interaction is specified as a user utterance-system response pair. These interactions end when the user requests to stop the conversation. At the end of each interaction, users are given the opportunity to leave a rating in the range of 1 to 5. We define these ratings as *1P rating* as they come from the same users who interacted with the conversational agent. We denote this dataset as *Real User Interactions (RUI)*[2]. Our data consists of approximately 100k interactions and 5 million turns. This dataset is used to train our *NRG Responder* mentioned in the previous section. We discuss its training details in the Appendix.

Not every user leaves a rating; therefore, we take a sample of interactions from *RUI* that contain user ratings and denote this dataset as *RUI-1P*.

In addition to real user interactions, we form a dataset of interactions from paid users who were

---

[2] All interactions are in English.

instructed to speak to the same dialog system. We denote these interactions as *paid user interactions PUI*[2]. The difference between paid and real users is that the former are internal workers who are recruited to rigorously test and probe the dialog system and as a result are much more proactive in the dialogs as opposed to real users who are known to be less proactive in these social conversations (Juraska et al., 2021; Finch et al., 2020). These internal workers are considered paid as their primary job consists of assisting with data collection. Real users, however, are consenting to a dialog with our dialog system but are not being paid.

To obtain turn quality labels, we annotate a subset of *RUI-1P* at the turn level. Given a complete interaction, an experienced annotator was asked to annotate each system response either as 1 or 0, where 1 indicates the response is appropriate and vice versa for 0. Additionally, we ask annotators to leave a dialog level rating in the range of 1 to 5. We define this turn and dialog level annotations as *3P turn quality* and *3P ratings* respectively, since they came from annotators who rated other users' interactions. We denote this annotated data as *RUI-3P*. An example of a turn level annotation is shown in the Appendix. We also perform the same annotation on the *PUI* data. Table 1 shows the statistics for each of these collections and available annotations for each dataset.[3]

To obtain sentiment labels, we leverage the BiLSTM sentiment model from (Kim et al., 2020), which was trained on spoken dialog data and automatically tag user utterances with sentiment. The model takes in both audio and textual features and outputs a real-valued valence score on a scale from -3 to 3, which measures the degree of the utterance's positivity/negativity.

3.3 Written Dialogs

We sample a set of dialogs released from the Interactive Evaluation of Dialog track (Gunasekara et al., 2020) to be annotated for turn quality. These dialogs were collected from invited participants conversing with knowledge-grounded response generation models through textual exchanges, and have been publicly released[4]. The original authors of this dataset asked Amazon Mechanical Turk (AMT) workers to rate 2200 interactions on multiple dialog level dimensions, such as coherent, informative, overall. The full list of dialog level annotation dimensions is included in the Appendix. However, these dialogs do not have turn level annotations. In order to evaluate our models at the turn level, we sample 119 dialogs with an average length of 8 turns. For each turn, we ask three AMT workers to rate whether they dislike, somewhat like or like the Chatbot's response with a score of either 0, 1, or 2 respectively. To help workers judge response quality, we ask them to look at how relevant and interesting a response is. We use majority voting to determine the final score. In the case of ties we use a score from an internal author. The Krippendorff's alpha score is 0.31 representing fair agreement between annotators. We denote these assessments as *3P turn quality* since the AMT workers are rating other workers' dialogs. We denote this dataset as *Conversational Turns Evaluation (ConTurE)* and publicly release it.[5]

4 Results and Discussions

We compare our method with a suite of open source models from (Yeh et al., 2021)[4] including RUBER, BERT-RUBER, PONE, PredictiveEngagement and FED (Tao et al., 2018; Ghazarian et al., 2019; Lan et al., 2020; Ghazarian et al., 2020; Mehri and Eskenazi, 2020).

Table 2 shows the automatic turn level quality estimation, measured using both Pearson and Spearman correlation against turn level annotations on three datasets for different methods. On the spoken dialog testsets(*RUI-3P* and *PUI*) the baseline models perform poorly. In contrast, our Classification(3P) model trained using *3P turn quality* achieves the highest correlation (0.29/0.28) on *RUI-3P*. This can be partly explained by the matched training and testing setup. We observe promising results for the Reg (Sentiment + User Stop) model which was trained with next user sentiment information combined with stop signal which achieves the highest correlation on the *PUI* test set and a correlation of (0.22/0.23) on *RUI-3P*. This demonstrates the effectiveness of weak supervision. We compare different training sizes *RUI-1P* (40%) versus *RUI-1P* and show the expected benefit of more data for model training. We also see that our models outperform the baseline models on the *ConTurE* testset. It is important to note that all the baseline models have been designed and evaluated

---

[3] We cannot release this data publicly as it is real user data.

[5] We release the ConTurE dataset at `https://github.com/alexa/conture`

Training Set	Model (Ref label)	RUI-3P (test set)		PUI		ConTurE	
		Pearson	Spearman	Pearson	Spearman	Pearson	Spearman
-	RUBER	-0.08	-0.07	-0.1	-0.1	-0.01	-0.03
-	BERT-RUBER	0.01	0.02	-0.02	-0.02	-0.007	0.004
-	PONE	0.01	0.004	-0.02	-0.03	0	0.01
-	PredictiveEng	-0.11	-0.11	-0.06	-0.05	-0.11	-0.09
-	FED	-0.006	-0.02	-0.03	-0.04	0.11	0.10
Our method							
RUI-3P	Classification (3P)	**0.29**	**0.28**	0.23	0.24	-0.01	0.11
RUI-1P	Reg (Sentiment)	0.15	0.12	0.19	0.16	**0.34**	**0.34**
RUI-1P	Reg (Sentiment + User Stop)	0.22	0.23	**0.35**	**0.3**	0.3	0.33
RUI-1P (40%)	Reg (Sentiment + User Stop)	0.2	0.22	0.29	0.24	0.31	0.32

Table 2: Correlation between both baseline and our model outputs against *3P turn quality* for spoken and written datasets. For our method, reference labels used for Classification or Reg (Regression) models are presented.

using written dialogs, and though our models were fine-tuned only on spoken dialog, they are able to generalize to a different modality. FED has been shown to be a good dialog-level evaluator (Yeh et al., 2021). However we see in Table 2 that FED achieves low performance for turn-level evaluation. This matches the conclusion in (Mehri and Eskenazi, 2020) who point out that FED captures the dialog-level qualities from its training data Reddit better than turn-level qualities.

Table 3 shows the correlation results of the aggregated turn level scores with *3P ratings* and *1P ratings* on the spoken dataset. From the first row, we can see that there is a moderate positive correlation between the aggregated mean of *3P turn quality* and *3P ratings* (0.50 / 0.46), but see a very low positive correlation with *1P ratings* (0.16 / 0.12). This may be due to the fact that Likert scale ratings can have lower inter-annotator agreement (Belz and Kow, 2010). Additionally, the 3P annotators had access to the whole interaction and could re-read the context. This is in contrast to 1P users who may forget what happened earlier in the interaction as it is spoken. Another reason is that 3P annotators only read the transcript of the dialog for turn or dialog evaluation, and may miss the tones in utterances that may affect 1P user ratings. When using the user sentiment scores, we can see through mean aggregation it has positive correlation with both *3P ratings* (0.48/0.46) and *1P ratings* (0.38/0.37). The higher correlation of user sentiment (as opposed to *3P turn quality*) with *1P rating* is partly because of the different signals used in 3P annotation as discussed above. These results suggest sentiment can be used to estimate dialog level ratings, as done in previous work such as (Kim et al., 2020).

Overall, we see that the next user utterance sentiment serves as a reasonable proxy to the quality of the previous system response, hence when there is not much data with turn level quality annotation, we can train models using weak supervision coming from the next user utterance. In this study, we use the sentiment scores obtained from user utterances in speech based dialogs, therefore, acoustic features were used to obtain such sentiment information. Since speech based sentiment or emotion recognition has been widely studied, it does not require much additional annotation to train the sentiment model for user utterances, and thus we can rely on existing models. We also explored using sentiment just based on text, but observed some issues in our preliminary study. For example, when users reply with a ‘no’ to a question, it is classified as negative, however, this may not indicate a problem with the previous system response. We plan to further investigate this in our future work, which will allow us to better utilize more available text based dialog data. Example outputs from both FED and our model are shown in the Appendix.

	3P Ratings		1P Ratings	
	P	S	P	S
3P turn quality	**0.50**	**0.46**	0.16	0.12
User sentiment	0.48	0.46	**0.38**	**0.37**

Table 3: Correlation between turn level information (3P turn quality and user turn sentiment) and dialog level rating on RUI-3P. P=Pearson, S=Spearman.

5 Conclusion

In this work, we show that instead of training on manually annotated data we can train on sentiment from the next user utterance in a weakly supervised manner to evaluate system responses. We show that our model has better cross domain generalization and performs well on a written dialog dataset. In our future work we will investigate other methods beyond simple aggregation for dialog level estimation and using more text based dialog data.

6 Ethics and Broader Impact

Our work involves leveraging user sentiment to evaluate the quality of system responses. We acknowledge that we are using data from real users who have not been paid for these interactions. We also acknowledge there may be biases in the demographics of the user population. We conducted our ConTurE annotation through Amazon Mechanical Turk. We pay turkers $12 per hour, which is well above the federal minimum age.

A Appendices

A.1 Hyperparameters for the turn level quality estimation model

All our BERT models were finetuned with a batch size of 8 and a learning rate of 1e-5 with the Adam optimizer (Kingma and Ba, 2014). We train each model for 10 epochs and select the best model by computing correlation on the *RUI-3P* (dev set).

A.2 NRG responder hyperparameters

We train our *NRG Responder* models on the *RUI* dataset described in Section 3.2. This dataset is split into a 80/10/10 train, valid, test set. Our model is initialized with GPT2-XL (Radford et al., 2019) and is finetuned with a batch size of 2 and a learning rate of 6.25e-5 with the Adam optimizer. We train the model for 3 epochs and we finetune both the language modeling head and multiple choice Head of GPT2 in a TransferTransfo fashion (Wolf et al., 2019). For the multiple choice head, one randomly selected negative candidate was used. We leverage the HuggingFace's transformers library for all our models.[6]

A.3 Turn level annotation example

Example

Dialog History:
System: I can talk about news, movies, music. What topic would you like to talk about today?
User: news

System: Sure. i love sports! what is the sport that you watched the most?
Turn quality: 0
Reason for annotation: The system response was off-topic

Figure 3: Example of 3P turn annotations. Due to privacy concerns, this example dialog is from an internal author.

A.4 Turn level statistics

ConTurE	
Percentage of Turns with score 0	30.7%
Percentage of Turns with score 1	22.2%
Percentage of Turns with score 2	47%
RUI-turn	
Percentage of Turns with score 0	35.3%
Percentage of Turns with score 1	64.7%

Table 4: Statistics of Turn level annotations for both ConTurE and RUI-3P datasets.

A.5 Dialog level scores for ConTurE

We take the mean aggregation of the turn level annotations and compute the correlation against each dialog level dimension in the original DSTC9 dataset. We see that the annotations have moderate correlation with all the parameters, with the highest being with 'human (overall)' (0.45/0.48). This shows that even though the turn and dialog level annotations were left by two different Turkers the turn annotations seem reliable.

Dialog level parameter	Pearson	Spearman
consistent	0.38	0.40
likeable	0.42	0.45
diverse	0.23	0.25
informative	0.30	0.34
coherent	0.32	0.37
human (overall)	**0.45**	**0.48**
understanding	0.36	0.42
flexible	0.33	0.40
topic depth	0.34	0.35
error recovery	0.37	0.40
inquisitive	0.20	0.27

Table 5: Correlation between ConTurE turn-level and dialog-level scores.

---

A.6 Example outputs of turn quality estimation

We pick a mixture of examples to show where our model works and fails. For each example we show the ground truth turn quality left by our human annotators and the score from each model.

Example 1

Dialog History:

User: Who is Donald Trump?

System: that's a funny question, well it isn't really surprising that he isn't one of the three wealthiest presidents in american history, i know they measure by inflation but still.

Human Annotation (0-2) = 2

Classification(3P) = 0

Reg(Sentiment) = 0.14

Reg(Sentiment + User Stop) = 1.24

Example 2

Dialog History:

...

User: Covid19 is a virus that's spreading all over the world

System: i guess it is his book then, do you like to read?.

Human Annotation (0-2) = 0

Classification(3P) = 0

Reg(Sentiment) = -0.12

Reg(Sentiment + User Stop) = 1.04

Figure 4: Examples from both our Classification and Reg (Regression) models on the ConTurE dataset. In example 1 the classification model incorrectly predicts the system response as a bad response. For the Reg models there is no threshold set on the output and scores must be looked at in a relative matter. We see for the Reg models that the output score from the model in example 2 is lower than that in example 1, showing the model is capturing that the system response in example 2 was of worse quality than the system response in example 1.

Example 1

Dialog History:

...

System: i see. i find sports so exciting.

User: i don't

System: well, lets switch the subject. i am fascinated with the world. are you interested in travel?

Human Annotation (0, 1) = 1

Classification(3P) = 1

Reg(Sentiment) = 0.004

Reg(Sentiment + User Stop) = 0.96

Example 2

Dialog History:

...

System: i like dogs as well. i think they are much better than dogs. so, what's one of your favorite places you've been?

User: i don't like dogs

System: i am not a big fan of dogs either. i would rather stay in the united states. so, what did you eat for dinner last night?

Human Annotation (0, 1) = 0

Classification(3P) = 0

Reg(Sentiment) = -0.15

Reg(Sentiment + User Stop) = 0.67

Example 3

Dialog History:

...

System: i recently read a really nice uplifting news article. want to hear about it?

User: yes

System: sure. here's some positive, uplifting news i found. every day, we find our balance. want to hear more?

User: yes

System: that's great. what do you think about it?

Human Annotation (0, 1) = 0

Classification(3P) = 0

Reg(Sentiment) = 0.20

Reg(Sentiment + User Stop) = 1.20

Figure 5: Examples from both our Classification and Reg (Regression) models on a spoken interaction. Due to privacy concerns, this example interaction is from an internal author. The classification model is able to predict all examples correctly, which makes sense as it was trained on similar annotations. Both Reg models output a lower score for the system response in example 2 than in example 1, showing they are both able to capture that the system response in example 2 is of worse quality. However in example 3 the Reg models incorrectly give a high score to the system response that ignores the user's request.

A.7 FED versus our turn quality estimation

We show examples from the ConTurE dataset to compare the FED model against our Reg (Sentiment) model, which had the best performance on ConTurE. The max and min value score from FED are 4.39 and 1.74 respectively. The higher the output score from the FED model means the response is more appropriate. Below are examples where the FED model incorrectly predicts the system response is appropriate even though it was marked as inappropriate by the human annotator.

Example 1

Dialog History:
System: probably!
User: you're not a good chat bot
System: i haven't been there myself

Human Annotation (0-2) = 0

FED = 4.13

Reg(Sentiment) = -0.01

Example 2

Dialog History:
...
System: do you like horses?
User: No
System: no, not really. you?

Human Annotation (0-2) = 0

FED = 4.39

Reg(Sentiment) = 0.09

Example 3

Dialog History:
...
System: hello! how are you? i just found out that judge judy makes $ 123,000 per episode!
User: oh wow! that's a lot! how much did oprah make?
System: she gets paid $ 123

Human Annotation (0-2) = 0

FED = 4.18

Reg(Sentiment) = 0.17

Example 4

Dialog History:
...
System: I love gold! Especially when I buy trucks with it!
User: hell yeah brother
System: Yeah. I also like gold, money, power metal, and trucks.

Human Annotation (0-2) = 0

FED = 4.03

Reg(Sentiment) = 0.29

Figure 6: In both example 1 and 2 the last system response ignores the previous user utterance and therefore is marked as inappropriate. The FED model assigns a high score to these system responses. For example 3 both the FED and Reg(Sentiment) model incorrectly give a high score to the system response, which is factually incorrect. For example 4 both the FED and Reg(Sentiment) model incorrectly give a high score to the system response, which shows repetition.

(a) Regression (Sentiment)

(b) Regression (Sentiment + User Stop)

Figure 7: We plot the model output scores for the Regression (Sentiment) and Regression (Sentiment + User Stop) models for each reference label i.e. Class 0 and Class 1. We see that for Regression (Sentiment + User Stop) in Figure 7b the separation between model outputs for Class 0 and Class 1 become more pronounced as compared to Regression (Sentiment) in Figure 7a.

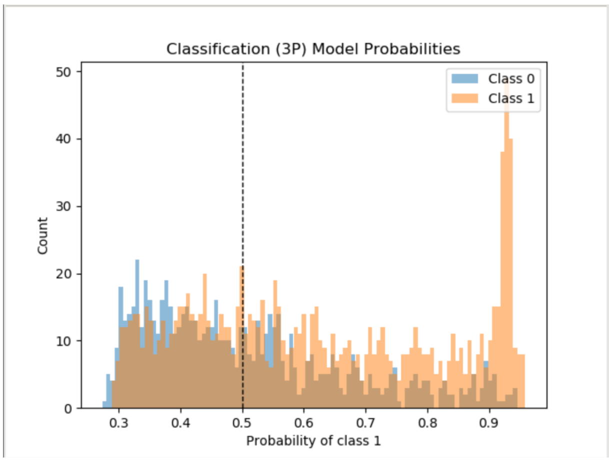

Figure 8: We plot the model probability outputs from the Classification(3P) model for each reference label i.e. Class 0 and Class 1. We use a threshold of 0.5 such that any score above or equal to that is considered a good response (1) and vice versa. We see that for the reference label Class 1 most probability scores are below the threshold.
