E2E	si entonces volví aquí a la casa si es fallbreak	yes so I came back to the house yes its fallbreak

Table 5: Example generated output from the CASCADE BIDIRECT and E2E BIDIRECT SHARED models. Note the error propagation in the cascade model.

performance on the Miami dataset.

We can also examine Table 4 to see how the cascade models compare to the E2E models. The results show that the **cascaded models perform the same or worse than the E2E models** they compare to w.r.t. parameter sharing, with the best overall model being the E2E BIDIRECT SHARED, beating the CASCADE BIDIRECT (e.g. 33.8 vs 37.2 WER or 23.3 vs 21.8 BLEU on Fisher No-FT).

Table 4 also illustrates that **fine-tuning models on CS data improves scores** on CS test sets (33.8 vs 30.0 WER for the E2E BIDIRECT SHARED on Fisher, 58.9 vs 53.0 for Miami). These gains are consistent for the Fisher dataset, which is the domain of the CS training set, however there are still gains for the out-of-domain Miami CS data. These results suggest that additional pre-training on natural or synthetic data (in both audio/text modalities) would likely be fruitful future work. When we examine how fine-tuning on CS data changes the model's monolingual scores, we find that they generally improve the monolingual results for the unidirectional models, but tend to make bidirectional models slightly worse, perhaps due to interference between the languages and tasks in the same weights. However, overall we find that fine-tuning provides large gains for CS with only minor decreases in monolingual performance.

5.2 Model Analysis

We also provide further analysis of the CS output of the best model and its cascaded counterpart (BIDIRECT CASCADE and E2E BIDIRECT SHARED). We perform three analyses: (1) comparing utterance level scores vs the proportion of CS words in the utterance, (2) computing the exact match accuracy of the CS spans in the model's output, and (3) qualitatively examining model output.

We check the correlation between the proportion of CS words in a sentence and the model's score, using a linear model to find the R^2 values. We found that surprisingly, there was **no correlation between the proportion of CS words and the models score** for any of the different models or metrics ($R^2 < 0.025$ for all models and metrics). A graphical depiction of the model's scores over CS proportions is in the Appendix, Figure 5. We note that this finding was the same for comparing the *number* of CS words instead of the *proportion*. This finding implies that the models are surprisingly robust to the amount of CS in a sentence.

Although BLEU and WER scores show how well the models do on the CS data, we can further isolate the performance of these models on only the code-switched parts of the utterances. To do so, we isolate all CS spans in the sentences and check to see if the model's output contains the exact-match of those spans. We note that this metric does not take into account synonyms or different tenses of the same word, making it a stricter metric serving as a lower bound of absolute performance. We see in Figure 4 that the E2E model still outperforms the cascade on CS spans, with Fisher No-FT scores around 20-30% and Fisher FT scores around 45%.

Finally, we can also examine the model's outputs. We inspected 200 output sentences for the monolingual subsets and found that both models generated the correct language in every case, indicating that they correctly learned the implicit LID. However, we can see that the cascade model does struggle with error propagation (especially so in the CS setting, Table 5), likely causing part of the difference between the E2E and cascade models.

Although the CS WER and BLEU scores are not as high as they are on cleaner monolingual datasets such as CoVoST (Appendix A), their performance is competitive with their respective monolingual performance on Miami and Fisher, even in the No-FT setting. We believe that with additional data and improvements ST models will be well-equipped to handle CS in practical situations and that **overall, models show strong CS performance**.

6 Conclusion

In this work, we expand the ST literature to explore code-switching, contributing a new task framework for ST that extends the joint transcription and translation setup. To further progress, we built and open-sourced a new ST corpus for CS from existing public datasets. We evaluated a range of models, showing that using bilingual joint decoders provides gains over using separate task decoders. We also showed that E2E systems provide better performance than their cascading counterparts on the CS task. Overall, our work shows that ST models can perform well on CS applications with both no fine-tuning and in low-resource settings, opening the door to new and exciting areas of future work.

A Training and Evaluation Details

We follow Gállego et al. (2021); Li et al. (2020) and use a triangular learning rate, adapting the step count to depend on the batch size (as not all models could fit the same batch size) with (64 / batch size) * 500 warm up steps, (64 / batch size) * 500 hold steps, (64 / batch size) * 3000 decay steps, a beta of 0.9, and a beta2 of 0.98. The learning rate was selected from running a search over {0.01, 0.005, 0.001, 0.0005, 0.0001, 0.0005}. We found that 0.0005 was best for all models, so we examined learning rates again between 0.0001 to 0.001 (by 0.0001) and found that they all performed similarly, thus we use 0.0005 in our experiments. For efficiency in batch size while training, we removed all instances whose audio length was longer than 20 seconds. We freeze the attention layers for the first 500 * (64 / batch size) steps, which is approximately the first epoch of training.

We initially trained the models on only CoVoST and MuST-C and found there was a large domain shift between these datasets and the comparatively noisier Fisher and Miami datasets. As domain shift was not the focus of this paper, we further trained the models on the Fisher and Miami monolingual training sets to reduce the effect of domain shift.

As a sanity check of the effectiveness of our training, we also include scores in Table 9 for the test sets of CoVoST and MuST-C. We note that our scores are close to the SoTA scores of Li et al. (2020) on CoVoST (and they use the large Wav2Vec2 model while we use the base version) and our MuST-C scores are higher than that of Gállego et al. (2021).

We evaluate using word error rate, character error rate, charcut, and BLEU. As the models learn different punctuation techniques from a variety of sources, including MuST-C, CoVoST, Miami, and Fisher, we remove all punctuation from the output before evaluating on the CS/Mono test sets, in order to only measure scores on the content. For BLEU, we use SacreBLEU with parameters case.lc+numrefs.1+smooth.4.0+tok.13a.

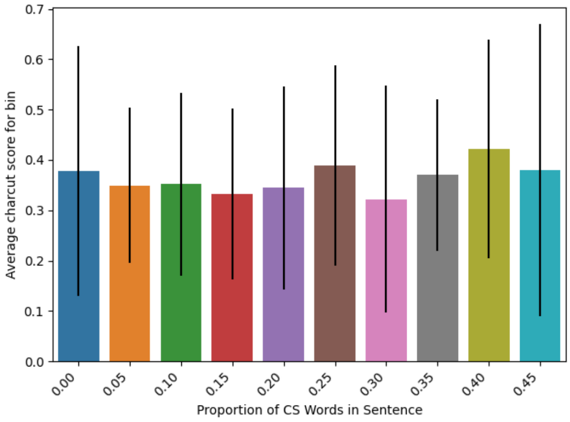

Figure 5: Charcut performance of the E2E BIDIRECT SHARED model on sentences with various levels of CS proportions. Note that there is no clear correlation, as described in Section 5.2. Black lines indicate error bars of 2 standard deviations while the bar represents the average.

B More LID Comparisons

We show results for all models that use LID on both datasets in Table 7. Note the conclusions remain the same as Table 3.

C Random Initialization Results

We also perform an ablation of these pre-trained scores (Table 6) for the E2E BIDIRECT SHARED model, as it is the best performing model overall. We tried many different setups for training it from from scratch rather than loading the pre-trained weights. We found that it was very difficult for this model to converge, and when it did, the results were sub-par.

D Training Results

We include the scores of evaluating our models on the test sets of the ST training data (MuST-C and CoVoST) in Table 9. We also include the results of fine-tuning performance on the CS dev set in Table 8, which roughly mirrors the main results.

E Expanded Results

For brevity, we do not include the CER and Charcut metrics in the main text. In this section we included tables with all metrics for all results (Table 10 for Miami and Table 11 for Fisher). We note however, that the WER and BLEU scores align with the CER and Charcut scores, and thus our conclusions remain the same.

Abstract

Recent interest in entity linking has focused in the zero-shot scenario, where at test time the entity mention to be labelled is never seen during training, or may belong to a different domain from the source domain. Current work leverage pre-trained BERT has the implicit assumption that BERT bridges the gap between the source and target domain distributions. However, fine-tuned BERT has a considerable underperformance at zero-shot when applied in a different domain. We solve this problem by proposing a Transformational Biencoder that incorporates a transformation into BERT to perform a zero-shot transfer from the source domain during training. As like previous work, we rely on negative entities to encourage our model to discriminate the golden entities during training. To generate these negative entities, we propose a simple but effective strategy that takes the domain of the golden entity into perspective. Our experimental results on the benchmark dataset Zeshel show effectiveness of our approach and achieve new state-of-the-art.

1 Introduction

Entity Linking (EL) is an important task in Natural Language Processing (NLP), which seeks to align entity mentions in a document to their referent entity in a knowledge base such as Wikipedia. EL has received widespread attention due to its application in a variety of tasks, including information extraction (Lin et al., 2012), knowledge base population (Dredze et al., 2010), content analysis (Weng et al., 2010), etc. There has been great achievement in building EL systems, however, majority of proposed works (Ganea and Hofmann, 2017; Cao et al., 2018) are built on the assumption that the entity set is shared among the train and test sets. In many practical cases, however, the train and test sets may come from different domain distributions. This potentially creates disjoint entity sets across the different domains, highlighting the importance of zero-shot EL (Sil et al., 2012; Logeswaran et al., 2019).

Zero-shot EL aims to label mentions in the test set that have never been seen during training. A line of works have proposed zero-shot learning techniques for entity linking (Sil et al., 2012; Wang et al., 2015). The common paradigm in these works is to link labelled mentions in a document to entities in well structured knowledge bases. Despite their promising successes, labelled data is typically expensive to produce or are not easily obtained for some specialized domains such as the legal domain. To enable research in this problem, Logeswaran et al. (2019) developed the Zeshel dataset which contains a diverse range of specialized domains, in which mentions and entities have rich textual content. Without adopting resources (e.g., structured knowledge base) or assumptions (e.g., labelled mentions, a shared entity set), they expand the scope of zero-shot EL to promote the generalizability of EL system on unseen domains.

So far, only few works have been proposed (Wu et al., 2020; Yao et al., 2020; Zhang and Stratos, 2021; Tang et al., 2021), where BERT (Devlin et al., 2018) is found to be the notable encoder. Majority of these works are devoted to retrieving candidate entities since this is essential to candidate entity ranking for EL systems. Zhang and Stratos (2021) achieved state-of-the-art for candidate entity generation by employing the Biencoder (Wu et al., 2020) to encode mentions and entities, an expressive Sum-Of-Max (SOM) score function (Khattab and Zaharia, 2020) to compute their relevance scores, and by optimizing with hard negative entities. To generate hard negatives, Zhang and Stratos (2021) use the score function to rank all entities across domains and select top-k entities.

Although the Biencoder has been successfully applied, it faces a fundamental weakness which limits its ability to successfully achieve zero-shot

transfer for the task. Specifically, the fine-tuned BERT as used in the Biencoder has been shown to degrade substantially on zero-shot transfer if there is a shift between source and target domains (Ma et al., 2019). Another problem is the high dimensionality of entities/mentions which poses a challenge for complex scorers (e.g., Sum-Of-Max). SOM requires $\mathcal{O}(n^2)$ in running time and storage complexity, which makes it almost infeasible when sampling hard negatives. As EL systems may have millions of entities, a more scalable solution is needed.

In this paper, we overcome the aforementioned weakness of the Biencoder by integrating it with a learnable transformation, developing an Transformational Bi-encoder (T-Biencoder). As the name suggests, we focus on learning a transformation in the BERT architecture to achieve zero-shot transfer from a source domain during training. With regard to the efficiency of the model and the optimization strategy, we recognize the performance advantages of sampling with hard negatives over sampling randomly. Hard negative sampling works because generated entities are semantically different and close to the golden entity in the embedding space. This encourages discrimination between the golden entity and negative entities. We hypothesize that, the condition of lexical similarity between the entity and golden entity will lead to harder negatives and better optimization. That is, we propose to random (or hard) sample in-domain of the golden entity. By sampling in-domain, the entity set in which we sample from is relatively small, making it a more efficient alternative to sampling across domains. Extensive experiments show the effectiveness of our approach as against prior works.

Our contributions can be summarized as follows:

- we propose a Transformational Biencoder, which incoporates a transformation into the Biencoder (Wu et al., 2020) to improve generalization on unseen domains for zero-shot EL.
- we propose in-domain negative sampling to encourage our model to discriminate the golden entity, which in effect improves optimization and efficiency.
- we perform extensive experiments to demonstrate the effectiveness of our approach, and achieve state-of-the-art on the Zeshel dataset (Logeswaran et al., 2019).

2 Related Works

To enable progress on the zero-shot entity linking task, Logeswaran et al. (2019) propose to use the naive baseline method BM25 (Robertson and Zaragoza, 2009) to measure the relevance score of mention-entity pairs. Following this work, a number of methods operating on Zeshel have been proposed (Wu et al., 2020; Yao et al., 2020; Zhang and Stratos, 2021; Tang et al., 2021), where BERT (Devlin et al., 2018) is found to be the notable encoder. This is not surprising as BERT has shown to produce state-of-the-art results in several NLP tasks. Among the existing works, Wu et al. (2020) propose a Biencoder architecture where two independent BERT encoders are employed to encode the textual descriptions of mentions and entities. A dot product is used as the scorer, referred to as DUAL by (Zhang and Stratos, 2021). The Biencoder provides a strong baseline for the task due to the expressiveness of BERT. Yao et al. (2020) adapts a BERT architecture that repeats the position embedding to solve the long-range modeling problem in entity textual descriptions. Tang et al. (2021) propose a bidirectional multi-paragraph reading model that leverages more textual information to enhance text understanding capability. Zhang and Stratos (2021) adopt the Biencoder framework but employ a more expressive Sum-Of-Max score function (Khattab and Zaharia, 2020) to measure the relevance between a mention and entity, achieving state-of-the-art results on the task. The majority of these works leverage negative entities during optimization. They also have an implicit assumption that BERT is sufficient for zero-shot transfer.

Unlike previous work, we adapt the BERT encoder with a transformation to improve zero-shot transfer. We also consider to sample negative entities in-domain of the golden entity rather than across all domains to improve optimization and efficiency.

3 Methodology

In this section, we describe Transformational Biencoder (T-Biencoder), our proposed method for zero-shot EL. First, we formally present the task definition in Section 3.1. Next, in Section 3.2 we introduce the Biencoder (Wu et al., 2020). Then, we describe our adaptation of the Biencoder to develop T-Biencoder in Section 3.3. Finally, we close by discussing our negative sampling strategy in Section 3.4.

3.1 Task Definition

The entity linking task is formulated as follows. Given a mention m in a document and a set of entities $\gamma = \{e_i\}_{i=1,\dots,N}$, EL aims to identify the referent entity $e \in \gamma$ corresponding to mention m. The goal is to obtain an EL model on a train set of mention-entity pairs $D^{\text{Train}} = \{(m_i, e_i) | e_i \in \gamma\}_{i=1,\dots,M}$, that correctly labels mentions in the test set D^{Test}. D^{Train} and D^{Test} are typically assumed to come from the same domain.

In this paper, we focus on the zero-shot EL (Logeswaran et al., 2019), where both $D^{\text{Train}} = \{D^i_{\text{src}}\}_{i=1,\dots,N_{\text{src}}}$ and $D^{\text{Test}} = \{D^i_{\text{tgt}}\}_{i=1,\dots,N_{\text{tgt}}}$ are found to contain multiple sub-datasets from different domains. Note that the entity sets $\gamma^1_{\text{src}}, \dots, \gamma^{N_{\text{src}}}_{\text{src}}, \gamma^1_{\text{tgt}}, \dots, \gamma^{N_{\text{tgt}}}_{\text{tgt}}$ corresponding to the sub-datasets are disjoint, with entities or mentions expressed as textual descriptions. Our goal is to build a model upon D^{Train} to label mentions in D^{Test}.

3.2 Biencoder

Our model is built on the Biencoder (Wu et al., 2020), that independently embeds the mention and corresponding entity in the same representation space. As shown in Figure 1, the Biencoder consists of a text encoder E_{θ_m} for encoding mentions, a text encoder E_{θ_e} for encoding entities and a score function f to compute a relevance score of mention-entity pairs. E_{θ_m} and E_{θ_e} share the same architecture but have independent parameters, θ_m and θ_e. BERT (Devlin et al., 2018) is employed to model E_{θ_m} and E_{θ_e}.

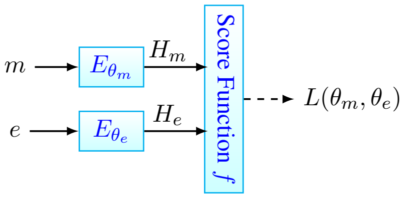

Figure 1: Architecture of Biencoder

Given the mention-entity pair (m, e), the mention m is characterized by the left context (ctx$_l$) and right context (ctx$_r$) of the mention as well as the mention itself. Thus, m is represented as the BERT input:

$$m = [\text{CLS}]\,\text{ctx}_l\,[\text{Ms}]\,\text{mention}\,[\text{Me}]\,\text{ctx}_r\,[\text{SEP}] \tag{1}$$

Similarly, the entity e is characterized by the entity name and its textual description.

$$e = [\text{CLS}]\,\text{name}\,[\text{ENT}]\,\text{description}\,[\text{SEP}] \tag{2}$$

where [CLS], [Ms], [Me], [ENT] and [SEP] are special tokens to mark the boundaries of the different pieces of information. Let the mention $m = \{\mathbf{x}^m_t\}_{t=1}^{|m|}$ with $|m|$ wordpieces, and the entity description $e = \{\mathbf{x}^e_{t'}\}_{t'=1}^{|e|}$ with $|e|$ wordpieces. We extract the corresponding representations $H_m \in R^{d\times|m|}$ and $H_e \in R^{d\times|e|}$ as follows:

$$\begin{aligned} H_m &= E_{\theta_m}(m) \\ H_e &= E_{\theta_e}(e) \end{aligned} \tag{3}$$

where d denotes the dimension of representations.

Then, the entity linking problem is reduced to quantifying the similarity between H_m and H_e using a score function f, i.e., $f(H_m, H_e)$. If the mention-entity pair (m, e) matches, the score $f(H_m, H_e)$ should be high, or low if otherwise. Wu et al. (2020) defines a DUAL score function that takes the [CLS] representations $h^m_{[\text{CLS}]} \in R^{d\times 1}$ and $h^e_{[\text{CLS}]} \in R^{d\times 1}$ of the respective representations H_m and H_e to compute the score $f(H_m, H_e)$.

DUAL:

$$f(H_m, H_e) = (h^m_{[\text{CLS}]})^T h^e_{[\text{CLS}]} \tag{4}$$

Recently, Zhang and Stratos (2021) followed the architecture of Wu et al. (2020) and showed that the Sum-Of-Max (SOM) scorer (Khattab and Zaharia, 2020) yields better results in comparison to DUAL. SOM computes $f(H_m, H_e)$ as follows.

SOM:

$$f(H_m, H_e) = \sum_{t=1}^{|m|} \max_{t'=1}^{|e|} (h^m_t)^T h^e_{t'} \tag{5}$$

However, it is worth to note that the SOM scorer comes at the expense of increased computational cost due to the consideration of all hidden states of H_m and H_e in the scorer.

Finally, the model is trained to encourage discrimination between golden mention-entity pairs and negative mention-entity pairs. We minimize a standard loss function L based on the empirical estimate of the NCE loss (Gutmann and Hyvärinen, 2010),

$$L(\theta_m, \theta_e) = -\frac{1}{M}\sum_{i=1}^{M} \log \frac{\exp(f(E_{\theta_m}(m_i), E_{\theta_e}(e_{i,1})))}{\sum_{j=1}^{C} \exp(f(E_{\theta_m}(m_i), E_{\theta_e}(e_{i,j})))} \tag{6}$$

where $\{(m_i, e_{i,1})\}_{i=1,...,M}$ are golden mention-entity pairs in the training set, and $\{e_{i,2}, ..., e_{i,C}\}$ are $C-1$ negative entities for the i-th mention.

Regarding model training, two main strategies have been considered in previous work to construct negative mention-entity pairs: (1) **Random Cross-Domain (Random-CD)**: negative entities for a given mention are randomly sampled from the entity set. (2) **Hard Cross-Domain (Hard-CD)**: In a training epoch, all entities are first ranked with the current trained model and the top-k entities are taken as hard negative entities. Both strategies sample negatives across all domains. While Random-CD aim to select negative entities that are semantically different from the golden entity, Hard-CD additionally aims to select negatives close to the golden entity in the representation space.

3.3 Transformational Biencoder

We found that the Biencoder assumes that leveraging the common knowledge in BERT is sufficient to achieve zero-shot transfer from source to target domain. However, while fine-tuned BERT in-domain can achieve state-of-the-art performance, its zero-shot performance on the target domain can deteriorate substantially (Ma et al., 2019). As a solution, we add a learnable transformation into the Biencoder to achieve zero-shot transfer in the training process. Otherwise, the training proceeds in the standard way and learns the parameters of E_{θ_m} and E_{θ_e}. We refer to this modified Biencoder as an Transformational Biencoder (T-Biencoder).

We present the architecture of T-Biencoder in Figure 2. $E_{\theta^1_m}$ and $E_{\theta^2_m}$ are the respective early and later transformer layers of the BERT architecture E_{θ_m}, where $\theta_m = \{\theta^1_m, \theta^2_m\}$. We use the parallel notations $E_{\theta^1_e}$ and $E_{\theta^2_e}$ for the BERT architecture E_{θ_e}, where $\theta_m = \{\theta^1_e, \theta^2_e\}$. The encoders $E_{\theta^1_m}$ and $E_{\theta^1_e}$ aim to map the respective mention m and entity e into a common space Z. Since the common space Z that best fit our model is unknown, the number of layers of $E_{\theta^1_m}$ and $E_{\theta^1_e}$ is taken as a hyper-parameter K. This is also the K-th layer of E_{θ_m} and E_{θ_e}. Now, Z_m and Z_e, the respective representations of m and e in the common space Z are computed as follows:

$$\begin{aligned} Z_m &= E_{\theta^1_m}(m) \\ Z_e &= E_{\theta^1_e}(e) \end{aligned} \tag{7}$$

where $Z_m \in R^{d\times|m|}$ and $Z_e \in R^{d\times|e|}$. In the common space we assume relatedness between source and target domains to achieve zero-shot transfer. Hence, there exist at least one transformation $\bar{A}_m$ (or $\bar{A}_e$) to transform the mention (or entity) pair in the source domain distribution $\mathcal{S}$ to the target domain distribution $\mathcal{T}$. Let A_m and A_e be the learnable transformation matrices which aims to approximate $\bar{A}_m$ and $\bar{A}_e$ respectively. The representations $Z_m \sim \mathcal{S}$ and $Z_e \sim \mathcal{S}$ are transformed into the representations $Z'_m \sim \mathcal{T}$ and $Z'_e \sim \mathcal{T}$:

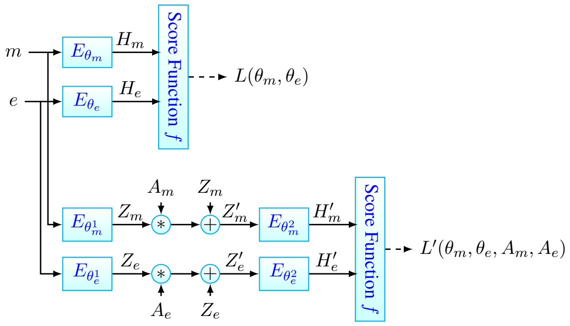

Figure 2: Architecture of T-Biencoder

$$\begin{aligned} Z'_m &= Z_m + A_m Z_m \\ Z'_e &= Z_e + A_e Z_e \end{aligned} \tag{8}$$

The final representations H'_m and H'_e are then constructed by feeding Z'_m and Z'_e into the encoders $E_{\theta^2_m}$ and $E_{\theta^2_e}$.

$$\begin{aligned} H'_m &= E_{\theta^2_m}(Z'_m) \\ H'_e &= E_{\theta^2_e}(Z'_e) \end{aligned} \tag{9}$$

Finally, we feed H'_m and H'_e into the score function f and calculate the loss $L'(\theta_m, \theta_e, A_m, A_e)$. The total loss $\mathcal{L}_{\text{total}}$ of our model is formulated as

$$\begin{aligned} \mathcal{L}_{\text{total}} = \min_{\theta_m, \theta_e} [&L(\theta_m, \theta_e) + \\ &\max_{||A_m||, ||A_e|| \leq \epsilon} L'(\theta_m, \theta_e, A_m, A_e)] \end{aligned} \tag{10}$$

where L is the standard loss function. L' is a transformational loss function which follows the same definition as L. The hyper-parameter ϵ quantifies the supremum of shift between source and target distributions. Besides learning θ_m and θ_e, the second term in $\mathcal{L}_{\text{total}}$ aims to find transformations A_m and A_e that maximizes L' conditioned by $||A_m||, ||A_e|| \leq \epsilon$. Specifically, we find the worst A_m and A_e such that $L'(\theta_m, \theta_e, \bar{A}_m, \bar{A}_e) \leq L'(\theta_m, \theta_e, A_m, A_e)$ given ϵ. The idea is that, if the encoders E_{θ_m} and E_{θ_e} can work for representations obtained through A_m and A_e, they can also work for representations obtained through the ground-truth transformations $\bar{A}_m$ and $\bar{A}_e$. Note, the transformations only serve to shift the source to the target distribution. Hence, at inference time the entities and mentions are fed directly to the encoders E_{θ_e} and E_{θ_m} without being transformed by A_m and A_e. We experiment with the DUAL and SOM scorers in our work.

3.4 Negative Sampling In-Domain

We point out that carefully constructing negatives is crucial to performance. By leveraging Hard-CD, Zhang and Stratos (2021) improves upon the task, indicating its benefit over Random-CD.

While these sampling strategies have shown its benefit, they disregard the domain of the golden entity. We posit that negatives that are lexically similar to the golden entity should be additionally considered to obtain harder negatives. That is, negatives that are lexically similar, semantically different and close to the representation of the golden entity are harder. We therefore propose two negative samplig strategies: (1) **Random In-Domain (Random-ID)**: randomly samples negative entities in-domain of the golden entity. (2) **Hard In-Domain (Hard-ID)**: all entities in-domain of golden entity are ranked in a training epoch, and the top-k entities are taken as hard negatives. We will demonstrate through extensive experiments to show the effectiveness of negative sampling in-domain.

4 Experiments

4.1 Dataset

We follow the recent works (Logeswaran et al., 2019; Wu et al., 2020; Tang et al., 2021; Zhang and Stratos, 2021) and evaluate on the Zeshel dataset (Logeswaran et al., 2019),[1] which is a prevailing benchmark dataset for zero-shot entity linking. Zeshel contains 16 specialized domains from Wikia,[2] partitioned into 8 domains for training, and 4 domains each for validation and testing. Table 4 shows the dataset statistics, including the number of entities and mentions.

Domains	Entities	Mentions	
		Train	Evaluation
Training			
American Football	31929	3898	743
Doctor Who	40281	8334	1521
Fallout	16992	3286	593
Final Fantasy	14044	6041	1156
Military	104520	13063	2764
Pro Wrestling	10133	1392	262

Lego	10076	0	1199
Star Trek	34430	0	4227
YuGiOh	10031	0	3374

Table 1: Statistic of the Zeshel dataset.

4.2 Evaluation Protocol

EL systems typically follow a two-stage pipeline: (1) a candidate generation stage, where an entity retriever is trained to select top-k candidates for each given mention, (2) a candidate ranking stage, where a ranker is trained to identify the golden entity among selected candidates for a given mention. The candidate generation is essential to the performance of candidate ranking because if the golden entity is not retrieved in the top-k candidates, the model can never recover the golden entity during candidate ranking. We therefore follow the evaluation protocol of previous work (Logeswaran et al., 2019; Wu et al., 2020; Zhang and Stratos, 2021) and evaluate at the candidate generation stage. We report micro-averaged top-64 recall for models on the validation set and testing set. Thus, we consider a mention's prediction to be correct if its golden entity is included in the top-64 candidates. Average results over 3 runs are reported for our models.

4.3 Implementation Details

To fairly compare with recent work (Wu et al., 2020), we use the BERT-base-uncased (Devlin et al., 2018) as the text encoder, where the embedding layer is kept frozen and the layers are fine-tuned during training. We directly use the preprocessed dataset provided by (Wu et al., 2020),[3] where mentions/entities are represented by $n = 128$ wordpiece tokens, i.e., $n = |m| = |e|$. Number of negative entities for each mention is 15. We employ AdamW (Loshchilov and Hutter, 2017) optimizer with a learning rate ($lr = 1e^{-5}$) warm-up schedule to smoothen the training process. We train

	SOM	Random-ID	94.56±0.32	90.68±0.21	23
	SOM	Hard-ID	**95.49±0.23**	**91.16±0.14**	625

Table 2: Results of compared models are retrieved from their original papers. Models' efficiency is the time cost per epoch in minutes. Results of our models are the average over 3 runs using different random seeds.

our models for 5 epochs using a batch size of 64 for mention-entity pairs. We perform a grid search to select the best set of hyper-parameters: ϵ in $[1e^{-3}, 1e^{-2}, 1e^{-1}, 1.0, 10, 20, \ldots, 100]$ and K in $[0, 1, 4, 8]$. Best hyperparameter values are shown in Table 3. All models are trained in parallel on four NVIDIA V100 32GB.

Scorer	Negative	ϵ	K
DUAL	Random-ID	32	1
DUAL	Hard-ID	42	1
SOM	Random-ID	20	1
SOM	Hard-ID	40	1

Table 3: Best observed hyper-parameter configurations of T-Biencoder on the validation set.

4.4 Performance Comparison

In this section we compare our model against recent work (Wu et al., 2020; Zhang and Stratos, 2021) for candidate generation. These works employ the Biencoder and generate negative entities for optimization. DUAL and SOM scorers are used in this work. As a baseline we include the work by Logeswaran et al. (2019) which uses the BM25. Note, the following works (Tang et al., 2021; Yao et al., 2020) are excluded since they evaluate at the candidate ranking stage, making their results uncomparable with ours.

4.4.1 Main Results

Results of compared models are shown in Table 2. BM25 shows poor performance due to the emphasis on lexical similarity between mention and candidate entity tokens. In contrast, methods (Wu et al., 2020; Zhang and Stratos, 2021) that generate semantic representations have shown to be effective, with an improvement of at least 12.93% on the test set. First, we compare the performance of these models with respect to the DUAL scorer on the test set. We find that T-Biencoder outperforms the Biencoder (Zhang and Stratos, 2021) by 3.92% for random sampling, and by 1.48% for hard sampling. With respect to the SOM scorer, we observe that T-Biencoder outperforms Biencoder by 3.06% for random sampling, and by 1.54% for hard sampling. These results indicate the effectiveness of our sampling strategies (i.e., Random-ID and Hard-ID) as well as the transformation approach. We also find that SOM yields better results over DUAL while hard sampling leads to better optimization. However, leveraging SOM and hard sampling increases computational cost by orders of magnitude, as we examine its efficiency in Section 4.4.3.

Interestingly, we find that by using Random-ID for either SOM or DUAL, we achieve better performance in comparison to Hard-CD, indicating the effectiveness and efficiency of our model. T-Biencoder achieves state-of-the-art results for either DUAL and SOM scorers, and additionally shows stability given the low standard deviations.

4.4.2 Domain Zero-Shot Performance

Our main results show that we achieve state-of-the-art on both validation and testing sets. To show that this improvement is true for all validation/test domains and not as a result of a specific validation/test domain, we show more fine-grained results. Specifically, we report the domain zero-shot performance for Biencoder and T-Biencoder using the Random-ID sampling strategy. Table 4 shows the results for the different validation and testing domains.

Due to the degree of dissimilarity between the train and validation/test domains, naive zero-shot transfer by the Biencoder produces unsatisfactory results. By learning the transformation, T-Biencoder outperforms Biencoder. We found that the test domain "YuGiOh" is closely related to the train domains "Star Wars" and "Final Fantansy" in the sense that they belong to the super-domain of comics. By exploiting the relatedness of these domains, we achieve impressive results on "YuGiOh". Specifically, "YuGiOh" improves by 2.37% for DUAL and 2.48% for SOM using the T-Biencoder.

Domains	Biencoder		T-Biencoder	
	DUAL	SOM	DUAL	SOM
Validation				
Coronation Street	88.87	92.28	**89.07**	**92.76**
Muppets	88.51	91.62	**89.89**	**92.75**
Ice Hockey	92.03	92.07	**92.39**	**93.42**
Elder Scrolls	94.32	96.05	**94.85**	**96.28**
Testing				
Forgotten Realms	93.83	97.00	**94.25**	**97.17**
Lego	92.16	94.50	**92.83**	**95.58**
Star Trek	85.78	89.05	**86.56**	**89.64**
YuGiOh	77.12	85.66	**79.49**	**88.14**

Table 4: Zero-shot Performance on Different Domains under Random-ID

4.4.3 Efficiency Analysis

We dive into the efficiency of compared models. Table 2 shows the cost per epoch, measured in minutes (last column). In spite of the performance advantages of using SOM and hard sampling, the computational and memory requirements is expensive. We draw this conclusion from the complexity of the SOM scorer and the mechanism behind hard sampling.

Given a mention-entity (m, e) pair in the train set, where n is the length of the mention/entity. DUAL has a complexity $\mathcal{O}(1)$ (see (4)) while SOM has a complexity $\mathcal{O}(n^2)$ (see (5)) to analyze (m, e). This means DUAL is bounded by a constant while SOM scales quadratically in computation and memory storage with the length of the mention or entity. On the other hand, hard sampling requires that the set of entities are ranked by the scorer before selecting the top-k negative entities. Random sampling requires no scorer. Taking these two factors (i.e., scorer's complexity and sampling technique) into consideration, it is not surprising to see (1) the time cost of hard sampling to be significantly higher than random sampling, (2) the time cost of SOM with hard sampling to be larger than that of DUAL with hard sampling. However, it is interesting to see that T-Biencoder with Hard-ID trains about 3.7 (2306/625) times faster than the Biencoder with Hard-CD for the SOM scorer. We attribute this efficiency to sampling in-domain, where the in-domain's entity set is significantly smaller than the entity set of all domains in the train set.

4.5 Ablation Study

Given the difference between the Biencoder (Zhang and Stratos, 2021) and T-Biencoder, our performance can be attributed to the learned transformation or/and our negative sampling strategy. In this section, we investigate the contribution of the different model components through ablation studies. We experiment with the negative sampling strategies using the DUAL and SOM scorers. Due to the computational cost constraints, we do not report results for SOM using Hard strategies. Table 5 shows the results of this experiment.

Model	**Scorer**	**Negatives**	**Evaluation**	
			Validation	Testing
Biencoder	DUAL	Random-CD	91.03	81.88
Biencoder	DUAL	Random-ID	92.08	84.82
T-Biencoder	DUAL	Random-ID	**92.43**	**85.72**
Biencoder	DUAL	Hard-CD	92.03	84.97
Biencoder	DUAL	Hard-ID	92.70	85.50
T-Biencoder	DUAL	Hard-ID	**93.03**	**86.35**
Biencoder	SOM	Random-CD	92.18	87.82
Biencoder	SOM	Random-ID	93.81	89.46
T-Biencoder	SOM	Random-ID	**94.56**	**90.68**

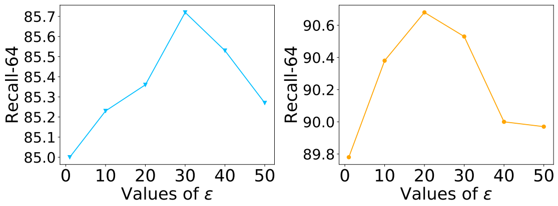
Table 5: Ablation Study: Model Performance by sampling negatives in-domain or across-domains of the golden entity.

We fix the negative sampling used, in order to determine the contribution of the learned transformation. Using Random-ID (or Hard-ID) and DUAL, we find that T-Biencoder outperforms the Biencoder by 0.9% (or 0.85%) on the test set. Using Random-ID and SOM, we find that T-Biencoder outperforms the Biencoder by 1.22% on the test set. We see similar performance situations on the validation set. These results demonstrate that the learned transformation leads to improvement irrespective of the score function or negative sampling strategy used.

We also demonstrate the effectiveness of in-domain sampling by comparing against cross-domain sampling. With the DUAL scorer, we find that the Biencoder achieves gains of 2.94% (or 0.53%) on the test set with Random-ID (or Hard-ID) as against using Random-CD (or Hard-CD). With the SOM scorer, we find that the Biencoder achieves gains of 1.64% on the test set with Random-ID as against using Random-CD. We see similar performance situations on the validation set. These results indicate that our in-domain negative sampling strategy produces harder negatives, resulting in strong gradient signals for optimization. By leveraging both in-domain negative sampling as well as transformation learning, we achieve state-of-the-art performance.

4.6 Impact of ϵ and K

In this section, we investigate the sensitivity of T-Biencoder in terms of the hyper-parameters ϵ and K. Recall, K indicates the layer in which we apply a transformation on its output during training. Suppose $K = 0$, a transformation is applied on the output of the embedding layer. ϵ on the other hand represents the upper bound for the norm of transformation in (10). We perform this experiment on the test set under Random-ID using our best hyper-parameter values. Figure 3 shows the Recall-64 curve for different values of ϵ, with $K = 1$. Table 6 also shows the performance for different values of K, with $\epsilon = 32$ on DUAL and $\epsilon = 20$ on SOM.



(A) DUAL (B) SOM

Figure 3: Recall-64 curves for different ϵ under Random-ID for T-Biencoder

Scorer	$K=0$	$K=1$	$K=4$	$K=8$
DUAL	85.45	85.72	85.12	84.36
SOM	90.23	90.68	90.05	88.69

Table 6: Recall-64 performance for different K under Random-ID for T-Biencoder.

In Table 6, we find that DUAL achieves the best performance in the early layers, i.e., $K = 1$. Meanwhile, with increasing K, the performance deteriorates. Since representations for source and target domains tend to share a low-level linguistic representation space in early transformer layers while reserving higher layers for the task or domain specific knowledge (Jawahar et al., 2019; Durrani et al., 2021), we believe a transformation easily bridges the domain gap in such layers to achieve performance. With regard to the impact of ϵ, Figure 3 shows that the performance of T-Biencoder increases with increasing values of ϵ up to a certain point, achieving scores of 85.72 on DUAL and 90.68 on SOM. After this point the performance becomes unstable and deteriorates, indicating the importance of controlling ϵ.

4.7 Analyzing the Importance of L

The loss functions L and L' both tune the parameters of the encoder. But L' additionally focuses on mitigating the domain shift problem at the same time. In this section, we wish to answer the question: Can we produce good mention-entity representations through only L'? To answer this question, we ablate T-Biencoder by removing the standard loss L, constructing the ablated model T-Biencoder$_{\mathrm{wo\,L}}$. We consider both DUAL and SOM under the Random-ID strategy. We use the best hyper-parameter values for ablated models. Table 7 shows the results of our experiments. The last two columns is the performance on the held-out mentions in the training set. (see Table 4). We find that the ablated model deteriorates for both DUAL and SOM, indicating that we cannot obtain good sentence representations by minimizing only L'.

Model	Scorer	Testing	Training	
			Seen	Unseen
Biencoder	DUAL	84.82	95.65	94.97
T-Biencoder	DUAL	85.72	96.07	95.52
T-Biencoder$_{\mathrm{wo\,L}}$	DUAL	82.11	91.97	91.52
Biencoder	SOM	89.46	96.30	96.12
T-Biencoder	SOM	90.68	96.68	96.56
T-Biencoder$_{\mathrm{wo\,L}}$	SOM	86.68	94.64	94.38

Table 7: Importance of L: Performance of different models, including the ablated model T-Biencoder$_{\mathrm{wo\,L}}$.

5 Conclusion

We introduced a Transformational Biencoder (T-Biencoder) that builds upon the recent proposed Biencoder (Wu et al., 2020) to solve the problem of zero-shot entity linking. Our work shows how to explicitly improve the zero-shot transfer capability of the Biencoder for EL. We hypothesized that negative samples drawn in-domain of the golden-entity results in better optimization. Our experimental analysis demonstrates that this assumption holds, where we see the benefits of our negative sampling strategy as well as the learned transformation. Our results show strong improvements for the task, in both effectiveness and efficiency. We envision that the T-Biencoder can further be improved by learning a transformation for each domain in the train set, since a single transformation may not effectively capture the relationship among different specialized domains. We leave this for future work.

Abstract

The Lottery Ticket Hypothesis suggests that for any over-parameterized model, a small subnetwork exists to achieve competitive performance compared to the backbone architecture. In this paper, we study whether there is a winning lottery ticket for pre-trained language models, which allow the practitioners to fine-tune the parameters in the ticket but achieve good downstream performance. To achieve this, we regularize the fine-tuning process with L1 distance and explore the subnetwork structure (what we refer to as the "dominant winning ticket"). Empirically, we show that (a) the dominant winning ticket can achieve performance that is comparable with that of the full-parameter model, (b) the dominant winning ticket is transferable across different tasks, (c) and the dominant winning ticket has a natural structure within each parameter matrix. Strikingly, we find that a dominant winning ticket that takes up 0.05% of the parameters can already achieve satisfactory performance, indicating that the PLM is significantly reducible during fine-tuning.

1 Introduction

Pre-trained Language Models (PLMs) have shown significant performance on various natural language processing (NLP) tasks (Devlin et al., 2018; Liu et al., 2019). However, as the number of model parameters gets huge, fine-tuning such models becomes inefficient. Many previous works target parameter-efficient fine-tuning approaches by freezing the PLM parameters. One can either freeze a subset of the parameters (Zaken et al., 2021) and fine-tune the remainings or freeze all of them and plug in light modules with new learnable parameters (Houlsby et al., 2019; Mahabadi et al., 2021; Hu et al., 2021).

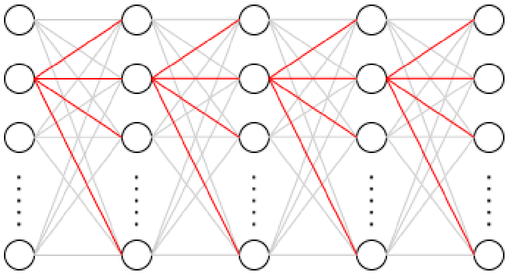

Figure 1: An illustration of the structure of the dominant winning ticket.

In parallel to this line of study, an emerging subfield has explored the possibility of training smaller subnetworks in place of the full models without hurting performance (Lee et al., 2018; Wang et al., 2020). Among them, the lottery ticket hypothesis (LTH) (Frankle and Carbin, 2018) has attracted much attention. LTH demonstrates that an over-parameterized network contains "winning tickets" (small-scale subnetworks) that can 1) match the performance of the full model; and 2) outperform randomly sampled subnetworks of the same size. Winning tickets have been verified to exist in PLMs (Prasanna et al., 2020).

In this paper, we provide an interesting result by showing that a subnetwork, which we refer to as the dominant winning ticket, exists in the PLM. It can make us to freeze all other parameters but only train the parameters of the subnetwork and obtain competitive performance for any downstream tasks. To achieve this, we fine-tune the PLM on one task

Findings of the Association for Computational Linguistics: ACL 2022, pages 1459 - 1472

(e.g., MNLI) and enforce the parameter weights close to their initial weights (pre-trained weights) by using the L1-distance penalty. This allows us to identify which parts of the model parameters change greater from the pre-trained weights during fine-tuning. We observe this ticket has some novel properties:

- The dominant winning ticket (i.e., the subnetwork) is extremely sparse, which only takes up to 0.05% of the total parameters on RoBERTa-large. But fine-tuning the subnetwork can achieve comparable performance with fine-tuning the whole model.
- Compared with randomly sampled subnetworks of the same size, the dominant winning ticket can achieve better performance with a faster convergence rate.
- The dominant winning ticket is insensitive to random seed and transferable across different downstream tasks. In other words, it is intrinsically determined by the pre-trained weights and can adapt to various downstream tasks.
- The dominant winning ticket is highly structured. It is like the "skeleton" of the network, which may give us some insights into the mechanism of PLMs.

We organize the paper as follows. After a brief overview of related works in section 2, we introduce how we are aware of the existence of the dominant winning ticket in PLMs and how we identify and extract it in section 3. Then we experiment on the dominant winning ticket in section 4. In section 5, we do further discussions about the dominant winning ticket. Section 6 is about some implications and future directions of the work.

2 Related Work

2.1 Pruning

Multiple studies of BERT concluded that it is considerably overparametrized (Kovaleva et al., 2019; Michel et al., 2019). In particular, it is possible to ablate elements of its architecture without loss in performance or even with slight gains (Voita et al., 2019; Li et al., 2021). There has been much recent work on compressing PLM. See overviews by Ganesh et al. (2021). Pruning is a promising line of work for model compression which involves obtaining smaller subnetworks with minimal performance loss (Gordon et al., 2020; Sajjad et al., 2020). A common approach is selecting the weights to be pruned by magnitude (Han et al., 2015).

Previous work has found that there exist subnetworks inside the neural network, which is called the lottery ticket hypothesis (Frankle and Carbin, 2018). Some of the recent findings are that the lottery ticket hypothesis holds for PLMs: inside large-scale pre-trained model there exist subnetworks that can be retrained alone to reach the performance close to that of the full model (Chen et al., 2020; Prasanna et al., 2020; Liang et al., 2021). Prasanna et al. (2020) claimed that "When BERT plays the lottery, all tickets are winning". Liang et al. (2021) shows that there exist super tickets inside PLMs that can improve generalization.

2.2 Parameter-efficient Fine-tune

Parameter-efficient fine-tuning aims at reducing the number of trainable parameters when fine-tuning the models across different downstream domains. Various approaches are invented to achieve the goal. Some inserted and only trained adapters, which have much lesser trainable parameters, between existing layers (Houlsby et al., 2019; Mahabadi et al., 2021; Rebuffi et al., 2017). Another line of the study proposed to update only a subset of parameters when fine-tuning. For example, Gordon et al. (2020) leveraged L0 regularization to limit the non-zero elements in the update vectors. Zaken et al. (2021) proposed that only tune bias terms can reach a decent performance. Zhao et al. (2020) applied the sparse binary mask to the pre-trained weights to reduce the trainable parameter size. Besides, some proposed that the PLM has a low intrinsic dimensionality (Aghajanyan et al., 2020). Hu et al. (2021) proposed a low-rank decomposition-based method that can also significantly reduce the number of trainable parameters. Chen et al. (2021) combined low-rank decomposition and sparse mask during fine-tuning.

3 The Dominant Winning Ticket in PLMs

We start with a question: which parts of the model parameters are more important when adapting PLMs to downstream tasks? To answer this question, we design the L1-regularized fine-tuning approach and then analyze the L1-regularized weights and reveal the existence of the dominant winning ticket.

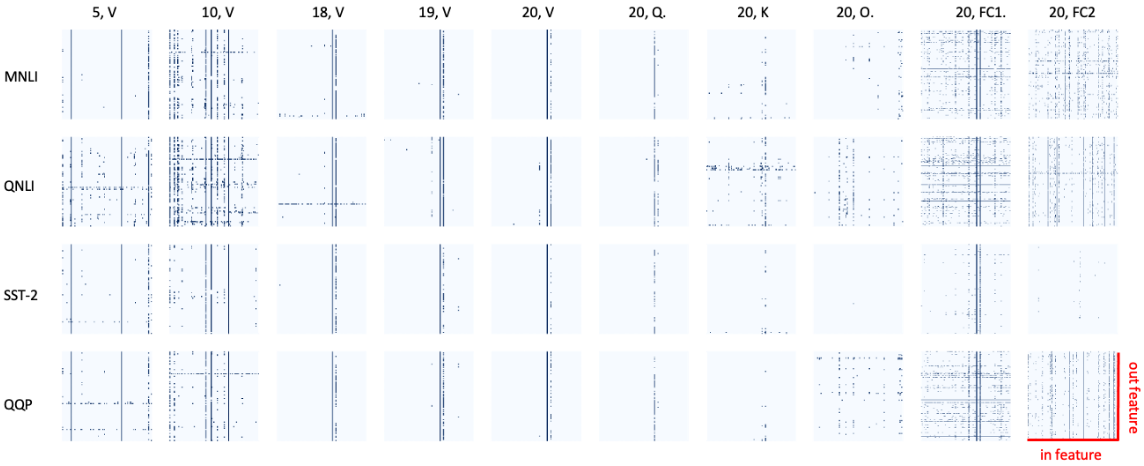

Figure 2: Visualization of out weighted parameters in RoBERTa-large. Each row is a model fine-tuned on different downstream tasks. Each column is the parameter matrix of different layers. For example, the top left block represents the value projection matrix of the 5th transformer layer from the model fine-tuned with the MNLI dataset. ("K", "Q", "V", "O" stand for the key, query, value, and output projection metrics of the self-attention module, "FC1" and "FC2" stand for the successive two fully-connected transformation metrics in each layer.)

3.1 L1-regularized Fine-tuning

To identify the subnetwork, we apply L1 regularization to all the transformer parameters. Specifically, we modify the original training objective, which results in the following minimization problem,

$$\underset{\boldsymbol{\theta}}{min}\ L(\mathcal{D}, f, \boldsymbol{\theta}) + \lambda||\boldsymbol{\theta} - \boldsymbol{\theta}_0||_1, \tag{1}$$

where $\mathcal{D}$ represents for the task-specific data, $\boldsymbol{\theta}$ is the model configuration(i.e., parameters), and $\boldsymbol{\theta}_0$ is the pre-trained model, which is fixed. λ is a hyper-parameter to control the weight of the regularization term, i.e., the strength of the sparsity. This training objective can make a large part of the parameters being close to their initial weights.

3.2 Regularized Weights Analysis

We use L1-regularized fine-tuning to answer the previous proposed question: which parts of the model parameters are more important when adapting PLMs to downstream tasks? We compute the difference between the post-fine-tune weights and the pre-trained weights to see how the weights change. Specifically, we get $\Delta\boldsymbol{\theta} = \boldsymbol{\theta} - \boldsymbol{\theta}_0$. Inspired by magnitude weight pruning (Han et al., 2015), we hypothesize that the magnitude of $\Delta\boldsymbol{\theta}$ can be an indicator. We observe that the magnitude of $\Delta\boldsymbol{\theta}$ is very small for most of the parameters (smaller than 1e-5 for 99% parameters), indicating that the L1 regularization does take effect. However, while most of the parameters remain close to their initial weights during fine-tuning, a very small fraction of parameters have much greater change. We define these parameters as out weighted parameters. Intuitively, we can choose a threshold σ to select out weighted parameters. Formally, we define σ-bounded out weighted parameters:

$$\boldsymbol{\theta}_\sigma = \boldsymbol{m}_\sigma \odot \boldsymbol{\theta}, \quad \boldsymbol{m}_\sigma \in \{0, 1\}^{|\boldsymbol{\theta}|} \tag{2}$$

where $\boldsymbol{m}_\sigma$ is a binary mask vector, $\boldsymbol{m}_{\sigma,i} = \mathbb{1}\{|\Delta\theta_i| > \sigma\}$.

We try to understand the mechanism of fine-tuning by analyzing the distribution of σ-bounded out weighted parameters. We visualize the distributions of the out weighted parameters on several different tasks (MNLI, QNLI, SST-2, QQP) as seen in Figure 2, where the parameter matrics are

$$W^Q, W^K, W^V, W^O \in \mathbb{R}^{d_{model} \times d_{model}}$$
$$W^{FC1} \in \mathbb{R}^{d_{model} \times d_{fc}}, W^{FC2} \in \mathbb{R}^{d_{fc} \times d_{model}} \tag{3}$$

For RoBERTa-large, d_{model} is 1024 and d_{fc} is 4096.

Observations 1. The locations of the out weighted parameters have strong correlations among different tasks. Each column in Figure 2 shows the out weighted parameters of the same matrix on different tasks, which has a very similar phenomenon. This high similarity indicates that the location of the out weighted parameters may be downstream task-agnostic. That is to say, the PLM

Table 1: The structure of the dominated ticket. For each matrix, we select the top 3 dominated dimensions. We highlight several "popular" dimensions across different layers with colors. Dimension `4096` in W^{FC2} and `1024` in W^{K}, W^{Q}, W^{V}, W^{O}, W^{FC1} are the symbol for the bias term.

itself determines which parameters tend to be out weighted.

Observations 2. If looking into each block in Figure 2, we can see that the out weighted parameters are distributed along with the output dimension. The out weighted parameters in the matrix tend to be dominated by a few output dimensions, what we refer to as dominated dimensions. We identify dominated dimensions by counting the number of out weighted parameters in each dimension and observe that this phenomenon exists in most of the parameter matrices in the PLM. We list all the dominated dimensions of the model to further analyze. Details can be found in Table 2. An interesting finding is that some dimensions consistently dominate several successive layers. For example, dimension `673`[1] and `631` dominate W^Q, W^K, W^V, and W^{FC1} for more than 10 successive transformer layers. These dimensions are like the skeleton of the PLM that exists from bottom to top.

With the above observations, now we can propose our hypothesis about the dominant winning ticket of PLMs.

Hypothesis. There exists a dominant winning ticket inside a PLM that is intrinsically determined by the pre-trained weights. When fine-tuned in isolation, we can only finetune the parameters of this ticket which can match the performance of full-parameter fine-tuning while converging faster than other methods.

3.3 Extracting the Dominant Winning Ticket

When it comes to extracting the dominant winning ticket, the first question is to decide the sparsity of the subnetwork (the number of trainable parameters). Generally, we extract the dominant winning ticket with algorithm 1.

Algorithm 1 Extracting the dominant winning ticket

```
1: Fine-tune a PLM $f(x; \theta_0)$ with L1 regularization on any dowmstream task dataset $\mathcal{D}$, get $f(x; \theta)$.
2: Calculate $\Delta\boldsymbol{\theta} = \boldsymbol{\theta} - \boldsymbol{\theta}_0$, then select out out weighted parameters $\boldsymbol{\theta}_\sigma$ with threshold $\sigma$.
3: Select the $k$ most dominated dimensions each matrix, which forms the dominant winning ticket.
```

We use hyperparameter k to control the sparsity of the subnetwork. We empirically find that the scale of the subnetwork is extremely small. k equals 1 (at most one dominated dimension for each matrix) is enough to achieve comparable results to full-parameter fine-tuning for most of the tasks.

It is worth noticing that our extracted dominant winning ticket excludes embedding and layer nor-

---

[1] All dimensions in the paper are zero-indexed.

malization. Besides, as bias terms are vital to some extend (Zaken et al., 2021), we include bias terms when identifying the dominated dimensions, so the bias term in each matrix also has a chance to be selected.

4 Testing the Dominant Winning Ticket for Fine-tuning

The previous section is about how we identify and extract the dominant winning ticket. In this section, we discuss the properties of the dominant winning ticket by conducting systematic experiments.

To extract the dominant winning tickets, we perform L1-regularized fine-tuning on MNLI, QNLI, SST-2, and QQP respectively. We find that the dominant winning tickets corresponding to different downstream tasks look very close to each other (detailed statistics can be found in Appendix A.1), which matches the observation in Section 3.2. So, for simplicity, we regard the subnetwork extracted from MNLI as the standard dominant winning ticket. Our evaluation experiments are conducted upon it.

We compare the dominant winning ticket with the subnetwork that has the same size as the dominant winning ticket, denoted as *Dominant-k* and *Random-k* respectively. The dimensions of *Random-k* are chosen from uniform distribution. As the scale of the extracted subnetwork is adjustable by choosing different k, we consider two different compression ratios, i.e., $k = 1$ (one dimension per matrix at most) and $k = 3$ (three dimension per matrix at most).

4.1 Exprimental Setup

Datasets and models. We conduct experiments on the GLUE benchmark (Wang et al., 2018). The evaluation is performed on the GLUE dev sets. We use the publicly available RoBERTa-large[2] (Liu et al., 2019) as pre-trained language models in all our experiments.

Implementation details. Our implementation is based on the fairseq toolkit[3] (Ott et al., 2019). We fine-tune on the GLUE tasks following the standard procedures. We optimize using AdamW (Loshchilov and Hutter, 2018), with batch size of 16. For L1-regularized fine-tuning, we empirically set the weight of L1 regularizer λ to 0.001, and the threshold σ to 5e-5. For dominant winning ticket fine-tuning, we perform a hyperparameter search over initial learning rate in $\{$5e-5, 1e-4, 2e-4, 4e-4$\}$. For full-parameter fine-tuning, we search initial learning rate in $\{$1e-5, 2e-5, 3e-5, 5e-5$\}$.

4.2 Performance

Our main results on the GLUE benchmark are shown in Table 2. Fine-tuning the dominant winning ticket can match the performance of fine-tuning the whole model while only requiring less than 0.2% trainable parameters per task. Performance of *Dominant-3* and *Dominant-1* has no significant difference for most of the tasks. For small datasets like MRPC and RTE, the smaller subnetwork even performs slightly better because less trainable parameters means free from overfitting. This phenomenon also indicates that the scale of the dominant winning ticket inside the PLMs can be extremely small. When comparing the dominant winning ticket with random tickets that has the same size, we can see that *Random-3* performs pretty well. We think this benifits from the strong reducibility of PLMs. However, when the sparsity grows, the performance of *Random-1* is much worse than *Dominant-1*, indicating that randomly sampled subnetworks unavoidable deletes useful information and become less expressive at such a level of sparsity.

Figure 3 shows the training and evaluation curves of different methods. We can clearly see that the dominant winning ticket has advantages over random subnetworks in terms of convergence rate. For large datasets like QNLI, *Dominant-1* and *Dominant-3* reach the best validation accuracy in the first several epochs, while random subnetworks require much more training steps to warm up. The dominant winning ticket also gets lower training losses in all tasks, indicating it fits the data better. Another observation is that, though *Dominant-3* and *Random-3* have no significant performance gaps in most of the tasks as seen in Table 2, their learning behaviors vary quite a lot. *Random-3* gets satisfactory results eventually, but it requires much more efforts to train. Meanwhile, there is no obvious difference between *Dominant-1* and *Dominant-3* from Figure 3, which is a good sign. This phenomenon suggests that when shrinking the parameter size from 0.19% to 0.05%, the capacity of the model almost keeps unchanged.

4.3 Stability of the Dominant Winning Ticket

We expect that subnetworks extracted from different L1-regularized fine-tuning runs (with different random seeds and different tasks) have similar structures. We use Jaccard similarity to measure the similarity between different tickets. Specifically, the Jaccard similarity between two sets is defined as:

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|}. \tag{4}$$

We test four random seeds and four tasks (MNLI, QNLI, QQP, and SST-2). The average Jaccard similarity is 0.69 across seeds and 0.67 across tasks while the similarity between random tickets is nearly 0. This means that the dominant ticket has a stable structure that utilize a certain portion of pre-trained weights. This structure is task-agnostic and irrelevant to random seeds as observed in Section 3.2. Details about the structures of subnetworks can be found in Appendix A.1.

5 Discussions

5.1 When BERT Plays the Lottery, Are All Tickets Winning?

The lottery ticket hypothesis (LTH) states that dense, randomly-initialized networks contain subnetworks (winning tickets) that–when trained in isolation–reach performance comparable to the original network.

Initialization is an important factor in LTH as the winning ticket extracted from a specific initialization generally behaviors poorly on other random reinitialized networks (Frankle and Carbin, 2018). This phenomenon is often ignored when discussing LTH in PLMs as the initialization of PLMs is deterministic. PLMs initialize via pre-training weights, which contain rich information and are potentially useful. As a result, many subnetworks inside PLMs are potential winning tickets

Indeed, Prasanna et al. (2020) claimed that even the "bad" subnetworks in BERT ("good" and "bad") have acceptable performance. We further argue that any randomly sampled subnetwork with the sparsity of 95% can serve as the winning ticket. We randomly select 5% of the parameters in each matrix and freeze the rest of the model, surprisingly finding that the performance is comparable with full-parameter fine-tuning. As seen in Table 3, a simple random subnetwork requiring no sophisticated pruning techniques can already match with fine-tuning.

However, we still argue that not all tickets are winning. *The smaller the ticket is, the rarer the winning ticket is.* When the sparsity of the subnetwork increases, the performance of subnetworks begins to vary. For RoBERTa-large, at the sparsity of 99.95%, most of the "ticket" fail to win while a well-selected subnetwork (the dominant winning ticket) can suffer little performance drops. In this sense, the dominant winning ticket we found can be regarded as the smallest winning ticket.

5.2 Structured Winning Ticket

One astonishing fact about the dominant winning ticket is that it is naturally structured. When we perform L1-regularized fine-tuning, the L1 regularization is equally applied to all parameters. But weights in some dimensions tend to deviate from the pre-trained weights more than others. These dimensions, which we refer to as dominated dimensions, are shared among different layers (like the `673`, `631`, `474`, and `106` dimensions in Table 1). It seems like there is a "skeleton" inside the PLM that can serve as the dominant winning ticket.

The structure of the dominant winning ticket is different from other structured pruning studies in two ways. First, while their structures usually refer to certain parts of the model (e.g., channels in convolutional layers and attention heads in Transformers), the structure of the dominant winning ticket is micro within each parameter matrix. Second, while most of the structured subnetworks rely on structured pruning methods (Liang et al., 2021), we do not apply structure-aware regularization techniques. In other words, the structure of the dominant winning ticket is naturally formed, waiting to be found.

5.3 Connections with Bias-terms Fine-tuning

The dominant winning ticket has some connections with bias-terms fine-tuning (BitFit) (Zaken et al., 2021). The idea of BitFit is to fine-tune only the bias terms in the transformer, which only requires updating a very small subset of parameters. If we treat the bias term of an extended dimension of the weight matrix, then the subnetwork forms by the bias terms have a similar structure with the dominant winning ticket when k equals one (one trainable dimension per matrix). And the trainable parameter size is close too.

As can be seen in Table 2, BitFit is quite promising with small-to-medium training data. When the size of the training data is large, it still has acceptable performance. The overall performance of BitFit is much better than *Random-1*, indicating that the bias terms indeed catch some additional semantics. We find that the subnetwork of bias terms overlaps the dominant winning ticket. As shown in Table 4, the bias term serves as one of the dominated dimensions in W^O and W^{FC2} a lot. We think this might be an explanation of why only tuning the bias terms works well.

6 Implications and Future Work

The dominant winning ticket can be utilized for parameter-efficient fine-tuning. As the dominant winning ticket is stable across different tasks, when deploying PLMs on different scenarios, we only need to record the same small group of parameters. Besides, benefiting from the structure of the ticket, we only need to store the optimizer states for certain dimensions of each parameter matrix. With decent code implementation, we can promisingly reduce memory usage and speed up the training process. In future work, we would examine the memory reduction and speedup abilities of the dominant winning ticket.

Besides the practical value, the dominant winning ticket raises some interesting questions about PLMs. Now that the dominant winning ticket is intrinsically determined by the pre-trained weights, then *how does the subnetwork emerge during pre-training?* Another worth investigating point lies in the natural structure of the ticket. *Why certain dimensions of parameter matrices behave so differently from others?* We still know little about the mechanism behind these phenomenons. We aim to study these questions in future work.

7 Conclusion

In this paper, we reveal the existence of the dominant winning ticket inside pre-trained models and introduce the L1-regularized fine-tuning to extract it. The dominant ticket is an extremely sparse subnetwork that can reach comparable performance with fine-tuning the whole model. We observe that the ticket has some novel properties. First, it is stable across different random seeds and tasks, which means once identified on one task, it can be transferred to other tasks with no performance loss. Second, the ticket has a natural structure within each parameter matrix, and this structure is shared across layers. Our study not only has practical values for parameter-efficient fine-tuning but also raises some questions about the pre-trained models.

Abstract

This paper presents the first Thai *Nested Named Entity Recognition (N-NER)* dataset. Thai N-NER consists of 264,798 mentions, 104 classes, and a maximum depth of 8 layers obtained from news articles and restaurant reviews, a total of 4894 documents. Our work, to the best of our knowledge, presents the largest non-English N-NER dataset and the first non-English one with fine-grained classes. To understand the new challenges our proposed dataset brings to the field, we conduct an experimental study on (i) cutting edge N-NER models with the state-of-the-art accuracy in English and (ii) baseline methods based on well-known language model architectures. From the experimental results, we obtain two key findings. First, all models produce poor F1 scores in the tail region of the class distribution. There is little or no performance improvement provided by these models with respect to the baseline methods with our Thai dataset. These findings suggest that further investigation is required to make a multilingual N-NER solution that works well across different languages. The dataset and code are available at: `github.com/vistec-AI/Thai-NNER.git`

1 Introduction

Named Entity Recognition (NER) is a task of extracting named entities from given text. It identifies the span of each entity and categorizes the identified span into an entity category. NER is essential in many downstream tasks, e.g., entity linking, question answering, and knowledge graph. In addition, Yamada et al. (2020) show that the contextualized representations that include entity information can improve many downstream tasks.

The conventional NER paradigm can only label one entity type for each entity span. For example, the entity "Chiang Mai University" will be considered as a single span ignoring the nested structure of the term "Chiang Mai," which is the name of the city that the university is situated in. As a result, we may overlook critical information that may have an impact on the language understanding in a downstream task. To mitigate this drawback, one may introduce a *nested* structure into the NER problem. Let us again consider the "Chiang Mai University" example. In addition to annotating the entire span as an organization, *N-NER* also identifies the sub-entity of "Chiang Mai" as a location. This feature can be useful in a downstream task that requires linking an entity to useful references, e.g., a university to its affiliated city.

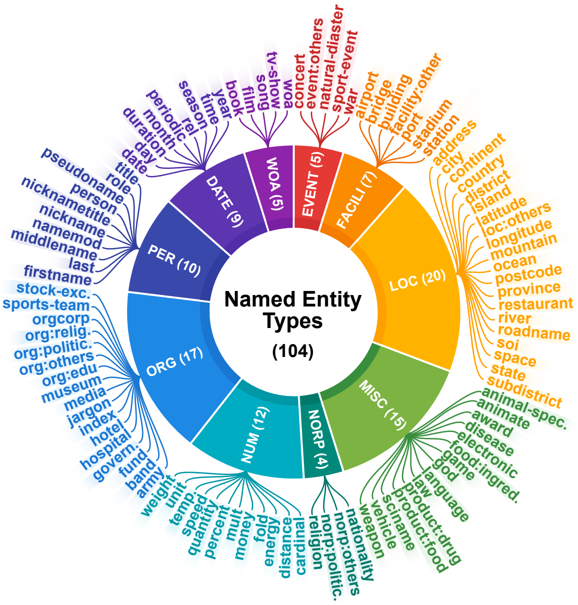

Figure 1: An overview of named-entity classes in Thai N-NER corpus. Our corpus contains 104 fine-grained classes which can be combined into 10 coarse-grained classes. Each box represents a coarse-grained class, and each row within a box represents a fine-grained class.

Considerable research attention has been dedicated to formulating a technique to solve the N-NER problem (Straková et al., 2019a,b; Lin et al., 2019; Wang et al., 2020a; Luo and Zhao, 2020; Shibuya and Hovy, 2020; Wang et al., 2020b). One can use an N-NER model to recursively decompose a complex entity into a tree structure of sub-

entities and have them annotated accordingly.

While N-NER has many potential benefits to downstream tasks that require deep language understanding, there is still a lack of datasets for low-resource languages to help develop reliable N-NER models. In order to train N-NER models, we need a dataset with hierarchical information of each named entity. N-NER datasets are available in several languages. Especially, English, a high resource language, has a few N-NER datasets available for multiple domains (Doddington et al., 2004; Walker et al., 2006; Kim et al., 2003; Ringland et al., 2019) including news, social media, and molecular biology.

The diversity of N-NER corpora is only available in English. N-NER datasets are not as widely available for other languages, let alone the diversity of corpora. In German, another high-resource language, there is only one N-NER dataset available (Benikova et al., 2014). For low-resource languages, such as Vietnamese, the two available datasets (Huyen and Luong, 2016; Nguyen et al., 2018) are still small compared to a large N-NER dataset in English (Ringland et al., 2019).

In this paper, we address the scarcity of non-English N-NER resources by introducing a Thai N-NER dataset. Despite over 58 million internet users[1], the Thai language suffers from the lack of annotated resources to build NLP systems. We propose a *Thai N-NER* dataset comprising 264,798 entity mentions obtained from 4,894 documents. In addition to the nested entity structure, we also have more than one hundred classes providing great fidelity in entity categorization as shown in Figure 1. The number of entity mentions and variety of entity classes are comparable to a large N-NER dataset in English (Ringland et al., 2019). Our dataset contains text samples, in both formal and colloquial settings, from news articles and restaurant reviews. Additionally, our corpus allows for the multilingual evaluation of "language-agnostic" deep learning models, which is the current NLP research trend. To facilitate future N-NER research, we make the dataset, the annotation guideline, and the model weights publicly available.

To summarize, our contributions are as follows:

- We create the first Thai N-NER dataset annotated with extensive tagsets that cover a wide range of use cases.
- We evaluate three recent state-of-the-art (SOTA) N-NER models on our dataset and study the effect of long-tail classes.
- We develop an N-NER benchmark comprising strong baselines for the Thai language that learn each annotation layer separately and achieve performance comparable with the three recent SOTA N-NER models.

2 Related Work

In this section, we discuss various attempts on N-NER corpora. As shown in Table 1, existing N-NER corpora are mostly high-resource languages, i.e., English and German, while Vietnamese is the only Asian language that has an N-NER dataset. In terms of the number of classes, it is also worth-noting that three out of six corpora has less than ten classes and only NNE (Ringland et al., 2019) has more than 100 classes. The details of these corpora are given as follows.

Dataset	Docs	Tokens	En.types	Depth	Mentions
English					
NNE	2,312	1.1M	114	6	279,795
GENIA	2,000	0.5M	36	4	92,681
ACE-2005	464	0.3M	7	6	30,966
German					
NoSta-D	-	0.6M	4	2	41,005
Vietnamese					
VLSP-2018	1,282	-	3	2	35,817
Danish					
Dan+	-	0.1M	4	2	6,425
Thai					
Our	4,894	1.2M	104	8	264,798

Table 1: The statistical information comparison between our Thai N-NER corpus and N-NER corpora in other languages. Note that, we obtain the statistical information of NNE, GENIA, and ACE-2005 from Ringland et al. (2019)

ACE-2004 (Doddington et al., 2004) and **ACE-2005** (Walker et al., 2006) are early examples of N-NER datasets. **ACE-2005** (Walker et al., 2006) dataset comprises 30,966 mentions from 12,548 sentences with 7 coarse-grained entity types. In addition to N-NER annotations, ACE-2005 also contains labels for other tasks such as recognition of relation and event extraction.

GENIA (Kim et al., 2003) introduces an N-NER data for bioinformatics. This project provides a high-quality corpus annotated for biological entity names. The dataset is composed of 2,000 abstracts, 92,681 mentions from 9,533 sentences with 32 entity types.

---

[1] https://www.internetworldstats.com/stats3.htm

NNE (Ringland et al., 2019) is a recent large fine-grained N-NER dataset composed of 114 classes. Unlike previous N-NER corpora, the NNE dataset annotates entities with more details. For example, "6 September 2019", a date named entity mention, in the NNE dataset, each element in this mention is annotated with finer detail, "6" is annotated with day tag, "September" with month tag, and "2019" with year tag.

NoSta-D (Benikova et al., 2014) is the first and only German N-NER dataset. NoSta-D is composed of 41,005 mentions, 12 entity types, and 31,300 sentences from the German Wikipedia and online news. The previous German NER dataset, CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003), shows that the performance of German is lower than English's[2]. However, the German CoNLL-2003 dataset is known to be inconsistent because it was annotated by non-native speakers. Hence, NoSta-D aims to provide a high quality free public NER dataset by using native speakers as annotators. In contrast to previous N-NER corpora, NoSta-D has a less restrictive copyright license.

VLSP–2018 (Nguyen et al., 2018) is a standard benchmark for Vietnamese N-NER. It was designed for the Vietnamese NER shared task to foster the development of high-quality open-source software. This dataset contains 35,817 mentions from 1,282 documents with 3 entity types.

DAN+ (Plank et al., 2020) presents the first N-NER dataset for Danish. This work investigates the possibility of transfer-learning between languages for the N-NER task. Moreover, DAN+ is a multi-domain dataset; they also study the challenges of domain-shift in their dataset. The dataset contains 6,425 mentions, 130,095 tokens, 4 classes from 6,867 sentences, obtained from multiple domains such as news and social media (Reddit, Twitter, and Arto).

NoSta-D, VLSP–2018, and DAN+ have a modest corpus size and a small number of entity types comparing to the NNE dataset. This shows that there is still a resource gap for non-English corpora. On the other hand, for Thai, there are only coarse-grained flatten-NER datasets which are publicly available (Tirasaroj and Aroonmanakun, 2009; Boonkwan et al., 2020).

3 Thai N-NER corpus

In this section, we introduce Thai N-NER–the first Thai-Nested Named Entity Recognition dataset. Our dataset is comparable to the NNE corpus (Ringland et al., 2019), which is the most elaborate English N-NER dataset in terms of the number of mentions, depth, and the number of classes. In particular, Thai N-NER comprises 264,798 mentions organized into 104 classes and has a maximum depth of 8 layers.

3.1 Data Collection Procedure

To create the dataset, we gather 4,894 documents from two different domains: news articles and restaurant reviews. In particular, we obtain 4,396 news articles from *Prachathai*[3], a news website, and 498 restaurant reviews from *Wongnai*[4], a crowd-sourced restaurant review platform.

The Thai language poses a challenge to the annotation process. Previous work often conducts the annotation at the token level, which is quite convenient for more accurate annotation. However, the lack of clear word boundaries in the Thai writing system does not allow us to easily annotate at the word-level because the data must be word-segmented first, automatically or not. Automatic word segmentation often makes errors around out-of-vocabulary words, which are exactly what we need to annotate. Consequently, the annotation at the word level is not suitable for our purposes if the data are not manually segmented first, which incurs more cost of annotation. Annotating character-level data does not solve the problem either, because annotators are more prone to make an error.

To ease and reduce annotation errors, we provide our annotators with syllable-segmented data instead. Aroonmanakun (2002) shows that syllable segmentation can resolve many word-level ambiguities in Thai. Plus, automatic syllable segmentation can be done at a near-perfect accuracy because the task is mostly solved by orthographic rules, assuming few typos exist in the data (Chormai et al., 2020). With syllable boundary indicators, we can avoid errors from word segmentation. In addition, syllable-segmented data reduces the number of indices drastically, which in turn reduces annotation errors. Appendix A.4 provides

Table 2: Our corpus is available in CoNLL format. The first column contains words and other eight columns contain labels in each layer

an example of how syllable-segmented data can help improve annotation experience.

3.2 Annotation Guideline

Inspired by the guideline from (Ringland et al., 2019), we design an N-NER annotation guideline for Thai. To cover a wide range of use cases, our N-NER tagsets comprises coarse-grained and fine-grained categories. While fine-grained categories create extra burden for the annotation and may result in more errors, the trade-off is worth it because finer-grained categories lend themselves to be nested within a coarser category. For example, as shown in Figure 2, พ.ต.อ.ประเวศน์ มูลประมุข (pʰan.tamrùat.ʔèk pràwê:t mu:npràmúk) *‘Police Colonel Prawet Munpramuk’* is tagged with PER–a coarse-grained class which encapsulates other fine-grained classes related to person name. Within a coarse-grained mention, we include nested fine-grained information to each nested named-entity element to give more detail. For example, we annotate พ.ต.อ. (pʰan.tamrùat.ʔèk) *‘Police Colonel’* with title name, ประเวศน์ (pràwê:t) *‘Prawet’* with first name, and มูลประมุข (mu:npràmúk) *‘Munpramuk’* with last name.

พ.ต.อ. ประเวศน์ มูลประมุข
pʰan.tamrùat.ʔèk pràwê:t mu:npràmúk
police colonel Prawet Munpramuk
‘Police Colonel Prawet Munpramuk’

Figure 2: An example of a nested named-entity annotation. Entity mentions in a deeper layer must be within the span of the entity mention in the previous layer to give finer details for the coarse-grained.

Apart from the description for each entity class, we provide annotators with case studies for common annotating complications. One frequent complication during the annotation process is ambiguous named entities that change their categories depending on the context. The same string annotated as one category in one context might be annotated as another in a different context. To illustrate this complication, we provide the following example:

(1) ทหาร ไทย โดน จับ
tʰáhǎ:n tʰaj do:n tɕàp
military Thai is arrested
‘Thai military is arrested’

(2) ทหาร ไทย สั่ง ห้าม ออก จาก บ้าน
tʰáhǎ:n tʰaj sàŋ hâ:m ɔ:k tɕà:k bâ:n
military Thai ordered prohibit leave from house
‘Thai military prohibits going outside of the house’

In the example above, the word ทหารไทย (tʰáhǎ:n tʰaj) *‘Thai military’* is not always a named entity depending on the context. In example sentence (1) ทหารไทยโดนจับ (tʰáhǎ:n tʰaj do:n tɕàp) *‘Thai military is arrested’*, *‘Thai military’* is not a named entity because *‘Thai military’* refers to a Thai soldier. In contrast, the example sentence (2) ทหารไทยสั่งห้ามออกจากบ้าน (tʰáhǎ:n tʰaj sàŋ hâ:m ɔ̀:k tɕà:k bâ:n) *‘Thai military prohibits going outside of the house’*, *‘Thai military’* is a named entity because it refers to the Thai military institution.

A named entity mention that is composed of nested named entities can be regarded as a tree structure. Specifically, the first level of a mention is the outermost or the largest entity span of the mention. The nested entities within the mention in each level must not overlap and cannot span outside of the mention. We provide an example of an issue that arises from overlapping annotations in Appendix A.3. Each coarse-grained entity type can appear in any level of the nested structure. However, fine-grained entity type must be nested under its coarse-grained entity type. As shown in Table 2, ประธานคณะกรรมการ 40 ปี 14 ตุลาเพื่อประชาธิปไตยสมบูรณ์ (pràtʰa:n.kʰáná.kammáka:n sì:sìp pi: sìpsì: tùla: pʰʉ̂a pràtɕʰa:tʰíppàtaj sŏmbu:n) *'The 40-year 14 Oct for complete democracy committee president'* is the first level of a named-entity mention which is annotated as a role type and the nested structure also contained other coarse-grained mentions such as date or duration. However, fine-grained entity mentions, such as day and month, can only be nested inside the date class.

3.3 Annotation Quality Control Procedure

To make our dataset reliable, we require that annotators have a background in linguistics and are properly trained to annotate under our guidelines. We also do quality control and evaluation to verify the quality of our dataset.

3.3.1 Annotators

The dataset is manually annotated by 47 linguistically trained annotators. The annotators have the necessary linguistic background and have passed the N-NER guideline understanding test. We provide a communication channel to discuss annotation issues among the annotators and the project manager. We use Datasaur.ai[5] platform for the annotators to label the data according to our guideline, using syllable span highlighting to designate each span as a specific entity.

3.4 Annotation Verification Process

Firstly, we manually check the quality of annotated randomly data to find common mistakes. To find more annotation errors, we extract only the first layer to train a simple flatten CRF model. Then we use the CRF model to filter its prediction errors for further error analysis. Combining the errors found by both humans and the model, we conduct an error analysis to find the pattern of mistakes from annotators. Frequent annotation mistakes are inconsistency tagging, incorrect tagging, and failure to follow the guideline. Then we compile a list of annotation errors and send it back to the annotators to reassess. After the first update, we use a rule-based program to filter overlapping annotations, which violate our guideline, then list all the documents with overlapping annotations. Moreover, we employ a gazetteer to filter mislabeled entities. Later, we report the list of overlapping documents and the list of mislabeled entities to the annotators to correct all the annotation errors.

After the second update, to inspect our dataset quality, we train an N-NER model from Shibuya and Hovy (2020) to see whether our data can be used to train the model and to filter out more annotation errors. The test score is 75.44% F1 score. We then use the model's prediction errors to filter out more annotation mistakes and report them to the annotators for another correction session.

Then, we split our dataset into 80% for a training set and 20% for a test set, then re-annotate the test set with two annotators to validate. Finally, the third annotator correct the annotation mismatches between the first two annotators.

We use the Cohen's Kappa agreement score to benchmark the reliability of our dataset. We compute the inter-annotator agreement using eight sampled documents composed of 2,922 tokens. We calculate the Cohen's Kappa agreement score using two labeling schemes: CoNLL and Pyramidal, see Appendix A.5 for further descriptions. The agreement scores are given as follows:

- CoNLL: 0.79;
- Pyramidal: 0.85;

These high agreement scores imply that our dataset is of good quality.

3.5 Data Format

To make our dataset convenient for research usage, we provide our dataset in CoNLL-format as shown in Table 2. We define the word boundaries in the dataset by using a maximal matching tokenizer from PyThaiNLP (Phatthiyaphaibun et al., 2016). In addition, we employ the BIOES tagging scheme to indicate the boundary of each named entity mention. Furthermore, we replace each empty space token with "_" in order to keep the integrity of the original text when we convert the CoNLL version back to the original text with no tokenization.

4 Data Statistics

This section discusses the dataset statistics and analyzes the distribution of classes in the dataset. Table 3 shows the dataset statistics of the Thai N-NER. The Thai N-NER corpus contains 1,272,381

---

[5] https://datasaur.ai

tokens from 4,894 documents. The dataset has 264,798 named entity mentions, 104 entity types, and 8 maximum depth.

Items	Train	Dev	Test	Total
Documents	2,935	979	980	4,894
Tokens	763,421	256,553	252,407	1,272,381
Entity types	104	101	104	104
Max. depth	7	8	6	8
Mentions	155,353	50,501	58,944	264,798
Layer 1	74,281	24,373	26,526	125,180
Layer 2	70,967	23,000	26,942	120,909
Layer 3	8,987	2,799	4,714	16,500
Layer 4	964	284	673	1,921
Layer 5	129	41	82	252
Layer 6	24	1	7	32
Layer 7	1	2	0	3
Layer 8	0	1	0	1

Table 3: The data statistics and distribution of entities in each layer.

The Thai N-NER dataset contains a nested structure for each named-entity mention. The first three layers contain 125,180, 120,909, and 16,500 mentions accounted for 99.2% and mentions all other levels contain 2,209 mentions combined accounted for only 0.8%. The 125,180 first-layer mentions can be divided into 67,168 nested mentions and 58,012 non-nested mentions. We split our dataset into training set, development set, and test set with proportion of 60%, 20%, and 20% respectively. The test set contains all the 104 classes appeared in the training set.

We compare our dataset with other N-NER datasets in other langaguges. Table 1 shows the statistics of N-NER datasets between NNE, GENIA, ACE-2005 (English), VLSP-2018 (Vietnamese), Dan+ (Danish), and our dataset (Thai). It should be noted that our dataset is comparable to the existing N-NER datasets in term of the number of tokens and the number of entity types.

One of the challenges in this dataset is class imbalance. Due to the number of classes, the scarcity of data for rare classes contribute to the severity of class imbalance. We visualize the distribution of classes in training set in Figure 3. The graph shows the distribution of mentions per class in training set sorted by frequency. To analyse the severity of class imbalance, we divided the classes into three groups follow Pareto principle: head, body and tail with samples per classes are 80%, 15% and 5% respectively. More precisely, in body and tail parts, they contain only 20% of samples in training set, but consist of 84 classes from 104 classes.

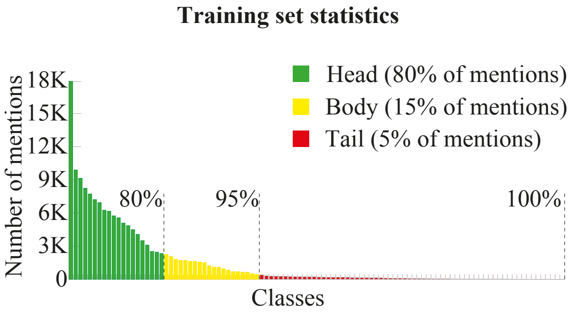

Figure 3: The distribution of classes sorted by frequency shows that rarer classes consist of more than 20% of all instances.

In conclusion, we introduce a dataset for Thai N-NER that is comparable to the standard N-NER dataset in English. Additionally, we point out a challenging long-tail distribution problem in N-NER that allows researchers to explore.

5 Experimental Settings and Results

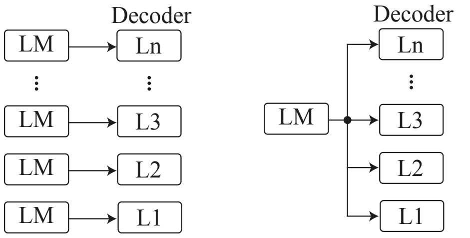
The objectives of the experimental studies are as follows: the first objective is to help researchers understand how existing techniques perform on our dataset and to help them choose the most appropriate baseline for future research. The second objective is concerned with the distribution of classes which follows the 80-20 Pareto principle. As shown in Figure 3, the top 20% most frequent classes account for 80% of the mentions. We also study how these techniques perform differently at the head, body, and tail parts of the distribution. The third objective is to compare how existing models perform on our Thai dataset with respect to results from existing studies conducted on English datasets.

5.1 Comparative N-NER Models

Since there is no existing Thai N-NER model, we formulate comparative solutions based on three approaches. The first approach is to build a baseline N-NER method from a classical machine learning technique. The second approach is applying a Thai language model to perform a span classification task. The third approach is to adapt existing N-NER methods to Thai by replacing their encoders with a Thai language model. For ease of comparison, we apply the best existing Thai language model called WangchanBERTa (Lowphansirikul et al., 2021) to second and third approaches.

Classical ML baseline: CRF model (Minh, 2018) We train multiple CRF models, each model is dedicated to each layer. Then, we merge the prediction results from all layers to form the final N-NER result. For this model, we use the IOB tagging scheme because our dataset has a large number of classes; hence the IOBES scheme will take longer to train.

Deep learning baseline: WangchanBERTa and XLM-RoBERTa. We finetune language model (LM) encoders on our corpus with two architectural variants, LM-separate and LM-shared as shown in Figure 4a and 4b, respectively. For both model, we simply use a fully-connected linear layer as a decoder. For *separate-weight (sp)* version, we assign one encoder-decoder model for each layer. For *shared-weight (sh)* version, we use multiple decoders, one for each layer, while sharing the same encoder. We provide more information about parameter settings in Appendix A.1.



(a) LM-separate (sp). (b) LM-shared (sh).

Figure 4: (a) LM–separate: each level in the nested structure has a full encoder-decoder model trained to predict tags in that specific level only. (b) LM–shared: each nested level has its own dedicated decoder, while sharing the same encoder. L_1 to L_n denotes the depth level.

To compare the performances between monolingual and multilingual BERT variants, we run experiments on both WangchanBERTa (Thai) and XLM-RoBERTa (multilingual).

State-of-the-art Models: We select three recent SOTA N-NER models with open-source accesses and train them on our corpus. To get these models to work for Thai, we replace their encoders with the same Thai language model as the deep learning baselines (Lowphansirikul et al., 2021). For parameter configurations, we use GENIA's parameter configurations to make it possible to do sanity check by reproducing previous results on GENIA

Second-best-learning (Shibuya and Hovy, 2020): This model learns to recursively decode the nested named entities from the outer to the inner nested entities. It is commonly used as a baseline in recent N-NER research. It has strong results for English N-NER.

Pyramid (Wang et al., 2020a): This model learns hierarchical representation from multiple nested levels by using pyramid and inverse pyramid mechanisms. This model currently has the highest score on the NNE dataset.

Locate and Label (Shen et al., 2021): This model divides entity detection into two stages: (i) it locates the entity spans; (ii) it assigns a label to each entity span. It is the most recent state-of-the-art model, it has top-performing scores on ACE-2004 and GENIA corpora.

5.2 Evaluation Settings

We follow the evaluation methodology from (Shibuya and Hovy, 2020), they consider a prediction as a true positive if both the predicted entity span and type are correct. In order to examine the long-tail issue as mentioned in Section 4, we evaluated the effect of long-tail distribution by dividing classes into three groups: head, body, and tail.

5.3 Thai N-NER Results

Table 4 shows the results on different parts of the long-tailed distribution, as well as the overall results on our dataset. Among the three existing SOTA models, the Second-best-learning model has the highest overall performance. It obtains higher F1 scores on the head and body parts of the long-tail distribution, while the Pyramid model obtains the highest F1 score on the tail part.

Interestingly, the deep learning baseline models, WangchanBERTa and XLM-R, can perform on par with all the current SOTA models. As shown in Table 4, the performances of WangchanBERTa models on the body and tail parts, and XLM-R models on the tail part are superior to the best SOTA model.

By having better performances on body and tail parts, while maintaining a high performance on the head part, both of the deep learning baseline models can obtain competitive results compared to all the SOTA models on our corpus.

The performances of models based on the multilingual encoder (XLM-R) are superior to Pyramid and Locate and label models. However, compared to the monolingual encoder (WangchanBERTa), XLM-R models' performances are better than the monolingual models. This suggests the possibility of cross-lingual N-NER tasks. (e.g. transferring cultural-specific named-entity knowledge from English to Thai).

		Head			Body			Tail			All		
	Models	**P**	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**	**F1**	**P**	**R**	**F1**

	Locate and label	77.60	80.38	78.97	64.42	56.21	60.04	77.43	18.86	30.33	75.57	72.61	74.06

Table 4: Experimental results nested-NER models divided into head, body, tail, and overall in our dataset

The long-tailed distribution of classes poses a challenge for the N-NER task. The performances across all models quickly deteriorate as we move from the head part of the long-tailed distribution, which represents common classes, to the tail part, which represents infrequent classes. Additionally, there are gaps between precision and recall for all models. These gaps imply that all models have a tendency to generate false negatives more than false positives. We can also see that the precision-recall gap has a tendency to increase as we move from the head to the tail part of the distribution. This result suggests that in order to improve the overall performance, we should pay attention to recall.

In addition, comparing to the results on English N-NER corpora, there is a performance gap for the Thai language. For example, the F1 score of the Pyramid model on the NNE corpus is 94.68, while its performance on our corpus is only 78.50. For the full comparison, see Appendix A.6.

6 Error Analysis

To understand the limitation of current N-NER solutions, we investigate reoccurring mistake patterns from the WangchanBERTa-sp models used in the experimental studies. We categorize the common prediction mistakes into four groups as follows: (1) *Incorrect span prediction*: out of 5,334 prediction errors, 3,103 errors are from span length mismatch as shown in Figure 5. (2) *Ambiguous entity mentions*: mentions with higher class distribution entropy have more error rates. (3) *Ambiguity between fine-grained classes*: there are 1,160 fewer errors when evaluated with coarse-grained ground truths. (4) *Scarcity of training samples*: the model only made 1,380 prediction attempts for mentions in tail classes. While 1,081 of the predictions are correct, there are 3,511 ground truths. The previous section also reveals this issue via the poor recall scores in the tail part of the long-tail distribution. We provide the description of each error pattern along with examples in Appendix A.8.

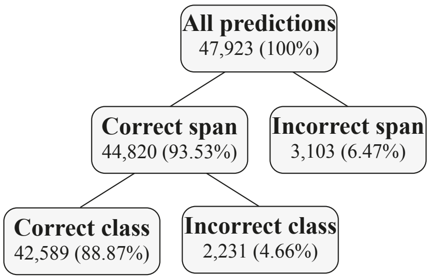

Figure 5: Tree diagram of mention predictions: this tree diagram breaks down predictions from the WangchanBERTa–sh model. It illustrates that a large chunk of prediction errors is from incorrect span predictions.

7 Summary

We present the first Thai N-NER corpus with 104 classes. It has 1,272,381 words, and 264,798 mentions. The size of our corpus is comparable to one of the large N-NER corpora in English. Unlike other Thai NER corpora, in addition to nested structure information, our dataset is annotated with fine-grained entity types to provide more detail of the named entities. This corpus addresses the data scarcity issue for Thai NLP. In addition, it allows NLP researchers to benchmark their methods in a multilingual setting. Moreover, this dataset allows researchers to explore the effect of long-tail distribution. We hope that our dataset will encourage researchers to include Thai in their benchmark and reduce the disparity between Thai and high resource languages.

Ethical Consideration

Our dataset consists of raw text data from two publicly available corpora: Prachatai-67k and Wongnai review. These corpora use public copyright licenses (LGPL and Creative Commons) that enable free distribution. The data has a minimal risk for privacy violation since all the data were published in a public space, such as a news site and a restaurant review site. All the news articles and restaurant reviews are meant to be shared publicly, not privately. Hence, the dataset does not contain any confidential information. Our preprocessing step, which includes cleaning data and tokenization, does not alter the original contents of the texts. On average, the annotators were compensated at least twice the local minimum wage. The annotators were paid by the number of entity-mentions annotated and the number of documents that they have read. We distributed the same amount of documents for each annotator for fair consideration. This dataset addresses the data scarcity issue for Thai, which can be considered as a lower-resource language. However, this dataset only includes the central Thai dialect, which most Thai understand. It is also the dialect for official usage and is often used as a written language by Thai internet users. It reduces the language technology disparity gap between Thai and high-resource languages. In addition, it can facilitate researchers and the NLP community to investigate the N-NER task in a multilingual setting. We will open-source the dataset and distribute it publicly under the CC by SA 3.0 license. We will also publish the source code and the models' weights from our experiments to assist the NLP community in N-NER research and reduce unnecessary energy usage from training the models.

Acknowledgments

We would like to thank team members from VISTEC-depa Thailand Research Institute and Hope Data Annotation. The Thai N-NER corpus is supported in part by the Digital Economy Promotion Agency (depa) Digital Infrastructure Fund MP-62-003 and Siam Commercial Bank. This dataset is released as `scb-nner-th-2022`.

We also thank reviewers for their thoughtful reviews and suggestions.

A Appendix

A.1 Parameter Settings

For all the deep learning baselines, we use the following parameter configuration: We employ Adam optimizer with a learning rate of 1e-5. We utilize a learning rate decay scheduler that reduces the learning rate every 50 epochs by multiplying the decay factor of 0.1. The maximum training epoch is 500, and we early stop if there is no improvement for 16 epochs. We use the last checkpoint for WanchanBERTa-sh and XLM-R-sh to evaluate, but for the WanchanBERTa-sp and XLM-R-sp, we use the epoch that model does not further improve when training.

For the Locate and Label model, we made further modifications to the model to use it for the Thai language. Unlike the original work, the sequence length limitation of WangchanBERTa is lower than BERT–large version (Devlin et al., 2019), we use only ten words from each neighboring sentence as the context words to keep the input sequence length within the limitation. In addition, apart from contextualized word embeddings, Locate and Labels also includes static word embeddings–GloVE. We replace the GloVE word embeddings with the static word embeddings layer of thai2fit (Polpanumas and Phatthiyaphaibun, 2021). thai2fit was trained on wisesight-sentiment [6], prachathai-64k [7], and TH-wikipedia [8].

A.2 Coarse-grained vs Fine-grained Scores

Table 5 compares the WangchanBERTa-sh model's performances between the coarse-grained and fine-grained ground truths. We converted fine-grained labels to their respective coarse-grained labels to examine the negative effect from the ambiguity between fine-grained classes. Table 5 shows that there is a small gap between coarse-grained and fine-grained evaluations. It suggests that adding fine-grained information to the dataset does not introduce a major challenge for N-NER models. Nevertheless, errors from ambiguity between fine-grained classes still constitute a considerable amount of models' prediction errors.

	Coarse-grained			Fine-grained		
Classes	**P**	**R**	**F1**	**P**	**R**	**F1**
PER	93.14	77.65	84.69	91.06	75.95	82.82

Table 5: Fine-grained and coarse-grained evaluations of the WangchanBERTa-sh model

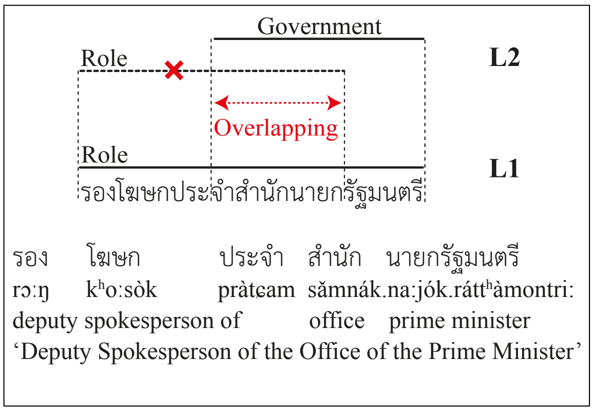

Figure 6: The annotation scheme does not allow overlapping between entities in the same layer.

A.3 Issue with Overlapped Annotations

Similar to a morphological parse tree, a nested entity annotation structure does not allow overlapping between entities in the same depth level. For example, in Figure 6, รองโฆษกประจำสำนักนายกรัฐมนตรี (rɔːŋ k^{h}oːsòk pràtɕam sǎmnák.na:jók.rátt^{h}àmontri:) *'Deputy Spokesperson of the Office of the Prime Minister'* is the first level of the nested named entity mention.

In the second layer, we do not allow an annotator to tag รองโฆษกประจำสำนักนายก (rɔːŋ k^{h}oːsòk pràtɕam sǎmnák.na:jók) *'Deputy Spokesperson of the Office of the PM'* with a role tag and สำนักนายกรัฐมนตรี (sǎmnák.na:jók.rátt^{h}àmontri:) *'Office of the Prime Minister'* with a government tag, because it creates two chunks that share the word สำนักนายก (sǎmnák.na:jók) which is a abbreviated form of *'Office of the Prime Minister'*. This would violate the tree structure. In addition, annotating รองโฆษกประจำสำนักนายก (rɔːŋ k^{h}oːsòk pràtɕam sǎmnák.na:jók) *'Deputy Spokesperson of the Office of the PM'* as an instance of named entity suggests that *'Deputy Spokesperson of the Office of the PM'*

Table 6: The performances of the recent SOTA N-NER models on English datasets, we include the performances from their original papers.

is a noun phrase and รัฐมนตรี (rátt^{h}àmontri:) *'Minister'* is a noun modifier, which is semantically incorrect. As far as compositional semantics is considered, the nested structure of named entities should not contain overlapping entities in the same level.

A.4 Annotation Experience Improvement with Syllable Segmentation

Syllable segmentation enhances the annotation experience since there are fewer choices than selecting named-entity boundaries at character-level. In addition, Thai syllable segmentation also has a near-perfect accuracy which makes it more suitable word segmentation.

For example, given an input text นายมะกะตา อาแวเซะ (Mr.Makata Arvasa), the syllable-segmented output is นา|ย|มะ|กะ|ตา| |อา|แว|เซะ and the word-segmented output from a standard word tokenizer is นา|ยมะ|กะ|ตา| |อา|แวเซะ.

Since นาย is a title word, we can find the NE's span from syllable tokens นา|ย → นาย. However, we cannot recover from a word segmentation error นา|ยมะ ↛ นาย.

As for the dataset, we present the word-level version because it is a common preprocess technique. We combine the results from word segmentation with the NE boundaries from annotators to ensure that the boundaries for NEs are guaranteed to be correct.

A.5 Annotation Verification Process

CoNLL: we format our dataset according to the CoNLL schema, then calculate the Cohen's Kappa by comparing agreements of annotated entities layer by layer. The CoNLL schema takes the mention's token length into account. For each disagreed mention, we count each disagreed token as one disagreement. Therefore, mentions with more token length may have more disagreement counts. In addition, if there is a mismatch within the same layer, we count it as a disagreement even though the annotations might agree if we were to compare them from different layers.

Pyramidal: we format the labels in a pyramidal manner, where we generate all possible n-gram entity span candidates for each text sequence and assign them to layers according to their lengths in the same fashion as the Pyramid model (Wang et al., 2020a). Then we compare agreements of annotated candidates between the two annotated data. We calculated the score on both character level and token level, and found no difference. We report the score on the token level. Pyramidal scheme counts each disagreed mention as one disagreement despite its length. Since Thai has no word boundary, the pyramid scheme always provides a consistent score despite using it on a different word segmentation that varies the token length.

A.6 The Performances of the Recent SOTA N-NER Models on English Datasets

This study compares the performances of the N-NER models between Thai and English N-NER datasets. Table 4 shows the results on the Thai N-NER dataset, and Table 6 shows the results on English N-NER datasets. We can see that, when compared to the English results, all N-NER models performed poorer on the Thai dataset. For example, the F1-score of Pyramid on the NNE dataset (the most similar dataset compared to our work) is 94.68%, while the overall F1-score of Pyramid for Thai N-NER is only 78.50%. Although both datasets are similar in size, design, and diversity of entity classes, the performance gap is 16.18%. Experimental results verify that there is a performance gap between Thai and English N-NER.

Furthermore, some model is based on the BERT-large model, but Thai has only one BERT-based pretrained model which is based on RoBERTa (WangchanBERTa). This may have a direct affect on the performance gap. For example, the Locate and Label is based on the BERT-large model; replacing BERT-large with WangchanBERTa can effect the performance directly. Despite having the best performances across multiple English N-NER datasets, Locate and Label has the lowest score on the Thai N-NER dataset when compared to other SOTA models.

A.7 Mention Distribution

Table 7 shows the mention frequency of each fine-grained entity type in our corpus before the train-test split. For each nested structure, we count all annotated mentions, not just the outermost mention. This table reveals classes with extremely low frequency which contribute to poor performances on the tail part of the long-tailed distribution.

A.8 Error Analysis

Incorrect span prediction: mismatches between the length of the predicted spans and the ground truths contribute to a large chunk of prediction errors.

Figure 5 shows that out of 47,923 predicted mentions, 5,334 are incorrect. 3,103 out of 5,334 incorrect predicted mentions are due to the fact that the positions of the predicted spans are not correctly aligned with the positions of the ground truths. Often, we can find this error in the predictions for entity mentions that are very long. For example, consider the following text segment:

(1)	อาคาร	รัฐประศาสนภักดี	ชั้น	6
	ʔa:ka:n.	rátt^{h}àpràsà:tsànáp^{h}ákdi:	tɕ^{h}án	hòk
	building	Ratthaprasatsanaphakdi	floor	6

ถนน	แจ้งวัฒนะ	แขวง
t^{h}ànǒn.	tɕɛ̂ːŋ.wátt^{h}áná	k^{h}wɛ̌ːŋ.
road	chaengwatthana	subdistrict

ทุ่งสองห้อง	เขต	หลักสี่
t^{h}ûŋsɔ̌ːŋhɔ̂ŋ	k^{h}èːt.	làk.sì:
thungsonghong	district	laksi

กรุงเทพมหานคร
kruŋt^{h}êːp.máhǎ:.ná.kɔːn
Bangkok
10210
nɯ̀ŋ.sǔ:n.sɔ̌ːŋ.nɯ̀ŋ.sǔ:n
10210
‘Ratthaprasasanabhakdi Building, 6th Floor, Chaeng Watthana Road, Thung Song Hong Subdistrict, Lak Si District, Bangkok 10210’

This large text segment is just one entity span for the address class. If a N-NER model yields a predicted span that does not cover the whole text segment, even by just one word, then we consider the prediction as incorrect.

Ambiguous entity mentions: models may fail to disambiguate entity mentions that can belong to different classes depending on the context. For example, “English” can be tagged with different classes such as Language, National, or Location depending on the context.

We use normalized class distribution entropy to quantify the effect of ambiguous entity mentions. We investigate entity mentions that can appear as different classes in the training set and calculate their entropy according to their class distribution in the training set. Then we measure the error rates of these mentions in the test set. We split entity mentions into three bins according to their entropy values: $[0, 0.33)$, $[0.33, 0.66)$,$[0.66, 1.0]$. We found that the average error rates of the three bins are as follows: 23.43%, 37.07%, and 69.28%, respectively. This confirms that ambiguity of entity mentions has a deleterious effect on the N-NER model.

Ambiguity between fine-grained classes: there are fine-grained classes that have subtle differences in meaning between them and often appear in similar contexts. For example, the *government* tag refers to governmental organizations such as, government departments, while *org:political* refers to political organizations, such as political parties and advocacy groups.

As mentioned in Appendix A.2, using coarse-grained ground truths to evaluate can reveal the detrimental effect of ambiguity between fine-grained classes. There are 1,160 mentions that would be predicted correctly, if we were to use coarse-grained ground truths instead.

Scarcity of training samples: there are some classes that models do not give any prediction because the number of training samples is too low, for example, *food:ingredient*, *vehicle*, *org:religious*, *periodic*, and *station*. As a result, all models have a tendency to generate false negatives more than false positives. This is the issue we mentioned in Section 5.3. Moreover, the best Thai N-NER model, WangchanBERTa-sh, tends to produce more predictions for the head classes, accounting for 80% of the mention distribution, than body and tail classes.

Abstract

The retriever-reader pipeline has shown promising performance in open-domain QA but suffers from a very slow inference speed. Recently proposed question retrieval models tackle this problem by indexing question-answer pairs and searching for similar questions. These models have shown a significant increase in inference speed, but at the cost of lower QA performance compared to the retriever-reader models. This paper proposes a two-step question retrieval model, **SQuID** (**S**equential **Qu**estion-**I**ndexed **D**ense retrieval) and distant supervision for training. SQuID uses two bi-encoders for question retrieval. The first-step retriever selects top-k similar questions, and the second-step retriever finds the most similar question from the top-k questions. We evaluate the performance and the computational efficiency of SQuID. The results show that SQuID significantly increases the performance of existing question retrieval models with a negligible loss on inference speed.[1]

1 Introduction

Retriever-reader models in open-domain QA require a long time for inference (Izacard and Grave, 2021; Lewis et al., 2020b; Sachan et al., 2021; Mao et al., 2021a; Karpukhin et al., 2020). This has been identified as a bottleneck in building real-time QA systems, and question retrieval and phrase-indexed QA have been proposed to resolve this problem (Seo et al., 2018, 2019; Lee et al., 2020, 2021a,b; Lewis et al., 2021a,b). These approaches directly search the answer of the input question from the corpus without conducting additional machine reading steps which are computationally inefficient. In phrase-indexed QA, retrievers pre-index all phrases in the corpus and find the most similar phrase to the input question. In question retrieval, synthetic question-answer pairs are pre-indexed and referenced by retrievers (Du et al., 2017; Duan et al., 2017; Fabbri et al., 2020; Lewis et al., 2020a).

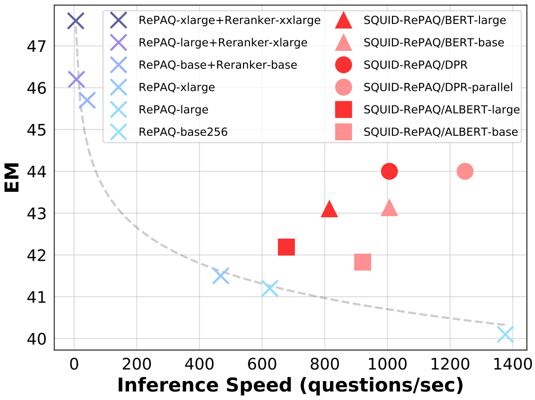

Figure 1: Trade-off relation between the open-domain QA performance and the inference time of existing question retrieval models (blue dots) and SQuID (red dots) on NaturalQuestions (NQ). The x-axis represents the inference speed and the y-axis represents the QA performance.

Although recent question retrieval models significantly increase the inference speed, this improvement accompanies QA performance degradation. Several approaches have been applied to question retrieval models to overcome the performance degradation, such as adopting the cross-encoder (Mao et al., 2021b; Xiong et al., 2020) for re-ranking and increasing the model size (Lewis et al., 2021b). However, these approaches cause a significant loss of computational efficiency. Figure 1 shows the trade-off between the open-domain QA performance and the inference speed of question retrieval models.

We propose **SQuID** (**S**equential **Qu**estion-**I**ndexed **D**ense retrieval) which significantly improves QA performance without losing computational efficiency. Our work follows previous work on neural re-ranking methods, which use a cross-encoder to re-rank the top-k passages retrieved from the first-step retriever (Lewis et al., 2021b;

Findings of the Association for Computational Linguistics: ACL 2022, pages 1487 - 1492

Xiong et al., 2020). Re-ranking methods have improved retrieval performance but require huge computation costs due to the cross-encoder architecture. We use an additional bi-encoder retriever in SQuID instead of the cross-encoder to prevent loss on computational efficiency. We also provide distant supervision methods for training the additional retriever in the absence of training data for question retrievers.

We evaluate SQuID on NaturalQuestions (NQ) (Kwiatkowski et al., 2019) and TriviaQA (Joshi et al., 2017). We conduct three types of experiments: open-domain QA, computational efficiency evaluation, and analysis on distant supervision methods for training the second-step retriever. Experimental results show that SQuID significantly outperforms the state-of-the-art question retrieval model by 4.0%p on NQ and 6.1%p on TriviaQA without losing computational efficiency. Our main contribution is in proposing a sequential question retriever model that successfully improves both QA performance and inference speed, thereby making a meaningful step toward developing real-time open-domain QA systems.

2 Related Work

The research problem of reducing the computational cost of open-domain QA has received much attention recently. The main bottleneck of a retriever-reader model is the machine reading step, and Seo et al. (2018, 2019); Lee et al. (2021a) propose phrase-indexed QA, which directly retrieves the answer from the corpus without the machine reading step. These models pre-compute the context of phrases in a corpus and conduct lexical and semantic similarity searches between the given question and the context of phrases (Zhao et al., 2021; Yamada et al., 2021). Most related to our work are the question retrieval models with question-generation models to build question-answer pairs and conduct a similarity search between the input question and the pre-indexed questions (Lewis et al., 2021a,b). These models significantly reduce the computational cost but results in lower performance. Our work provides an efficient question retrieval pipeline with distant supervision methods for training, while previous question retrieval models focus on the indexing methods with less attention on the retrieval pipeline.

3 Method

Our method is constructed based on the question retrieval pipeline proposed by Lewis et al. (2021b), where question retrievers find the most similar question to the input question and return the answer of the selected question. In this study, we note that previous question retrievers are optimized not just for improving the retrieval performance but for maintaining the inference speed to cover millions of text (Lewis et al., 2021b). In this process, the performance of retrievers decreases as they are more optimized for computational efficiency. We propose to use an additional retriever that takes the top-k predictions from the first retriever and selects the most similar question from the top-k results. The second-step retriever has a lower constraint in the inference speed than the first retriever since its search space contains only a few samples. This enables us to focus only on the retrieval performance when designing the training method. The overall training and inference procedure of SQuID is illustrated in Figure 2. We describe the details of SQuID below.

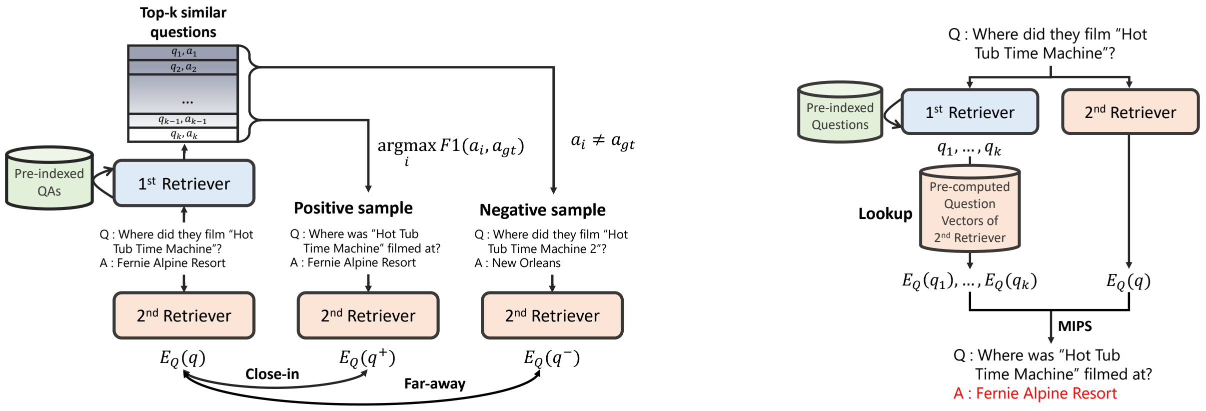
3.1 Training

Since the annotated question-question pairs are unavailable, we distantly supervise SQuID with heuristically selected positive and negative samples. We first select top-k similar questions with the first-step retriever. Among the top-k questions, we choose the positive samples and the negative samples as the following. For positive samples, we choose questions with the most similar answer to the ground truth answer in terms of F1-score, the evaluation metric used in extractive QA (Rajpurkar et al., 2016). For negative samples, we sample questions with answers that differ from the ground truth answer (Karpukhin et al., 2020; Xiong et al., 2021).

When the input question is provided with a positive sample (q^+) and m negative samples ($q_1^-, ..., q_m^-$), our second-step retriever is trained to distinguish the positive and negative samples. The loss function is as follows:

$$L(q, q^+, q_1^-, ..., q_m^-) = - \log\left(\frac{e^{\text{sim}(q,q^+)}}{e^{\text{sim}(q,q^+)} + \sum_{i=1}^{m} e^{\text{sim}(q,q_i^-)}}\right). \quad (1)$$

The similarity function is defined as the dot product of two vectors: $\text{sim}(q_1, q_2) = E_Q(q_1)^T E_Q(q_2)$. Where $E_Q(\cdot)$ is the question encoder of the second-step retriever.



(a) Training procedure

(b) Inference procedure

Figure 2: Illustrations of training and inference processes of SQuID. SQuID consists of two retrievers. The first-step retriever selects top-k similar questions among the pre-indexed QAs. From the top-k results, (a) the second-step retriever is trained to distinguish the positive sample from the negative samples, and (b) it selects the most similar question at the inference time.

3.2 Inference

Given a question q, the two retrievers of SQuID work in two steps. The first-step retriever selects top-k similar questions. The retrieved questions are then mapped to the question vectors pre-computed by the second-step retriever. The second-step retriever selects the most similar question q' from the top-k results with the question vectors. We use Maximum Inner Product Search (MIPS) for the second-step retrieval. Finally, SQuID puts the answer of q' as the answer for q.

4 Experimental Setup and Results

We evaluate the performance and computational efficiency of SQuID on two open-domain QA datasets: NaturalQuestions (NQ) and TriviaQA. We also compare various distant supervision methods for training SQuID. We use exact match (EM) (Rajpurkar et al., 2016) for performance evaluation and the number of questions per second (Q/sec) for evaluation of inference speed. The details of our experimental setup is described in Appendix A.2.

Question Retrievers on Open-Domain QA: We evaluate SQuID with two different first-step retrievers: BM25 and RePAQ-base256[2] (Lewis et al., 2021b). Table 1 shows that SQuID-BM25/DPR and SQuID-RePAQ/DPR achieve the best performance among question retrieval models on TriviaQA and NQ, respectively. Note that SQuID-RePAQ/DPR outperforms RePAQ-base256 significantly with a negligible loss of inference speed; 4.0%p EM gain on NQ and 6.1%p gain on TriviaQA at 92.0% speed (1266 Q/sec vs. 1376 Q/sec).

Trade-off between QA Performance and Computational Efficiency: Table 1 shows the trade-off between the open-domain QA performance and the inference speed of the three types of open-domain QA models. Comparing RePAQ-large and RAG-Sequence, we see a large performance gap of 3.3%p on NQ and 18.0%p on TriviaQA, and we also see a large speed gap of 624 Q/s and 0.8 Q/s. SQuID bridges this gap, achieving comparable performances to RAG-Sequence on NQ while maintaining the high inference speed. The performance gain on TriviaQA is not as high, and we conjecture that this is because RePAQ uses only questions from NQ in its filtering step. We leave a deeper study of this discrepancy for future research.

Figure 1 illustrates the QA performance and inference speed of various configurations of RePAQ SQuID. We vary the encoder of the second-step retriever with different pre-trained models: DPR (Karpukhin et al., 2020), BERT-base/large (Devlin et al., 2019), and ALBERT-base/large (Lan et al., 2019). The first and second-step question encoders can be executed concurrently, so we run them in parallel and set the batch size as half to measure the inference speed (SQuID-DPR-parallel). We use the maximum batch size possible on a single V100-16GB GPU. The figure shows that results of SQuID all lie to the top right of the curve fitted to the RePAQ results, meaning that SQuID succeeds in improving both QA performance and inference

---

[2] We use RePAQ-base256 provided by the official implementation. RePAQ-base256 has slightly lower performance than RePAQ-base.

Model Type	Model	NQ	TriviaQA	Inference speed (Q/sec)
Question retrieval	RePAQ-base256 (Lewis et al., 2021b)	40.0	38.8	1376
	RePAQ-base (Lewis et al., 2021b)	40.9	39.7	738
	RePAQ-large (Lewis et al., 2021b)	41.2	38.8	624
	SQuID-BM25/DPR	43.1	**45.6**	328
	SQuID-RePAQ/DPR	**44.0**	44.9	1006 (1266†)
Phrase-indexed	DensePhrase (Lee et al., 2021a)	40.9	50.7	20.6*
Retriever-reader	RAG-Sequence (Lewis et al., 2020b)	44.5	56.8	0.8
	FiD-large (Izacard and Grave, 2021)	51.4	67.6	0.5*

Table 1: The open-domain QA performance (EM) and inference speeds of SQuID and baselines on NQ test set and TriviaQA test set. We use the performance and the inference speed of each baseline reported from their results. * indicates the inference speed is from the original paper. † indicates that the inference speed is computed in the parallel computing setting.

Supervision	BM25	RePAQ
w/o 2nd retriever	34.4	40.0
+ Self	39.5	40.4
+ Similar	43.1	44.0
+ Similar / Self	43.6	44.1
+ Same Answer	43.4	44.4

Table 2: The open-domain QA performance (EM) of SQuID in four different distant supervision methods on NQ test set.

speed. The detailed results are in Appendix A.1.

Analysis on Positive Sampling Methods: We distantly supervise the second-step retriever because annotated question-question pairs are unavailable. We conduct experiments on various positive sampling methods for distant supervision: "Self", "Similar", "Similar/Self", and "Same Answer". Each method uses the following as the positive sample:

1) the input question itself ("Self"), 2) a similar question with a similar answer ("Similar"), 3) a similar question if it has the ground truth answer, or the input question itself ("Similar/Self"), and 4) a random question with the ground truth answer ("Same Answer").

Table 2 shows the performance of SQuID-BM25 and SQuID-RePAQ-base256 on the NQ test set with the four distant supervision methods. The first row (w/o 2nd retriever) indicates the performance based only on the first-step retriever (BM25 or RePAQ-base256). The second-step retriever with "Self" method improves the performance slightly, and the others improve the performance more significantly. The large gap between "Self" and the other methods shows that using the answer information is essential for distant supervision.

Error Propagation Analysis: The error rate of each stage in a multi-stage model provides a better understanding of the model's performance boundary. In SQuID, the second-step retriever only predicts the correct answer when the top-50 question-answer pairs retrieved by the first-step retriever contain the answer. This indicates that the upper-bound performance of SQuID is determined by the performance of the first-step retriever. We measure the R@50 accuracy of the first-step retrievers on NQ and TriviaQA. The performance of BM25 and RePAQ are 64.07% and 64.34% on NQ and 61.73% and 59.10% on TriviaQA, respectively.

5 Conclusion

The trade-off between the performance and the inference speed is an important problem in open-domain QA. Recently proposed question retrieval models have shown significantly improved inference speed. However, this improvement came at the cost of a significantly lower QA performance by the question retrieval models compared to the state-of-the-art open-domain QA models. In this paper, we proposed a two-step question retrieval model, SQuID. We evaluated the open-domain QA performance and the inference speed of SQuID on two datasets: NaturalQuestions and TriviaQA. From the results, we showed that the sequential two-retriever approach in SQuID achieves a significant QA performance improvement over the existing question retrieval models, while retaining the advantage of faster inference speed. This improvement in both

QA performance and inference speed is a meaningful step toward the development of real-time open domain QA systems.

A.1 Detailed results of Figure 1

Table 3 shows the detailed results of Figure 1.

A.2 Experimental Setup

Training Details: We set the batch size to 2 per GPU and the number of negative samples to 16. We used validation EM score for early stopping. SQuID was trained on a machine with four V100-16GB GPUs. We report the result of a single trial.

Computational Environment for Measuring the Inference Speed: The inference speed of baseline models and SQuID is measured with a V100-16GB GPU and 32 CPUs (Intel Xeon E5-2686v4). We report mean of three separate trials.

A.3 License or Terms of Artifacts

We use BERT whose license is under the Apache License 2.0 free with modification and distribution. Also, we use RePAQ whose license is under the CC BY-NC 4.0 free with modification and distribution. All models we used are publicly available.

Semantically Distributed Robust Optimization for Vision-and-Language Inference

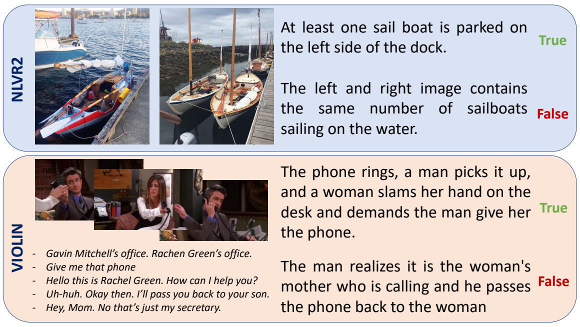
Abstract

Analysis of vision-and-language models has revealed their brittleness under linguistic phenomena such as paraphrasing, negation, textual entailment, and word substitutions with synonyms or antonyms. While data augmentation techniques have been designed to mitigate against these failure modes, methods that can integrate this knowledge into the training pipeline remain under-explored. In this paper, we present **SDRO**[†], a model-agnostic method that utilizes a set linguistic transformations in a distributed robust optimization setting, along with an ensembling technique to leverage these transformations during inference. Experiments on benchmark datasets with images (NLVR^2) and video (VIOLIN) demonstrate performance improvements as well as robustness to adversarial attacks. Experiments on binary VQA explore the generalizability of this method to other V&L tasks.

1 Introduction

"Does the text match the image?" – this simple question represents the Vision-and-Language Inference (VLI) task, as shown in Figure 1. Image-text matching forms the backbone for V&L pre-training (Sun et al., 2019; Tan and Bansal, 2019; Lu et al., 2019) and has resulted in improvements in downstream tasks such as visual question answering, image retrieval, referring expressions, and visual commonsense reasoning. While natural language inference (without visual inputs) has been extensively studied (Bowman et al., 2015; Williams et al., 2018; Khot et al., 2018; Demszky et al., 2018), VLI demands the additional capability of being grounded in the scene while understanding semantics. Although pre-trained language models (PLMs) (Vaswani et al., 2017; Devlin et al., 2019; Raffel et al., 2020) have been useful for encoding text into vector embeddings, recent findings point to undesirably high cosine similarity of two random words (Ethayarajh, 2019), the struggle with negation (Kassner and Schütze, 2020; Ettinger, 2020), and semantically equivalent adversarial examples (Ribeiro et al., 2018). These findings call for robust training protocols to avoid propagation of these findings into VLI models.



At least one sail boat is parked on the left side of the dock.

The left and right image contains the same number of sailboats sailing on the water.

- *Gavin Mitchell's office. Rachen Green's office.*
- *Give me that phone*
- *Hello this is Rachel Green. How can I help you?*
- *Uh-huh. Okay then. I'll pass you back to your son.*
- *Hey, Mom. No that's just my secretary.*

The phone rings, a man picks it up, and a woman slams her hand on the desk and demands the man give her the phone.

The man realizes it is the woman's mother who is calling and he passes the phone back to the woman

Figure 1: VLI models predict whether a sentence is `True` or `False`, given the visual input. *(Top)* sample from NLVR^2 with two images as input; *(bottom)* sample from VIOLIN with video and subtitles as input.

Adversarial training (AT) and distributed robust optimization (DRO) (Madry et al., 2018; Hu et al., 2018a; Sinha et al., 2018) have emerged as effective solutions to related problems in robust image classification, such as adversarial defense and domain generalization (Volpi et al., 2018). DRO assumes a perturbation set (typically an ℓ_p norm ball) around the training distribution, and minimizes the worst-case performance over this perturbation set. AT and DRO are popular for computer vision tasks, since the small perturbations of pixel intensities do not change the categorical meaning of the image.

However, in the case of text inputs, even small perturbations of their vector embeddings may result in absurd sentences or vectors that do not map to any word-token in vocabulary. The topology of the PLM embedding space is not well understood, especially with regard to what kind (and magnitude) of perturbations result in specific changes in

Findings of the Association for Computational Linguistics: ACL 2022, pages 1493 - 1513

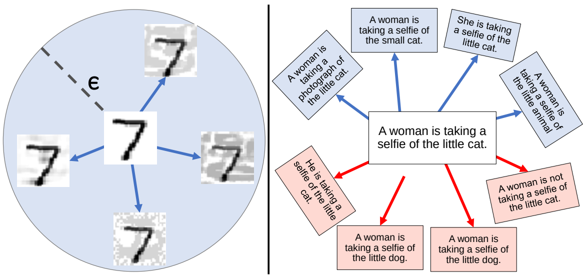

Figure 2: Comparison between *(left)* ϵ-bounded image perturbations and *(right)* linguistics-based *semantics-preserving* (blue) as well as *semantics-inverting* (red) transformations for sentences.

semantics, such as similar meanings (speak → talk) or opposite meanings (Heaven → Hell) without resulting in random or absurd words. Vector-based additive perturbations of text inputs thus restrict interpretability. However, in the domain of natural language, knowledge of logic, grammar, and semantics can be leveraged to transform sentences as shown in Table 1. Such linguistically-informed perturbations provide us control over the semantics of the resulting sentence and label, as shown in Figure 2.

We present a technique that modifies robust optimization by incorporating linguistically-informed transformations. Our approach: **S**emantically **D**istributed **R**obust **O**ptimization (SDRO) utilizes a pre-defined set of linguistic transformations (such as negation, word substitution, and paraphrasing) as the perturbation set instead of optimizing over the vector-space. We dub this set of transformations "SISP" i.e., semantics-inverting (SI) and semantics-preserving (SP) transformations. SDRO is *model-agnostic* since it can be applied to text inputs of any existing VLI model and *dataset agnostic* since it uses automated transformations without explicit knowledge of the text domain.

We apply SDRO to two VLI benchmark datasets: image-based NLVR^2 (Suhr et al., 2019) as well as video-based VIOLIN (Liu et al., 2020). To demonstrate the generalizability of SDRO to other V&L tasks, we also report results on the "yes/no" subset of VQA-v2 (Goyal et al., 2017). Our experiments show model-agnostic improvements in accuracy for all three benchmarks. While models trained with naive data augmentation using SISP suffer from a trade-off between robustness and accuracy, models that utilize SDRO improve along both metrics. SDRO also allows us to learn in low-resource settings, serving as a smart data augmentation tool – SDRO models trained only with 80% of the original dataset outperform existing state-of-the-art which utilizes the entire dataset.

Since SISP transforms do not require the ground truth label to either produce an SP or SI transformed sentence, we can also apply them to any new input sentences that are observed at test-time. Given a test input sentence, we generate its SISP versions, and obtain the prediction from our model for each SISP version. These predictions are ensembled using weighted averaging, giving equal weight to the prediction for the original sentence and the average predictions for all transformed sentences. We find that this ensembling of predictions of the SDRO model at test-time pushes the state-of-the-art further, thereby demonstrating the usefulness of semantic sentence transformations, both during training and testing.

2 Method

2.1 Preliminaries

Consider a training distribution P_{tr} consisting of inputs $\mathbf{x}$ and labels $\mathbf{y}$. For VLI, input $\mathbf{x}$ is multi-modal (visuals and text), with labels $\mathbf{y} \in \{\texttt{True}, \texttt{False}\}$. Under the empirical risk minimization (ERM), the following risk is minimized:

$$\mathcal{R}_{ERM} = \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim P_{tr}} \ell(f(\mathbf{x};\theta), \mathbf{y}), \qquad (1)$$

where ℓ is a suitable loss function such as cross-entropy loss for classification tasks. ERM provides generalization guarantees (Vapnik, 1991) for i.i.d. test samples, but not for out-of-distribution or adversarial examples.

Distributed Robust Optimization (DRO) (Hu et al., 2018b; Sagawa et al., 2020) searches for loss-maximizing perturbations of the input within an ϵ-divergence ball around P_{tr} and minimize the risk over such perturbed distributions.

$$\mathcal{R}_{DRO} = \sup_{P:D(P,P_{tr})<\epsilon} \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\sim P} \ell(f(\mathbf{x};\theta), \mathbf{y}). \quad (2)$$

The solution to Equation 2 guarantees robustness inside such ϵ-bounded distributions P. The inner maximization is typically solved using gradient-based methods (Madry et al., 2018) over additive perturbations δ such that $\mathbf{x} + \delta$ fools the classifier.

2.2 SDRO

For sentence inputs, additive perturbations are intangible and may result in ambiguity. An alterna-

	Category	Original	Transformed
SI	Noun-Antonym	The two women are driving on the street with the convertible top down.	The two ***men*** are driving on the street with the convertible top down.
	Verb-Antonym	There are children standing by the door.	There are children **sitting** by the door.
	Comparative-Antonym	There are more monitors in the image on the right than on the left.	There are ***few*** monitors in the image on the right than on the left.
	Number-Substitution	There are three bowls of dough with only one spatula.	There are ***eleven*** bowls of dough with only one spatula.
	Pronoun-Substitution	In one of the images, a woman is taking a selfie.	In one of the images, ***he*** is taking a selfie.
	Subject-Object Swap	The two women are driving on the street with the convertible top down.	The two ***top*** are driving on the street with the convertible ***women*** down.
	Negation	The closet doors on the right are mirrored.	The closet doors on the right are ***not*** mirrored
SP	Noun-Synonym	The right image shows three bottles of beer lined up.	The right ***picture*** shows three bottles of beer lined up.
	Verb-Synonym	Someone is using a kitchen utensil	Someone is ***utilizing*** a kitchen utensil.
	Comparative-Synonym	The bottle on the right is larger than the bottle on the left.	The bottle on the right is ***bigger*** than the bottle on the left.
	Number-Substitution	The two white swans are swimming in the canal gracefully.	The ***less than seven*** white swans are swimming in the canal gracefully.
	Pronoun-Substitution	In one of the images, a woman is taking a selfie.	In one of the images, ***she*** is taking a selfie.
	Paraphrasing	A man in a green shirt came on the porch and knocked on the door.	A man in a green shirt came ***up to*** the porch and knocked on the door.

Table 1: Examples illustrating the effect of each SISP transformation on input sentences.

tive approach is to consider *groups* $\mathcal{G}$ representing certain sub-populations or semantic categories within the data distribution. For text inputs in VLI, we consider the use of semantic sentence transformations as the perturbation mechanism – thus each transformation creates a sub-population or group of sentences. Examples of these transformations and their resulting effect on sentences is shown in Table 1. These transformations $g(x, y) = (\mathbf{x}_g, \mathbf{y}_g)$ are of two types: semantics-preserving (SP) if $\mathbf{y}_g = \mathbf{y}$, or semantics-inverting (SI) if $\mathbf{y}_g \neq \mathbf{y}$.

In this paper we propose the use of SI and SP transformations to create groups within the training data which can be leveraged by a robust optimization techniques to minimize worst group error. While previous work on adversarial training uses vector perturbations of sentence embeddings, our sentence-level transformations are interpretable as shown in Table 1). The ability of generating adversarial samples with inverted meanings is a key distinction between adversarial training (AT) and SDRO. While AT is restricted to SP perturbations inside an ϵ norm-ball, SDRO can impart larger linguistic perturbations (both SI and SP) beyond the norm-ball, by minimizing the worst-case expected risk over these groups:

$$\mathcal{R}_{SDRO} = \sup_{g \in \mathcal{G}} \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y}) \sim g} \ell(f(\mathbf{x}; \theta), \mathbf{y}). \quad (3)$$

Implementation. As a first step of SDRO, we randomly sample a subset $\mathcal{C}$ of the training dataset $\mathcal{D}$ s.t. $|\mathcal{C}|/|\mathcal{D}| = T$. We find adversarial samples after every epoch and create an augmented dataset $\mathcal{D}_{aug}$ which contains $(1 - T)|\mathcal{D}|$ original samples and $T|\mathcal{D}|$ adversarial samples, thus retaining the size of the training dataset. We define ℓ_g as the classification loss for a transformed sample $(\mathbf{x}_g, \mathbf{y}_g)$:

$$\ell_g(\mathbf{x}, \mathbf{y}) \triangleq \ell(f(\mathbf{x}_g), \mathbf{y}_g), \ \forall g \in \mathcal{G}. \quad (4)$$

2.3 Variants of SDRO

We design two variants of SDRO: Sample-Wise (SW) and Group-Wise (GW) SDRO.

Sample-Wise SDRO is a greedy version of SDRO, in which, for every input $\mathbf{x}$, a transformation that maximally fools the classifier: $g^* = \operatorname{argmax}_{g \in \mathcal{G}} \ell_g(\mathbf{x}, \mathbf{y})$, is added to the set of adversarial examples $\mathcal{D}_{adv}$. The model is then fine-tuned on the augmented dataset.

$$\mathcal{D}_{adv} = \{g^*(\mathbf{x}, \mathbf{y}) \colon (\mathbf{x}, \mathbf{y}) \in \mathcal{C}\}, \quad (5)$$

$$\mathcal{D}_{aug} = \mathcal{D}_{1:(1-T)|\mathcal{D}|} \cup \mathcal{D}_{adv} \quad (6)$$

However, this greedy approach is susceptible to the model's biases towards certain transformations. For instance, if negation and verb-antonym are universally hard for most sentences, i.e., result in the maximum classifier loss amongst all transformations g, then $\mathcal{D}_{adv}$ will be dominated by these groups, resulting in an unbalanced training set.

Group-Wise SDRO is devised to mitigate against the model becoming biased towards the "hardest" transformations. Using Equation 4, we calculate the transformation losses for each transformation of each sample in a training batch, yielding a set of classifier losses per "group" g:

$$L_g \colon \mathcal{C} \to \mathbb{R}; \ L_g = \{\ell_g(\mathbf{x}, \mathbf{y}) \colon (\mathbf{x}, \mathbf{y}) \in \mathcal{C}\}. \quad (7)$$

We obtain the top-k losses per group g as:

$$L_G^k = \underset{\Lambda\subset L_G, |\Lambda|=k}{\operatorname{argmax}} \sum_{\lambda\in\Lambda} \lambda, \text{ where } k = \left\lfloor \frac{|\mathcal{C}|}{|\mathcal{G}|} \right\rfloor. \quad (8)$$

Then $\mathcal{D}_{adv}$ is compiled as the union of per-group adversaries using Equation 8, and augmented to the training dataset using Equation 6.

Test-Time Ensembling of Predictions. Semantic transformations g allow us to obtain multiple "views" $\mathbf{x}_g = g(\mathbf{x})$ of the input, and the corresponding predictions $\hat{\mathbf{y}}_g = f(\mathbf{x}_g)$. We ensemble these predictions and the original prediction $\hat{\mathbf{y}} = f(\mathbf{x})$ with a simple weighted-average. Note that $\mathcal{G}$ contains both SP and SI transformations, $\mathcal{G}_{SP}$ and $\mathcal{G}_{SI}$. Since the expected label for $\mathcal{G}_{SI}$ is flipped, during ensembling we use the flipped probabilities $1-f(\mathbf{x}_g)$. The ensembled prediction is:

$$\hat{\mathbf{y}}_e = \alpha f(\mathbf{x}) + \frac{1-\alpha}{2} \sum_{g\in\mathcal{G}_{SP}} \frac{f(\mathbf{x}_g)}{|\mathcal{G}_{SP}|} + \frac{1-\alpha}{2} \sum_{g\in\mathcal{G}_{SI}} \frac{1-f(\mathbf{x}_g)}{|\mathcal{G}_{SI}|}. \quad (9)$$

Note that our method is a test-time ensemble and does not require training multiple models. This method is, in principle, similar to the ensembling strategy in image classification used by Chai et al. (2021) who train a generative model g to output different views of an image, and tune α over a validation set. In our work, g are semantic sentence transformations, and the value of α does not need to be tuned over a validation set – we find that the simple intuitive choice of α=0.5 (equal weight to the original sample and the SISP versions) improves performance. We find that:

- training models with SDRO using SISP transformations improves results on VLI tasks, and
- ensembling predictions of SDRO at test-time using Equation 9 further improves results.

3 SISP Sentence Transformations

This section describes the generation of semantics-preserving (SP) and semantics-inverting (SI) statements. **SISP** transforms are implemented using Spacy (Honnibal et al.). Dataset statistics and additional visualizations are in the Appendix.

Noun Synonym/Antonym: We extract nouns (subjects and objects) with dependency parsing, and find two nearest (synonyms) or farthest (antonyms) neighbors in the GloVe space (Pennington et al., 2014) using a threshold of 0.55.

Method	NLVR2			VIOLIN		
	Clean	SP	SI	Clean	SP	SI
Data-Aug	51.07	50.92	40.74	61.12	62.78	62.15
SW-SDRO	51.14	50.97	40.75	62.78	58.13	64.78
GW-SDRO	51.07	50.92	40.73	62.15	52.79	74.98

Table 2: Text-only evaluation of biases due to SISP transformations. 50% indicates no bias.

Verb Synonym/Antonym: We extract verbs using POS tagging and obtain their synonyms or antonyms. Verbs are lemmatized and inflected to the correct form using Lemminflect (Jascob, v0.2.1 (February 22, 2020).

Comparative Synonym/Antonym: Adjectival complements and modifiers are replaced with synonyms (*large* → *big*) or antonyms (*large* → *small*).

Number Substitution: Numerals are replaced by number-words (2 → *two*) or vice versa for SP transformations, or by their lower or upper bounds, (SP: *3* → *more than two*, SI: *two* → *less than two*).

Pronoun Substitution: Human-related nouns (such as *woman, boy, people*) are substituted by pronouns, while pronouns are substituted by generic descriptors (*something, someone, somebody, they*).

Negation: We use template-based negation (Gokhale et al., 2020b) with Subject-Verb Agreement (Wren and Martin, 2000). We add *'did not'* before a past-tense verb, *'do not'*, *'does not'*, or *'not'* before a base-form verb, gerund, or participle, or a *'not'* before an adposition or adjective.

Subject-Object Swap: Nominal or clausal subjects and direct or prepositional objects from the sentence are swapped for inverting semantics.

Paraphrasing: Input sentences are translated to Russian and then back-translated to English using neural machine translation (Ott et al., 2019).

3.1 Data Analysis

Quantification of Bias: Since SISP transforms are based on templates, they can potentially introduce spurious linguistic correlations in the dataset. For example, in NLVR^2 and VIOLIN datasets, negations and indefinite pronouns are infrequent. To quantify how this could impact models, we mask out the entire image and evaluate models (with VILLA as the backbone for NLVR^2 and HERO for VIOLIN). This acts as a 'text-only' evaluation, with accuracies $\sim$50% implying lesser bias since models do not have access to visual information. Table 2 shows that SP transforms inflict lesser bias on models than SI transforms. The effect of bias is dataset-specific; SI makes the prediction of NLVR^2 samples harder than random (less than 50% accuracy) but easier for VIOLIN.

Transformation Fidelity: We employ human subjects to evaluate the quality of SISP-transformed sentences on (1) correctness of labels, (2) grammar, (3) semantics, and (4) visual grounding. We report a unified average 'transformation fidelity' (details are in Appendix). Fidelity is higher for SP samples than SI (90.50% v/s 79.51%), which resonates with the complexities of inversion of meaning (Russell, 1905) and leaves room for improvement in SI transformation.

4 Experiments

Datasets. For all datasets, given images/videos and natural language text as input, the system is expected to predict a binary class label. NLVR^2 (Suhr et al., 2019) contains $\sim 86K, 7K, 7K$ samples for training, development, and testing respectively. Each sample in NLVR^2 consists of a pair of images (from search engines) and a sentence (crowd-sourced). VIOLIN (Liu et al., 2020) contains video clips from popular TV shows and movies along with subtitles and crowd-sourced statements. VIOLIN contains $76K$, $9.5K$, $9.5K$ samples for training, validation and testing. VQA Yes/No consists of image-question-answer triplets from VQA-v2 dataset (Goyal et al., 2017). While VQA-v2 consists of multiple question and answer types, we focus on the subset of questions with binary *yes/no* answers ($\sim$38% of VQA-v2).

Evaluation Metrics. We use two evaluation metrics: (1) **Clean Accuracy**: accuracy on the i.i.d. benchmark test set, and (2) **SISP Accuracy**: average performance on SISP transformations of the test set. Since SISP transformations are automated and can be noisy (Sec 3.1), evaluation on the SISP test set can be considered a proxy for robustness.

4.1 Results

We compare SDRO with backbone models that use standard training data *(BASE)* and data-augmentation *(+data-aug)*. We train SDRO and backbones with the same hyperparameters. We apply test-time ensembling to the best SDRO model.

Model	Clean Acc.	SISP Acc.		
		SP	SI	Avg.

Table 4: Results on VIOLIN test set.‡

NLVR^2: We use Transformer-based models LXMERT (Tan and Bansal, 2019), UNITER (Chen et al., 2020b), and VILLA (Gan et al., 2020) as backbones for SDRO. VILLA (the current state-of-the-art for NLVR^2) uses standard adversarial training. The percentage of SISP-transformed samples is fixed at T=20%. Table 3 shows results on the NLVR^2 test set, with consistent model-agnostic improvements in clean accuracy over each baseline model and improved robustness on average. Both variants of SDRO improve over VILLA$_{BASE}$ by 0.84% and 1.02%, respectively. Test-time ensembling using Equation 9 leads to further gains, resulting in a new state-of-the-art accuracy of 82.22%, an improvement of 3.83% over VILLA$_{BASE}$. GW-SDRO results in the highest SI accuracy when used with each backbone model.

---

‡Notation: **bold**: > SOTA; shaded: > respective backbone model ($BASE$); underlined: best SI/SP accuracies.

Model	**Clean Acc.**	**SISP Acc.**

Table 5: Results on the VQA yes/no subset.[‡] Not to be compared with VQA-v2 leaderboard since we use a smaller training set of *yes/no* questions.

VIOLIN: We consider VIOLIN$_{BASE}$ (Liu et al., 2020) and HERO (Li et al., 2020), the current state of the art, as baselines. VIOLIN$_{BASE}$ separately computes visual features using Faster-RCNN (Ren et al., 2015) and textual features using BERT (Devlin et al., 2019), and fuses them to be used as input to a classifier model. On the other-hand, HERO is a large-scale transformer-based pre-trained model which uses various V&L pre-training tasks to compute cross-modal features. We set T=40%. The results can be seen in Table 4. SW-SDRO model with the HERO backbone improves the state-of-the-art to 68.83%, and test-time ensembling further improves it to 69.90%. Interestingly, similar improvements in clean accuracy are not observed for VIOLIN$_{BASE}$, potentially because it does not use cross-modal pre-trained features.

VQA Yes/No: We use UNITER and VILLA as the backbone models, with T=20%. The motivation behind VQA experiments is to show that SISP transforms and SDRO can be extended to other V&L tasks. Table 5 shows that GW-SDRO is the best performing model in terms of clean accuracy, and is further improved by test-time ensembling.

5 Analysis

5.1 Visualization of Perturbations

In order to quantify the diverse and larger semantic transformations compared to additive perturbations, we study the tSNE (Van der Maaten and Hinton, 2008) embeddings of (i) original samples from NLVR^2 (P), (ii) their SISP-transformed versions (P_{SISP}), and (iii) their adversarially perturbed versions (P_{adv}). Input sentences are encoded using the UNITER text encoder for (i) and (ii), and the adversarial perturbation mechanism (Gan et al., 2020) for (iii). 3D tSNE embeddings are visualized in Figure 3; SISP transformed sentences (blue) are farther away than the perturbed versions. This shift is quantified by the KL-divergence (Kullback et al., 1951) between the distributions, with $D_{KL}(P_{SISP}||P) > D_{KL}(P_{adv}||P)$ implying that the diversity of SISP transformations is higher.

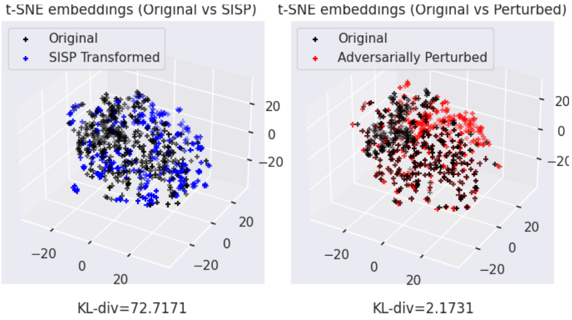

Figure 3: Comparison of original sentences (black) with *(left)* SISP-transformed sentences (blue) and *(right)* ϵ-bounded perturbations as a tSNE plot.

5.2 Comparison of Model Calibration

Figure 4 contains qualitative examples from NLVR^2 to compare output probabilities. We observe that SDRO models have higher clean accuracy, but lower confidence in the predictions than baseline and *data-aug* methods.

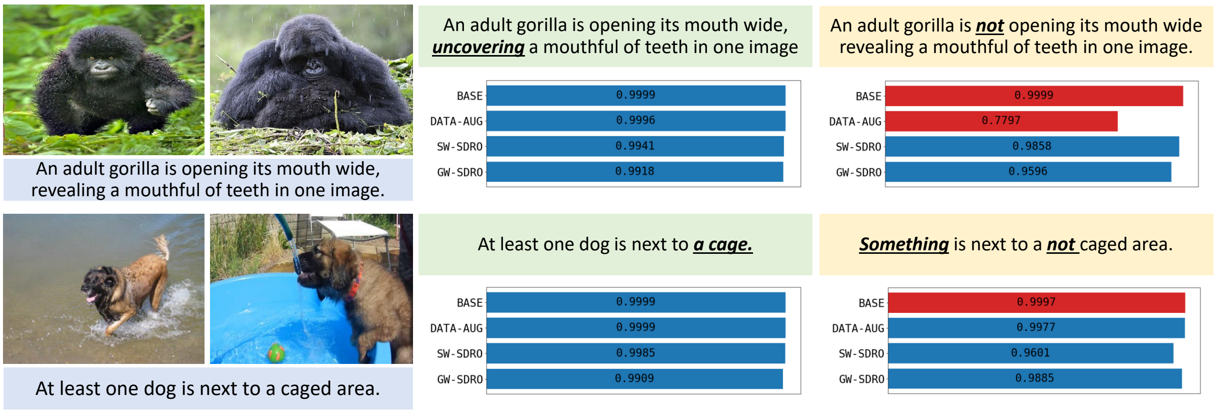
Reliability Diagrams. To validate this observation at scale, we use reliability diagrams to visualize model calibration (Niculescu-Mizil and Caruana, 2005), and plot model accuracy as a function of confidence (Guo et al., 2017). We use the softmax probability $\hat{p}$ of the predicted class as model confidence, split the range of probabilities into $M = 20$ equal-sized bins, and calculate bin accuracy $acc(B_m)$ and bin confidence $conf(B_m)$. If B_m is the set of all samples that fall in the m^{th} bin,

$$\text{acc}(B_m) \triangleq \frac{1}{|B_m|} \sum_{X_i \in B_m} \mathbb{1}(\hat{y}_i = y_i), \qquad (10)$$

$$\text{conf}(B_m) \triangleq \frac{1}{|B_m|} \sum_{X_i \in B_m} \hat{p}_i. \qquad (11)$$

A model with perfect calibration should have a reliability diagram such that $acc(B_m)$=$conf(B_m)$. We also report Expected Calibration Error (Naeini et al., 2015) over all n test samples:

$$ECE = \sum_{m=1}^{M} \frac{|B_m|}{n} |\text{acc}(B_m) - \text{conf}(B_m)|. \qquad (12)$$



An adult gorilla is opening its mouth wide, revealing a mouthful of teeth in one image.

Figure 4: Qualitative examples showing test inputs from the NLVR^2 test set (left) with their respective SP (green) and SI (yellow) test samples. The predicted class (`True`/`False`) and the confidence of the predicted class is shown for baseline, data augmentation using SISP transforms, SW-SDRO and GW-SDRO. All models are built on the VILLA backbone. Wrong predictions are highlighted in red.

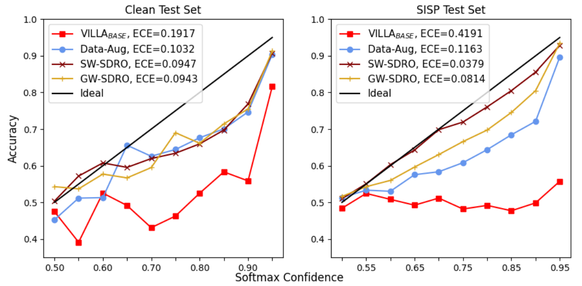

Figure 5: Comparison of reliability curves on the clean test set *(left)* and SISP test set *(right)*.

Reliability diagrams and corresponding ECE values for the VILLA trained with naive data augmentation and SDRO methods for NLVR^2 are shown in Figure 5. On both the clean test set and SISP test set, SDRO models have the lowest ECE. While the ECE for SDRO is marginally better than data augmentation for the clean test set, SDRO is better calibrated for the SISP test set, with SW-SDRO closest to ideal calibration among all evaluated models.

5.3 Size of Training Dataset

We evaluate models trained on small subsets of the original dataset, and compare their performance in Figure 6. SDRO models are significantly better at all sizes of training datasets as shown by accuracy and AUC (area under the curve). Notably, SDRO models trained with only 10% ($\sim 8.6K$) samples have performances similar to the baseline trained with 30% samples; SDRO models with 20% data are better than the baseline model with 40% data. While models trained with naive augmentation saturate below SOTA, at $\sim$80% data size, SDRO models cross the existing SOTA of 78.39%.

Figure 6: Effect of size of training data *(left)* NLVR^2, *(right)* VIOLIN. SDRO models are consistently better than baselines, even in low-data settings.

5.4 Proportion of Augmented Samples.

The final dataset has the same size as the original training set, but with T% transformed samples and $(100-T)\%$ original samples. The effect of this hyperparameter T is reported in Figure 7 as a percentage improvement of accuracy w.r.t. VILLA$_{BASE}$. An optimal value of T=20% leads to improvements in clean accuracy, but a larger proportion of augmented samples degrades performance. Similarly, higher T leads to higher robust accuracy, pointing to a trade-off between clean accuracy and robust accuracy at values of T higher than the optimal. This conforms with similar findings from Tsipras et al. (2019). While models trained with naive data-augmentation have better SISP accuracy than SDRO models as in Ta-

Model	SP only			SI Only			Both		
	Clean	SP	SI	Clean	SP	SI	Clean	SP	SI
Data-Aug	76.07	74.89	35.77	69.51	53.68	94.89	78.34	72.11	84.44
SW-SDRO	79.79	76.93	30.72	79.27	55.53	88.76	79.23	69.23	67.35
GW-SDRO	79.46	75.72	33.04	79.13	54.31	93.25	79.41	68.67	84.54

Table 6: Comparison of performance when only SP, only SI, or both types of transformations are performed.

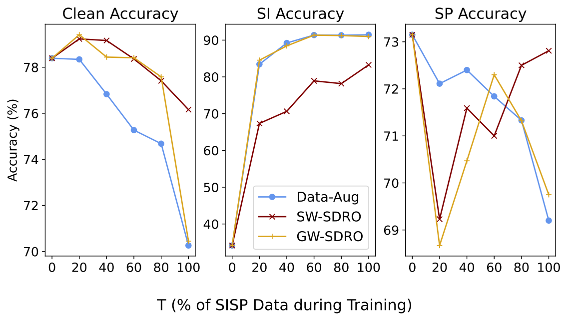

Figure 7: Plots showing the effect of the percentage of augmented samples on Clean, SP, and SI accuracies on NLVR^2, when using data-augmentation, and SDRO.

Model	SISP (Pos)			SISP (All)		
	Clean	SP	SI	Clean	SP	SI
Data-Aug	78.23	68.02	57.48	78.34	72.11	84.44
SW-SDRO	78.81	62.06	66.07	79.23	69.23	67.35
GW-SDRO	79.10	63.47	62.29	79.41	68.67	84.54

Table 7: Comparison of performance if only positive samples are used as inputs for SISP transformations

ble 3, they do so by sacrificing clean accuracy, while SDRO models improve along both dimensions compared to the baselines.

5.5 Ablation Studies

Contributions of SI and SP independently: We analyze which of the two categories (semantics-inverting (SI) or semantics-preserving (SP)) is the most effective by performing SDRO with only SI transforms, or with only SP transforms, and when using both. Table 6 shows that SDRO models trained only with SI suffer in terms of SP robustness and vice versa. However, there is still an increase in clean accuracy in both cases. This indicates that both SI and SP contribute towards improvements in robustness and clean accuracy.

Transformations of only `True` statements: Transforming *False* (negative) statements can lead to ambiguous and subjective meanings (Russell, 1905). We investigate if transforming only *True* (positive) statements is better than transforming both *True* and *False* statements. Table 7 shows that SISP transformations of both types of statements lead to higher clean accuracy and robustness.

	Model	**CR**	**CS**	**CL**	**EDA**	**Emb**	**WN**	**Avg.**
NLVR^2	VILLA	77.5	74.4	74.4	69.6	75.5	75.9	74.5
	+ SDRO	78.5	77.2	72.1	71.1	75.8	76.4	**75.2**
VIOLIN	HERO	66.1	63.0	68.6	60.9	63.8	63.4	64.3
	+ SDRO	68.7	65.0	69.0	61.3	65.5	64.6	**65.7**
VQA Yes/No	VILLA	80.5	75.7	84.9	74.6	78.6	76.4	78.5
	+ SDRO	86.0	84.5	84.1	87.0	84.3	84.0	**85.0**

Table 8: Performance evaluation on "text-attack" (Morris et al., 2020) versions of NLVR^2, VIOLIN, and VQA-Yes/No test sets.

5.6 Robustness to Text-Attacks

In this section, we test each model against text-based adversarial attacks – these attack samples are not seen by the models during training. Thus, this experiment seeks to verify if training with SDRO and SISP samples can also make VLI models robust against automated adversarial attack recipes. We utilize six common attack recipes implemented using the Text-Attack tool by Morris et al. (2020); these are – CLARE (CR) (Li et al., 2021a), character-swap (CS) (Pruthi et al., 2019), Checklist (CL) (Ribeiro et al., 2020), Easy Data Augmentation (Wei and Zou, 2019), counter-fitted embeddings (Emb.) (Alzantot et al., 2018), and WordNet-based swap (WN) (Ren et al., 2019). Table 8 shows results on each benchmark, using the best performing backbone for that benchmark and our SDRO model. On NLVR^2, VILLA+SDRO is better than VILLA for 4 out of 6 attack categories, and 0.7% on average. On VIOLIN, HERO+SDRO outperforms the baseline on all attack categories, leading to an average gain of 1.4%. On VQA-Yes/No, VILLA+SDRO outperforms the baseline on all attack categories, and 6.5% on average.

6 Related Work

Adversarial Training (AT) has been studied under a game-theoretic (Dalvi et al., 2004) and min-max setup (Madry et al., 2018). Volpi et al. (2018)

use AT to adversarially augment image classification datasets and show improved domain generalization for digit classification. Wong and Kolter (2020); Gokhale et al. (2021) modify AT for real-world adversaries beyond norm-bounded perturbations. AT has been used for text classification with LSTMs (Miyato et al., 2017) and for pre-training transformer-based models by adding label-preserving adversarial perturbations to embeddings of word tokens (Zhu et al., 2020; Jiang et al., 2020; Gan et al., 2020) Contrastive examples have been explored, collected from humans (Agrawal et al., 2018), negative mining (Shi et al., 2018), or synthetic generation (Agarwal et al., 2020; Chen et al., 2020a; Gokhale et al., 2020a; Teney et al., 2020).

Robustness in V&L has been explored for VQA, such as performance under prior probability shift (Agrawal et al., 2018) and domain adaptation (Chao et al., 2018; Xu et al., 2020), along with robustness for implied questions (Ribeiro et al., 2019) and novel compositions (Johnson et al., 2017; Agrawal et al., 2017), and robustness to logical connectives (including negation) Gokhale et al. (2020b). Teney et al. (2020) have shown that many V&L, image classification, and sentiment analysis models are sensitive to image editing. There has been a recent effort of model-in-the-loop dataset collection to guide humans to create harder VQA samples (Li et al., 2021b; Sheng et al., 2021).

Robustness in NLP: Generation of SP adversarial examples (Jia and Liang, 2017; Ribeiro et al., 2018; Iyyer et al., 2018; Alzantot et al., 2018), and approaches to defend against word substitution (Jia et al., 2019) have been explored in natural language processing tasks. Evaluation datasets have also been proposed for textual entailment that are manually crafted (Gardner et al., 2020) or template-based (McCoy et al., 2019; Glockner et al., 2018; Naik et al., 2018). Our method uses automated linguistically-informed SI and SP transforms for both training and inference.

7 Discussion

On Ensembling Coefficients. While designing our ensembling approach, we used $\alpha = 0.5$, i.e., equal contribution from the original output and the average of all outputs for transformed samples. This choice is generic and does not rely on dataset- or model-specific characteristics of SISP accuracy. While treating α as a hyperparameter and tuning it on validation datasets could lead to further gains, our intuitive choice of $\alpha = 0.5$ is effective by itself.

On SI Samples. Tables 3, 4, 5 show that existing models perform well on SP transforms, implying that equivalent semantics are captured in transformer-based models. However, these models fail on SI samples resulting in a close-to-random (50%) average SISP accuracy. While images perturbed with noise, blur, weather, or digital artifacts (Hendrycks and Dietterich, 2019) retain semantics (an image of a "cat" remains a cat after perturbation), minimal changes to text inputs, such as a single word changing from "sitting" to "standing" or "not sitting", inflict large changes in meaning. We hope that future work on design of V&L evaluation criterion along the SI axis, could benefit from our findings. While we generated SI and SP text for VLI tasks, the idea could be extended to design SISP transformations for images, by operating at object-level instead of pixel-level

On combination of AT and SDRO. We show that combining AT with SDRO can improve VLI performance and incorporate domain knowledge into the training process, such as semantic knowledge that often exists in natural language or linguistic rules. This is explicitly observed with VILLA, which is pre-trained and fine-tuned using standard adversarial training (Gan et al., 2020). When fine-tuned with SDRO, VILLA+SDRO further improves compared to UNITER+SDRO. The combination of standard adversarial training, (which accounts for local adversaries inside a ϵ norm-ball) and SDRO, (which accounts for linguistic adversaries and contrastive examples, typically outside the norm-ball as shown in Figure 2) could lead to improved generalization in many other V&L tasks.

On differentiability. Linguistic transformations are not differentiable and prohibit gradient-based solutions to the inner maximization in SDRO. However, most V&L tasks would benefit from the incorporation of semantic knowledge into the optimization framework. Through SDRO, we show that explicitly choosing the $argmax$ over a pre-defined set of transformations leads to model-agnostic improvements for binary classification tasks in V&L. More sophisticated methods may emerge in the future to address non-differentiability by leveraging proximal point or trust-region methods (Eckstein, 1993; Conn et al., 2000) or Interval Bound Propagation (Dvijotham et al., 2018), to incorporate semantic knowledge into adversarial training.

Appendix

In this supplementary material, we provide fine-grained results of our experiments, along with detailed analysis for VIOLIN and VQA-Yes/No similar to Section 5 in the main paper. We also provide visualizations of the SISP data creation process, statistics for SISP-transformed samples, and details of our human evaluation study.

A Fine-Grained Results

A.1 Baseline Performance on SISP

In Tables 9, 10, 11 we compare the performance of baseline models on all 13 categories of SISP transforms. All baseline models are below random performance on all three datasets for all SI categories, except for VIOLIN$_{BASE}$ (Liu et al., 2020). This is an interesting finding since VIOLIN$_{BASE}$ is the only model that is not a pretrained transformer-based model, but uses simple fusion of visual and textual modalities. In this paper, we've considered 3 benchmarks, and $3 + 2 + 3 = 8$ backbone models in total. Of these, only VIOLIN$_{BASE}$– a non-transformer model, retains above-random performance on SISP samples. Performance on SP categories is the best for VILLA (Gan et al., 2020) for NLVR^2 and VQA Yes/No, and HERO (Li et al., 2020) for VIOLIN.

A.2 SDRO Performance on SISP

In Tables 12, 13, 14 we compare performance for the state-of-the-art model VILLA, as well as mod-

els trained with naive data augmentation and our SDRO methods.

B Analysis for VIOLIN

Proportion of Augmented Samples. We perform an analysis by varying T (proportion of augmented samples) and report performance in Figure 8 as a percentage improvement of accuracy w.r.t. HERO$_{BASE}$. It can be seen that there exists an optimal value of T (40%), which leads to improvements in clean accuracy, but higher values of T, i.e., a larger proportion of augmented samples degrades performance. Similarly, higher T leads to higher robust accuracy, but lower clean accuracy. Models trained with naive data-augmentation may be more robust on SP and SI test samples than SDRO models, but they do so by sacrificing clean accuracy, while SDRO models improve along both dimensions compared to the baselines.

Table 14: Evaluation of SDRO models (with VILLA backbone) on VQA Yes/No SISP Data

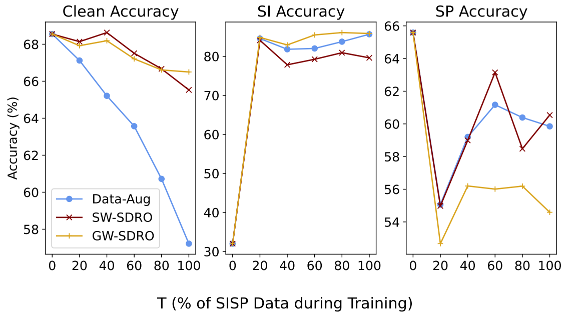

Figure 8: Plots showing the effect of the percentage of augmented samples on Clean, SP, and SI accuracies on VIOLIN, when using naive data-augmentation, SW-SDRO, and GW-SDRO.

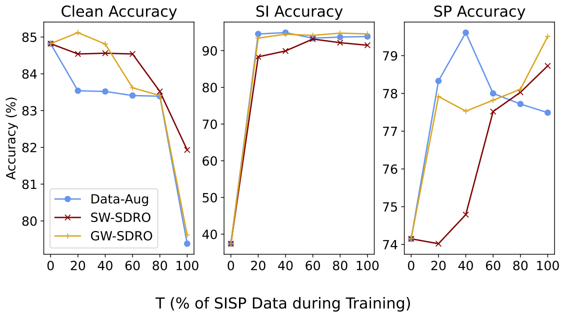

Figure 9: Plots showing the effect of the percentage of augmented samples on Clean, SP, and SI accuracies on VQA Yes/No, when using naive data-augmentation, SW-SDRO, and GW-SDRO.

SI suffer in terms of SP robustness and vice versa. However, there is still an increase in clean accuracy in both cases, thus indicating the efficacy of both SP and SI transformations. The increase in clean accuracy is greater for models trained with both SP and SI transformations.

Transformations of only `True` statements Table 18 shows that training with transformations of both `True` and `False` helps both robustness and accuracy.

D SISP Dataset

D.1 Statistics

In Tables 19, 20, 21, we show the number of SISP-transformed samples generated for the test sets of NLVR^2, VIOLIN and VQA Yes/No respectively. While we generate samples exhaustively for each category of transformation, during training these are sampled according to the proportion of augmented samples T, using three sampling strategies – naive data augmentation, SW-SDRO or GW-SDRO. On average, we obtain 5.69 SI samples and 5.65 SP samples per original sample for the NLVR^2 dataset, 11.14 SI samples and 10.83 SP samples for VIOLIN, and 2.75 SI samples and 3.5 SP sample for the VQA-Yes/No subset.

D.2 Data Generation

Figures 10 and 11 show flowcharts for our SISP transformation process for Semantics Preserving (SP) and Semantics Inverting (SI) respectively. For each image-sentence pair, the sentence is parsed using Spacy (Honnibal et al.) into tokens, dependencies, POS-tags, and noun chunks. Using this, each SISP function (for instance "Noun Synonym") generates insertions, deletions, substitutions, or paraphrasing as shown.

D.3 Transformation Fidelity

For each of the 13 SISP categories, we sampled 100 SISP-transformed examples from NLVR^2, thus giving us a total of 1300 samples. We employed 10 human subjects to evaluate the quality of SISP-transformed sentences. These human subjects were all proficient in English and at the time of the study were enrolled in graduate programs in an English-speaking country. The subjects were shown samples with the original images, sentences, and labels, as well as the new sentence and new label as shown in Figure 12. These subjects evaluated each sample with a binary (0/1) score, according to 4 metrics described below, along with an average "Transformation Fidelity":

1. Label Correctness (LC) – *Is the new label correct for the new sentence?*
2. Grammatical Correctness (GC) – *Does the sentence appear to be grammatically correct?*
3. Visual Grounding (VG) – *Does the sentence*

refer to at-least one visual entity from the image?

4. Semantic Correctness (SC) – *Is the sentence semantically sound and not absurd?*

The subjects were asked to view each sample and rate the new sentence and label on a binary scale for each of the four metrics. A snapshot of the interface used for the study as viewed by the human subjects is shown in Figure 12. Results are shown in Table 22 – split by the category of SISP transformation and in Table 23 – split by the ground-truth label of the original sample. Overall, our SISP transformed test set for NLVR^2 was rated at an average fidelity of 75.10%. It can be observed that on average, SP samples were rated to have higher average fidelity than SI samples, and False samples higher than True samples.

We also split the ratings (2 SISP categories and 2 labels: 2×2) and show results in Table 24. Overall, $SP(False)$ has the highest average fidelity, and $SI(False)$ has the lowest. LC (label correctness) for SI transformations of False statements is only 50%, probably because the inversion of a False statement using template-based methods may not always result in a True statement. On the other hand an SP transformation of a False statement remains False and got 100% LC. It is surprising

Abstract

Commonsense inference poses a unique challenge to reason and generate the physical, social, and causal conditions of a given event. Existing approaches to commonsense inference utilize commonsense transformers, which are large-scale language models that learn commonsense knowledge graphs. However, they suffer from a lack of coverage and expressive diversity of the graphs, resulting in a degradation of the representation quality. In this paper, we focus on addressing missing relations in commonsense knowledge graphs, and propose a novel contrastive learning framework called SOLAR[1]. Our framework contrasts sets of semantically similar and dissimilar events, learning richer inferential knowledge compared to existing approaches. Empirical results demonstrate the efficacy of SOLAR in commonsense inference of diverse commonsense knowledge graphs. Specifically, SOLAR outperforms the state-of-the-art commonsense transformer on commonsense inference with ConceptNet by 1.84% on average among 8 automatic evaluation metrics. In-depth analysis of SOLAR sheds light on the effects of the missing relations utilized in learning commonsense knowledge graphs.

1 Introduction

Commonsense inference, reasoning of unobserved conditions from an observed event, is an important but challenging task in natural language processing (NLP) (Rashkin et al., 2018; Bosselut et al., 2019; Yuan et al., 2020; Hwang et al., 2021). This is easy for humans, but still out of the reach of current artificial intelligence systems. Commonsense inference aims to generate textual descriptions of the inference results, which is more in line with the process of humans reasoning based on their knowledge. For a given event "X walks into a hospital", the causal conditions (e.g., what to do before and after the event), physical conditions (e.g., capability and location of entities), and social conditions (e.g., the intention and reaction of X) of the event are to be inferred.

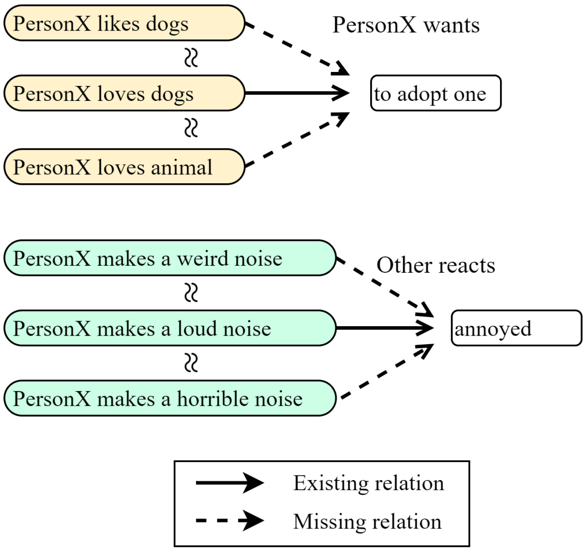

Figure 1: Illustration of missing relations of semantically similar events in commonsense KGs.

Recent studies on commonsense inference have adopted commonsense transformers (Bosselut et al., 2019), which are large-scale language models trained on commonsense knowledge graphs (KGs) like ATOMIC (Sap et al., 2019) and ConceptNet (Speer et al., 2017). Such models are grounded on the hypothesis that language models can memorize facts in their parameters during training (Petroni et al., 2019; Roberts et al., 2020). It is observed that training language models on commonsense KGs allows them to express commonsense knowledge more accurately (Bosselut et al., 2019; Hwang et al., 2021). Despite these efforts, commonsense trans-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1514 - 1523
May 22-27, 2022

former models still suffer from two main obstacles inherent in commonsense KGs: (1) *lack of coverage* and (2) *expressive diversity* of the graphs. First, commonsense KGs lack the coverage required to be applicable for diverse situations in the real world (Li et al., 2016; Saito et al., 2018). In ATOMIC, even with the possibility of far more commonsense properties being relevant, any single node has only 2.2 commonsense properties directly related on average(Malaviya et al., 2020). Second, with the non-canonical and free-form text representation for the nodes in commonsense KGs, semantically identical or similar expressions of events are represented as distinct nodes (Malaviya et al., 2020). For example, "PersonX is fond of dogs" and "PersonX likes dogs" are semantically identical, but represented as distinct nodes. The expressive diversity makes commonsense KGs substantially sparser than conventional KGs. Owing to the lack of coverage and expressive diversity, a significant amount of valid relations between nodes are missing in commonsense KGs.

In this study, we focus on learning from missing relations in commonsense KGs for commonsense inference. Our key observation is that semantically identical or similar events can have the same relations as shown in Figure 1. For example, "PersonX likes dogs" and "PersonX loves animals" are semantically similar to "PersonX loves dogs", and the inference that "PersonX wants to adopt one" can be drawn from any of those events. Modeling such missing relations helps the model learn richer representations from commonsense KGs. Current approaches for alleviating the sparsity of commonsense KGs, such as automatic commonsense KG completion (Li et al., 2016; Saito et al., 2018; Malaviya et al., 2020), do not effectively address missing relations, because the completion models only learn existing relations as valid.[2] Therefore, this problem remains unexplored.

We propose a novel learning framework of commonsense transformers, called ***S**elf-supervised c**O**ntrastive **L**e**A**rning with missing **R**elations* (SOLAR), to address the aforementioned problem. Our framework trains large-scale language models to learn both existing and missing relations with self-supervised contrastive learning, distinguishing between the missing and valid relations as positive and the invalid relations as negative. Specifically, we construct sets of examples including semantically similar events and their relation-object pairs based on the similarity of language representations (e.g., Person likes dogs and PersonX loves animals). We then contrast each set of examples with the sets including dissimilar events and their relation-object pairs. Our contrastive learning framework allows the model to identify the interrelationship between semantically similar events and their relation-object pairs, leading to a better understanding of missing relations in commonsense KGs than a data augmentation approach.

We evaluate our framework for commonsense inference on three commonsense KGs: ConceptNet (Speer et al., 2017), ATOMIC (Sap et al., 2019), and ATOMIC$^{20}_{20}$ (Hwang et al., 2021). Empirical results show that SOLAR outperforms the state-of-the-art commonsense transformers on commonsense inference. In particular, for ConceptNet, SOLAR with BART-large (Lewis et al., 2020) outperforms COMET (Hwang et al., 2021) with BART-large by 1.84% on average among 8 automatic evaluation metrics. In addition, we observe that SOLAR with BART-base produces comparable results to COMET with BART-large, which validates that our framework is superior to existing approaches in terms of both effectiveness and efficiency. Our main contributions are as follows:

- We present a novel contrastive learning framework for commonsense transformers, called SOLAR, that learns from both existing and missing relations in commonsense KGs.
- We develop a principled scheme for constructing positive and negative sets of examples with commonsense KGs based on similarities of events in language representations.
- We verify that SOLAR establishes new state-of-the-art results in commonsense inference across diverse commonsense KGs.

2 Related Work

2.1 Commonsense Inference

In the NLP domain, several studies have proposed commonsense inference models that utilize commonsense KGs. Rashkin et al. (2018) proposed Event2Mind, a commonsense KG that involves a textual description of a person's response or intention of daily events. Sap et al. (2019) proposed ATOMIC knowledge graph as an extension

---

[2] Note that Malaviya et al. (2020) train their model only on existing relations as valid, although utilizing synthetic links in encoding node representations.

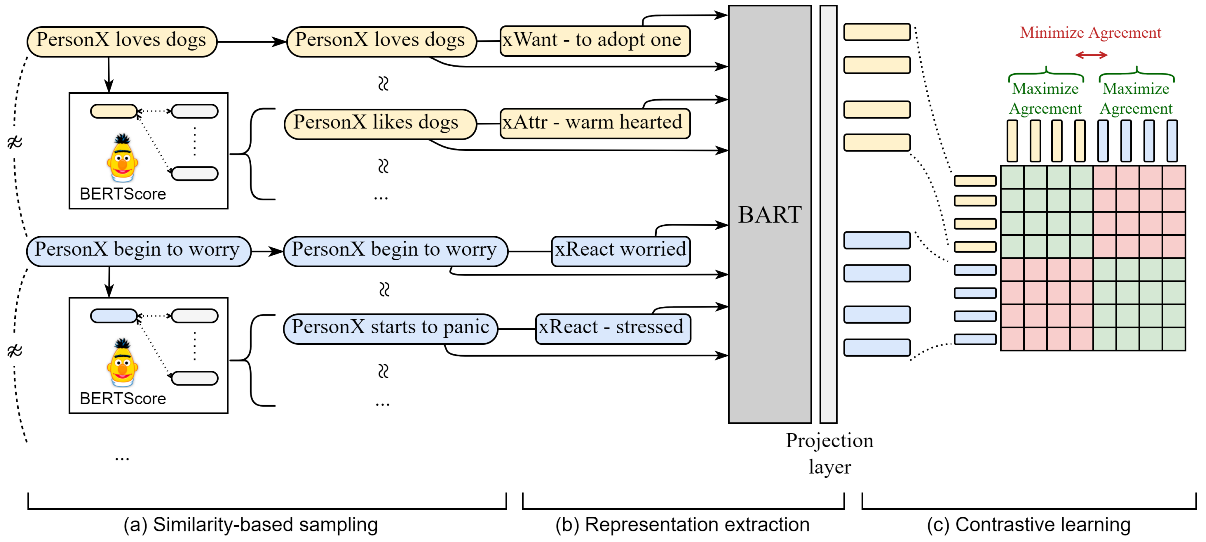

Figure 2: Illustration of contrastive learning of commonsense tuples. (a) Based on adversarially sampled root subjects, semantically similar subjects are sampled. (b) Subjects and relation-object pairs connected to them are projected to separate hidden representations through a generative language model and a projection layer. (c) Hidden representations obtained from the same root subject are considered as positive pairs, and those obtained from other root subjects are considered as negative pairs for contrastive learning.

of Event2Mind with more relations and tuples. Both studies trained on the GRU model based on their proposed graph to learn commonsense inference. Moreover, recent studies have shown that pre-trained language models store various types of fact knowledge in their latent parameters (Petroni et al., 2019; Roberts et al., 2020). Bosselut et al. (2019) revealed that language models can directly express commonsense knowledge by training them on commonsense KGs. Hwang et al. (2021) showed that KGs must be designed to contain knowledge that is not already expressible by language models. Gabriel et al. (2021) focused on discourse-level commonsense inference, and Yuan et al. (2020) proposed a language model architecture for logically consistent commonsense reasoning. Previous studies have proposed training language models on existing relations in commonsense KGs for commonsense inference. In our work, we focus on addressing the missing relations of commonsense KGs for better commonsense inference.

2.2 Contrastive Learning

Contrastive learning has shown promising performances in computer vision (Chopra et al., 2005; Henaff, 2020; He et al., 2020). SimCLR (Chen et al., 2020b) introduced a simple but powerful contrastive learning approach and showed a competitive performance with supervised learning approaches. Contrastive learning is also widely used in natural language processing, where a model obtains unsupervised representations by learning to predict positive or negative pairs. Mikolov et al. (2013) proposed an efficient method for learning word representations by classifying whether given words appear in the same context or not. Furthermore, contrastive learning has been adopted to improve the representations of pre-trained language models. Reimers and Gurevych (2019); Zhang et al. (2020b); Yan et al. (2021) introduced contrastive learning frameworks for enhancing the sentence representations. Lee et al. (2020) proposed a contrastive learning method to mitigate the exposure bias problem. Inspired by these studies, we propose a novel contrastive learning framework for commonsense representation learning with commonsense KGs. With our proposed framework, the model learns inferential knowledge from both existing and missing relations.

3 Methodology

In this section, we describe the model architecture and training procedure of the proposed framework.

3.1 Notation

We define $G = (V, E)$ as the commonsense knowledge graph that consists of a set of nodes V and a set of edges E. Following the notation from COMET (Bosselut et al., 2019), we denote each knowledge tuple from the knowledge graph as

Algorithm 1 Set Construction Algorithm.

```
Input: root subjects $S_{root}$, number of root subjects $N$, edges $E$, set size $2m$, threshold $\delta$, BERTScore function $b(\cdot,\cdot)$, base model $f(\cdot)$, projection layer $g(\cdot)$
for $s_i \in S_{root}$ do
    Initialize $G_i$ as $\emptyset$
    for $j \in \{1, ..., m\}$ do
        if $j = 1$ then
            $s_j^i \leftarrow s_i$
        else
            repeat                        ▷ Sample similar subject
                $s_j^i \leftarrow$ sample($S$)
            until $b(f(s_j^i), f(s_i)) > \delta$
        end if
        get tuple $\{s_j^i, r_j^i, o_j^i\} \in E$ containing $s_j^i$
        $z_{2j-1}^i \leftarrow g(f(s_j^i))$
        $z_{2j}^i \leftarrow g(f(r_j^i \oplus o_j^i))$
        $G_i \leftarrow G_i \cup \{z_{2j-1}^i, z_{2j}^i\}$
    end for
end for
return $G_1, G_2, ..., G_N$
```

$\{s,\ r,\ o\}$, where s is the phrase subject, r is the relation, and o is the phrase object of the tuple. Here, s and o are natural language sequences, and r is a single special token (e.g., <xIntent>). Note that $s,\ o \in V$ and $\{s,\ r,\ o\} \in E$. We define S as the set of all existing subjects from the knowledge graph, and it follows that $S \subset V$. Finally, we denote the generative language model to be trained as $f(\cdot)$ and a projection layer at the top of the model as $g(\cdot)$. We use nonlinear projection layer proposed by Chen et al. (2020b).

3.2 Commonsense Representation Learning

To improve commonsense representations of the language model prior to learning commonsense inference, we first proceed with commonsense representation learning through contrastive learning of commonsense tuples and commonsense reconstruction.

Contrastive learning of commonsense tuples. Inspired by our key observation that semantically identical or similar events can have same relations, we propose a novel commonsense representation learning method based on contrastive learning.

The overall procedure of the proposed method is depicted in Figure 2. First, we obtain a set of N root subjects $S_{root} = \{s_1, s_2, ..., s_N\}$ through adversarial sampling on S. The adversarial sampling procedure is designed such that pairwise semantic similarity of subjects in S_{root} lies between minimum similarity α and maximum similarity β. Here, we use BERTScore (Zhang et al., 2020a) between phrase subjects as the semantic similarity metric.

We then obtain positive and negative pairs by constructing N sets $G_1, G_2, ..., G_N$ containing hidden representations, where each G_i corresponds to a root subject $s_i \in S_{root}$. For an arbitrary element $s_i \in S_{root}$, we first sample m tuples $\{s_j, r_j, o_j\}$ $(j = 1, 2, ..., m)$ from E that contain subjects s_j semantically similar to s_i. Each s_j and $r_j \oplus o_j$ is projected to hidden representations $z_{2j-1}^i = g(f(s_j))$ and $z_{2j}^i = g(f(r_j \oplus o_j))$, and added to G_i. Here, $\oplus$ denotes concatenation of two sequences. Repeating for m times, the constructed set G_i contains $2m$ hidden representations derived from subjects that are semantically similar to the root subject s_i, and the relation-object pairs connected to them. Algorithm 1 summarizes the construction procedure.

We consider samples from the same set as positive pairs, and those from different sets are negative pairs in contrastive learning. We use NT-Logistic (the normalized temperature-scaled logistic) objective function (Chen et al., 2020b) as our training objective to maximize the agreement between positive pairs while minimizing the agreement between negative pairs. The formal expression of our objective function is given by the following equations:

$$l_i^{pos} = -\frac{\sum_{p,q=1}^{2m} \log \sigma({z_p^i}^T z_q^i/\tau)}{2m}, \tag{1}$$

$$l_i^{neg} = -\frac{\sum_{i<j\leq N} \sum_{p,q=1}^{2m} \log \sigma(-{z_p^i}^T z_q^j/\tau)}{m(N-1)}, \tag{2}$$

$$L_{cont} = \frac{1}{N} \sum_{i=1}^{N} (l_i^{pos} + l_i^{neg}), \tag{3}$$

where l_i^{pos} is the loss function over positive pairs in set G_i, and l_i^{neg} is the loss function over negative pairs among set G_i and the other sets. In addition, τ denotes the temperature parameter for temperature scaling. The model is trained to minimize the final objective L_{cont}, which is the mean of l_i^{pos} and l_i^{neg} for all $i = 1, 2, ..., N$.

Commonsense reconstruction. To further improve the representation of a single tuple, we propose a commonsense reconstruction task inspired by Lewis et al. (2020), in which the model learns to reconstruct corrupted tuples into their original form. More specifically, we corrupt a commonsense tuple $\{s,\ r,\ o\}$ by randomly choosing one of the three elements, masking the span of the chosen element, and shuffling the order of the tuple. The model is trained to reconstruct the original tuple from the corrupted tuple. We expect that the reconstruction task allows the model to better understand the tuple itself by learning to predict the masked span with tuple context and reordering tuple elements. The objective of the commonsense reconstruction task is to minimize L_{recon} computed by cross-entropy between the decoder output and the original tuple.

The model learns commonsense representations through multitask learning on the two aforementioned tasks simultaneously. Therefore, the final objective function of our framework is to minimize the combined loss:

$$L_{rep} = \omega L_{cont} + (1 - \omega) L_{recon}. \qquad (4)$$

3.3 Fine-tuning on Commonsense KGs

After learning commonsense representations, we remove the projection head and fine-tune the model with commonsense KGs to learn commonsense inference. The model learns to generate a phrase object o given a concatenation of phrase subject s and relation r. The objective function of the task is as follows:

$$L_{infer} = - \sum_{i=0}^{|E|} \log P_{\theta}(o_i | s_i, r_i) \qquad (5)$$

3.4 Language Model Architecture

While SOLAR is agnostic to its generative language model architecture, for our experiments, we use BART (Lewis et al., 2020) with its pre-trained parameters as our base generative language model. BART is a transformer-based sequence-to-sequence language model with a bidirectional encoder and a left-to-right autoregressive decoder. For commonsense representation learning (Section 3.2), we add a projection layer that maps the BART decoder output representations to a space where contrastive loss is applied. The projection head is then removed for fine-tuning on commonsense KGs (Section 3.3).

4 Experiments

In this section, we demonstrate the efficacy of our framework by comparing the commonsense inference performances of SOLAR with those of the state-of-the-art commonsense transformers.

4.1 Dataset

Commonsense KGs are widely used for evaluating the commonsense inference capability by measuring the plausibility of the generated inferences given unobserved events or entities. Hwang et al. (2021) developed an adversarial splitting method for dividing training, validation, and test sets that prevent overlapping subjects of knowledge tuples between the sets. We utilize the splitting method to evaluate the inference capability of the model for unseen events or entities. We use three commonsense KGs in our experiments: ConceptNet (Speer et al., 2017), ATOMIC (Sap et al., 2019), and ATOMIC$^{20}_{20}$ (Hwang et al., 2021).

ConceptNet is a general commonsense knowledge graph. We use a subset of the graph provided by Li et al. (2016), which involves 36 relations and 300K tuples. The subset is divided into 265K, 5K, and 30K tuples for training, validation, and testing respectively.

ATOMIC is a social commonsense knowledge graph that involves 9 relations with 877K tuples. The split of ATOMIC includes 710K, 80K, and 87K tuples for training, validation, and testing, respectively.

ATOMIC$^{20}_{20}$ is a recently proposed large-scale commonsense knowledge graph, which involves 23 commonsense dimensions and contains 1.33M tuples. It includes physical-entity, social-interaction, and event-centered commonsense. ATOMIC$^{20}_{20}$ is split into 1.08M, 10K, and 15K tuples for training, validation, and testing, respectively.

4.2 Experimental Settings

Baseline We use COMET (Bosselut et al., 2019), the state-of-the-art commonsense transformers in commonsense inference, as the baseline. We use the public HuggingFace (Wolf et al., 2019) implementation of pre-trained BART (Lewis et al., 2020) as a language model and train it using SOLAR and COMET for comparison. BART-base has 6 transformer layers for encoder and decoder each with a hidden size of 768, whereas BART-large has 12 transformer layers for encoder and decoder each with a hidden size of 1024. For fine-tuning, we empirically choose the best number of epochs, learning rate, and batch size among {1, 3, 5, 7, 9, 12}, {1e-5, 5e-5}, and {16, 32, 64, 128}, respectively, and use the Adam optimizer with $\beta_1 = 0.9$,

$\beta_2 = 0.999$.

Training details of SOLAR. In contrastive learning of commonsense tuples, we extract $n \in \{4, 8, 16, 32\}$ root subjects while maintaining the similarity (%) between subjects[3] with a minimum of $\alpha \in \{40, 50\}$ and a maximum of $\beta \in \{70, 80\}$. It is because too low minimum similarity (α) can lead to trivial negative examples (e.g., PersonX adopts a dog $\leftrightarrow$ A banana), while too high maximum similarity (β) can lead to training of similar events as negative examples (Figure 4). We then sample $\{4, 16, 32\}$ semantically similar subjects with greater than $\{85, 90\}$ similarity to previously extracted subjects. Note that the root subjects and similar subjects are randomly sampled at each iteration so that most tuples in the KG can be learned. We set the temperature parameter τ to 0.1.

In reconstructive learning tasks, we corrupt tuples by masking the span of each tuple elements and randomly shuffling the order. The span length is drawn from a Poisson distribution ($\lambda = 3$). SOLAR learns commonsense representation through multi-task approach, and we set the task weight as $\omega = 0.8$. In addition, we optimize the model using the RecAdam (Chen et al., 2020a) optimizer to prevent catastrophic forgetting during commonsense representation learning. We set the hyperparameters of the optimizer to $k = 0.001$ and $t_0 = 1000$. After representation learning, we set the same hyperparameters as the baseline. All the above-mentioned hyperparameters are empirically determined. We report the best results among possible hyperparameter settings.

Metrics. To measure the commonsense inference capability of SOLAR, we use common evaluation metrics in the text generation: BLEU (Papineni

---

[3] When measuring the similarity, we manually add the prefix "concept related to" to subject with a sequence length less than 3.

Subject	Relation	Ground truth	COMET	SOLAR
PersonX is always busy	xReact	exhausted	busy	tired
sugar cube	ObjectUse	eat as food	mix with sugar	sweeten coffee
PersonX gives PersonY a cup	HinderedBy	PersonY is not thirsty	PersonX is allergic to water	PersonX doesn't have a cup
PersonX likes the movie	HinderedBy	They were too busy texting	PersonX is allergic to the movie	The movie is too boring

Table 4: Examples of commonsense inference from COMET and SOLAR in ATOMIC$^{20}_{20}$.

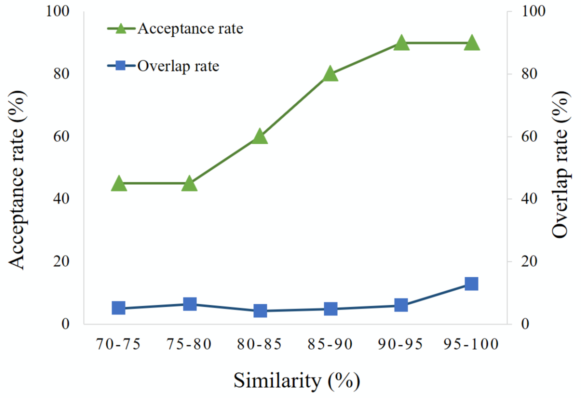

Figure 4: Acceptance and overlap rates of generated missing relations. Similarity is measured by BERTScore.

et al., 2002), ROUGE (Lin, 2004), CIDEr (Vedantam et al., 2015) and BERTScore (Zhang et al., 2020a).

Overall performance. We evaluate SOLAR and COMET on three commonsense KGs and report the automatic evaluation results of generated inferences. In our result tables, we denote model names in form of (framework)-(BART model configuration). For example, SOLAR and COMET with BART-base are denoted by SOLAR-base and COMET-base, respectively.

Table 1 shows that SOLAR-base outperforms COMET-base for all KGs. By averaging over all metrics, SOLAR-base improves the performance of COMET-base on ConceptNet, ATOMIC, and ATOMIC$^{20}_{20}$ by 1.74%, 0.57%, and 0.65%, respectively. Experiments on large model configurations establish the new state-of-the-art results on commonsense inference with KGs. Table 2 shows that SOLAR-large outperforms COMET-large, the previous state-of-the-art, for all KGs and evaluation metrics. We observe 1.84%, 0.70%, and 0.58% average performance improvement on ConceptNet, ATOMIC, and ATOMIC$^{20}_{20}$ respectively. Furthermore, SOLAR-base performs comparably to COMET-large on ATOMIC and ATOMIC$^{20}_{20}$, and performs better on ConceptNet, despite using only one-third of parameters. This shows the parameter-efficiency of our approach compared to COMET.

4.3 Results

Analysis on commonsense inference. We provide further analysis on commonsense inference results of SOLAR and COMET. Figure 3 shows the validation loss curve for COMET-large and SOLAR-large. It is clearly observed that SOLAR gives smaller loss than COMET on validation sets, which indicates that SOLAR generalizes commonsense better than COMET. In addition, Table 4 shows examples of commonsense inference results by COMET and SOLAR. It can be observed that SOLAR generates plausible inferences with novel expressions, whereas COMET extracts words from the subject phrase to generate inferences, leading to trivial or wrong results. Another observation is that COMET is vulnerable to the annotation bias in KGs. For example, in ATOMIC$^{20}_{20}$, the word "allergic" frequently appears with relation "HinderedBy", and COMET is biased to generate wrong inferences like "allergic to the movie". In contrast, SOLAR makes better inference results without such bias.

Ablation study. We conduct an ablation study to measure the effectiveness of each component of our proposed framework. Table 3 shows that learning on both tasks performs better than learning on only one of the two tasks. We observe that contrastive learning of commonsense tuples is the key to our performance improvement that SOLAR achieves, and the reconstruction task also plays a role in the

Similarity (%)	Subject	Relation – object	Plausible
95.8	PersonX throws a huge party PersonX throws a big party	oReact-important oEffect-smile	✓

Table 6: Evaluation results of methods for learning from missing relations.

framework.

Acceptance of missing relations. We conduct a qualitative analysis of missing relations generated through our approach. Table 5 shows examples of tuple pairs and their similarity values measured by BERTScore. In the first row, “PersonX throws a huge party” and “PersonX throws a big party” are semantically similar, and each relation-object can be shared with the subject of the other (e.g., PersonX throws a huge party - oEffect - smile). In contrast, as in the last example, tuple pairs with a low similarity between subjects cannot share relation-object with one another. From these examples, we observe that tuple pairs with higher similarity between subjects generate more plausible tuples when their relation-object pairs are shared, consistent with our intuition.

We further provide a quantitative analysis by measuring the acceptance rate of missing relations generated through our approach and comparing it with the overlap rate. Overlap rate is the probability of a missing relation already existing in the graph. To measure the acceptance rate of missing relations, we randomly sample 20 missing relations per similarity interval (total 120 samples) and ask human annotators to determine their plausibility[4]. Three workers annotated each missing relation as *accept* if it is plausible or *reject* otherwise, and we used majority voting as the final annotation. Figure 4 shows the acceptance rate of the missing relations regarding semantic similarity of subjects. It shows that the acceptance rate of missing relation is proportional to the similarity, and if the tuples have a similarity of greater than 90%, then 90% of the missing tuples are then valid. In contrast, when the similarity drops below 85%, the acceptance rate decreases drastically. The blue line in Figure 4 represents the overlap rate according to the similarity. For tuple pairs of high similarity exceeding 90%, the overlap rate is significantly lower (< 20%) than the acceptance rate, which shows that novel missing relations can be effectively identified through our method.

Methods for learning from missing relations. We investigate the effectiveness of our method for learning from missing relations. We compare our contrastive learning method with a data augmentation method where missing relations are directly added to a commonsense KG and learned in fine-tuning. We use missing relations generated on subjects with exceeding 90% similarity. Table 6 shows that our proposed contrastive learning method shows best performance, whereas the data augmentation method is worse than the baseline. We speculate that direct fine-tuning on augmented KGs is vulnerable to unacceptable relations, while

---

[4] We evaluate the missing relations with three graduate students fluent in English.

our proposed contrastive learning framework is robust to them. These results indicate that directly learning from missing tuples harm the commonsense inference capability of the model. We speculate that our approach can handle noises (e.g., unacceptable relations) owing to the implicit nature of contrastive learning.

5 Conclusion

We have presented a novel contrastive learning framework of commonsense transformers, called SOLAR, to effectively learn from missing relations in commonsense KGs. Moreover, we have developed a new construction scheme for positive and negative sets of examples based on similarities in language model representations. By utilizing our carefully designed methods, SOLAR effectively learns both existing and missing relations of events, alleviating the difficulties in learning commonsense KGs. Our empirical evaluations of diverse commonsense KGs demonstrate the efficacy of SOLAR in commonsense inference. In particular, SOLAR consistently outperforms the state-of-the-art commonsense transformers across all the evaluation metrics and commonsense KGs.

Abstract

Natural Language Inference (NLI) datasets contain examples with highly ambiguous labels due to its subjectivity. Several recent efforts have been made to acknowledge and embrace the existence of ambiguity, and explore *how to capture the human disagreement distribution*. In contrast with directly learning from gold ambiguity labels, relying on special resource, we argue that the model has naturally captured the human ambiguity distribution as long as it's calibrated, i.e. the predictive probability can reflect the true correctness likelihood. Our experiments show that when model is well-calibrated, either by label smoothing or temperature scaling, it can obtain competitive performance as prior work, on both divergence scores between predictive probability and the true human opinion distribution, and the accuracy. This reveals the overhead of collecting gold ambiguity labels can be cut, by broadly solving *how to calibrate the NLI network*.

1 Introduction

Ambiguity is intrinsic to natural language. Previously, it's common to disregard it as noise or as a sign of poor-quality data, because we implicitly make the assumption that there is only one correct label given an example, indicating the unique class it belongs to. However, it is against the subjectivity of many natural language understanding (NLU) tasks, such as natural language inference (NLI) and semantic textual similarity (STS), as their annotations are heavily based on personal experience and opinions. More recent research has gravitated towards the necessity to acknowledge and embrace the existence of ambiguity in NLI.

Pavlick and Kwiatkowski (2019) shows that human disagreements, very often, are not dismissible as annotation noise, but rather persist as collecting more ratings and varying the amount of context provided to raters. Humans judgments cannot be adequately summarized by a single aggregate label or value, [1] but a distribution. ChaosNLI (Nie et al., 2020) provides an empirical distribution by collecting 100 annotations for each instance, to simulate true soft label distribution, which is always used as the ambiguity NLI benchmark.

Premise	Look, there's a legend here.

Table 1: Ambiguous examples from ChaosNLI. Label: the first element is the class, the second is the number of annotators among 100 choosing this class. C E N refers to classes of *Contradiction*, *Entailment* and *Neutral*.

For the first example in Table 1 extracted from ChaosNLI, it's totally reasonable to assign either *Neutral* or *Entailment*, depending on the annotators' understanding of relationship between "legend" and "hero". The second shows the disagreement between *Contradiction* and *Neutral* when differing from the context and the annotators' background knowledge.

The challenge is *how to capture this linguistic ambiguity?* In other words, how to model the human disagreement distribution? Pavlick and Kwiatkowski (2019) demonstrated NLI systems trained to predict an aggregate label do not learn the uncertainty that exists among humans' perceptions. So Meissner et al. (2021) explored to train directly on the crowd-sourcing soft label distribution of the annotators. They find training on the same amount of data but targeting the ambiguity distribution instead of one-hot labels can improve the

Findings of the Association for Computational Linguistics: ACL 2022, pages 1524 - 1535
May 22-27, 2022

prediction accuracy, and narrow the ChaosNLI JSD scores. However, is the success of JSD reduction and accuracy improvement completely attributed to the usage of special resources with ambiguity labels? What essentially makes the contribution?

In our view, it's the label smoothing of soft labels that plays an important role, owing to its effectiveness on regularisation, re-calibration and loss correction (Patrini et al., 2016; Lukasik et al., 2020; Müller et al., 2019). Specifically, the ambiguity distribution employed by Meissner et al. is just a special soft label, targeting label smoothing outputs is believed to have comparable performance, much cheaper than collecting crowdsourcing labels.

We further posit that the linguistic ambiguity have been learned by a well-calibrated model, trained either hard or soft labels. The predictive probability of a perfectly-calibrated model can reflect the true correctness likelihood, i.e. empirical accuracy is equal to the prediction confidence. Empirical accuracy is obtained from observations across the human judges. That is, predictive confidence (uncertainty) can represent the human judgment distribution when model is calibrated. To this end, not only label-smoothing, but other re-calibration approaches such as temperature scaling can reach the same goal. Our experiments confirmed our hypothesis, when model is calibrated, it can obtain competitive ChaosNLI divergence scores and bring accuracy boost.

Our contributions are two folds: (1) We propose the hypothesis: a well-calibrated network can naturally capture linguistic ambiguity, regardless of using special resource. It reasonably explains the success of training with ambiguity labels, and converts question of "how to capture human disagreement distribution?" to a more general one "how to train a calibrated model?" Our experiments confirm that commonly-used re-calibration methods are as effective as targeting at ambiguous annotations. (2) Knowledge of linguistic ambiguity learned from the general domain benefits biomedical domain as well, which suggests ambiguity signals can be transferred across domains. But calibration is not an intrinsic property of a model, it's data-dependent.

2 Background

Label smoothing (LS) is a mixture of one-hot label vector $\mathbf{y}_{hot}$ and the uniform distribution:

$$\mathbf{y}_{ls} = (1-\alpha)\mathbf{y}_{hot} + \alpha/K$$

where K is the number of label classes, α is a hyper-parameter that determines the amount of smoothing. α = 0, $\mathbf{y}_{ls} = \mathbf{y}_{hot}$, α = 1, $\mathbf{y}_{ls}$ is the uniform distribution.

In the setting, where the loss function L is cross entropy, and the model applies the *softmax* (σ_{SM}) to the penultimate layer's logit vector $\mathbf{z}$ to compute probability $\mathbf{p}$, the gradient of the cross entropy loss function with respect to the logits is:

$$\nabla L = \sigma_{SM}(\mathbf{z}) - \mathbf{y}; \partial L/\partial z_i = p_i - y_i$$

We can see that gradient descent will try to make $\mathbf{p}$ as close to $\mathbf{y}$ as possible. When $\mathbf{y}$ is the one-hot label, models will classify every training example correctly with the confidence of almost 1. This not only conflicts with the inherent disagreement of NLI, but tends to result in over-confident and less-generalised models as well.

Concretely, suppose K = 3, $\mathbf{z} = [z_1, z_2, z_3]$, the consequence of using one-hot encoded label $y = [1, 0, 0]$ is that z_1 will be extremely large and the other logits will be extremely small: $z_1 \gg z_2$ and $z_1 \gg z_3$. In other words, one-hot labels encourage the largest possible logit gaps to be fed into the *softmax* function. Moreover, the gradient is bounded between -1 and 1, as p_i and y_i is probability value $\in [0, 1]$. Large logit gaps combined with the bounded gradient lead models to be less adaptive and too confident. In contrast, smoothed labels encourages small logit gaps. Label smoothing restrains the largest logit from becoming much bigger than the rest, improving model generalisation ability, and prevents overconfident predictions, making model more calibrated instead of over-confidence.

Pereyra et al. (2017) explains label smoothing by connecting it to a maximum entropy based confidence penalty through the direction of the KL divergence. Specifically, to penalize confident (low entropy) output distributions, adding the negative entropy to the negative log-likelihood L_{NLL} during training as Eq (1). Applying label smoothing is interpreted as adding a confidence penalty $D_{KL}(u||\mathbf{p})$ to original loss as a regularizer, where u is uniform distribution.

$$L = L_{NLL} - \beta H(\mathbf{p}) \quad (1)$$

$$L = L_{NLL} - D_{KL}(u||\mathbf{p}) \quad (2)$$

Müller et al. shows label smoothing implicitly calibrates learned models so that the confidences of their predictions are more aligned with the accuracy of predictions. Beside, it's functional in backward loss correction and denoising (Patrini et al., 2016; Lukasik et al., 2020).

Classification Re-calibration Apart from label smoothing, post-hoc scaling, such as matrix and vector scaling and temperature scaling, is demonstrated to be effective to re-calibrate DNNs (Guo et al., 2017). They apply a linear transformation $\mathbf{W}\mathbf{z}_i + \mathbf{b}$ to the logits $\mathbf{z}_i$: $\hat{\mathbf{q}}_i = \sigma_{SM}(\mathbf{W}\mathbf{z}_i + \mathbf{b})$. The parameters $\mathbf{W}$ and $\mathbf{b}$ are optimized with respect to NLL on the validation set. As the number of parameters for matrix scaling grows quadratically with the number of classes K, vector scaling is defined as a variant where $\mathbf{W}$ is restricted to be a diagonal matrix.

Temperature scaling uses a single scalar parameter T>0 for all classes. T is optimized with respect to NLL on the validation set as well.

$$\hat{\mathbf{q}}_i = \sigma_{SM}(\mathbf{z}_i/T)$$

Because the parameter T does not change the maximum of the *softmax* function, the class prediction remains unchanged, temperature scaling does not affect the model's accuracy.

Related Work Several recent studies, in parallel with ours, explore to capture NLI label distribution. The most similar work is Zhang et al. (2021). They also train with multi-annotated examples, label smoothing and temperature scaling, but differ from the motivation, implementation and results. Specifically, we pay much attention to analyzing why re-calibration approaches are useful, and investigating the connection between model calibration error, sharpness with NLI distribution distance, while they merely conduct an empirical case study without any deep analysis. In the experiment, they train with the majority of ChaosNLI and test on only 500 examples sampled from ChaosNLI, but we train using SNLI/MNLI corpus and evaluate on the whole ChaosNLI. Statistically, our results are more convincing; In addition to the result, their distribution divergence declines at the cost of declining accuracy of 4 points, from 0.72 to 0.68, whereas our accuracy remains the same level.

Zhou et al. (2021) paid more attention to Bayesian estimation and model distillation to learn label distribution, without focusing on label smoothing on which we concentrate and analyzed deeply, including uncertainty metrics and soften factor selection. Overall, our work complements concurrent studies with lots of comprehensive and useful analysis in terms of label smoothing and temperature scaling.

3 Hypothesis

While softmax of NLI models trained with hard labels allows the model to represent predictive confidence, this probability does not necessarily mimic the uncertainty that exists among humans' perceptions (Pavlick and Kwiatkowski, 2019). We speculate targeting one-hot labels leads model to be overconfident. The miscalibration of over-confidence results in the disability to represent human disagreement distributions correctly.

Meissner et al. (2021) explores to train on the empirically-gold soft labels collected by crowdsourcing annotations. They find training on the same amount of data but targeting the ambiguity distribution instead of hard labels can reduce ChaosNLI divergence scores (JSD) and achieve higher performance. So they advocate to use crowdsourcing techniques to obtain a label distribution by collecting multiple annotations given an instance, instead of only one as before.

However, is the success completely attributed to the usage of empirically-gold label distribution as training target? What essentially makes difference? In our view, it's the soft label — output of label-smoothing, as an effective technique on recalibration, regularisation and loss correction that plays an important role in this success. The ambiguity distribution they employed is just a special soft label, targeting other label smoothing outputs is believed to have comparable performance, but much cheaper than crowdsourcing distribution.

Moreover, we argue that even training with gold soft labels as AmbiNLI (Meissner et al., 2021), cannot always obtain improvements. It may bring degradation when model has been under-confident or calibrated, as continuous training with soft labels will exacerbate under-confidence, which deviates prediction away from the correct one. Besides, AmbiNLI only showed performance on one special benchmark — ChaosNLI which concentrates on ambiguous cases. How about performance on other corpus that consist of both ambiguous and extreme non-ambiguous instances?

Therefore, we posit that the linguistic ambiguity have been learned by models that is well-calibrated, even if just trained on previous one-hot labels. And not only label-smoothing, but other re-calibration approaches can reach the same goal.

Dataset	Train	Dev	Test	Prem

AmbiNLI-M	18,048	–	–	
AmbiNLI-U	55,517	–	–	

Table 2: Statistics information of NLI datasets. Prem is the mean token count among premise sentences.

So we conduct a case study to explore: 1) Can other soft labels generated from the label smoothing achieve competitive results as crowdsourcing ambiguity distribution? 2) Is training using soft labels always better than using one-hot labels? and vice versa? 3) Without soft labels, can other recalibration methods narrow the distance to true correctness probability either?

4 Dataset and Metric

This section gives descriptions of datasets throughout this work, and metrics to assess predictions.

4.1 Datasets

SNLI (Bowman et al., 2015) is a large-scale (570k pairs) NLI resource based on image captioning, in which 56,951 (10%) pairs are validated after the first-stage construction of three hypothesis sentences given a premise towards "definitely true", "may be true" and "definitely false". In validation, additional four annotators are asked to assign labels for a pair of *(premise, hypothesis)*, yielding five annotations. If any one of the three labels was chosen by at least three of the five annotators, it was chosen as the gold label. All examples in the test and development sets have been validated.

MultiNLI (MNLI) (Williams et al., 2018) improves upon SNLI in both its coverage and difficulty by offering data from ten distinct genres of written and spoken English, making it possible to capture more of the complexity of modern English, and supplying explicit setting for evaluating cross-genre domain adaptation.

The disagreement and subjectivity among humans in NLI annotation results in the reflection of ambiguous labels. Many efforts have been made to embrace linguistic ambiguity, regarding them as an intrinsic property of the populations, instead of noise of the data collection and the uncertainty of individual annotators.

ChaosNLI (Nie et al., 2020) is created, by collecting 100 annotations per example for 3,113 examples in SNLI (1,514) and MNLI (1,599), denoting as Chaos-SNLI and Chaos-MNLI respectively. Two sets are a subset of the SNLI development set and a subset of MultiNLI-matched development set, in which the examples satisfy the requirement that their majority label agrees with only three out of five individual labels collected by the original work. It's extensively used as a standard benchmark in ambiguity evaluation.

UNLI (Chen et al., 2020) shifts NLI task away from categorical labels, targeting subjective probability assessment (a numerical value $\in [0, 1]$). UNLI re-annotated a subset of SNLI, resulting in 55,517, 3,040 and 3,040 for train, validation and test set, where annotators are asked to estimate how likely the situation described in the hypothesis sentence would be true given the premise.

AmbiNLI (Meissner et al., 2021) is constructed based on existing datasets, converting one-hot or regression numerical labels to a probability distribution. On SNLI development, test set, and MNLI (matched and mismatched) development set with 5 annotations, it converts an ambiguity distribution by simply counting the number of annotations for each label and then scaling it down into probabilities, denoting to AmbiSNLI and AmbiMNLI. Their combination is named as AmbiSM. To avoid overlap with ChaosNLI, they remove the samples used in ChaosNLI. Samples of UNLI training set are converted by a simple linear approach. [2]

MedNLI (Romanov and Shivade, 2018) is a dataset annotated by doctors, grounded in the medical history of patient. Statistical information is exhibited in Table 2.

Overall, gold labels of SNLI, MNLI and MedNLI are one-hot, or refer to hard labels. The label of UNLI is continuous value, which are not directly applied in our experiment, but the corresponding discrete converted version in AmbiNLI. The gold label of AmbiNLI and ChaosNLI is a distribution, we denote as gold ambiguous label, ambiguity label or distributional labels. Note that these two ambiguity datasets have hard label as well, i.e. the largest-probability class. And AmbiNLI is split and employed in both training and test, while ChaosNLI is only utilized as test set.

---

[2] See details in original paper or appendix.

4.2 Metrics

Accuracy and F1 only focus on the class type of maximum probability, which is inadequate to evaluate ambiguity distributions.

Jensen-Shannon Distance (JSD) (Endres and Schindelin, 2003) is used to measure the distance between the softmax multinomial distribution of the models and the distributions over human labels.

Calibration Metrics: Calibration is a frequentist notion of uncertainty which measures the discrepancy between subjective forecasts and empirical frequencies. In perfect calibration, neural networks produce confidences that do represent true probabilities. It can be measured by expected calibration error (**ECE**), and proper scoring rules such as negative log likelihood (**NLL**) (Guo et al., 2017). ECE is defined as:

$$ECE = \sum_{m=1}^{M} \frac{|B_m|}{N} |acc(B_m) - conf(B_m)|$$

To estimate the expected accuracy from finite N samples, we group predictions into M interval bins (each of size 1/M) and calculate the accuracy of each bin. Let B_m be the set of indices of samples whose prediction confidence falls into the interval $I_m = (\frac{m-1}{M}, \frac{m}{M}]$. The accuracy and the average confidence within bin B_m is

$$acc(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \mathbb{I}(\hat{y}_i = y_i)$$

$$conf(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} \hat{p}_i$$

where $\hat{y}_i$ and y_i are the predicted and true class labels for sample i, $\hat{p}_i$ is corresponding confidence.

Reliability Diagram is a visual representation of model calibration in classification, plotting expected sample accuracy as a function of confidence. If the model is perfectly calibrated, the diagram should plot the identity function. Any deviation from a perfect diagonal represents miscalibration.

Sharpness measures the average confidence on the dataset as a whole, rather than on a bin. Aligning with empirical accuracy, it tells the model overall is under- or over-confident.

$$sharpenss = \frac{1}{N} \sum_{i=1}^{N} max([p_1, p_2 . p_3])$$

5 Case Study

This section empirically verifies our hypotheses.

Experimental Setup For fair comparison, we follow the setup of AmbiNLI (Meissner et al., 2021), and reproduce the experiments completely. We use BERT-base (Devlin et al., 2019) with pre-trained weights and a softmax classification head. We use a batch size of 64 and learning rate of 1e-5. [3]

We first obtain a base-NLI model by pre-training 3 epochs on the gold-labels of the combination of SNLI and MNLI training sets. Meissner et al. observed that this pre-training step is necessary to provide the model with a general understanding of the NLI task. We then finetune the model on other NLI dataset, setting the training objective to be the minimization of the cross-entropy between the output probability distribution and the target ambiguity distribution. For evaluation, we compute the ChaosNLI divergence scores, calibration error and sharpness. The reproduced results are closely similar to the original paper shown in Table 4. [4]

5.1 Label Smoothing VS Ambiguity Labels

We decompose the comparison between label smoothing and gold ambiguity soft labels into three sub-problems: (1) Label smoothing empirically has been shown to improve both predictive performance and model calibration in image classification and machine translation (Müller et al., 2019; Lukasik et al., 2020), is it effective on NLI task either, decreasing ECE?
(2) How to search for an optimal soften factor α?
(3) Can label smoothing reduce JSD and improve accuracy when it obtains small ECE?

We apply the unigram label smoothing (Xie et al., 2016). The hyperparameter $\alpha \in (0, 1)$ controls the soften strength, meanwhile reflecting the correctness probability of the target label.

$$y_i = \begin{cases} \alpha & i = target \\ \frac{1-\alpha}{K-1} & i \neq target \end{cases}$$

For example, α=0.8, **y**=$[0.8, 0.1, 0.1]$ when target is the first class, contrasting with ambiguous labels.

How to search an optimal α used in ChaosNLI evaluation? What relates to a proper α given a dataset? In prior work, α is generally tuned by a validation set. It tends to be set as 0.9 over many corpus (Pereyra et al., 2017; Müller et al., 2019), regarded as introduced label noise to help the model

---

[3] Limited by our GPU memory, 64 is used instead of 128.

[4] The results are not exactly same perhaps due to different training batch size.

to be more robust, by moving the decision boundary closer to a class (Lukasik et al., 2020).

Li et al. shows that the inductive bias of the label smoothing is dependent on the statistical structure of the data. They concretely cluster data by Bayes error rate (BER) bias $\mathcal{R}(\mathbf{x})$, and then learn cluster-dependent smoothing strength $\alpha(\mathbf{x})$, where $P(y = k|\mathbf{x})$ is the conditional posterior probability.

$$\mathcal{R}(\mathbf{x}) = 1 - \max_{k \in [K]} P(y = k|\mathbf{x})$$

In our experiment, we simplify the learnable $\alpha(\mathbf{x})$ to conventional tuning manner, but maintain the cluster-dependent. We first predict label probability $\hat{P}$ for AmbiSNLI and AmbiMNLI using the base-NLI model, and then extract validation sets for AmbiSNLI and AmbiMNLI respectively, by the condition of $\hat{p}_i \in (a, b)$, $\hat{p}_i = \max(\hat{P})$ is the predictive confidence ("conf" in short), remaining partition of both datasets are combined as the training set. Then we search the best α depending on the validation set.

From the perspective of calibration, label smoothing aims to align accuracy with the predictive probability, when α is the target probability in our setting, we expect that $\alpha \rightarrow Accuracy$, obtains the smallest ECE. During investigation, conditioned conf interval (a,b) ∈ {(0.3,0.4), (0.4,0.6), (0.6,0.8), (0.8,0.9), (0.9,1.0)}. [5] We evaluate a set of α=[1.0, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3] for each validation set filtered by (a,b), α=1.0 is the setting using one-hot labels.

Label smoothing can effectively calibrate NLI model, and decrease ECE. In Figure 1, training on soft labels either of gold ambiguity labels collected by crowdsourcing or label smoothing are useful to calibrate the base-NLI model (red line), i.e. yellow and green lines are both closer to the black diagonal line that represents the perfect calibration. And continuous fine-tuning on one-hot hard labels gets the blue line more deviate from the diagonal line than the base-NLI model, leading to a more over-confident one. This can also be observed in Figure 2 — ECE bar chart of 0.8-0.9 conf interval. Fine-tuning using ambiguous soft labels and label smoothed labels can obtain lower ECE than base-NLI, while hard labels leads to higher ECE. However, the interval of 0.9-1.0 demonstrates the opposite results. This indicates using ambiguous labels is not always better than hard labels.

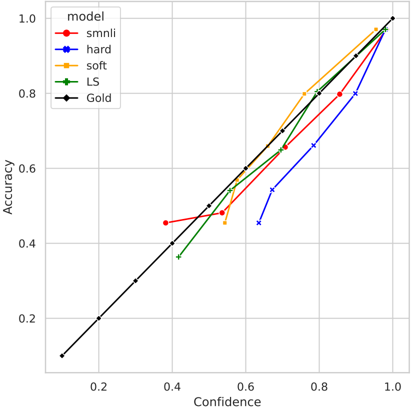

Figure 1: Reliability diagram of AmbiSNLI validation set under different models. smnli=base-NLI model, hard=fine-tune smnli on one-hot labels of remained AmbiSNLI+AmbiMNLI training data, soft=gold ambiguous labels, LS=soft labels from label smoothing with the optimal α. Gold=diagonal line representing the perfect calibration, under this line means over-confidence, over the line is under-confidence.

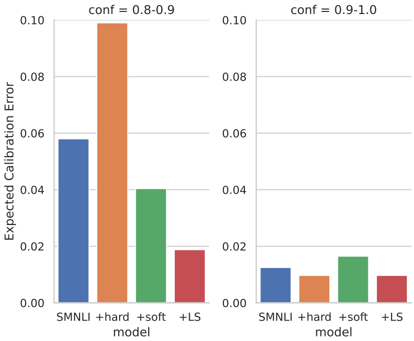

Figure 2: ECE of AmbiSNLI validation set over conf intervals (0.8,0.9) and (0.9,1.0).

The optimal α is not only dependent on the statistical structure of the data, but also the state of the model. In the conf interval of 0.9-1.0, the base-NLI model has almost reached the perfect calibration, ambiguity labels cuts the legitimate confidence. So we can see the yellow line is mostly above the diagonal line (Figure 1), it's the indication of being under-confident. Table 3 shows the best choice of α for each interval. It relates to the varying predictive confidence and the empirical accuracy, but not being equal to either of them, while empirically higher than the accuracy.

Label smoothing can improve accuracy and reduce JSD, being comparable to using gold ambiguity labels. We draw the accuracy (left) and JSD (right) of three edge intervals in Figure 3. On low-confidence interval 0.3-0.4, label smoothing

---

[5] NLI is a three-class classification task, $\hat{p}_i > 0.33$, so start from (0.3,0.4) rather than (0,0.1)

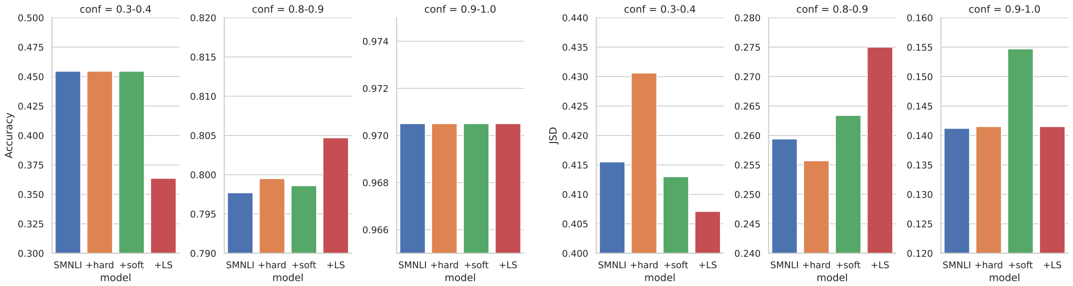

Figure 3: Accuracy and JSD of AmbiSNLI validation sets over three edge intervals. +hard=continuous fine-tuning on one-hot labels of AmbiSNLI+AmbiMNLI training set, +soft=gold ambiguous labels, +LS=label smoothing.

(a,b)	(0.3,0.4)	(0.4,0.6)	(0.6,0.8)	(0.8,0.9)	(0.9,1.0)
num_val	11	538	1080	1152	15371
Acc_{smnli}	0.45	0.48	0.65	0.80	0.97
$\alpha_{optimal}$	0.60	0.80	0.90	0.90	1.00

Table 3: The size and empirical accuracy of AmbiSNLI validation sets under varying conf interval condition, and the corresponding optimal soften strength α.

(LS) reduces JSD by a larger margin than using gold ambiguous labels. But one may argue that applying LS is harmful, since it declines the accuracy. It's not a rigorous conclusion in the context of ambiguity. As accuracy is less meaningful in low-confidence cluster. Accuracy is strictly applicable in deterministic setups, counting the percentage of exact matching pairs, based on the assumption that there is only one correct score. So JSD is favored over accuracy in low-confident cluster.

On middle-confidence interval 0.8-0.9, both improve accuracy, but increase divergence distance. On high-confidence interval of 0.9-1.0, accuracy remains steady in a high level, but ambiguity labels results in large JSD. AmbiMNLI validation sets exhibit similar consequences as these three findings of AmbiSNLI, see Appendix for details.

5.2 Soft Labels VS Hard Labels

Is training using soft labels always better than using one-hot labels? and vice versa? From Figure 3, we know the answer is *NOT*. In high accuracy cluster with high confidence, hard labels is needed to force model to be certain for the predictions. That's why when conf=0.8-1.0, hard labels can reduce JSD while soft labels are unable to do so. Therefore, targeting soft labels are not always superior to one-hot labels. It tends to show positive effect in the highly-uncertain cluster, such as conf=0.3-0.4, in which both gold ambiguity labels and LS decrease JSD, while hard labels make it rise significantly.

5.3 Evaluation on ChaosNLI

To confirm findings induced above and make direct comparison with AmbiNLI original results, we evaluate on ChaosNLI. Based on the finding that soften strength α should be set higher than the accuracy, we set α=0.8 and 0.6 for Chaos-SNLI and Chaos-MNLI respectively in label smoothing.

As shown in Table 4, compared with the baseline model, continuous fine-tuning on AmbiSM hard improves the accuracy, but predictive probability deviates more from the true distribution, resulting in larger JSD. While fine-tuning over cheap soft labels generated by label smoothing is as effective as ambiguity distribution collected by expensive crowdsourcing to narrow JSD, improve accuracy simultaneously. Moreover, they demonstrate sufficient strength to calibrate the model, forcing the predictive probability closer to the true correctness likelihood. reflecting in small ECE and matched sharpness value with the empirical accuracy.

We also experiment with other α settings, results verify that α=0.8 is the best on Chaos-SNLI and 0.6 on Chaos-MNLI.

5.4 Re-calibrate by Temperature Scaling

We posit once the model is calibrated, it naturally has captured the human agreement distribution. In this section, we investigate whether other recalibration method like temperature scaling (TS) can reduce JSD, capturing linguistic ambiguity.

We search the optimal temperature T based on AmbiSM as validation set, and evaluate on Chaos-SNLI and Chaos-MNLI. As models tend to be overconfident, we search T>1.0. Table 5 shows, on validation set, T=1.2 and 1.5 can obtain the smallest ECE for AmbiSNLI and AmbiMNLI resp. We find that temperature scaling can reduce ECE and make the sharpness be more matched with empirical accuracy, but seemingly cannot decrease JSD. We

Table 6: Results with varying temperature T on Chaos-SNLI (upper) and Chaos-MNLI (bottom).

speculate it's due to the inaccurate "gold" ambiguity distribution of AmbiSM (5 annotations) used in calculation of JSD between predictive probability.

As shown in Table 6, applying temperature scaling on both Chaos-SNLI (T=1.2) and Chaos-MNLI (T=1.5) are effective to decrease ECE, forcing the predictive probability closer to the empirical accuracy, and we observed JSD and NLL decline at the same time, compared with baseline model trained using smnli without temperature scaling. This indicates that in addition to label smoothing, temperature scaling is also useful to capture human linguistic ambiguity as long as they are calibrated with small calibration error.

We find after temperature scaling using T=1.2 and 1.5, models are still over-confident with large ECE, we wonder: can proper T calibrate them furthermore? Will JSD decrease with the decline of ECE? Note that it's not correct to choose the optimal T according to the held-out test set, we do so here just for case study. [6] Therefore, we increase T=1.2 to 2.0 for Chaos-SNLI, it reaches the smallest ECE, JSD is observed to decline as the same time, as demonstrated in Table 6. On Chaos-MNLI, T increases from 1.5 to 4.0, JSD consecutively drops from 0.29 to 0.23.

6 Domain Transfer

It's well-known that accuracy will drop in domain transfer. But how about JSD and ECE? Is calibration an intrinsic property of the model which is independent of evaluation benchmark? Can knowledge of linguistic ambiguity transferred across domains? Can the property of calibration learned from general domain transfer to the biomedical?

To observe how accuracy, JSD and ECE varies in domain transfer, we first evaluate AmbiSNLI, AmbiMNLI and MedNLI test set, under three NLI models: snli, mnli and smnli trained using SNLI, MNLI training set and their combinations resp. Evaluation of snli model on AmbiMNLI is across textual genres, same as mnli model on AmbiSNLI. All models on MedNLI is across-domain, contrasting with in-domain evaluation — snli and smnli on AmbiSNLI, mnli and smnli on AmbiMNLI.

Metrics of JSD and ECE are data-dependent as accuracy. Table 7, 8 show that they become larger in textual genre and domain transfer. In other words, the model is perfectly-calibrated on benchmark A, but it may poorly-calibrated in other benchmarks that are distantly-distributed from its training data. Calibration is not an intrinsic property of the model, but varies according to data.

The knowledge of linguistic ambiguity learned from general-purpose domain can be transferred to the medical. In middle of Table 8,

Table 8: Results on the MedNLI validation and test sets.

training on general NLI dataset: AmbiSM gold ambiguous labels, label smoothing and temperature scaling can improve accuracy and reduce NLL of MedNLI, compared with hard labels. [7] This suggest linguistic ambiguity information can be transferred, though not remarkable. Continuous fine-tuning over MedNLI training set improves performance by a large margin over all metrics. Two commonly-used re-calibration methods are effective in biomedical domain as well.

7 Conclusion

In this paper, we explore *how to capture the human linguistic ambiguity* from the perspective of model calibration. We empirically verify our hypothesis that NLI models have naturally captured the linguistic ambiguity as long as it's well-calibrated. In such case, model predictions can truly reflect the correct human subjective distribution. Moreover, we find it's not always better to train with soft labels than hard ones, particularly in highly-certain data cluster. And the knowledge of linguistic ambiguity can be transferred across domains, benefiting low-resource setups. These takeaways are significant for future work in ambiguous NLI.

A Appendices

A.1 Ambiguity Dataset Details

In the case of UNLI, AmbiNLI had taken only the 55,517 samples from the training set, so there is no overlap with ChaosNLI. They apply a simple linear approach to convert the UNLI regression value p into a probability distribution z_{NLI}, as described in the following composed function:

$$z_{\text{NLI}} = \begin{cases} (0, 2p, 1-2p) & p < 0.5 \\ (2p-1, 2-2p, 0) & p \geq 0.5. \end{cases}$$

The resulting AmbiNLI dataset has 18,152 SNLI examples, 18,048 MNLI examples, and 55,517 UNLI examples, for a total of 91,717 premise-hypothesis pairs with an ambiguity distribution as the target label.

Three datasets: ChaosNLI, UNLI and AmbiNLI are all derived from existing SNLI and MNLI, their

Table 10: Results of AmbiNLI. Gold means that gold one-hot labels. Filt. indicates that extreme examples in UNLI have been filtered out. soft. means apply label smoothing (α=0.9) to examples satisfied the condition in brackets. RS-N=random selecting N examples from UNLI to include into training data.

relation can be see in Table 9, which is completely referred to (Meissner et al., 2021) Table 1. It can help readers to understand their overlap relation intuitively.

A.2 Evaluation Results of AmbiMNLI

In Figure 4, both gold ambiguity soft labels (soft-yellow line) and label smoothing (LS-green line) drag baseline (red line) much closer to the diagonal black line, while the hard label fine-tuning goes towards the opposite. This indicates label smoothing is as effective as gold ambiguity labels to calibrate models, and decreases ECE as show in left of Figure 5.

In addition, we find training on soft labels does not always lead to accuracy improvement and JSD decline, this particularly is exhibited in high confidence intervals. In conf=0.9-1.0, accuracy over all types of labels remains on a high level, but gold ambiguity labels has much high JSD. This is consistent with the findings in AmbiSNLI.

A.3 Results and Analysis of ChaosNLI

We reproduced results of AmbiNLI Table 2 in Table 10 below, and further did some ablation studies and analysis.

Random sampling of instance-specific soften factor α: In conventional label smoothing, all training examples are softened by a same fixed α, resulting in same probability of the target class, while the maximum probability of the crowdsourcing soft ambiguity label differs from each other. So we simulate a setting at risk of introducing much noise, where for each instance, they have an unique soften factor α which is uniformly sampled from the real interval (0.6. 1.0), i.e. the row "+AmbiSM (>0.6)" α is set greater than 0.6 because we assume gold label is agreed by at least 60% annotators. It's inferior to using gold ambiguous labels.

Discussion Ambi-UNLI: Using AmbiU, looking at the AmbiU and AmbiSMU results in Table 10, apparently UNLI data is not always beneficial. Specifically, it seems to worsen scores in all metrics except for ChaosMNLI accuracy. The original paper supposes that UNLI's skewed distribution worsens scores. The distribution of labels in UNLI is drastically different from SNLI and MultiNLI, including textual topic, style and label type, when a model is fine-tuned on it, this distribution shift has a negative influence.

They found a very large number of samples with labels very close to 0 or 1, which translate into very extreme non-ambiguous distributions when converted. They confirm their hypothesis by filtering out all UNLI samples that had a probability label $p < 0.05$ or $p > 0.97$, and ran the "Filtered" experiments. Following this line, if it's due to extreme non-ambiguous distributions, label smoothing (α=0.8) over these samples should have obtained comparable results as filtering, even better because of more training data, but the fact is that it's better than +AmbiU, worse than +AmbiU Filt., enlarging the range of soft samples to $p < 0.1$ or $p > 0.9$ worsens more. This indicates filtering is occasionally a useful remedy in this setting, it does not result from non-ambiguous labels.

We further confirm this by randomly select (RS) subset of AmbiU to AmbiSM, i.e. AmbiSMU RS32924 [8], AmbiSMU RS18000, AmbiSMU RS9000, the number behind SR represents the size of the subset, we can see that the less AmbiU is incorporated, the better scores can be gained. Thus, UNLI data, under the current conversion approach, is somewhat problematic. We only apply AmbiSNLI and AmbiMNLI in the experiments.

---

[8] 32924 is the number of examples of AmbiU which is remained for after filtering by ($p<0.05$ || $p>0.97$), we randomly sample the same number of cases to make a comparison, result shows Filt. is better than RS.

Efficient, Uncertainty-based Moderation of Neural Networks Text Classifiers

Jakob Smedegaard Andersen and **Walid Maalej**
University of Hamburg
Hamburg, Germany
`{jakob.smedegaard.andersen,walid.maalej}@uni-hamburg.de`

Abstract

To maximize the accuracy and increase the overall acceptance of text classifiers, we propose a framework for the efficient, in-operation moderation of classifiers' output. Our framework focuses on use cases in which F1-scores of modern Neural Networks classifiers (ca. 90%) are still inapplicable in practice. We suggest a semi-automated approach that uses prediction uncertainties to pass unconfident, probably incorrect classifications to human moderators. To minimize the workload, we limit the human moderated data to the point where the accuracy gains saturate and further human effort does not lead to substantial improvements. A series of benchmarking experiments based on three different datasets and three state-of-the-art classifiers show that our framework can improve the classification F1-scores by 5.1 to 11.2% (up to approx. 98 to 99%), while reducing the moderation load up to 73.3% compared to a random moderation.

1 Introduction

Accurately classifying an overwhelming amount of textual data is a common research challenge (Pouyanfar et al., 2018). In recent years, machine learning approaches, particularly Neural Networks (NNs), have received great attention to support textual classification (Lai et al., 2015). However, in practice, fully automated approaches are still rare due to the general lack of top, almost-perfect classification accuracy. If the accuracy of a trained and hyper-tuned state-of-the-art classifier still does not meet the domain requirements, a full manual approach is likely to be the fall-back solution.

To prevent classification mistakes and strengthen the overall acceptance of artificial decision making, socio-technical approaches that integrate human domain experts in the decision loop are gaining in importance (Holzinger, 2016). Recent research has shown that including the prediction uncertainty of NNs can detect more complex text inputs, i.e., either short or very long texts with less informative tokens (Xiao and Wang, 2019), and probably wrong (Hendrycks and Gimpel, 2017) predictions, which are worth checking manually. Since human resources are cost intensive and do not scale well to larger workloads, moderation processes should be designed with human-resource-efficiency in mind. Yet, the efficient in-operation integration of human efforts for building semi-automated decision-making systems – i.e. moderated classifiers – remains largely unexplored.

This paper introduces a novel framework for the efficient moderation of NN text classifiers. Our framework extends a given NN with human expertise to create a semi-automated decision-making system. Text instances are moderated manually when classifier outcomes are likely to be false. We use the concept of prediction uncertainty (Der Kiureghian and Ditlevsen, 2009) to quantify the reliability of a classification. When a classifier is highly uncertain, we let human moderators intervene. To minimize human efforts, we propose to limit the moderation to the point where the classification accuracy gain saturates. While active learning (Settles, 2009) aims to limit human efforts during the *training* of classifiers, our moderation framework seeks to substantially enhance the accuracy of *trained* and *already deployed* classifiers – surpassing the maximum achievable accuracy of an automatic classifier to still achieve an almost-perfect in-operation accuracy.

Our contribution is twofold. First, we introduce a novel saturation-based framework for the efficient, in-operation moderation of NN-based text classifiers. Second, we empirically evaluate the accuracy improvement and needed moderation load for three English text classification tasks including hate speech detection, sentiment analysis, and topic classification. We run multiple training trails using different predictive uncertainty estimation approaches and compare their initial and post-moderation F1-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1536 - 1546
May 22-27, 2022

scores and evaluate their suitability.

The remainder of the paper is structured as follows: Section 2 introduces our moderation framework and outlines the uncertainty estimation techniques to decide when to moderate. Then, Section 3 describes the setting to evaluate our framework. Afterwards, we report on the experiment results in Section 4 and discuss the implications and limitations of our findings in Section 5. Finally, Section 6 discusses related work and Section 7 concludes the paper.

2 Moderating NN Classifiers

2.1 Moderated Classifiers

In order to prevent low confident classifications and increase the accuracy of NN text classifiers, we propose the concept of a moderated classifier. A moderated classifier combines an artificial classifier with a human oracle. The oracle steers the decision-making in case the machine is unable to provide a reliable outcome. The level of reliability is measured based on the predictive uncertainty of the artificial classifier.

Misclassifications occur when the inferred label y_i of an input x_i does not correspond to the actual true label $\hat{y}_i$ and thus $\hat{y}_i \neq y_i$ holds. If only classifications made under a high uncertainty are delegated to a human oracle, the number of misclassifications can be significantly reduced while keeping manual workloads low.

A moderated classifier f^{ω}_{mod} is created from an artificial classifier f^{ω} as follows:

$$f^{\omega}_{mod}(x) := \begin{cases} f^{\omega}(x) & \text{if } u[y|x,\omega] \leq \vartheta_u \\ o_H(x) & \text{else} \end{cases} \tag{1}$$

where $o_H : X \rightarrow Y$ represents the human oracle, $u[y|x,\omega] \in U \subset \mathbb{R}^+$ an uncertainty measure of $f^{\omega}(x)$ and ω the learned parameters of f. If the uncertainty is below a threshold $\vartheta_u \in U$, the inferred label $y = f^{\omega}(x)$ is considered to be reliable and will be kept. If the threshold is breached ($u[y|x,\omega] > \vartheta_u$), a human oracle o_H is consulted and his or her decision is deemed correct. The oracle can also include a group of moderators to share the workload or increase accuracy in the case of contradictions. Conflicts could, e.g., be solved following inter-annotator agreement approaches (Artstein and Poesio, 2008). In this paper, we focus on single human moderation.

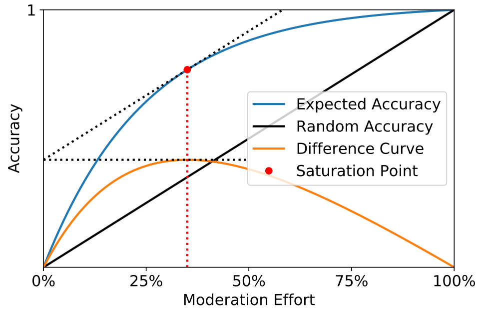

Figure 1: Saturation detection for manual moderation. Saturation is reached at the highest point of the difference between the expected and random accuracy curve.

2.2 Determining Uncertainty Thresholds

The efficient use of (the usually limited) human resources is essential for semi-automated classification approaches. The moderation of text classification can be particularly time-consuming and cost intensive, as moderators might need to carefully read and think about the text. It is thus important to limit the moderation effort to a reasonable and worthwhile amount. Limiting the moderation effort is a trade-off between saving resources and increasing accuracy.

We suggest a **saturation-based** moderation strategy to determine the uncertainty threshold ϑ_u. As we assume misclassifications to occur more frequently with high uncertainty scores, the moderation is expected to become less efficient with an increasing moderation load. At some point, significant improvements may not be achieved and further efforts have a decreasing impact in terms of increasing accuracy. A saturation-based strategy seeks to limit the moderation up to a point, where the expected accuracy improvement turns and becomes less rewarding.

Figure 1 shows a hypothetical saturation curve for a moderated classifier. The blue curve represents the expected accuracy of our framework when a certain amount of the most uncertain predictions are manually moderated. The accuracy of a moderated classifier is based on (a) the manual classification and (b) the accuracy of the model classifying the instances which are not passed to a human. An accuracy of 100% is reached when 100% of the instances are correctly decided manually. The plotted accuracy curve is of shape $f(x) = a(1 - \mathrm{e}^{-bx})$. The black line shows the moderation accuracy when instances are randomly sampled for moderation. A random moderation selects the to-be-moderated instances independently and evenly distributed from a dataset. Since a random sample is expected to include the same proportions of misclassifications, the accuracy gain increases linearly over the moderation effort.

A natural **point of saturation** can be calculated as the highest point of the difference curve between the expected and the random accuracy (Satopaa et al., 2011). It describes the situation where a continued uncertainty-based moderation would become less effective than the moderation of randomly selected instances. We argue that the moderation should be stopped at this natural limit for keeping the manual effort efficient.

2.3 Uncertainty Modeling Techniques

Uncertainty in NNs classifications generally occurs when inputs are corrupted by noise or not from the distribution of the training dataset (Der Kiureghian and Ditlevsen, 2009). To estimate model and data uncertainties in f^{ω} we use techniques which have performed well in similar uncertainty-based tasks like computer vision (Kendall and Gal, 2017) and active learning (Burkhardt et al., 2018; Gal et al., 2017). We focus on the following uncertainty modeling techniques and on a baseline:

Baseline We consider deterministic softmax outcomes of a usual NN as a baseline indicator of confidence (e.g. Hendrycks and Gimpel 2017). A softmax activation function applied to the last layer of a NN normalizes the network's outcome into pseudo class probabilities.

Monte Carlo Dropout (MCD) According to Gal and Ghahramani (2016), Dropout can be interpreted as a Bayesian approximation of a Gaussian process. Dropout is generally used as a stochastic regularization technique for NNs to prevent overfitting (Srivastava et al., 2014). To perform approximate Bayesian inference, a NN is trained with Dropout applied before every weight layer and a softmax activation function after the last layer. Then, Dropout is additionally performed at prediction time to sample from an approximated distribution of the real class posterior.

Bayes by Backprob (BBB) Bayes by Backprob is another Bayesian approximation technique to model uncertainties in NNs (Blundell et al., 2015). In BBB, a probability distribution is placed over the NNs weights ω. The approach seeks to learn the posterior distribution $p(\omega|D)$ given the training data D. Due to intractabilities, the posterior distribution is approximated by a variational distribution $q(\omega|\theta)$ by minimizing the Kullback–Leibler divergence (Kullback, 1997). As for MCD, multiple forward passes are performed to sample over different weights $\hat{\omega}_t \sim q(\omega|\theta)$.

Ensemble An Ensemble of multiple independent deterministic NNs is an alternative approach to Bayesian approximation (Lakshminarayanan et al., 2017). The idea is to use M independent trained NN classifiers and average their softmax outcomes to a single classification score. The parameters of the different models are randomly initialized and individually optimized.

We use score functions based on the uncertainty modeling techniques to quantify the uncertainty of individual classifications (Lewis and Gale, 1994; Burkhardt et al., 2018; Gal et al., 2017). Score functions aim to report high uncertainty values for unreliable classifications. Commonly used metrics are the *Least Confidence* (Culotta and McCallum, 2005), *Smallest Margin* (Scheffer et al., 2001), and *Mutual Information* (Houlsby et al., 2011).

3 Experimental Design

3.1 Research Questions and Method

To evaluate our saturation-based moderation framework, we conduct benchmarking experiments using different public datasets and NN classifiers. We focus on the following research questions:

RQ1 How does uncertainty modeling improve the performance of unmoderated and moderated classifiers?

RQ2 How much accuracy improvement would the saturation-based moderation bring and at what cost?

With RQ1, we particularly aim to check whether a mere uncertainty modeling (i.e. still a full automated classification without moderation) would solve the problem and lead to top classification accuracy close to 99%. With RQ2, we aim to evaluate our framework's cost/effect in different settings.

To answer the research questions, we perform a series of machine learning experiments. First, we assess the initial performance of three classifiers extended with the different uncertainty modeling techniques. We apply the micro F1-score to measure the accuracy of classifiers on the actual classification task. Further, we assess a model's ability to detect misclassifications. We compute the AUC-ROC score, which measures the *Area Under the Receiver Operating Characteristics* curve, based on the correct (positive class) and misclassified (negative class) outcomes. All experiments are performed on the held-out evaluation set.

Second, to evaluate the moderated classification and determine the best suited uncertainty estimation technique, we examine how a moderation affects the overall F1-score when a certain number of uncertain instances get moderated manually. Further, we calculate the points of saturation to estimate the achievable F1-scores while limiting human moderation efforts.

3.2 Research Data and Setup

For the experimental evaluation, we use three publicly available datasets. The **Hate Speech** dataset provided by a recent Kaggle competition[1] consists of Wikipedia comments manually labeled for toxic behavior. We unify different types of toxicity in the datset to a binary classification task (toxic / non-toxic) and run our experiments on a subset of random 40,000 comments. The **IMDB** dataset (Maas et al., 2011) consists of 50,000 highly polarized English film reviews, which either are associated with a positive or negative user sentiment. Finally, the **20NewsGroups** dataset (Lang, 1995) comprises 18,846 English documents which are grouped in 20 different news topics. As training, test, and evaluation sets, we randomly sample from the Hate Speech, IMDB, and 20NewsGroups datasets and apply train-test-evaluation splits of 20,000:10,000:10,000, 25,000:12,500:12,500 and 9,846:4,500:4,500 respectively. We perform all experiments five times with randomized train-test data splits and a constant held-out evaluation set.

Moreover, we use three common NN architectures from the literature, further referred to as CNN, KimCNN, and DistilBERT. **CNN** consists of one convolutional layer, a global max pooling layer and two fully connected dense layers similar to recent studies on app reviews and tweets classification (Stanik et al., 2019). We apply Dropout before each weight layer with a rate of 0.4 and use L2-Regularisation with a kernel penalty of 1e-05. As word representations, we take 100 dimensional trainable vectors which are randomly initialized. For **KimCNN**, we follow the NN architecture and configuration suggested by Kim (2014). The author proposes a multichannel convolutional NN with different filter region sizes, followed by a 1-max pooling layer. As word representations, we take static 300 dimensional Google word2vec embeddings which are pretrained on 100 billion news articles (Mikolov et al., 2013). Lastly, we use the popular state-of-the-art text classification approach **DistilBERT** (Sanh et al., 2019), a distilled version of the Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019). DistilBERT consists of 40% fewer parameters compared to BERT and is thus much more efficient to train while retaining about 97% of its performance. We fine-tune DistilBERT via the default settings of the Huggingface Trainer API.[2]

We apply the three uncertainty modeling techniques MCD, BBB, and Ensemble (described above) to each of the classifiers. For MCD and BBB, 50 stochastic forward passes are applied. We use 5 NNs as the size of our ensemble. It has been shown that larger ensembles do not significantly improve uncertainty estimations (Lakshminarayanan et al., 2017). For the MCD and Baseline approach, we perform inference on the same trained model since they share the same training procedure. For DistilBERT we only implement MCD by activating the model's internal Dropout layer at inference time as performed by Miok et al. (2021). For the implementation of BBB into CNN and KimCNN we exchange the network's layers with Bayesian layers using the TensorFlow Probability library.[3] BBB cannot be directly applied to DistilBERT. This would require altering the network's architecture and retraining the model from scratch. Finally, we use the Kneedle algorithm (Satopaa et al., 2011) to detect the point of saturation as discussed in Section 2.2. Since real saturation curves are usually not smooth we use polynomial interpolation to fit a spline used for detecting saturation points. Our replication package is publicly available online.[4]

4 Experiments Results

4.1 Extending Classifiers with Uncertainty Modeling

Table 1 presents the initial performance of the classifiers when no manual moderation is performed.

The table is organized in evaluation metrics and uncertainty modeling techniques which are applied to each dataset and classifier. Each cell consists of the mean followed by the standard deviation of five independent classification runs. For each classifier and dataset the scores of the best performing uncertainty modeling techniques are highlighted in green and the lowest scores in red. *Mean Conf.* represents the mean confidence score of all misclassified *(Mis.)* and successful classifications *(Suc.)*. The mean confidence range (*Range*) is computed as the range between the mean confidences.

The results reveal that CNN and KimCNN reach similar F1-score across all experiments ranging from 86.9 to 91.3%. DistilBERT performs as expected better, particularly for binary classification (Hate Speech and IMDB) with an F1-score of up to 94.1%. However, DistilBERT also leaves room for improvements still being away from a top F1-score around 99%. The results show that across all experiments the explicit modeling of uncertainty only has a small effect compared to the F1-scores of the Baselines (less than 1%). Only an Ensemble on CNN and 20NewsGroups (multi label classification) attains an improvement of 3.2% reaching $\sim$90%. MCD performs best on the Hate Speech dataset whereas an Ensemble performs best on the 20NewsGroups and IMDB datasets. BBB never reaches the overall highest F1-score.

The confidence scores reveal that an explicit modeling of uncertainty implies less overconfident wrong outputs compared to the Baseline. The uncertainty modeling does increase the confidence range between successful and misclassified classifications. KimCNN provided the least overconfident wrong outcomes followed by DistilBERT. Our results also indicate that MCD, BBB, and an Ensemble generally outperform the Baseline in terms of misclassification detection (AUC-ROC). No specific technique consistently outperforms the others.

4.2 Moderated Classification

Next, we investigate the overall F1-scores of our moderated classifier framework. Figure 2 shows the F1-scores for the Hate Speech, IMDB, and 20NewsGroups datasets. The y-axis plots the F1-score and the x-axis indicates the corresponding manual moderation effort. The F1-score considers artificial classification outcomes as well as the manual labeled examples. In our experiments, manual labeling is done by picking the ground truth label. The *Least Confident* score function[5] is used for all experiments as it reaches the highest F1-score in most cases and performs most consistently.

The accuracy gains with our framework depicted in Figure 2 reveal a significant accuracy increase compared to a random moderation strategy, which is depicted by the dotted lines. Furthermore, as expected, the moderation becomes less efficient with an increasing moderation load, as misclassifications are more common when a classifier reports large uncertainty scores.

All studied classifiers show a similar moderation behavior. All accuracy curves follow the shape of a saturation curve assumed in Section 2. The high-

---

[5] $unc_{LC}[y|x, D] := 1 - \max_c p(y = c|x, D)$

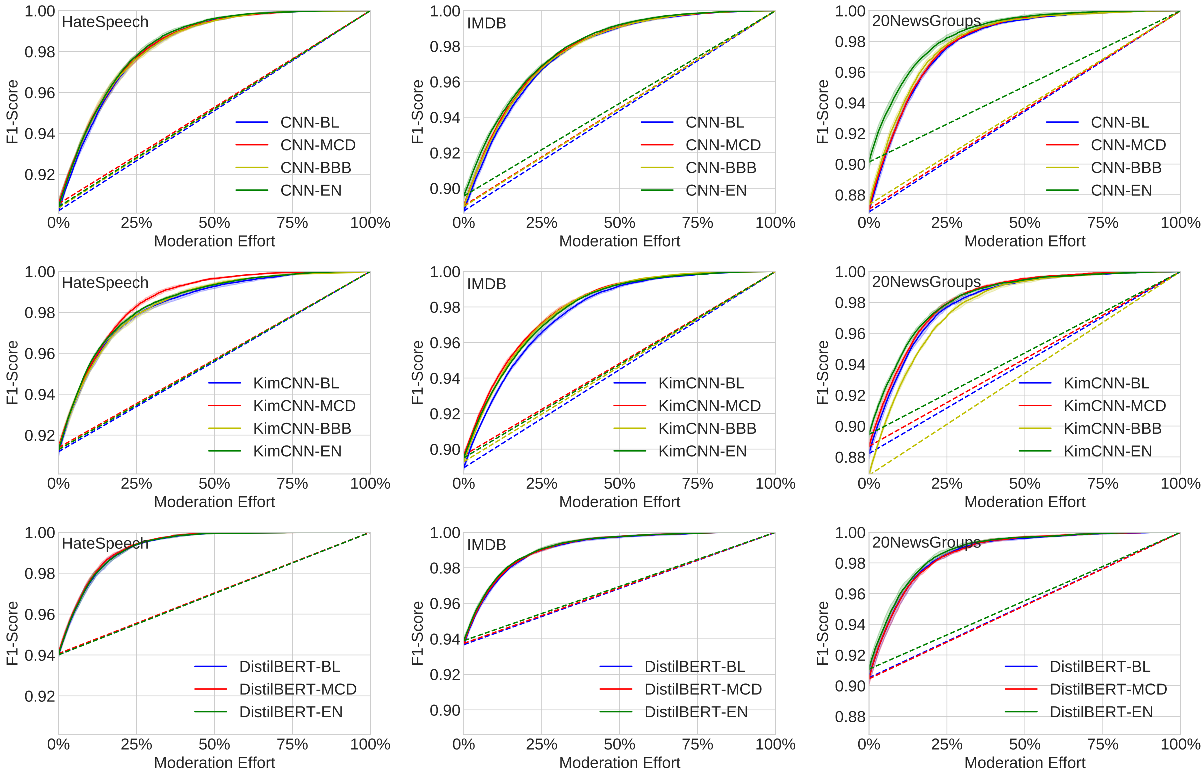

Figure 2: Accuracy gain for the three considered datasets **with the proposed moderation** using different uncertainty modeling and the Baseline (BL). Dotted-lines illustrate the F1-scores of a random moderation strategy.

Table 2: Top F1-scores and moderation load (in %) achieved using our saturation-based moderation strategy.

	Hate Speech				**IMDB**				**20NewsGroups**				
Saturation	Baseline	MCD	BBB	Ensemble	Baseline	MCD	BBB	Ensemble	Baseline	MCD	BBB	Ensemble	
Moderation Load	31.7	31.6	31.2	31.8	33.2	32.2	32.9	33.8	28.5	28.6	27.5	27.7	**CNN**
F1-score	98.08 (+7.9)	98.10 (+7.5)	97.94 (+7.6)	98.25 (+7.8)	97.80 (+9.1)	97.77 (+8.8)	97.77 (+8.8)	98.03 (+8.4)	98.10 (+11.2)	98.15 (+11.1)	98.13 (+10.8)	98.46 (+8.3)	
Moderation Load	26.6	29.1	28.7	26.2	35.5	33.4	33.1	34.9	27.8	28.2	30.7	27.7	**K.CNN**
F1-score	97.57 (+6.4)	98.39 (+7.0)	97.77 (+6.5)	97.70 (+6.4)	98.01 (+9.1)	98.13 (+8.5)	98.12 (+8.8)	98.20 (+8.7)	98.00 (+9.8)	98.32 (+9.6)	98.04 (+11.2)	98.24 (+8.8)	
Moderation Load	24.5	23.9	-	24.5	25.3	25.1	-	24.6	25.5	25.9	-	25.5	**D.BERT**
F1-score	99.36 (+5.3)	99.37 (+5.3)	-	99.37 (+5.4)	99.03 (+5.4)	99.01 (+5.3)	-	99.04 (+5.1)	98.60 (+8.1)	98.62 (+8.2)	-	98.82 (+7.7)	

est variations occur on the 20NewsGroups dataset. Furthermore, the difference between all approaches becomes less with an increasing moderation effort. By moderating more instances manually, more similar F1-scores are reached by all classifiers. Overall, an Ensemble of homogeneous NNs and MCD reaches the overall highest F1-score with the least moderation effort (and BBB slightly less). On average, the Baseline requires slightly more manual effort to reach the same F1-score.

As the accuracy gains decrease with an increasing moderation effort, we calculate saturation points to stop the moderation before it becomes inefficient. Table 2 lists those saturation points for the LC score function. The absolute improvement of the F1-score is shown in brackets. The table shows that our moderation approach is able to achieve a F1-score of 98 to 99% on all classification tasks while maintaining an efficient human moderation. These F1-scores can be achieved with all evaluated classifiers and uncertainty estimation techniques. Saturation points are reached after moderating ≤33.1% of the dataset using CNN and KimCNN and ≤25.5% using DistilBERT. All classifiers provide a similar trade-off between achieved F1-score and moderation effort. However, the Baseline is not optimal since it either saturates with slightly higher moderation efforts or provides a lower F1-score compared to MCD, BBB, and an Ensemble. On IMDB the MCD reaches saturation with the least moderation effort, while providing a high level of accuracy. On 20NewsGroups an Ensemble performs slightly better.

Interestingly, DistilBERT requires the least manual effort while achieving the highest level of accuracy, i.e., a F1-score of $98.6 - 99.37\%$. The results also reveal that models with a low initial F1-score reach higher absolute F1-score improvements. Overall, using our framework, a moderator has to label up to 73.3% (Hate Speech), 71.0% (IMDB) and 70.9% (20NewsGroups) *less data* instances compared to a random moderation strategy. Based on these results, we conclude the answers to our research questions:

Answer RQ1 Explicitly modeling uncertainties of NN classifiers only has a minor impact on the accuracy compared to the baseline. All techniques provide similar F1-score improvements when a human is moderating a certain number of classification outcomes. Only on a multi-class classification problem (20NewsGroups) an Ensemble provides slightly better ($\geq$1%) F1-scores compared to a traditional deterministic NN (Baseline). Overall, a five NN Ensemble and MCD achieves the best accuracy improvements compared to the Baseline and BBB. The moderated classifiers performed best with the Least Confident score function.

Answer RQ2 Moderating the outcomes of classifiers can lead to top F1-scores between 97 and 99% using both rather weak (CNN / KimCNN) and strong (DistilBERT) classifiers while efficiently limiting human involvement. Using DistilBERT an absolute F1-score improvement of +5.3 (Hate Speech) +5.1 (IMDB) and +7.7% (20NewsGroups) is reached by moderating $\leq$25.5% of the data. A saturation-based moderation saves up-to 73.3% (Hate Speech) 71.0% (IMDB) and 70.9% (20NewsGroups) of effort compared to a random moderation to reach the same F1-score.

5 Discussion

5.1 Implications

Our results indicate that the mere explicit uncertainty modeling can barely enhance the accuracy of automatic text classifiers. However, our moderation framework can substantially improve the accuracy and thus the acceptance of rather weak (CNN / KimCNN) as well as strong (DistilBERT) classifiers. Compared to cases where classification decisions have to be done fully manually when the accuracy of automatic classifiers is inapplicable in practice, our semi-automated framework would require one fourth to one third of the manual effort to obtain a top accuracy of $\sim$98-99%. This is a substantial saving of resources. The major advantage of the framework is the ending of the moderation when it becomes inefficient. Further, our results indicate that the framework also works well with usual NNs (Baseline). Even if the accuracy improvement and effort minimization are not as good as with explicit uncertainty modeling, the Baseline reaches similar top F1-scores. Thus, the cost of implementing and adopting the framework to existing classifiers is rather limited. Additional costs of explicit uncertainty modeling should be assessed against the marginal achievable improvements.

Clearly, the usefulness of our framework depends on the application scenario at hand. In particular, it is crucial to first investigate:

- Whether a top accuracy, of e.g. 99% is expected by users or not.
- Whether and how human moderation is applicable, and if the moderation can be trusted.
- Whether the goal of maximizing the accuracy while minimizing the human effort is desired.

We think that semi-automated approaches are particularly important in domains with a very large number of classifications and where classification mistakes are costly, for instance when user comments need to be moderated in a public debate space such as comments in news outlets (Loosen et al., 2018; Boberg et al., 2018) or in Wikipedia as in the Hate Speech dataset. A pure automated classification and analysis of inherently ambiguous text, e.g. reflecting human opinions or outlining novel ideas will quickly reach its limits. Even humans might not totally agree on a uniform labeling of complex texts (Ross et al., 2016). As shown in our experiments, most documents can accurately be labeled by a machine and do not require human effort. However, complex or ambiguous texts might not be handled appropriately by black-and-white categorization and machines might be unable to make reliable classifications. By placing a human in the loop, human creativity and reasoning contribute to efficiently solving such difficult tasks.

With moderation, additional data is continuously collected and can be used to re-train the classifier from time to time. Re-training often prevents an accuracy decay of the underlying classifier over time (Moreno-Torres et al., 2012) and can (but do not necessarily) improve its accuracy (Arnt and Zilberstein, 2003). Our results suggest that the moderation would benefit from a higher initial accuracy as the amount of human involvement seems lowest here. Further research is required to better understand the interplay between in-operation moderation and active learning.

5.2 Limitations

Our moderation framework builds on the assumption that a classifier's expected accuracy curve can be used to estimate how it would perform in operation. This assumption depends on whether the dataset used for the evaluation and the derived saturation point represent the real data distribution. In cases where this assumption is not reasonable and the real data distribution is significantly different (e.g. due to particular events), more research would be needed e.g. to monitor and potentially adjust the operational data distribution and the saturation curve accordingly.

In our experiments we assume that human moderators do not commit errors. While a flawless moderator is generally assumed in the review of interactive machine learning approaches like active learning (Burkhardt et al., 2018; Gal et al., 2017; Houlsby et al., 2011), the assumption does not have to apply to all real scenarios (Sheng et al., 2008). Generally, as already discussed above, annotations from domain experts are seen as more trustful than machines, especially on difficult tasks such classification of ambiguous text. Human annotations are often considered as the ground truth for classification tasks and are used to initially train a classifier (Lewis and Gale, 1994). Therefore, we assume that domain experts annotate instances more reliably than machines in real-world domains. This assumption may have limitations in practice, as people may make mistakes too.

Interactive ML approaches such as our framework are confronted with the limitation of scalability. Even a small fraction of human involvement can lead to an enormous manual effort when the data to be classified is very large. Our framework can limit human involvement to $23.9 - 25.4\%$ of the data assessment in order to reach a top F1-score. Finally, human moderators have to decide whether spending these efforts is applicable and desired.

Our approach also faces the limitation that uncertainty estimation approaches are unable to identify highly certain classifications which are actually wrong (unknown-unknowns) (Attenberg et al., 2011). Thus, it is unrealistic to avoid all misclassifications without manually checking all the data. However, we have shown that the majority of misclassifications can be efficiently identified by our approach leading to high F1-scores $\sim$98-99%.

Finally, as for every empirical evaluation, our results are dependent on the datasets, metrics and setting used. While we refrain from claiming the generalizability of the concrete quantitative results, the diversity of the datasets and classification models used give us enough confidence on the general observed trends for text classification. For other classification tasks, a replication using other datasets and model architectures would be required.

6 Related Work

The moderation of classifier outputs can clearly be considered as an application of the Human-in-the-Loop (HiL) paradigm (Holzinger, 2016). So far, most HiL implementations focus on querying additional labels from humans for the purpose of training in order to reduce a classifier's uncertainty, commonly referred to as active learning (Settles, 2009). In comparison, our framework aims to efficiently prevent error-prone classifications during operation and thus to further enhance the accuracy of an already trained classifier.

Different approaches have been previously discussed to coordinate human involvement in semi-automatic text classification. To our best knowledge, we are the first to investigate the *human efficient*, moderation of text classifiers. Pavlopoulos et al. (2017) propose to search for confidence thresholds which maximize a classifier's accuracy, when classification outcomes are moderated manually. However, this approach requires moderators to set the amount of data they are willing to moderate. Assessment of the efficiency is not made. Another approach to reduce error prone classifications is to let classifiers abstain when no clear decisions can be made (Cortes et al., 2016; Ramaswamy et al., 2018). This can be performed by adding an additional label to the classification task or by training a separate and independent classifier. Abstained instances could be, similarly to our approach, passed to human moderators. Our work focuses on uncertainty modeling using NNs. Geifman and El-Yaniv

(2017) propose a classification approach with a reject option which additionally allows practitioners to set a desired level of risk. Similar to our approach, they aim to ensure a certain classification performance. In contrast, they do not focus on the efficiency of human involvement.

Lee et al. (2018) propose an approach to detect whether an instance is out-of the distribution of the training dataset and thus probably wrongly classified. However, their approach requires an auxiliary dataset representing out-of-distribution samples during training which is difficult to create. De et al. (2021) introduce a semi-automated approach which directly optimizes a classifier for different automation levels. However, their approach is only applicable to convex-margin based classifiers and not to NNs. Xiao et al. (2021) suggest a self-checking mechanism for NN, where the features of the internal layers are used to check the reliability of predictions. In contrast, our approach uses predictive uncertainties obtained via a softmax function, which is rather simple to implement.

Moderating classifiers' outcomes is also related to the field of explainable ML, in particular explaining individual classification outcomes (Ribeiro et al., 2016). Studies indicate that explaining relevant words of a class outcome support human annotation tasks by, e.g., reducing the annotation time needed per instance and increasing user trust (Švec et al., 2018; Ribeiro et al., 2016). Our approach is likely to benefit from explaining artificial decision-making as well as model uncertainties (Andersen et al., 2020) during the moderation process.

7 Conclusion

This paper contributes to the Human-in-the-Loop AI paradigm. We particularly present a rather simple, semi-automated text classification framework to efficiently minimize unreliable and error-prone classification outcomes. Based on explicit uncertainty modeling, the framework seeks to prevent unconfident classifications by consulting human moderators. At its core, the framework uses a saturation-based moderation strategy, which limits the moderation load and keeps it human-resource-efficient. We conduct several benchmarking experiments including state-of-the-art classifiers and public datasets to examine the effectiveness of the suggested moderated classification.

Our evaluation shows that a moderated classifier can achieve a major increase in accuracy while limiting the moderation efficiency. With moderation, the F1-score of a convolutional NN for hate speech detection increases from initially 90.6 to 98.10% limiting the manual effort to 31.6%. Using DistilBERT, the benefits of a moderated classifier seems even stronger. Here, our framework accomplishes an improvement of the absolute F1-score from 94.1% to 99.37% while only moderating 23.9% of the data. Across all our experiments, we increased the F1-score from initially ∼89-94% to ∼98-99% by manually moderating between a third to a fourth of the data. Our results indicate that an uncertainty-based moderated classification can increase the applicability and reliability of text classifiers, particularly in domains where a top accuracy of ∼99% is required and a full manual classification would be more expensive.

Revisiting Automatic Evaluation of Extractive Summarization Task: Can We Do Better than ROUGE?

Mousumi Akter, Naman Bansal, Shubhra Kanti Karmaker Santu
BDI Lab, Auburn University, Alabama, USA
{mza0170, nzb0040, sks0086}@auburn.edu

Abstract

It has been the norm for a long time to evaluate automated summarization tasks using the popular *ROUGE* metric. Although several studies in the past have highlighted the limitations of *ROUGE*, researchers have struggled to reach a consensus on a better alternative until today. One major limitation of the traditional *ROUGE* metric is the lack of semantic understanding (relies on direct overlap of n-grams). In this paper, we exclusively focus on the extractive summarization task and propose a semantic-aware *nCG* (normalized cumulative gain)-based evaluation metric (called *Sem-nCG*) for evaluating this task. One fundamental contribution of the paper is that it demonstrates how we can generate more reliable semantic-aware ground truths for evaluating extractive summarization tasks without any additional human intervention. To the best of our knowledge, this work is the first of its kind. We have conducted extensive experiments with this new metric using the widely used CNN/DailyMail dataset. Experimental results show that the new *Sem-nCG* metric is indeed semantic-aware, shows higher correlation with human judgement (more *reliable*) and yields a large number of disagreements with the original *ROUGE* metric (suggesting that *ROUGE* often leads to inaccurate conclusions also verified by humans).

1 Introduction

Text summarization is a difficult NLP task and an automatic evaluation of this task is even more challenging. However, automatic evaluation is vital for large-scale experiments as it acts as a replacement for time consuming and pricey human evaluation. As such, the reliability and robustness of automatic evaluation is very crucial.

The most commonly used metric for evaluating text summarization is *ROUGE* (Lin, 2004). Although *ROUGE* has been criticized for considering direct lexical overlap and thus not being semantic-aware, the majority of summarization models' assessments today are still based on *ROUGE* scores. In this paper, we revisit the popular *ROUGE* metric exclusively in the context of evaluating *extractive* summarization task, a task where phrases and sentences from the original text are extracted to create a summary. As such, if the human-written summary includes more novel words than the original document, ROUGE will provide a poor score to extractive summaries due to a lack of semantic awareness. Another limitation of the *ROUGE* metric in the context of *extractive* summarization is the following: while the *extractive* summarization task is generally framed as a sentence ranking problem, the *ROUGE* metric was not originally proposed for evaluating the quality of a ranker. Indeed, the heavily used technique behind *extractive* summarization is to rank sentences from the original document according to how well they reflect the overall description and then create a summary by concatenating the top-ranked sentences. Thus, the "right" evaluation metric for the *extractive* summarization task should also consider the quality of the sentence ranker. Again think about a human-written summary which is highly abstractive in nature. A good ranker that ranks the most informative sentences at the top may still suffer from low ROUGE scores due to fewer direct lexical overlaps between the system summary and human-written summary.

To address these limitations, we propose an alternative *gain*-based evaluation metric in this paper (called *Sem-nCG*) for evaluating extractive summarization tasks, which is both 1) semantic-aware and 2) rewards a system-generated summary based on some groundtruth ranking of sentences from original document. *nCG* (Normalized cumulative gain) is a widely used metric for evaluating the performance of ranking systems, especially when conducting multi-level relevance judgements (Järvelin and Kekäläinen, 2002). Although *nCG* evaluation

Findings of the Association for Computational Linguistics: ACL 2022, pages 1547 - 1560
May 22-27, 2022

is not entirely new (Karmaker Santu et al., 2017; Kuzi et al., 2019; Karmaker et al., 2020), one fundamental contribution of this paper is that it demonstrates how we can automatically generate a reliable semantic-aware groundtruth ranking of sentences within a source document, which essentially enables automatic *Sem-nCG* based evaluation without any additional human intervention. To the best of our knowledge, this work is the first of its kind. To be more specific, given an original document and a human-written summary for evaluation purposes, we used several state-of-the-art sentence embedding techniques (including InferSent, Sentence Transformer, Elmo, Google Universal Sentence Encoding and their ensemble) to prepare groundtruth ranking of sentences from original document by computing semantic similarity between each individual sentence of original document and entire human written summary. Finally, this groundtruth ranking is compared against model-inferred ranking to compute *Sem-nCG* score, where a higher number means a better extractive summary.

We have conducted extensive experiments with this new metric using the CNN/DailyMail dataset and 6 state-of-the-art extractive summarization models ($\text{BERT}_{\text{base}}$, MobileBERT, DistilBERT, RoBERTa, XLNET, GPT-2). Experimental results show that the new *Sem-nCG* metric is: 1) semantic-aware, 2) shows higher correlation with human judgement (more reliable), and 3) yields a large number of disagreements with the original *ROUGE* metric (suggesting *ROUGE* often leads to inaccurate conclusions). When cross-examined by humans, we found *Sem-nCG* to be more accurate (62% of the time) than *ROUGE* on average where the two metrics disagreed on the relative performance of a pair of *extractive* summarization models. Thus, in response to the question of whether we can do better than *ROUGE* for evaluating extractive summarization tasks, the answer appears to be “YES”.

2 Related Work

Evaluation of the text summarization task is challenging and has been studied vastly in the past. (Radev and Tam, 2003) proposed the *Relative Utility* (RU) metric, which evaluates extractive summarization as a ranking task (similar to our formulation), but has not gained much popularity, because their approach requires manual labor to rank each sentence of a document, and it is not practical to manually annotate such large data-sets.

ROUGE (Lin, 2004) is perhaps the most popular metric used today for the evaluation of the automated summarization techniques, mainly because it is a simple and automatic process. However, *ROUGE* has been criticized a lot for primarily relying on lexical overlap (Nenkova, 2006) of n-grams. Later, (Zhou et al., 2006) suggested using a broad domain-independent paraphrase table derived from a bilingual parallel corpus to enable paraphrase matching for summary evaluation. (Cohan and Goharian, 2016) showed that *ROUGE* suffers from poor performance in cases of terminology variation and paraphrasing. As of today, around 192 variants of *ROUGE* have been proposed (Graham, 2015) including *ROUGE* with word embedding (Ng and Abrecht, 2015) and synonym (Ganesan, 2018), graph-based lexical measurement (ShafieiBavani et al., 2018), Vanilla *ROUGE* (Yang et al., 2018) and highlight-based *ROUGE* (Hardy et al., 2019). However, none of the variants of *ROUGE* considers the ranking quality (core technique of extractive summarization); let alone providing an automatic way to do it, which is the primary goal of our work.

Researchers have also proposed metrics alternative to *ROUGE*: factoids-based (atomic information units for sentence meaning) (Teufel and van Halteren, 2004) and pyramid-based (Nenkova and Passonneau, 2004) approaches are two of them. Multiple different reference summaries are a must for both approaches, where the pyramid-based approach requires additional manual labor to construct the pyramid. Since the pyramid must be built by hand and gives imprecise scores, this technique failed to gain much attraction. Many enhancements have been made to the pyramid-based approach: precise automated system for calculating pyramid ratings (Passonneau et al., 2013), pyramid evaluation via automated information extraction (Yang et al., 2016), lightweight sampling-based version that is crowdsourcable (Shapira et al., 2019) and facet-aware evaluation (Mao et al., 2020) for better assessment of knowledge coverage in extractive summarization. Still, the pyramid-based approach necessitates significant additional manual labour making it less appealing for large-scale evaluation.

Researchers also attempted to develop methods for evaluating reference-free model summaries (Louis and Nenkova, 2013; Xenouleas et al., 2019). Distance measures between the system summary and reference summary based on word embeddings have also been proposed (Zhao et al., 2019; Sun and Nenkova, 2019). Moreover, model based evaluation for text generation (also adopted for text summarization) has also been a recent trend (Sellam et al., 2020; Zhang et al., 2020; Yuan et al., 2021). Yet, none of these metrics explicitly assess the quality of ranking performed by an *extractive* summarization method.

3 Background

nCG (Normalized Cumulative Gain) is a popular measure for evaluating information retrieval (IR) systems (Järvelin and Kekäläinen, 2002). Given a query and a ranked list of search results, computation of *nCG* involves summing the gains of the top k documents, and normalizing by the maximum possible gain that can be obtained for the query. Mathematically:

$$CG@k = \begin{cases} G@1, & \text{if } k = 1 \\ CG@[k-1] + G@k, & \text{otherwise} \end{cases} \tag{1}$$

Here, k is the cutoff position (e.g., $k = 5$ is a common choice), $G@k$ and $CG@k$ are the gain and cumulative gain, respectively, at the k-th position in the list. $nCG@k$ is $CG@k$ divided by the maximum achievable $CG@k$, also called Ideal CG ($ICG@k$), which is computed from the ideal ranking of the documents with respect to the query. The ideal ranking places the document(s) with the highest gain on the very top, followed by the documents with the next level of gain, etc. Mathematically:

$$nCG@k = \frac{CG@k}{ICG@k} \tag{2}$$

4 *Sem-nCG* for Extractive Summary

The main motivation for introducing the *Sem-nCG* metric is to ensure a fair evaluation of the *extractive* summarization task where the metric is both semantic-aware as well as captures the ranking quality of the extractive summarizer. Indeed, for *extractive* summarization, sentences in the original document are ranked based on how well they reflect the overall description, and thus, evaluating it with a rank-aware metric like *Sem-nCG* is more equitable. But, how can we develop a *Sem-nCG* metric for the extractive summarization task that was originally designed for *Information Retrieval* systems? What would be the query in this case? What would be the definition of a document? How do we define the gains? How can we compute the groundtruth ideal ranking? All of these are important questions we need to answer before one can use *Sem-nCG* evaluation for extractive summarization tasks.

Problem Formulation: We formulate *extractive* text summarization as a ranking problem, where the output is a ranked-list of sentences based on how well they convey the overall content of the original document. Let us assume that, input is a document $D = [S_D^1, S_D^2, S_D^3, S_D^4..., S_D^{|D|}]$, where S_D^i denotes i^{th} sentence of document D and output is the *Sem-nCG@*k score for the top-k sentences extracted from Document D by the *extractive* summarization model. Now, in order to compute *Sem-nCG@*k, we need to know what the gains of the top-k ranked sentences are, as well as the gains of the top-k ideal (desired) sentences. In other words, without knowing the groundtruth gains for each sentence in the original document, we cannot compute the *Sem-nCG@*k metric.

Groundtruth Gains: It is indeed a philosophical question to ask what should be the definition of gains in case of the extractive summarization. In this work, we define gain as the following:

Definition 4.1 *Given document D and a sentence s from D, gain of s with respect to D is proportional to the degree of how well s captures the overall semantic meaning of document D.*

One way to measure this capturing power is to ask human judges. However, human judgment in this case is problematic for multiple reasons as follows: 1) Human evaluation is time-consuming and expensive, 2) Some human raters have the tendency to give higher ratings than deserved, this is known as the *Leniency* problem, which results in higher variance (Harman and Over, 2004), 3) Natural language descriptions are noisy and ambiguous, which makes manual ordering of sentences by annotators even harder resulting in low inter-rater agreement. This is why we opted for an automated way to create the groundtruth gains without involving humans, as demonstrated by Algorithm 1.

Automatic Gain Computation: How can we automatically infer groundtruth gains in order to automate *Sem-nCG@*k computation? Fortunately, in most summarization benchmark datasets, one or more reference summaries written by humans are also provided along with the original documents. We leverage these human-written reference summaries to automatically infer groundtruth gains.

The exact process is presented in Algorithm 1, where we utilize the semantic similarity between

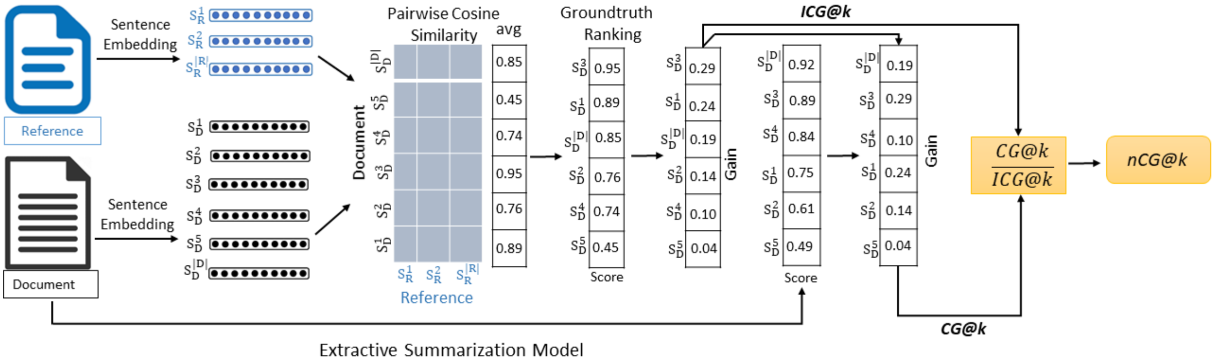

Figure 1: Pipeline for *Sem-nCG@k* evaluation of extractive summarization task, *CG@k* stands for Cumulative Gain at k$^{\text{th}}$ position and *ICG@k* for Ideal *CG@k*.

Algorithm 1 *Sem-nCG@k* Computation

INPUT: Document D, Reference R, Model's top-k extracted sentences, number of sentences in D as N
OUTPUT: *Sem-nCG@k* score

```
Phase 1: Groundtruth Gain Computation
$GT \leftarrow \{\}$
$GT_{gain} \leftarrow \{\}$
Represent sentences in $D$ and $R$ by embedding vectors
for each $S_D^i \in D$ do
    for each $S_R^j \in R$ do
        $Sim(S_D^i, S_R^j) \leftarrow Cosine\_Similarity(S_D^i, S_R^j)$
    end for
    $GT[S_D^i] \leftarrow mean(Sim)$
end for
$GT_{sorted} \leftarrow$ Sort GT based on $mean(Sim)$
$GT_{gain}[S_D^i] \leftarrow N - rank(S_D^i, GT_{sorted}) + 1$
Normalize $GT_{gain}$ into a probabilistic gain
return $GT_{gain}$

Phase 2: Sem-nCG@k Computation
Compute ICG@k from $GT_{gain}$
$M \leftarrow$ Model's top-$k$ extracted sentences
Retrieve $M$'s gain from $GT_{gain}$
Compute CG@k for $M$
return Sem-nCG@k = $\frac{CG@k}{ICG@k}$
```

each sentence in the input document and the entire reference summary to generate groundtruth gains. For semantic similarity, we have experimented with different embeddings, including InferSent, Sentence Transformer, Elmo, Google Universal Sentence Encoding and their ensembles (details in section 5.3). Specifically, we measure the cosine similarity between each sentence in the original document and each reference sentence and then calculate an average cosine similarity for each source-sentence with respect to the whole reference. This average cosine similarity score is then used to rank all the sentences in the original document and a simple greedy approach is taken to assign the groundtruth gains as follows: sentences are assigned a groundtruth gain of $N, N-1, ..., 1$, sequentially from the top, where N denotes the number of sentences in the document. Later, the gain of each sentence is normalized to probabilistic scores ensuring the range of the *Sem-nCG* metric to be between 0 and 1. The intuition here is that a higher-ranked sentence gets more rewards than a lower-ranked one.

The gains computed by algorithm 1 are then used in equation 1 to compute the corresponding cumulative gain for ideal ranking (*ICG@k*) and for model's ranking (*CG@k*), respectively. The ratio of *CG@k* and *ICG@k*, which is *nCG@k* (equation 2), captures the quality of the system generated ranking with respect to the groundtruth ranking. Figure 1 visually demonstrates the pipeline for computing *Sem-nCG@k* metric.

5 Experimental Setup

5.1 Dataset

We conducted extensive experiments with our proposed *Sem-nCG* metric using the popular CNN/DailyMail (Hermann et al., 2015) benchmark dataset. The CNN/DailyMail dataset provides a collection of news articles and related highlights, and these highlights are used as a reference (gold summary). Also, the reference summaries are somewhat *extractive* in nature (a few bullet points providing a brief overview of the article) (Liu and Lapata, 2019). We collected the dataset from huggingface (Wolf et al., 2020)[1]. As we are not explicitly doing any training/fine-tuning of the summarizer models, we have only used the testing set for our experimental evaluation. We excluded any sample that has a sentence count less than 5 from our analysis as we report *Sem-nCG@5* scores. There were 64 such samples in the testing set, which brings

---

our sample size to $11,426$ (Details can be found in Table 1).

Feature	Description
Train/Validation/Test	287113/13368/11490
#Mean Tokens	781 per Article/56 per Highlights
Reference	Single
Strategy	Extractive

Table 1: Overview of CNN/DailyMail Dataset

5.2 *Extractive* Summarization Models

We collected six pre-trained models: $\text{BERT}_{\text{base}}$ (Liu and Lapata, 2019), MobileBERT (Sun et al., 2020), DistilBERT (Sanh et al., 2019), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), GPT-2 (Radford et al., 2019), from huggingface (Wolf et al., 2020) that were fine-tuned on the CNN/DailyMail dataset for the *extractive* summarization task[2]. We then evaluated these six models using both our proposed *Sem-nCG@k* metric and traditional *ROUGE* metric.

5.3 Embedding Sensitivity

We recognize that the groundtruth gains we considered are not absolute since they are derived from a pre-trained sentence embedding. Therefore, we investigated the sensitivity of the gains by varying eight cutting-edge sentence embedding techniques. Specifically, we experimented with Infersent (v1&v2) (Conneau et al., 2017), Semantic Textual Similarity benchmark (STSb - bert/roberta/distilbert) (Reimers and Gurevych, 2019), Elmo (Peters et al., 2018) and Google Universal Sentence Encoder (USE) (Cer et al., 2018): i) enc-2 (Iyyer et al., 2015) based on the deep average network ii) enc-3 (Vaswani et al., 2017) based on transformers. We also created an ensemble method to aggregate the gains (in terms of raw similarity, rank and relevance) provided by different embeddings and combine them into a single gain with an expectation that the ensemble technique will provide a more reliable way for preparing the groundtruth gains. Furthermore, we have also experimented with 3 different variations of the ensemble technique: $\text{Ensemble}_{\text{sim}}$, $\text{Ensemble}_{\text{rank}}$ and $\text{Ensemble}_{\text{rel}}$, with the hope of obtaining more robust groundtruth gains. Specifically, $\text{Ensemble}_{\text{sim}}$ aggregates the cosine similarity first and then gives gains according to Algorithm 1, $\text{Ensemble}_{\text{rank}}$ generates a sentence ranking for each embedding variation and then aggregates the ranking to create a more robust ranking and then provide the gains according to Algorithm 1 and $\text{Ensemble}_{\text{rel}}$ calculates the gain first according to Algorithm 1 for all embedding variations and then takes an average over the gains. Please note that we compare sentences from original documents with highlights (written by humans) to prepare these groundtruth gains.

6 Quantitative Evaluation

6.1 *ROUGE* is not Robust to Perturbation

One of the major criticisms of ROUGE is that it is not semantic-aware. Table 2 confirms that the ROUGE score highly varies if the original document is perturbed with synonyms [3]. Clearly, this is not desired from a "good" summary evaluation metric. Indeed, humans have various ways to express the same thing and often humans write summaries in their own words rather than picking the same key words from the original document (for example if the document uses "vacation", human references can have "trip", "tour", "break" etc.). For our experiments, we substituted around 20% of the words (excluding stop words) of the original document with their synonyms and computed ROUGE scores for these perturbed documents using the CNN/DailyMail dataset, assuming a 5-sentence summary. We utilized *wordnet*[4] from *nltk.corpus* to perform synonym replacement. As seen from Table 2, for ROUGE-1 and ROUGE-3, the score drop was around 5-7%, where for ROUGE-L it was around 3-5%. Interestingly, for ROUGE-2, the score drop was 5-16%.

As the groundtruth gain computation of *Sem-nCG* is dependent of embeddding techniques, we have also inspected whether the ROUGE variant with word embedding (ROUGE-we) (Ng and Abrecht, 2015) is also sensitive to perturbation. Interestingly, table 2 shows ROUGE-we scores are also sensitive to perturbation. For all ROUGE-we-$\{1,2,3\}$, the score drop was around 5-6%. One can reasonably expect that the score drop would be more significant if more words are replaced in original document ($> 20\%$).[5]

6.2 *Sem-nCG* is Robust to Perturbation

We have conducted the same experiment mentioned in Section 6.1 with *Sem-nCG* metric for

---

[2] Appendix contains model architecture details

[3] The objective was to reduce the lexical overlap between extractive summary and reference. The reference can also be perturbed to do this experiment.

Table 3: *Sem-nCG@5* scores for the top-5 sentences of the extractive summarization models ($\text{BERT}_{\text{base}}$, MobileBERT, DistilBERT, RoBERTa, XLNet, GPT-2) on CNN/DailyMail test dataset for different embedding variations.

top-5 extracted sentences. As shown in Table 3, we can see that Ensemble techniques (especially for $\text{Ensemble}_{\text{rel}}$) show more robustness which is somewhat expected as it utilizes the benefits of multiple sentence embeddings. Among non-ensemble techniques, STSb-distilbert seems to be the most robust. If computational time is a bottleneck (Table 4), we would recommend utilizing the STSb-distilbert embedding for our proposed *Sem-nCG* metric.

6.3 *Sem-nCG* is Robust across Multiple Sentence Embedding Techniques

In this experiment, we tested the sensitivity of the proposed *Sem-nCG* metric with respect to the sentence embedding used to create the groundtruth gains. Specifically, we experimented with eight different sentence embedding techniques (Table 3). The findings reveal that the *Sem-nCG@k* score is stable across different sentence embeddings as evident from the low standard deviation of both *Sem-nCG@5* scores for the top-5 extracted sentences. Also, the relative performance of the models always remain same (DistilBERT $>$ $\text{BERT}_{\text{base}}$ $>$ MobileBERT $>$ XLNet $>$ GPT-2 $>$ RoBERTa) for all embedding variations.

6.4 *Sem-nCG* often disagrees with *ROUGE*

Although *ROUGE* and *Sem-nCG@k* agree on relative performances of multiple summarization models in the average case, as we explored further, we discovered that the agreement does not hold for individual document samples. As shown in Table 5, there is a considerable amount of disagreements between *ROUGE* and *Sem-nCG@k* for each pair of models. Here, disagreement means when comparing Model_{A} and Model_{B}, *Sem-nCG@k* indicates Model_{A}'s output is better, while *ROUGE* implies Model_{B}'s output is better and vice-versa. To resolve these conflicts, we further involved humans to perform meta-evaluation of *ROUGE* and *Sem-nCG@k*, where human judgement agreed with *Sem-nCG@k* most of the time (see Section 7).

7 Human Evaluation

7.1 Human judgment favors *Sem-nCG* over *ROUGE* in case of disagreements

We next took a deeper look into the cases where *Sem-nCG* disagreed with *ROUGE* (Table 5) while comparing two extractive summarization models. We asked humans to blindly evaluate the quality of the summaries generated by two models and make a judgement on which summary was better as suggested by (Peyrard, 2019) as well. Specifically, we considered 5 pairs of models ($\text{BERT}_{\text{base}}$ vs. MobileBERT, MobileBERT vs. DistilBERT, DistilBERT vs. RoBERTa, RoBERTa vs. XLNet, and XLNet vs. GPT-2) and provided humans with outputs for each pair of models, hiding the model's name. We took 10 conflicting examples between *Sem-nCG* and *ROUGE-L* for each pair of models. This means that humans evaluated $10 \times 2 = 20$ summaries, each 5 sentences long, for each model pair. In total, annotators labeled $5 \times 20 \times 5 = 500$ sentences for model output, after reading around $5 \times 10 \times 50 = 2500$ sentences for articles and $5 \times 10 \times 3 = 150$ sentences for highlights. We asked the annotators to say which *extractive* summary is better and matched their decision against both *ROUGE* and *Sem-nCG@k*'s conclusions. Our annotators were three doctoral students all working in NLP. We took the majority voting judgement from annotators and the results are reported in Table 6. As summarized in Table 6, blind evaluation by humans indicated *Sem-nCG@k* was more accurate than *ROUGE* in the case of disagreements between the two, thus confirming that *Sem-nCG@k* captures semantics better than *ROUGE*.

7.2 Meta-Evaluation of *Sem-nCG*

We further performed meta-evaluation of the *Sem-nCG* metric using data provided by (Fabbri et al., 2021)[6]. The dataset includes summaries generated by 16 models (both extractive and abstractive) from 100 source news articles (1600 summaries in total). For our experiments, we only considered the extractive summaries and omitted samples containing less than 3 sentences (as we report *Sem-nCG@3*), and that resulted in 252 samples. Each of these summaries was annotated by 5 indepedent crowd-source workers and 3 independent experts (8 annotations in total). Summaries were evaluated across 4 dimensions: consistency, fluency, coherence, relevance after looking into the CNN/DailyMail reference and 10 additional crowd-sourced reference summaries. As mentioned in (Gillick and Liu, 2010), non-expert annotation can be risky, so we only considered expert annotations as followed by (Fabbri et al., 2021) as well. Next, we computed kendall's tau correlation between the *Sem-nCG* score and each of consistency, fluency, coherence, relevance scores rated by humans in the case of single reference setting for the following 3 different scenarios (example in Table 8):

- *Less Overlapping Reference (LOR)*: Highly abstractive references with fewer lexical overlap with the original document.
- *Medium Overlapping Reference (MOR)*: Somewhat extractive references (CNN/DailyMail) with moderate lexical overlap.
- *Highly Overlapping Reference (HOR)*: Highly extractive references with high lexical overlap.

Table 7 shows that our proposed metric outperforms ROUGE in terms of consistency (the most crucial dimension perhaps) for all 3 types of references (even for HOR) with a considerable margin. Interestingly, we found that there is not a clear winner among the embedding choices. However, the STSb-distilbert embedding shows good performance in the consistency dimension both for less overlapping and high overlapping references. Note that STSb-distilbert also takes less computation time (Table 4) and can be a better choice for low-resource evaluation scenarios.

Along the fluency dimension, our proposed *sem-nCG@k* correlates better with humans for all types of references (except for less overlapping references with a comparable performance). Of particular interest from Table 7 are the more abstractive (LOR) references with little overlaps, where *sem-nCG@k* correlation is higher than *ROUGE* for 3 dimensions, including consistency, coherence, and relevance. For medium and highly overlapping references, *ROUGE* correlation along the coherence and relevance dimension was higher, which is somewhat expected, since *ROUGE* mainly computes lexical overlaps. *These results suggest that,*

	Win	**Lose**	**Tie**
Sem-nCG@5 vs. *ROUGE*	**62**%	36%	2%

Table 6: Statistics for *Sem-nCG@5* wins, loses, and ties against *ROUGE-L (F1).* Results report average of 5 pairs ($\text{BERT}_{\text{base}}$ vs. MobileBERT, MobileBERT vs. DistilBERT, DistilBERT vs. RoBERTa, RoBERTa vs. XLNet and XLNet vs. GPT-2) evaluated by humans.

while there may not be a clear winner between sem-nCG and ROUGE when the testing corpus mostly contains medium and highly overlapping references, however, ***sem-nCG@k is clearly a superior metric when evaluating summaries against a more abstract (low overlap) reference****.*

8 Discussions and Conclusion

In this paper, we revisited the problem of automatic evaluation for the *extractive* summarization task, exclusively focusing on the popular *ROUGE* metric. We first argued that any summary evaluation should be more semantic-aware and demonstrated that *ROUGE* fails to capture semantics through comprehensive experiments. Indeed, *ROUGE* score drops (5-7%) even only for small percentages (20%) of synonym perturbation, and thus is not optimal for evaluating any summarization task.

Next, we argued that a "good" metric for evaluating extractive summarization task should assess its core ranking quality, which *ROUGE* does not. To address this issue, we proposed a new metric called *Sem-nCG* which is both semantic-aware and considers ranking quality. More importantly, *Sem-nCG* provides an automated way to compare a set of top-ranked model-extracted sentences (the system-extracted summary) against an ideal ranking of sentences, where the ideal ranking is automatically inferred by computing gains based on some human-written summary. This saves us from tedious process of manual annotation of each sentence within the original document, thus making it practically suitable for large scale automated evaluation.

The correctness of the *Sem-nCG* metric depends largely on the reliability of the groundtruth gains computed by algorithm 1. Therefore, to verify the quality of the groundtruth gains, we conducted extensive quantitative evaluations which confirm that the *Sem-nCG* metric is stable across multiple sentence embedding techniques (very robust) [section 6.2]. Through additional experiments, we have demonstrated the following as well: 1) *Sem-nCG* correlates better with humans [section 7.2]; 2) *Sem-nCG* often disagrees with *ROUGE* for pair-wise comparison of summarization methods [section 6.4]; 3) In the cases of such disagreements, further verification from human judges confirmed that *Sem-nCG* is more reliable than the *ROUGE* metric [section 7.1]; and 4) *Sem-nCG* is a superior metric when evaluating summaries against a more abstract (low overlap) reference [section 7.2]. To conclude, we recommend the following practice:

- For extractive summarization evaluation, please refrain from overemphasizing a substantial improvement over *ROUGE* solely.
- While evaluating extractive summaries, mitigate the limitations of the *ROUGE* metric by reporting additional metrics which are semantic-aware and can generate reliable gains from human references (e.g., *Sem-nCG*), especially when the human-references are more abstractive in nature.
- Human judgment must still be the gold standard, and while making a conclusion of making substantial improvement over previous work, make sure it is backed by human evaluation.

We recognize that our proposed *Sem-nCG* metric overlooks redundancy when computing groundtruth gains; thus, our immediate future goal is to design a redundancy-aware *Sem-nCG*, as well as expand *Sem-nCG* for multi-references and multi-document summarization settings.

A Appendix

A.1 Extractive Summarization Models

BERT$_{\text{base}}$: Transformer models achieve state of the art performance on different NLP tasks. A simple variant of BERT for extractive summarization has been shown in paper (Liu and Lapata, 2019) which consists of 2 parts: a BERT encoder and a summarization classifier. The BERT model here consists of the pretrained BERT$_{\text{base}}$ encoder from masked language model by (Devlin et al., 2019).

MobileBERT (Sun et al., 2020): In an effort to make BERT available for low resource devices, MobileBERT has been proposed which is a thin version of BERT$_{\text{large}}$, with carefully designed balance between self-attentions and feed-forward.

DistilBERT (Sanh et al., 2019): Model size reduction has been studied extensively in the literature due to huge computational expenses of large models. DistilBERT uses knowledge distillation during pre-training to reduce the size of BERT model. It has 40% less parameter than BERT$_{\text{base}}$ and runs 60% faster while achieving 97% of BERT's performance.

RoBERTa (Liu et al., 2019): RoBERTa is another variant of BERT that modified key hyperparameters and removed the next sentence prediction objective while training with larger mini batches and learning rates. The authors have shown the importance of design choices in BERT architecture while improving the performance.

XLNet (Yang et al., 2019) : While BERT has been pre-trained on mask language model, XLNet proposes a generalized autoregressive method for pre-training and an extension of the Transformer-XL that outperforms BERT on 20 NLP tasks.

GPT-2 (Radford et al., 2019): GPT-2 is similar to decoder only transformer but trained on a very large dataset which outperforms BERT on NLP tasks like question answering, reading comprehension, summarization.

A.2 Various Sentence Embeddings used for *Sem-nCG*

Infersent (Conneau et al., 2017): BiLSTM network with max-pooling generates 4096-

Model	Layers	Hidden Units	Parameters	Size
BERT$_{\text{base}}$	12	768	108M	100%
MobileBERT	24	128	25.3M	25%
DistilBERT	12	768	66M	60%
RoBERTa	12	768	125M	113%
XLNet	12	768	110M	100%
GPT-2	24	1024	355M	328%

Table 9: Summary of the Model Architecture

dimensional sentence embedding. Infersent-v1 (trained with GloVe) and Infersent-v2 (trained with fastText) are the two versions of Infersent sentence embedding.

Semantic Textual Similarity benchmark (STSb) (Reimers and Gurevych, 2019): Sentence Transformer allows to generate dense vector representations of sentences. We considered three of the best available models that were optimized for semantic textual similarity (STSb-bert, STSb-roberta and STSb-distilbert).

Elmo (Peters et al., 2018): A fixed mean-pooling of all contextualized word representations with shape 1024 has been considered, effectively transforming the contextualized word-embedding into a sentence embedding.

Google Universal Sentence Encoder (USE) (Cer et al., 2018): USE converts the input text to a 512-dimensional vector. There are two kinds available, i) enc-2 (Iyyer et al., 2015) based on the deep average network ii) enc-3 (Vaswani et al., 2017) based on transformer.

A.3 *Sem-nCG@k* and ROUGE Scores for Top-3 Sentences

To generalize our remarks, we repeated the same experiments (mentioned in Section 5) for ROUGE and *Sem-nCG@k* for the top-3 sentences. Table 10 demonstrates that ROUGE is sensitive to synonym perturbation for the top-3 sentences of extractive models. Table 11, on the other hand, confirms that *Sem-nCG@k* is merely sensitive to sentence perturbation (especially Ensemble$_{\text{rel}}$) and also robust across various sentence embedding variations (confirms from lower standard deviation).

A.4 Dimensions of Human Evaluation

We have considered four quality dimensions following (Fabbri et al., 2021) to measure the Kendall's tau rank correlation between *Sem-nCG@3* and ROUGE.

Consistency: facts between the summary and its source are consistent. Factually consistent summaries contain just assertions from the summarized source, and do not include any trippy facts.

Fluency: sentence structure and quality. Referring to the DUC quality criteria (Dang, 2005), summary sentences "should have no formatting problems, capitalization errors or obviously ungrammatical sentences (e.g., fragments, missing components) that make the text difficult to read."

Coherence: the overall quality of summary sentences while retaining a coherent body of information about a topic rather than just a jumble of related information (Dang, 2005).

Relevance: extracting the most significant information from the source. Summaries with redundancy and extra information were to be penalized by the annotators. Only relevant information from the original should be provided in the summary.

Abstract

The extreme multi-label classification (XMC) task aims at tagging content with a subset of labels from an extremely large label set. The label vocabulary is typically defined in advance by domain experts and assumed to capture all necessary tags. However in real world scenarios this label set, although large, is often incomplete and experts frequently need to refine it. To develop systems that simplify this process, we introduce the task of open vocabulary XMC (OXMC): given a piece of content, predict a set of labels, some of which may be outside of the known tag set. Hence, in addition to not having training data for some labels–as is the case in zero-shot classification–models need to invent some labels on-the-fly. We propose GROOV, a fine-tuned seq2seq model for OXMC that generates the set of labels as a flat sequence and is trained using a novel loss independent of predicted label order. We show the efficacy of the approach, experimenting with popular XMC datasets for which GROOV is able to predict meaningful labels outside the given vocabulary while performing on par with state-of-the-art solutions for known labels.

1 Introduction

Extreme multi-label classification (XMC) aims at predicting a set of labels for a given input instance from an extremely large labels set (Yen et al., 2016, 2017; Babbar and Schölkopf, 2017, 2019). Examples for applying extreme classification are labeling a new article with Wikipedia's categories, classifying a product with catalog labels, classifying a resume into a collection of pertinent job titles.

Despite the the scale of the label space, it is challenging to a priori capture all the possible ways in which an input instance can be categorized, especially at the industrial scale. Real-world e-Commerce platforms, for instance, contain billions of products from thousands of different categories that are continuously updated by human curators for all sort of reasons (*e.g.*, see category changes in eBay (2021)).

In this work we introduce the open vocabulary XMC task, where we measure the ability of models to go beyond the given vocabulary and automatically propose new labels that might complement the existing ones and fill gaps in the vocabulary. Note that this differs from a zero-shot formulation of the XMC problem (Gupta et al., 2021) where, although no training instance is available for some labels, they are still present in the given vocabulary.

To tackle the problem we propose GROOV, an autoregressive model that maps input sequences to a set of sequences. Inputs are documents/text, and outputs are collections of textual labels from an open vocabulary. We investigate multiple sequence-to-set-of-sequences instantiations, in particular an off-the shelf approach based on a encoder-decoder language model (T5, Raffel et al. (2019)) and a variant that uses a modified softmax function (*i.e.*, multi-softmax) that does not penalize the model for assigning high probability to any gold label. This latter version inherently treats the target as a set of sequences (instead of a flat sequence) and outperforms the off-the shelf approach.

To evaluate the out-of-vocabulary behaviour, we use popular XMC datasets for which a portion of the test labels do not appear in the train set. Differently from previous works, we assume models are unaware of such labels (*i.e.*, they don't appear in the given label vocabulary) and need to find them with open-ended text generation. We show that GROOV can indeed generate some of these labels while being competitive with state-of-the-art results on in-vocabulary metrics.

In summary, the key contributions of this work are as follows:

- introduce the open vocabulary XMC task, where models are requested to classify content with meaningful labels that might not be present in the given vocabulary;

Findings of the Association for Computational Linguistics: ACL 2022, pages 1561 - 1583
May 22-27, 2022

- propose GROOV, a sequence-to-set-of-sequences model that can tag textual content with a set of labels from an open vocabulary;
- present extensive analysis on the out-of-vocabulary behaviour of GROOV, including a human review of the generated labels.

2 Related Work

Traditionally Extreme Multi-Label Classification is done by the one-vs-all method. One-vs-all methods such as DiSMEC (Babbar and Schölkopf, 2017), ProXML (Babbar and Schölkopf, 2019), PDSparse (Yen et al., 2016), and PPDSparse (Yen et al., 2017), which treat each label as a binary classification problem, can achieve acceptable performance. One-vs-all methods suffer from computationally expensive complexity and large model size. Also, the classification tasks are independent of each other, and label dependency is not directly modeled. The high computational complexity in one-vs-all methods can be further improved by incorporating different partitioning techniques on the label spaces. For instance, Parabel (Prabhu et al., 2018) partitions the labels through a balanced 2-means label tree using label features constructed from the instances. Recently, several approaches have been proposed to improve Parabel. Bonsai (Khandagale et al., 2019) relaxes two main constraints in Parabel; allowing multi-way instead of binary partitionings of the label set at each intermediate node and also removing strict balancing constraints on the partitions. SLICE (Jain et al., 2019) considers building an approximate nearest neighbor (ANN) graph as an indexing structure over the labels. For a given instance, the relevant labels can be found quickly from the nearest neighbors of the instance via the ANN graph. These models rely on sparse features engineered from the text, which is cumbersome and, most importantly, doesn't benefit from the knowledge of pre-trained LMs. Moreover, the partitioning of the label space is done independently from the classifier's training. In this paper, we leverage pre-trained language models and show that generative models efficiently partition the label space, token by token, and there is no need for crafting a tree of labels separate from the classifier.

Deep learning models have improved extreme multi-label classification by learning better text representation from raw text. But the main challenge to these methods is how to couple with millions of labels. AttentionXML (You et al., 2019) shows success in extreme multi-label classification, overpassed all traditional machine learning methods, and proved the superiority of the raw text compared to sparse features. AttentionXML uses a label tree, and a new classification model is trained for each layer of this tree that makes inference slow in predicting. X-Transformer (Chang et al., 2020) only uses pre-trained LMs to match the label clusters for a given raw text and then ranks these labels by linear classifications with the sparse features. X-Transformer is the first method of using pre-trained LMs in extreme multi-label classification. Due to the high computational complexity of transformer models, it only fine-tunes transformer models as the label clusters matcher, which can not fully exploit the power of transformer models.

Recently, GENRE (Cao et al., 2021) showed that seq2seq auto-recursive models using pre-trained models could effectively partition and traverse a set of large labels by generating tokens incrementally. In extreme multi-label classification, the output is a **set** of labels. Turning the set to a sequence of labels requires an ordering among labels, which might not be straightforward in many applications. (Vinyals et al., 2016) shows that this ordering can significantly impact the performance. Authors in (Yang et al., 2018) propose an RL-based approach to relax the need for a fixed ordering among labels. We propose using a multi-softmax to relax the need for a fixed ordering which is much easier to train and implement than RL algorithms. Another advantage of our work to other set-output methods is that we model the multi-label classification as a set of sequences of tokens instead of a set of label identifiers. Therefore, we leverage more effectively the LM's knowledge in understanding each label. (Gupta et al., 2021) tackles the problem of zero-shot learning in extreme multi-label classification in which it tags each input with a set of labels consisting of both seen and unseen labels during the training. Not only do we build an effective and efficient zero to few-shot learning, but we also want to go beyond that and tackle the problem of open vocabulary classification in which the taxonomy is not known to us entirely.

Related to the open vocabulary extreme classification is the Open Set Recognition(Geng et al., 2021) in the computer vision community. Models proposed to solve the open set recognition have a different signature from our work. They define novel classes only in terms of sets of data points and do not generate names for classes that could then be compared against the true labels in a test set. Also, they operate only on images, and the methods' generalization to other modalities is not examined. Similar in spirit, (Wang et al., 2019) generates hashtags for microblogs and measures the ability of their model in generating new hashtags. The authors use a GRU-based dual encoder to generate hashtags. While there are similarities, our work is first in studying large generative pretrained LM for open vocabulary extreme tagging by jointly modeling all golden labels using a novel loss (multi-softmax).

3 Open-Vocabulary Tagging

Consider N training data points $\{(X_i, Y_i)\}_{i=1..N}$ where X_i is the text corresponding to the i-th instance and $Y_i \subseteq Y^*$ is the set of tags X_i was annotated with. Importantly, we consider the set of all possible tags Y^* to be unknown both at training and inference time. We do assume, however, that each tag $l_k \in Y^*$ can be described by natural language, that is by a sequence of tokens, $\mathrm{tok}(l_k) = \{t_{k,j}\}_{j=1..len(l_k)}$. Lastly let $Y_{seen} = \bigcup_{i=1}^{N} Y_i$ denote the set of labels encountered at training time. Throughout this work we will pay special attention to labels outside of this set, which we refer to as unseen labels.

The above presented formulation of the topic tagging task is incompatible with currently prevalent XMC paradigms in several ways: First, most traditional classifiers require not only Y^* to be known in advance, but assume that for each label l_k there are some examples tagged with l_k so that a classifier can be learned for that particular label. These methods often don't rely on the label representation $\mathrm{tok}(l_k)$ itself. Second, more recent zero-shot work (Gupta et al., 2021) makes tagging possible even for previously unencountered labels $y_k \notin Y_{seen}$. To our best knowledge, all of these methods rely on access to Y^* in order to build some kind of index using label features. Finally, current datasets have their limitations too: (Jain et al.) and (Schultheis et al.) highlight that as the set of possible label grows it is unrealistic to expect that human annotators consider every single possible label in Y^* when annotating a document, thus we can expect all extreme classification datasets to be generally under-annotated. As we will see in Section 7 this hinders our ability to measure the precision of any open vocabulary tagging system.

In the following section we introduce a novel class of models that is particularly well-suited for exploring the whole label space Y^* while maintaining good performance on the set of known labels Y_{seen}.

4 Model

Below we illustrate how to frame OXMC as seq2seq problem, propose a loss captures the set-nature of label sets more directly and then show how individual labels in the sets can be scored.

4.1 Seq2Seq for Sets of Sequences

Given input text X, and some already produced output tokens $y_1, .., y_{i-1}$, *seq2seq* models predict the probability of the next token in the output: $p(y_i|X, y_1, .., y_{i-1})$. Open-vocabulary topic tagging can also be formulated as such sequence-to-sequence problem: Given text X_i, a set of tags Y_i and a permutation π that returns an ordered list of the elements of Y_i, we ask the model to predict the concatenation of the appropriate tags[1] in the order defined by π. Formally, the target output can be defined as

$$T(Y_i, \pi) = \mathrm{Concat}\left(\left[\mathrm{tok}(\pi(Y_i)[k])\right]_{k=1}^{|Y_i|}\right).$$

The need for the extra permutation input π in T reflects the fact that we are attempting to use a *sequential* model that produces ordered list of tokens to predict an *unordered set* of labels. This has a number of practical implications that we need to address. At training time one needs to decide which ordering of the labels to feed to the model as target. At inference time, the model might assign different probabilities to different orderings of the very same set of labels (as opposed to traditional classifiers that would assign a well defined probability to a particular set of labels)

Training During finetuning, for each training example, we uniformly sample a random permutation π of the gold labels. Formally, this method corresponds to a loss function described in Equation 1

---

[1] In practice, we insert a special [SEP] token between each tag, making this mapping bijective which is required for decoding

$$\mathcal{L}(\theta) = -\mathop{\mathbb{E}}_{\pi}\left[\log\left(P_\pi(Y_i|X_i,\theta)\right)\right]$$
$$P_\pi(Y_i|X_i,\theta) = \prod_{k=1}^{|Y_i|} P\Big(T[k]\Big|T[1:k-1],X,\theta\Big)$$
$$T = T(Y_i,\pi) \tag{1}$$

Inference At inference time we decode the model naively choosing the most likely next token at each decoding step. We then split the produced output text by the separator token, resulting in a set of strings - these will be our predicted tags. Note that there's no guarantee that the tags generated this way will be part of the labels used in the dataset, but our hope is that the model will learn what constitutes a good tag. For the purpose of computing position-based metrics such as Precision@K, PSP@K, NLSR@K we use the order in which the model produced the labels.

We refer to our training and inference approach as GROOV (GeneRative Out-Of-Vocabulary) tagging.

4.2 Multi-Softmax Loss

Assume a training example has gold labels A, B, and C and that in a particular training step we feed the permutation B, A, C to the model as the target. Let the logit corresponding to the first tokens of labels A, B, C be z_A, z_B, z_C. The softmax function inside the Cross-Entropy loss will be as follows:

$$\sigma_B(z) = \frac{e^{z_B}}{\sum_{i=1}^{N} e^{z_i}} \tag{2}$$

The sum in the denominator also includes terms for the logits z_A, z_C and thus the loss will eventually increase if the model assigns higher probabilities to tokens corresponding to labels A and C - even though those predictions would be completely reasonable. Unfortunately, the more labels an example has on average, the more prevalent this problem will become.

In order to overcome this issue, we propose a modified softmax function dubbed *Multi-Softmax* (MSM) that does not penalize the model for assigning a high probability to any token that could lead to decoding a gold label that has been not produced yet. At a given decoding step let G be the set of token indices that could lead to producing a gold label (in our example A, B or C). Then the multi-softmax function is defined as:

$$\sigma_G(z) = \frac{\sum_{i\in G} e^{z_i}}{\sum_{i=1}^{N} e^{z_i}} \tag{3}$$

We experiment with replacing the softmax term in the Cross-Entropy loss of T5 to this newly proposed version in the hope that it will learn more efficiently.

4.3 Scoring Labels

With the proposed sequential approach there is no simple way to compute a score for an individual label: at decoding time we can only access the probability of the next label *given the previously decoded labels*. Instead, all we have is a binary decision whether the label appeared in the model output or not. In real life applications this can be problematic as one can not control the sensitivity of the model by thresholding the scores. It also makes the model perform suboptimally on metrics (e.g. P@K) where the ordering of labels w.r.t their probability is crucial.

In order to compute a robust score for a given label, one might compute its marginal probability over all possible output sequences. Of course this is computationally intractable, so instead in practice we can run a beam search of beam size B and sum up the probabilities of the beams that contain a particular label in order to approximate its marginal probability. Let $b_1, .., b_B$ be the label sequences resulting from such a beam search. Our approximation to the marginal probability of label l_i can be written as:

$$P(l_i) = \sum_{k=1}^{B} \mathbb{1}(l_i \in b_k)P(b_k) \tag{4}$$

5 Experimental Setting

5.1 Datasets

In order to focus on the ability of models to tag text with previously unseen labels, one might consider using the same datasets that are used to benchmark traditional zero-shot XMC. We evaluate our models on the two topic tagging datasets[2] (Gupta et al., 2021) report results on. EURLex-4.3K (Chalkidis et al., 2019) is a collection of roughly 50K EU Legal documents annotated

---

[2] Other datasets in that work are focused on item similarity-based recommendation rather than real tagging.

with 4.3K tags. Wikipedia-1M (Gupta et al., 2021) is a large collection of Wikipedia articles associated with 1M+ Wiki categories.

The above two datasets all contain some amount of unseen labels (see Table 1) but are on the two extreme sides of the spectrum: EURLex-4.3K only contains 163 unseen labels, whereas most of the labels in the test set of Wikipedia-1M are in fact not present in the training set. In order to effectively study the open-vocabulary tagging properties of this new class of models, we construct a third dataset motivated by a real world scenario that aims to be in the middle of this spectrum.

The AmazonCat13K dataset introduced by Mcauley and Leskovec contains descriptions of products on Amazon and categories in the product taxonomy associated with them. This dataset does not contain unseen labels in its test set, so we create a new dataset by 1) randomly choosing 1000 labels from the set of labels that appear in the training split and 2) moving all examples in the training set that contain any of these 1000 labels to the test set.[3] We refer to this newly introduced version of the AmazonCat13K dataset as AmazonCat-OV, as it enables measuring the Open Vocabulary performance of models.

Dataset name	N_{train}	N_{test}	$\lvert Y_{seen} \rvert$	$\lvert Y_{unseen} \rvert$
EURLex-4.3K	45K	6K	4,108	163
AmazonCat-OV	1.1M	0.4M	11,460	1,870
Wikipedia-1M	2.3M	2.7M	495,107	776,612

Table 1: Basic statistics of datasets used in this work

5.2 Evaluation Metrics

We expect two basic properties from the proposed new class of models:

- Irrespective of the new labels, these models need to perform just as well as other XMC models on the overall dataset (including more frequent tags too).
- Additionally, we expect our proposed models to produce some of the labels that it has never seen and has no knowledge of - demonstrating some understanding of the structure of the label space and the ability to generalize beyond a predefined taxonomy.

To that end, we evaluate our models using the following metrics:

Propensity-Scored Precision @ K (PSP@K) is a variant of the commonly used Precision@K metric introduced by Jain et al. that assigns higher rewards for getting infrequent labels right (and by extrapolation, even higher reward for previously unseen labels). The scoring function is motivated by the observation that less frequent tags are more likely to be under-labeled as well as by the intuition that tagging with more granular, less frequent tags is likely of more value. We refer to the original paper for the implementation details of this metric. Code for computing this metric is provided by the Extreme Classification Repository (Bhatia et al., 2016)

Metrics on unseen labels. For a data point with model predictions $\widetilde{Y}_i$ and gold labels Y_i, let $Y_{\text{unseen},i} = Y_i \setminus Y_{\text{seen}}$ and $\widetilde{Y}_{\text{unseen},i} = \widetilde{Y}_i \setminus Y_{\text{seen}}$.

We calculate the standard Precision@K and Recall@K metrics considering these two sets, $\widetilde{Y}_{\text{unseen},k}$ and $Y_{\text{unseen},k}$. On top of these instance-wise metrics we also define a metric on the entire test set that measures how many of the unseen labels in the test set has the model produced at least once. We call this the Novel Label Set Recall and define it as

$$NLSR@K = \frac{\left| \bigcup_{i=1}^{N_{test}} sorted(\widetilde{Y}_{\text{unseen},i})[:K] \right|}{\left| \bigcup_{i=1}^{N_{test}} Y_{\text{unseen},i} \right|}$$

This formulation is motivated by potential future use cases of this novel family of models. One might run model inference on a new batch of data and collects the top-K out-of-vocabulary labels produced by the model from each data point. This set of novel tags could now be inspected manually and used to expand the taxonomy of labels if deemed appropriate. NLSR@K is an approximation for what percentage of the expansion of the label space could be captured by such a process.

Soft-matching based metrics Since the model has no knowledge of what the gold labels might look like, it is possible that it would produce some labels that are semantically equivalent to a gold label but would have a slightly different surface form. We investigate this and propose new metrics to address this in Section 6.3

---

[3] Due to strong correlations between labels, some labels outside of the original 1000 also disappear from the training set and becomes an unseen label

5.3 Training and Evaluation Setup

Unless otherwise reported, we use the T5-base model obtained from Huggingface (Wolf et al., 2020). We finetune these models on 4 Nvidia V100 GPUs using batch size 32 and AdamW optimizer with LR=0.0001. On datasets where validation set is not provided, we train for a fix number of Epochs (100 and 1 for EURLex and AmazonCat-OV respectively) and use beam size 15 for decoding. For the experiments on Wikipedia dataset, we train T5-base models for 3 epochs and T5-large model for 1 epoch, respectively. Beam size is set to 15 for decoding purpose.

6 Quantitative Results

First, this section looks at our model's overall performance on XMC, considering all the tags. Then, we look at the out of vocabulary performance by relaxing the definition of label matching to account for semantically similar labels with different surface forms.

6.1 Overall Performance

Table 2 contains our results on entire label set, as measured by the PSP@K metric introduced above. Given the large number of XMC models available today, we only show the top-few best performing models from each family of models that we referenced in Section 2. Note that all models *except for our proposed models* have access to the overall set of labels at inference time. Our simplest method that uses T5 as-is outperforms many of the XMC models developed in the past years. Using the methods described in Section 4 we established a system that performs on par with the best available model on EUR-Lex4.3K and is the second-best model on Wikipedia-1M, only 2% point below the designed explicitly for the zero-shot model. No model outperforms our models on both datasets. Our scoring by marginalization improves the performance in **Wikipedia-1M** dataset, especially at the top 3 and 5 tags, showing it effectively builds a calibrated score for labels. But, in **EUR-Lex 4.3K**, the default order of the labels in the vanilla T5 model scores as high as ranking by marginalization. We conjecture the generative model learns to output the more confident tags first and then moves to the less confident ones. Our MultiSoftmax loss consistency improves the performance in comparison to the base model.

6.2 Out-Of-Vocabulary Performance

What distinguishes our model from previous zero-shot approaches is that it is able to generate previously unseen labels without being told about their existence in advance. Table 3 shows our measurements of recall and precision when only considering unseen labels. For this section, we use the two larger datasets with a reasonably large set of unseen labels. To our best knowledge *no other XMC system can achieve a non-zero score in this setting*. Recall@K metrics on both of these datasets demonstrate that the model can generalize beyond the labels it has seen and produce correct, novel labels in some percentage of the cases - although there is room for significant improvements still. A highlight is that on the AmazonCat-OV dataset, nearly one-quarter of the labels that we removed from the training set were generated as the top out-of-vocabulary prediction at least once in the test set. Due to the ambiguous nature of evaluating open-vocabulary tags produced by generative models, recall and precision measurements based on exact label match are merely a lower bound on the practical performance of the model. We investigate this further in the following sections and find that these numbers are underestimating our model's true ability to produce previously unseen but valid tags.

6.3 Lexical/Semantic Similarity instead of Exact Matching

Some of the reasonable labels produced by the model may not exactly match the labels from the golden label set. This mismatch could be due to small lexical differences such as different spelling, hyphenation, pluralization, lexical form or capitalization. Additionally, the mismatch can be due to related terms or synonyms being generated instead of the exact label (for example *"Kids' books"* instead of *"Childrens' books"*). Metrics like precision and recall would count all such generations as false positives, and this may not accurately describe the generative model's performance. To tackle this, we also measure soft precision and soft recall. We introduce Soft Lexical Recall/Precision, which addresses the lexical differences. These metrics work exactly in the same way as normal precision and recall with the difference that any generated label $\hat{Y}$ is matched with a label from the golden set Y if their edit distance is smaller than $|\hat{Y}|/DF + 1$, where DF is the division factor used to regulate

the flexibility and accuracy of this matching. In our measurements we set $DF = 10$. We also introduce Soft Semantic Recall/Precision to address the problem with slightly different formulations of the same label or synonym words in the labels. Similar to the Soft Lexical metrics described above, we change the matching criteria between $\hat{Y}$ and Y from exact lexical match to a BertScore (Zhang et al., 2020) based metric. We check the F1 score generated by BertScore and use a threshold of 0.94 [4]. This threshold is selected to make sure soft semantic matches correlates highly with sensibility in our human evaluation. This is shown in Table 5. Table 4 shows the performance on the AmazonCat dataset using soft lexical and semantic matching alongside the exact precision and recall. The threshold in semantic and lexical matching is stringent; they highly correlate with sensibility in our human evaluation (e.g., 96% in table 5). Still, we observe significant improvement in our precision/recall compared to the exact match, confirming that the model generates some correct tags with slight surface differences.

7 Human Review of Out of Vocabulary Generations

7.1 Interpreting Model Behavior

In our experiment with the AmazonCat-OV dataset, our model correctly generated more than 400 different, novel categories that only appeared in the test set as ground truth labels. In order to qualitatively understand what type of model behavior led to producing these labels, we manually compared the input texts and the generated novel labels.

---

[4] BertScore Hash: roberta-large_L17_no-idf_version=0.3.10(hug_trans=4.12.3)_fast-tokenizer

We found that in most cases (89%) the model effectively employs a very simple two-step strategy. First it identifies an n-gram in the input text that could be a meaningful category. Then the model decides if it makes sense to generate a label that is the verbatim copy of this n-gram (”London”, ”Table Tennis”, ”Bartending”) or alternatively, it converts the n-gram into its plural form (”Kitchen Sinks”, ”Sleeping Pads”).

In the rest of the cases (11%), however, we found evidence that the model is able to creatively *compose information* from across the item description in order to produce a label that does not appear verbatim in the text. Some examples of these labels are: ”Wine Glasses”, ”Baby Food”, ”Patio Furniture Sets”, ”Lens Accessories”.

7.2 Sensibleness and Informativeness of Novel Labels

Sometimes the model generates completely new terms that do not appear as a ground truth label in the test set. Even though these could indeed be false positives - as no taxonomy is ever complete - they could also be *sensible*, and *informative* new tags that could help the taxonomists expand the known label set. Due to this, our quantitative precision results might significantly underestimate the usefulness of the generated novel labels.

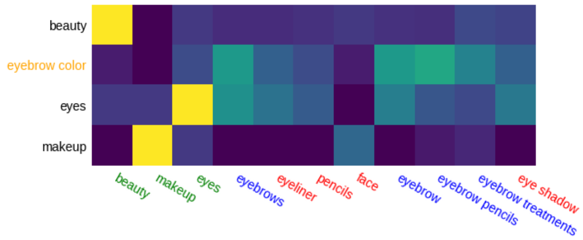
We inspected a random sample of 100 model predictions (142 novel labels) containing out of vocabulary labels and manually assessed their sensibleness and informativeness using human review. This is similar to the work of Shuster et al. (2021), where Consistency, Engagingness, and Knowledgeability of the responses of generative models in a conversational setting were manually measured. We focus on the two characteristics of sensible and informative as a new tag in the taxonomy needs to be both. It needs to make sense while being different enough from existing labels.

In Figure 1 we present two examples of novel, entirely out of vocabulary generated labels. The color-map denotes the lexical similarity of generated predictions to the golden set, with gold meaning a perfect match and black being a complete mismatch. For this lexical similarity we use the Levenshtein distance similar to section 6.3 with $DF = 10$. The Y-Axis of the color map corresponds to the golden set labels, and the individual labels in the golden set are colored gold when they are missing from the training set. The X-Axis represents the generated labels. The labels that are predicted correctly(potentially with soft lexical matching) are colored green. Those predicted falsely from the label set are colored red. The labels that could not be matched with any labels from the known label set are colored blue. In Figure 1a we see that the model generates several completely novel labels *”eyebrow pencils”*, *”eyebrow treatments”* and both singular and plural forms of *”eyebrow”*. These labels better describe the input text; however, they are missing from both the label set and the golden set. Taxonomists could use such a prediction to improve the taxonomy and potentially the training dataset itself. On the contrary, the novel label generated in Figure 1b is not related to the input text at all and is just a false positive.

Quantified results of manual review of a subsample of novel predictions by the model can be seen in Table 5. 65% of the novel generations in this subset are sensible. This means they can be safely used as labels/tags. But more interestingly, 26% of the novel generated labels we observed were both sensible and informative. These are typically more precise labels (more granular) for the input text than the golden set labels. This result is interesting as it provides a direct tool for taxonomists to expand/improve their taxonomy. By going over the $1-5\%$ of novel generated labels, they can find a lot of new sensible and informative labels.

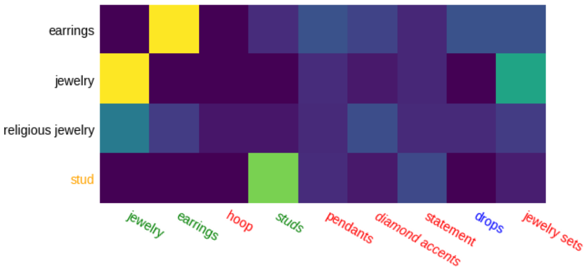
We also want to measure the ability of the semantic soft matching introduced in section 6.3 against the newly introduced sensitive and informative framework. We see in Table 5 that using the semantic matching with the mentioned threshold detects with 96% precision the sensibleness and it also improves the precision for detecting informativeness. Decreasing the threshold decreases the precision of detecting sensible tags. However, its recall is not very high, and if we wanted to find all the sensible and informative labels, we would still need to do human labeling.

Some more examples of these novel labels generated by the model and their evaluation based on the sensible and informative characteristics can be found in Appendix A. Note that as this manual labeling process is expensive and time-consuming, our initial sample sets have been small. In the future, the novel generated labels can be studied more thoroughly from different aspects.



Input Text: NARS Eyebrow Pencil Sculpts and defines the eyebrow with rich, natural looking pigment to softly frame the eyes. The firm texture allows for maximum control and provides long-lasting definition.

(a) Sensible and Informative novel generated label



Input Text: 1/2 Carat Sterling Silver CZ Cross Stud Earrings The look of white gold at a silver price! These sterling silver earrings perfectly mimic white gold and diamonds with their rhodium finish and cubic-zirconia stones. Rhodium is a metal that is part of the platinum family. High-end silver and gold are rhodium treated to prevent oxidation and to have the white shiny look associated with platinum and white gold. These earrings' rhodium finish will prevent them from tarnishing.

(b) Not Sensible and not Informative novel generated label

Figure 1: Showing examples generated by the model. Figure 1a showing a sensible and informative prediction while the prediction in Figure 1b is both not sensible and not informative

Semantic Match	# Labels	Sen %	Inf %
Yes	26	96	38
No	116	59	23
Total	142	65	26

A Appendix: Detailed Summary of Novel Generated Labels or Unseen Labels in Gold Set

In this appendix we list the subset of novel generated labels or instances with unseen labels in their gold set by the model that we studied in section 7. Table 6 shows a subsample of predictions using our model on the Amazon dataset and Table 7 shows the same for the Wiki dataset. The color-map denotes the lexical similarity of generated predictions to the golden set with gold meaning a perfect match and black being a complete mismatch. For this lexical similarity we use the Levenshtein distance similar to section 6.3. The Y-Axis of the color map corresponds to the golden set labels and the individual labels in the golden set are colored gold when they are missing from the training set. The X-Axis represents the generated labels. The labels that are predicted correctly are colored green, those predicted falsely from the label set are colored red and the labels that could not be matched with any labels from the known label set are colored blue. In the left column, we discuss each such novel generated label and evaluate it based on our sensible and informative framework.

Abstract

Few-shot named entity recognition (NER) systems aim at recognizing novel-class named entities based on only a few labeled examples. In this paper, we present a decomposed meta-learning approach which addresses the problem of few-shot NER by sequentially tackling few-shot span detection and few-shot entity typing using meta-learning. In particular, we take the few-shot span detection as a sequence labeling problem and train the span detector by introducing the model-agnostic meta-learning (MAML) algorithm to find a good model parameter initialization that could fast adapt to new entity classes. For few-shot entity typing, we propose MAML-ProtoNet, *i.e.*, MAML-enhanced prototypical networks to find a good embedding space that can better distinguish text span representations from different entity classes. Extensive experiments on various benchmarks show that our approach achieves superior performance over prior methods.[1]

1 Introduction

Named entity recognition (NER) aims at locating and classifying text spans into pre-defined entity classes such as locations, organizations, *etc*. Deep neural architectures have shown great success in fully supervised NER (Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016; Peters et al., 2017) with a fair amount of labeled data available for training. However, in practical applications, NER systems are usually expected to rapidly adapt to some new entity types unseen during training. It is costly while not flexible to collect a number of additional labeled data for these types. As a result, the problem of few-shot NER, which involves learning unseen entity types from only a few labeled examples for each class (also known as *support examples*), has attracted considerable attention from the research community in recent years.

Previous studies on few-shot NER are typically based on token-level metric learning, in which a model compares each query token to the prototype (Snell et al., 2017) of each entity class or each token of support examples and assign the label according to their distances (Fritzler et al., 2019; Hou et al., 2020; Yang and Katiyar, 2020). Alternatively, some more recent attempts have switched to span-level metric-learning (Yu et al., 2021; Wang et al., 2021a) to bypass the issue of token-wise label dependency while explicitly utilizing phrasal representations.

However, these methods based on metric learning might be less effective when encountering large domain gap, since they just directly use the learned metric without any further adaptation to the target domain. In other words, they do not fully explore the information brought by the support examples. There also exist additional limitations in the current methods based on span-level metric learning. First, the decoding process requires careful handling of overlapping spans due to the nature of span enumeration. Second, the class prototype corresponding to non-entities (*i.e.*, prototype of the "`O`" class) is usually noisy because non-entity common words in the large vocabulary rarely share anything together in common. Moreover, when targeting at a different domain, the only available information useful for domain transfer is the limited number of support examples. Unfortunately, these key examples are only used for inference-phase similarity calculation in previous methods.

To tackle these limitations, this paper presents a decomposed meta-learning framework that addresses the problem of few-shot NER by sequentially conducting *few-shot entity span detection* and *few-shot entity typing* respectively via meta-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1584 - 1596
May 22-27, 2022

learning. Specifically, for *few-shot span detection*, we model it as a sequence labeling problem to avoid handling overlapping spans. Note that the detection model aims at *locating* named entities and is class-agnostic. We only feed the detected entity spans to the typing model for entity class inference, and hence the problem of noisy "O" prototype could also be eliminated. When training the span detector, we specifically use the model-agnostic meta-learning (MAML) (Finn et al., 2017) algorithm to find a good model parameter initialization that could fast adapt to new entity classes with learned class-agnostic meta-knowledge of span boundaries after updating with the target-domain support examples. The boundary information of domain-specific entities from the support examples is supposed to be effectively leveraged via these update steps such that the model could better transfer to the target domain. For *few-shot entity typing*, we implement the typing model with standard prototypical networks (Snell et al., 2017, ProtoNet), and propose MAML-ProtoNet to narrow the gap between source domains and the target domain. Compared with ProtoNet which only uses support examples for inference-phase similarity calculation, the proposed MAML-Proto additionally utilizes these examples to modify the shared embedding space of spans and prototypes by clustering spans representations from the same entity class while dispersing those from different entity classes for more accurate predictions.

We evaluate our proposed framework on several benchmark datasets with different few-shot settings. Experimental results show that our framework achieves superior performance over previous state-of-the-art methods. We also conduct qualitative and quantitative analyses over how the different strategies to conduct meta-learning might affect the performance.

2 Task Definition

Given an input sequence $\boldsymbol{x} = \{x_i\}_{i=1}^{L}$ with L tokens, an NER system is supposed to output a label sequence $\boldsymbol{y} = \{y_i\}_{i=1}^{L}$, where x_i is the i-th token, $y_i \in \mathcal{Y} \cup \{\texttt{O}\}$ is the label of x_i, $\mathcal{Y}$ is the pre-defined entity class set, and O denotes non-entities.

In this paper, we focus on the standard N-way K-shot setting as in Ding et al. (2021). An example of 2-way 1-shot episode is shown in Table 1. In the training phase, we consider training episodes $\mathcal{E}_{train} = \{(\mathcal{S}_{train}, \mathcal{Q}_{train}, \mathcal{Y}_{train})\}$ built from source-domain labeled data, where $\mathcal{S}_{train} = \{(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})\}_{i=1}^{N\times K}$ denotes the support set, $\mathcal{Q}_{train} = \{\boldsymbol{x}^{(j)}, \boldsymbol{y}^{(j)}\}_{j=1}^{N\times K'}$ denotes the query set, $\mathcal{Y}_{train}$ denotes the set of entity classes, and $|\mathcal{Y}_{train}| = N$. In the testing phase, we consider novel episodes $\mathcal{E}_{new} = \{(\mathcal{S}_{new}, \mathcal{Q}_{new}, \mathcal{Y}_{new})\}$ constructed with data from target domains in a similar way. In the few-shot NER task, a model learned with training episodes $\mathcal{E}_{train}$ is expected to leverage the support set $\mathcal{S}_{new} = \{(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})\}_{i=1}^{N\times K}$ of a novel episode $(\mathcal{S}_{new}, \mathcal{Q}_{new}, \mathcal{Y}_{new}) \in \mathcal{E}_{new}$ to make predictions on the query set $\mathcal{Q}_{new} = \{\boldsymbol{x}^{(j)}\}_{j=1}^{N\times K'}$. Here, $\mathcal{Y}_{new}$ denotes the set of entity classes with a cardinality of N. Note that, $\forall\, \mathcal{Y}_{train}, \mathcal{Y}_{new}, \mathcal{Y}_{train} \cap \mathcal{Y}_{new} = \emptyset$.

Target Types $\mathcal{Y}$	[person-actor], [art-film]
Support set $\mathcal{S}$	(1) *Jack Gordon*$_{\text{[person-actor]}}$ (born 27 June 1985) is an English actor . (2) This location had also been used to shoot the film " *Saving Private Ryan*$_{\text{[art-film]}}$ " .
Query Set $\mathcal{Q}$	Kurland starred in " Taps " , which won first prize at the Rhode Island International Film Festival in 2006 .
Expected output	*Kurland*$_{\text{[person-actor]}}$ starred in " *Taps*$_{\text{[art-film]}}$ " , which won first prize at the Rhode Island International Film Festival in 2006 .

Table 1: An example of the simplest 2-way 1-shot setting, which contains two entity classes and each class has one example (shot) in the support set $\mathcal{S}$. Different colors indicate different entity classes.

3 Methodology

Figure 1 illustrates the overall framework of our decomposed meta-learning approach for few-shot named entity recognition. It is composed of two steps: *entity span detection* and *entity typing*.

3.1 Entity Span Detection

The span detection model aims at locating all the named entities in an input sequence. The model should be type-agnostic, *i.e.*, we do not differentiate the specific entity classes. As a result, the parameters of the model can be shared across different domains and classes. With this in mind, we train the span detection model by exploiting model-agnostic meta-learning (Finn et al., 2017) to promote the learning of the domain-invariant internal representations rather than domain-specific features. In this way, the meta-learned model is

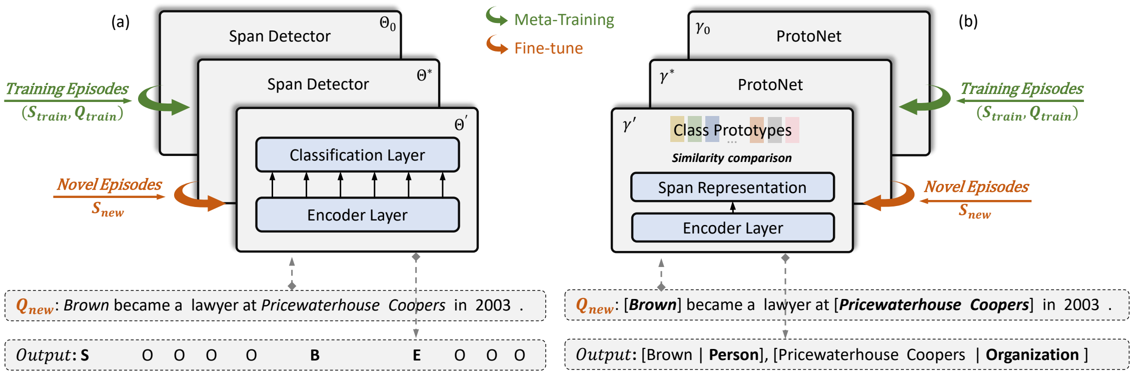

Figure 1: The framework of our proposed approach is decomposed into two modules: (a) entity span detection with parameters Θ and (b) entity typing with parameters γ. Two modules are trained independently using (S_{train}, Q_{train}). At meta-test time, these two modules firstly are finetuned on the support set S_{new}, then given a query sentence in Q_{new}, the spans detected by (a) are sent to (b) for entity typing.

expected to be more sensitive to target-domain support examples, and hence only a few fine-tune steps on these examples can make rapid progress without overfitting.

3.1.1 Basic Detector

Model In this work, we implement a strong span detector via sequence labeling. We apply the BIOES tagging scheme instead of the standard BIO2 to provide more specific and fine-grained boundary information of entity spans.[2] Given an input sequence $\boldsymbol{x} = \{x_i\}_{i=1}^{L}$ with L tokens, we first leverage an encoder f_θ to obtain contextualized representations $\boldsymbol{h} = \{h_i\}_{i=1}^{L}$ for all tokens:

$$\boldsymbol{h} = f_\theta(\boldsymbol{x}). \tag{1}$$

With each h_i derived, we then use a linear classification layer to compute the probability distribution of labels that indicate whether the token x_i is inside an entity or not, using a *softmax* function:

$$p(x_i) = \text{softmax}(W h_i + b), \tag{2}$$

where $p(x_i) \in \mathbb{R}^{|C|}$ with $C = \{B, I, O, E, S\}$ being the label set. $\Theta = \{\theta, W, b\}$ are trainable parameters.

Training Generally, the learning loss *w.r.t.* $\boldsymbol{x}$ is modeled as the averaged cross-entropy of the predicted label distribution and the ground-truth one over all tokens. Following Wu et al. (2020), we add a maximum term here to mitigate the problem of insufficient learning for tokens with relatively higher losses, which can be formulated as:

$$\mathcal{L}(\Theta) = \frac{1}{L}\sum_{i=1}^{L} \text{CrossEntropy}\left(y_i, p(x_i)\right) + \lambda \max_{i \in \{1,2,\ldots,L\}} \text{CrossEntropy}\left(y_i, p(x_i)\right), \tag{3}$$

where $\lambda \geq 0$ is a weighting factor.

Inference For inference, we use the learned model to predict the label distribution for each token in a given test case. We apply the Viterbi algorithm (Forney, 1973) for decoding. It is worthy to note that we do not train a transition matrix here, but simply add constraints to ensure that the predicted label sequence would not violate the BIOES tagging scheme.

3.1.2 Meta-Learning Procedure

Here we elaborate on the proposed meta-learning procedure which consists of two phases: meta-training on $\mathcal{E}_{train}$ and meta-testing on $\mathcal{E}_{new}$. The Appendix A.1 describes the general framework of meta-learning for reference.

Meta-Training In this phase, we train a mention detection model $\mathcal{M}_\Theta$ by repeatedly simulating the *Meta-Testing* phase, where the meta-trained model is fine-tuned with the support set of a novel episode and then tested on the corresponding query set.

Specifically, we first randomly sample an episode $(\mathcal{S}_{train}^{(i)}, \mathcal{Q}_{train}^{(i)}, \mathcal{Y}_{train}^{(i)})$ from $\mathcal{E}_{train}$ and perform *inner-update*:

$$\Theta'_i = U^n(\Theta; \alpha, \mathcal{S}_{train}^{(i)}), \tag{4}$$

---

[2] We found BIOES to be stronger than BIO for *type-agnostic span detection* as it explicitly encourages the model to learn more specific and fine-grained boundary information. Besides, our entity typing model aims to assign an entity type for each *detected* span, which does not involve any tagging scheme.

where U^n denotes n-step gradient updates with the learning rate α to minimize $\mathcal{L}(\Theta; \mathcal{S}_{train}^{(i)})$, *i.e.*, the loss in Eq. (3) derived from the support set $\mathcal{S}_{train}^{(i)}$.

We then evaluate Θ' on the query set $\mathcal{Q}_{train}^{(i)}$ and perform *meta-update* by aggregating multiple episodes:

$$\min_{\Theta} \sum_i \mathcal{L}(\Theta'_i; \mathcal{Q}_{train}^{(i)}). \tag{5}$$

Since Eq. (5) involves the second order derivative, we employ its first-order approximation for computational efficiency:

$$\Theta \leftarrow \Theta - \beta \sum_i \nabla_{\Theta'_i} \mathcal{L}(\Theta'_i; \mathcal{Q}_{train}^{(i)}), \tag{6}$$

where β denotes the learning rate used in meta-update.

Meta-Testing In this phase, we first fine-tune the meta-trained span detection model $\mathcal{M}_{\Theta^*}$ with the loss function defined in Eq. (3) on the support set $\mathcal{S}_{new}$ from a novel episode, and then make predictions for corresponding query examples $\mathcal{Q}_{new}$ with the fine-tuned model $\mathcal{M}_{\Theta'}$.

3.2 Entity Typing

For entity typing, we aim to assign a specific entity class for each span output by the mention detection model. In the few-shot learning scenario, we take the prototypical networks (ProtoNet) (Snell et al., 2017) as the backbone for entity typing. To explore the knowledge brought by support examples from a novel episode, we propose to enhance the ProtoNet with the model-agnostic meta-learning (MAML) algorithm (Finn et al., 2017) for a more representative embedding space, where text spans from different entity classes are more distinguishable to each other.

3.2.1 Basic Model: ProtoNet

Span Representation Given an input sequence with L tokens $\boldsymbol{x} = \{x_i\}_{i=1}^{L}$, we use an encoder g_γ to compute contextual token representations $\boldsymbol{h} = \{h_i\}_{i=1}^{L}$ in the same way as Eq. (1):

$$\boldsymbol{h} = g_\gamma(\boldsymbol{x}). \tag{7}$$

Assume $x_{[i,j]}$ being the output of the span detection model which starts at x_i and ends at x_j, we compute the span representation of $x_{[i,j]}$ by averaging representations of all tokens inside $x_{[i,j]}$:

$$s_{[i,j]} = \frac{1}{j-i+1} \sum_{k=i}^{j} h_k. \tag{8}$$

Class Prototypes Let $S_k = \{x_{[i,j]}\}$ denotes the set of entity spans contained in a given support set $\mathcal{S}$ that belongs to the entity class $y_k \in \mathcal{Y}$, we compute the prototype c_k for each entity class y_k by averaging span representations of all $x_{[i,j]} \in S_k$:

$$c_k(\mathcal{S}) = \frac{1}{|S_k|} \sum_{x_{[i,j]} \in S_k} s_{[i,j]}. \tag{9}$$

Training Given a training episode denoted as $(\mathcal{S}_{train}, \mathcal{Q}_{train}, \mathcal{Y}_{train})$, we first utilize the support set $\mathcal{S}_{train}$ to compute prototypes for all entity classes in $\mathcal{Y}_{train}$ via Eq. (9). Then, for each span $x_{[i,j]}$ from the query set $\mathcal{Q}_{train}$, we calculate the probability that $x_{[i,j]}$ belongs to an entity class $y_k \in \mathcal{Y}$ based on the distance between its span representation $s_{[i,j]}$ and the prototype of y_k:

$$p(y_k; x_{[i,j]}) = \frac{\exp\left\{-d\left(c_k(\mathcal{S}_{train}), s_{[i,j]}\right)\right\}}{\sum_{y_i \in \mathcal{Y}} \exp\left\{-d\left(c_i(\mathcal{S}_{train}), s_{[i,j]}\right)\right\}}, \tag{10}$$

where $d(\cdot,\cdot)$ denotes the distance function. Let $y_{[i,j]} \in \mathcal{Y}$ denote the ground-truth entity class *w.r.t.* $x_{[i,j]}$, the parameters of the ProtoNet, *i.e.*, γ, are trained to minimize the cross-entropy loss:

$$\mathcal{L}(\gamma) = \sum_{x_{[i,j]} \in \mathcal{Q}_{train}} -\log p(y_{[i,j]}; x_{[i,j]}). \tag{11}$$

Inference During inference time, given a novel episode $(\mathcal{S}_{new}, \mathcal{Q}_{new}, \mathcal{Y}_{new})$ for inference, we first leverage the learned model to compute prototypes for all $y_k \in \mathcal{Y}_{new}$ on $\mathcal{S}_{new}$. Then, upon the mention detection model, we inference the entity class for each detected entity span $x_{[i,j]}$ in $\mathcal{Q}_{new}$ by taking the label $y_k \in \mathcal{Y}_{new}$ with the highest probability in Eq. (10):

$$\hat{y}_{[i,j]} = \arg\max_{y_k} p(y_k; x_{[i,j]}). \tag{12}$$

3.2.2 MAML Enhanced ProtoNet

Here, we elaborate on the procedure to integrate the ProtoNet and the model-agnostic meta-learning.

Meta-Training Given a randomly sampled episode $(\mathcal{S}_{train}^{(i)}, \mathcal{Q}_{train}^{(i)}, \mathcal{Y}_{train}^{(i)})$ from $\mathcal{E}_{train}$, for *inner-update*, we first compute prototypes for each entity class in $\mathcal{Y}_{train}$ using $\mathcal{S}_{train}^{(i)}$ via Eq. (9), and then take each span $x_{[i,j]} \in \mathcal{S}_{train}^{(i)}$ as the query item in conventional ProtoNet for gradient update:

$$\gamma'_i = U^n(\gamma; \alpha, \mathcal{S}_{train}^{(i)}), \tag{13}$$

where U^n denotes n-step gradient updates with the learning rate α to minimize the cross-entropy loss $\mathcal{L}(\gamma; \mathcal{S}_{train}^{(i)})$ as in Eq. (11).

As for *meta-update*, we first re-compute prototypes for each entity class in $\mathcal{Y}_{train}^{(i)}$ with γ', *i.e.*, the model parameters obtained from *inner-update*. After that, we perform *meta-update* by evaluating γ' on the query set $\mathcal{Q}_{train}^{(i)}$. We employ the first-order approximation again for computational efficiency. When aggregating gradients from multiple episodes, it could be formulated as:

$$\gamma \leftarrow \gamma - \beta \sum_i \nabla_{\gamma_i'} \mathcal{L}(\gamma_i'; \mathcal{Q}_{train}^{(i)}), \tag{14}$$

Meta-Testing Given $(\mathcal{S}_{new}, \mathcal{Q}_{new}, \mathcal{Y}_{new})$, a novel episode unseen during training, conventional ProtoNet directly adopts the meta-trained model to compute prototypes with $\mathcal{S}_{new}$, and then inference on $\mathcal{Q}_{new}$. Here, we first take the support examples from $\mathcal{S}_{new}$ to fine-tune the meta-learned model γ^* for a few steps in a way the same as Eq. (13), however, the loss is computed on $\mathcal{S}_{new}$. Then, we leverage $\mathcal{S}_{new}$ again to compute prototypes with the fine-tuned model, and further inference the entity class for each detected span in $\mathcal{Q}_{new}$ as in Eq. (12).

4 Experiments

4.1 Settings

4.1.1 Datasets

We conduct experiments to evaluate the proposed approach on two groups of datasets.

Few-NERD (Ding et al., 2021). It is annotated with a hierarchy of 8 coarse-grained and 66 fine-grained entity types. Two tasks are considered on this dataset: i) **Intra**, where all entities in train/dev/test splits belong to different coarse-grained types. ii) **Inter**, where train/dev/test splits may share coarse-grained types while keeping the fine-grained entity types mutually disjoint. [3]

Cross-Dataset (Hou et al., 2020). Four datasets focusing on four domains are used here: CoNLL-2003 (Tjong Kim Sang, 2002) (news), GUM (Zeldes, 2017) (Wiki) , WNUT-2017 (Derczynski et al., 2017) (social), and Ontonotes (Pradhan et al., 2013) (mixed). We take two domains for training, one for validation, and the remaining for test. For fair comparison, we directly use sampled episodes by Hou et al. (2020). For more details of these datasets, please refer to the Appendix A.2.

4.1.2 Evaluation

For evaluation on **Few-NERD**, we employ episode evaluation as in Ding et al. (2021) and calculate the precision (P), recall (R), and micro F1-score (F1) over all test episodes. For evaluation on **Cross-Dataset**, we calculate P, R, F1 within each episode and then average over all episodes as in Hou et al. (2020). For all results, we report the mean and standard deviation based on 5 runs with different seeds.

4.1.3 Implementation Details

We implement our approach with PyTorch 1.9.0[4]. We leverage two separate BERT models for f_θ in Eq. (1) and g_γ in Eq. (7), respectively. Following previous methods (Hou et al., 2020; Ding et al., 2021), we use the BERT-base-uncased model (Devlin et al., 2019). The parameters of the embedding layer are frozen during optimization. We train all models for 1,000 steps and choose the best model with the validation set. We use a batch size of 32, maximum sequence length of 128, and a dropout probability of 0.2. For the optimizers, we use AdamW (Loshchilov and Hutter, 2019) with a 1% linearly scheduled warmup. We perform grid search for other hyper-parameters and select the best settings with the validation set. For more details, please refer to the Appendix A.3.

4.2 Main Results

Baselines For FewNERD, we compare the proposed approach to ESD (Wang et al., 2021a), CONTAINER (Das et al., 2021), and methods from Ding et al. (2021), *e.g.*, ProtoBERT, StructShot, *etc*. For Corss-Dataset, we compare our method to L-TapNet+CDT (Hou et al., 2020) and other baselines from Hou et al. (2020), *e.g.*, TransferBERT, Matching Network, *etc*. Please refer to the Appendix A.4 for more details about baselines.

Results Table 2 and Table 3 report the results of our approach alongside those reported by previous

state-of-the-art methods.[6] It can be seen that our proposed method outperforms the prior methods with a large margin, achieving an performance improvement up to 10.60 F1 scores on Few-NERD (*Intra*, 5way 1∼2 shot) and 19.71 F1 scores on Cross-Dataset (*Wiki*, 5-shot), which well demonstrates the effectiveness of the proposed approach. Table 2 and Table 3 also depict that compared with the results of Few-NERD *Inter*, where the training episodes and test episodes may be constructed with the data from the same domain while still focusing on different fine-grained entity classes, our approach attains more impressive performance in other settings where exists larger transfer gap, *e.g.*, transferring across different coarse entity classes even different datasets built from different domains. This suggests that our approach is good at dealing with difficult cases, highlighting the necessity of exploring information contained in target-domain support examples and the strong adaptation ability of our approach.

4.3 Ablation Study

To validate the contributions of different components in the proposed approach, we introduce the following variants and baselines for ablation study: *1) Ours w/o MAML*, where we train both the mention detection model and the ProtoNet in a conventional supervised manner and then fine-tune with few-shot examples. *2) Ours w/o Span Detector*, where we remove the mention detection step and integrate MAML with token-level prototypical networks. *3) Ours w/o Span Detector w/o MAML*, where we further eliminate the meta-learning procedure from *Ours w/o Span Detector*, and thus becomes the conventional token-level prototypical networks. *4) Ours w/o ProtoNet*, where we directly apply the original MAML algorithm to train a BERT-based tagger for few-shot NER.

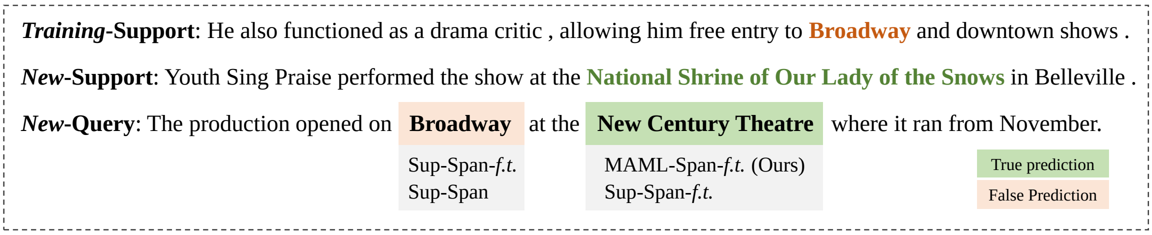
	Intra	**Inter**
Ours	**52.04**	**68.77**
1) Ours w/o MAML	48.76	64.44
2) Ours w/o Span Detector	36.06	53.56
3) Ours w/o Span Detector w/o MAML	23.45	44.44
4) Ours w/o ProtoNet	21.20	45.71

Table 4: Ablation study: F1 scores on Few-NERD 5-way 1∼2-shot are reported.

Table 4 highlights the contributions of each component in our proposed approach. Generally speaking, removing any of them will generally lead to a performance drop. Moreover, we can draw some in-depth observations as follows. 1) *Ours* outperforms *Ours w/o MAML* and *Ours w/o Span Detector* outperforms *Ours w/o Span Detector w/o MAML* in-

---

[6] We also provide the intermediate results, *i.e.*, F1-scores of entity span detection in the Appendix A.5.



***Training*-Support**: He also functioned as a drama critic , allowing him free entry to **Broadway** and downtown shows .

***New*-Support**: Youth Sing Praise performed the show at the **National Shrine of Our Lady of the Snows** in Belleville .

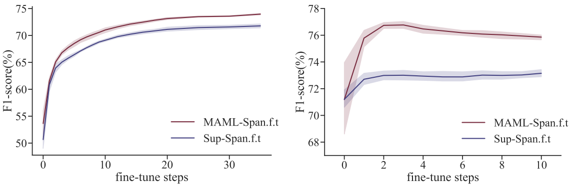
***New*-Query**: The production opened on **Broadway** at the **New Century Theatre** where it ran from November.

Figure 2: Case study of span detection. **Sup-Span**: train a span detector in the fully supervised manner on available data from all training episodes, and then directly use it for span detection. **Sup-Span-f.t.**: further fine-tune the model learned by *Sup-Span* as in the proposed approach.

dicate that exploring information contained in support examples with the proposed meta-learning procedure does bring performance gain for few-shot transfer. 2) *Ours* outperforms *Ours w/o Span Detector* and *Ours w/o MAML* outperforms *Ours w/o Span Detector w/o MAML* demonstrate the essentiality of the decomposed framework (*i.e.*, mention detection and entity typing) to mitigate the problem of noisy prototype for non-entities. 3) Though MAML plays an important role in learning from few-shot support examples, *Ours w/o ProtoNet*, which requires the model to adapt the up-most classification layer without sharing knowledge with training episodes leads to unsatisfactory results, verifying the reasonableness and the effectiveness of our decomposed meta-learning procedure.

How does MAML promote the span detector? To bring up insights on how MAML promotes the span detector, here we introduce two baselines and compare them to our approach by case study. As shown in Figure 2, given a query sentence from a novel episode, *Sup-Span* only predicts a false positive span "Broadway" while missing the golden span "New Century Theatre". Note that "Broadway" appears in training corpus as an entity span, indicating that the span detector trained in a fully supervised manner performs well on seen entity spans, but struggles to detect un-seen entity spans. Figure 2 also shows that both our method and *Sup-Span-f.t.* can successfully detect "New Century Theatre". However, *Sup-Span-f.t.* still outputs "Broadway" while our method can produce more accurate predictions. This shows that though fine-tuning can benefit full supervised model on new entity classes to some extend, it may bias too much to the training data.

We further investigate how performances of aforementioned span detectors vary with different fine-tune steps. As shown in Figure 3, our model (*MAML-Span-f.t.*) consistently outperforms *Sup-Span-f.t.*, suggesting that the proposed meta-learning procedure could better leverage support examples from novel episodes and meanwhile, help the model adapt to new episodes more effectively.



(a) Intra (b) Inter

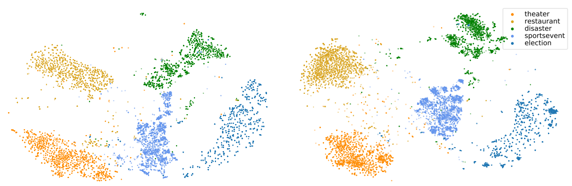
	Intra	**Inter**
Ours (w/ MAML-ProtoNet)	**52.04**	**68.77**
Ours w/ ProtoNet	50.53	67.79

Table 5: Analysis on entity typing under Few-NERD 5-way 1∼2-shot setting. F1 scores are reported. **Ours w/ ProtoNet**: built upon the same span detection model as *Ours*, directly leverage ProtoNet for inference.

How does MAML enhance the ProtoNet? We first compare the proposed MAML-Proto to the conventional ProtoNet based on the same span detector proposed in this paper. Table 5 shows that our MAML-ProtoNet achieves superior performance than the conventional ProtoNet, which verifies the effectiveness of leveraging the support examples to refine the learned embedding space at test time. To further analyze how MAML adjusts the representation space of entity spans and prototypes, we utilize *t-SNE* (van der Maaten and Hinton, 2008) to reduce the dimension of span representations obtained from ProtoNet and MAML-ProtoNet



(a) Proto (b) MAML-Proto

Figure 4: t-SNE visualization of span representations for entity typing on Few-NERD *Intra*, 5-way 5∼10-shot dev set. The representations are obtained from BERT trained with ProtoNet, and our MAML enhanced ProtoNet respectively.

for entity typing, the visualization is shown in Figure 4. We can see that MAML enhanced Proto can cluster span representations of the same entity class while dispersing span representations of different entity classes . Therefore, compared with ProtoNet, it is easier for the proposed MAML-ProtoNet to assign an entity class for a query span by measuring similarities between its representation and the prototype of each entity class.

5 Related Work

Neural NER Modern NER systems usually formulate the NER task as a sequence labeling problem and tackle it by implementing deep neural networks and a token-level classification layer with a conditional random field (Lafferty et al., 2001, CRF) layer on top (Ma and Hovy, 2016; Chiu and Nichols, 2016; Liu et al., 2019; Devlin et al., 2019). Alternative approaches for NER are also proposed to handle the problem based on span classification (Ouchi et al., 2020; Fu et al., 2021), machine reading comprehension (Li et al., 2020b), and sequence generation (Yan et al., 2021).

Few-Shot Learning and Meta-Learning Recently, few-shot learning has received increasing attention in the NLP community (Han et al., 2018; Geng et al., 2019; Chen et al., 2019; Brown et al., 2020; Schick and Schütze, 2021; Gao et al., 2021). and meta-learning has become a popular paradigm for few-shot settings. Typical meta-learning approaches can be divided into three categories: black-box adaption based methods (Santoro et al., 2016), optimization based methods (Finn et al., 2017), and metric learning based methods(Vinyals et al., 2016; Snell et al., 2017). Our work takes advantages of two popular meta-learning approaches, *i.e.*, prototypical network (Snell et al., 2017) and MAML (Finn et al., 2017). The most related work of this paper is Triantafillou et al. (2020), which similarly implements MAML updates over prototypical networks for few-shot image classification.

Few-Shot NER Studies on few-shot NER typically adopt metric learning based approaches at either token-level (Fritzler et al., 2019; Hou et al., 2020; Yang and Katiyar, 2020; Tong et al., 2021) or span-level (Yu et al., 2021; Wang et al., 2021a). Athiwaratkun et al. (2020) and Cui et al. (2021) also propose to address the problem via sequence generation and adapt the model to a new domain within the conventional transfer learning paradigm (training plus finetuning). Differently, Wang et al. (2021b) propose to decompose the problem into span detection and entity type classification to better leverage type description. They exploit a traditional span-based classifier to detect entity spans and leverage class descriptions to learn representations for each entity class. When adapting the model to new domains in the few-shot setting, they directly fine-tune the model with the support examples. In this paper, we propose a decomposed meta-learning based method to handle few-shot span detection and few-shot entity typing sequentially for few-shot NER. The contribution and novelty of our work lie in that: i) Previous work transfers the metric-learning based model learned in source domains to a novel target domain either without any parameter updates (Hou et al., 2020; Wang et al., 2021a) or by simply applying conventional fine-tuning (Cui et al., 2021; Das et al., 2021; Wang et al., 2021b), while we introduce the model-agnostic meta-learning and integrate it with the prevalent prototypical networks to leverage the information contained in support examples more effectively. ii) Existing studies depend on one (Hou et al., 2020) or multiple prototypes (Tong et al., 2021; Wang et al., 2021a) to represent text spans of non-entities (“`O`”) for class inference, while we avoid this problem by only locating named entities during span detection. Moreover, meta-learning has also been exploited in a few recent studies (Li et al., 2020a; de Lichy et al., 2021) for few-shot NER. However, our work substantially differs from them in that we proposed a decomposed meta-learning procedure to separately optimize the span detection model and the entity typing model.

6 Conclusion

This paper presents a decomposed meta-learning method for few-shot NER problem, *i.e.*, sequentially tackle few-shot span-detection and few-shot entity typing using meta-learning. We formulate the few-shot span detection as a sequence labeling problem and employ MAML to learn a good parameter initialization, which enables the model to fast adapt to novel entity classes by fully exploring information contained in support examples. For few-shot entity typing, we propose MAML-ProtoNet, which can find a better embedding space than conventional ProtoNet to represent entity spans from different classes more distinguishably, thus making more accurate predictions. Extensive experiments on various benchmarks show that our approach achieves superior performance over prior methods.

A Appendix

A.1 Meta learning

The goal of meta-learning is to learn to fast adapt to a new few-shot task that is never-seen-before. To train a meta-learning model, a large number of episodes $\mathcal{T}_{train}$ (few-shot tasks) are constructed from training data D_{train}, which usually follows the N-way K-shot task formulation and are used to train the meta-learning model. One episode contains a small training set $\mathcal{S}_{train}$, called support set, and a test set $\mathcal{Q}_{train}$, called query set. The meta-learner generates a task-specific model for a new task $\mathcal{T}_i$ via updating on support set $\mathcal{S}_{train}$, then the task-specific model is tested on $\mathcal{Q}_{train}$ to get a test error. The meta-learner then learns to learn new tasks by considering how to reduce the test error on $\mathcal{Q}_{train}$ by updating on $\mathcal{S}_{train}$. To evaluate the task learning ability of a meta-learner, a bunch of episodes $\mathcal{T}_{test}$ are constructed from the normal test data D_{test}, and the expectation of performance on $\mathcal{Q}_{test}$ from all test episodes is severed as evaluation protocol. To distinguish the training phase of meta-learner on episodes $\mathcal{T}_{train}$ and training of a task-specific model on support set $\mathcal{S}$, the former is called meta-training and the latter is called training. Similarly, the testing of a meta-learner on $\mathcal{T}_{test}$ is called meta-testing, and the evaluating of a task-specific model on query set $\mathcal{Q}$ is called testing.

A.2 Datasets

Table A.1 shows the dataset statistics of original data for constructing few-shot episodes.

Dataset	Domain	# Sentences	# Classes
Few-NERD	Wikipedia	188.2k	66
CoNLL03	News	20.7k	4
GUM	Wiki	3.5k	11
WNUT	Social	5.6k	6
OntoNotes	Mixed	159.6k	18

Table A.1: Evaluation dataset statistics

For Few-NERD, we use episodes released by Ding et al. (2021)[7] which contain 20,000 episodes for training, 1,000 episodes for validation, and 5,000 episodes for testing. Each episode is an N-way K$\sim$2K-shot few-shot task. As for Cross-Dataset, two datasets are used for constructing training episodes, one dataset is used for validation, and episodes from the remained dataset are used for evaluation. We use public episodes[8] constructed by Hou et al. (2020). For 5shot, 200 episodes are used for training, 100 episodes for validation, and 100 for testing. For the 1shot experiment, 400/100/200 episodes are used for training/validation/testing, except for experiments on OntoNotes(Mixed), where 400/200/100 episodes are constructed for train/dev/test.

A.3 Additional Implementation Details

Parameter Setting We use `BERT-base-uncased` from Huggingface Library (Wolf et al., 2020) as our base encoder following Ding et al. (2021). We use AdamW (Loshchilov and Hutter, 2019) as our optimizer with a learning rate of 3e-5 and 1% linear warmup steps at both the meta-training and finetuning in meta-testing time for all experiments. The batch size is set to 32, the max sequence length is set to 128 and we keep dropout rate as 0.1. At meta-training phase, the inner update step is set to 2 for all experiments. When finetuning the span detector at meta-testing phase, the finetune step is set to 3 for all inter settings on Few-NERD dataset and 30 for other experiments. For entity typing, the finetune step at meta-testing phase is set to 3 for all experiments on Few-NERD dataset, 20 for all Cross-Dataset experiments. To further boost the performance, we only keep entities that have a similarity score with its nearest prototype greater than a threshold of 2.5. We set max-loss coefficient λ as 2 at meta-training query set evaluation phase, 5 at other phases. We validate our model on dev set every 100 steps and select the checkpoint with best f1 score performance on dev set within the max train steps 1,000. We use grid search for hyperparameter setting, the search space is shown in Table A.2. The total model has 196M parameters and trains in ≈60min on a Tesla V100 GPU.

Learning rate	{1e-5, 3e-5, 1e-4}
Meta-test fine-tune steps	{3, 5, 10, 20, 30}
Max-loss coefficient λ	{0, 1, 2, 5, 10}
Type similarity threshold	{1, 2.5, 5}
Mini-batch size	{16, 32}

Table A.2: Hyper-parameters search space used in our experiments.

A.4 Baselines

We consider the following metric-learning based baselines:

SimBERT (Hou et al., 2020) applies BERT without any finetuning as the embedding function, then assign each token's label by retrieving the most similar token in the support set .

ProtoBERT (Fritzler et al., 2019) uses a token-level prototypical network (Snell et al., 2017) which represents each class by averaging token representation with the same label, then the label of each token in the query set is decided by its nearest class prototype.

MatchingBERT (Vinyals et al., 2016) is similar to ProtoBERT except that it calculates the similarity between query instances and support instances instead of class prototypes.

L-TapNet+CDT (Hou et al., 2020) enhances TapNet (Yoon et al., 2019) with pair-wise embedding, label semantic, and CDT transition mechanism.

NNShot (Yang and Katiyar, 2020) pretrains BERT for token embedding by conventional classification for training, a token-level nearest neighbor method is used at testing.

StructShot (Yang and Katiyar, 2020) improves NNshot by using an abstract transition probability for Viterbi decoding at testing.

ESD (Wang et al., 2021a) is a span-level metric learning based method. It enhances prototypical network by using inter- and cross-span attention for better span representation and designs multiple prototypes for O label.

Besides, we also compare with the finetune-based methods:

TransferBERT (Hou et al., 2020) trains a token-level BERT classifier, then finetune task-specific linear classifier on support set at test time.

CONTAINER (Das et al., 2021) uses token-level contrastive learning for training BERT as token embedding function, then finetune the BERT on support set and apply a nearest neighbor method at inference time.

A.5 Results of Span Detection

Table A.3 and Table A.4 show the performance of our span detection module on Few-NERD and Cross-Dataset.

Models	**1∼2-shot**		**5∼10-shot**	
	5 way	10 way	5 way	10 way
Intra	73.69±0.14	74.32±1.84	77.76±0.24	78.66±0.15
Inter	76.71±0.30	76.63±0.24	75.97±0.14	76.62±0.11

Table A.3: F1 scores of our entity span detection module on **Few-NERD** for both inter and intra settings.

Models	**News**	**Wiki**	**Social**	**Mixed**
1-shot	65.06±0.91	35.63±2.17	38.89±0.55	46.52±1.24
5-shot	74.20±0.33	46.26±1.28	43.16±1.23	54.70±0.88

Abstract

Generating natural and informative texts has been a long-standing problem in NLP. Much effort has been dedicated into incorporating pre-trained language models (PLMs) with various open-world knowledge, such as knowledge graphs or wiki pages. However, their ability to access and manipulate the task-specific knowledge is still limited on downstream tasks, as this type of knowledge is usually not well covered in PLMs and is hard to acquire. To address the problem, we propose augmenting TExt Generation via Task-specific and Open-world Knowledge (TEGTOK) in a unified framework. Our model selects knowledge entries from two types of knowledge sources through dense retrieval and then injects them into the input encoding and output decoding stages respectively on the basis of PLMs. With the help of these two types of knowledge, our model can learn what and how to generate. Experiments on two text generation tasks of dialogue generation and question generation, and on two datasets show that our method achieves better performance than various baseline models.

1 Introduction

Enabling natural models to generate natural and informative sequences is a challenging yet intriguing problem of artificial intelligence and has attracted increasing attention due to its promising potentials and alluring commercial values (Bahdanau et al., 2015; Du et al., 2017; Kepuska and Bohouta, 2018; Berdasco et al., 2019; Zhou et al., 2020; Gehrmann et al., 2021). Thanks to the achievements on neural sequence modeling and pre-training technologies, current generative models are able to generate nature and fluency target sequences using either encoder-decoder architectures (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) or language models (Radford et al., 2019; Brown et al., 2020; Lewis et al., 2020a) Despite these methods being the state-of-the-art frameworks for NLG, they are often provided limited knowledge to generate the desired output. Thus, the performance of text generation is still far from satisfaction in many real-world scenarios (Yu et al., 2020a).

Recently, much effort has been dedicated into incorporating traditional generative models or pre-trained language models (PLMs) with a variety of open-world knowledge, such as structural knowledge bases (e.g., ConceptNet) (Speer and Havasi, 2012; Speer et al., 2017) or unstructured documents (e.g., documents from Wikipedia) (Zhou et al., 2018c; Dinan et al., 2019). By providing the supplementary knowledge of an entity mentioned within or the background knowledge of a source text, it can help to better understand the input text and its surrounding context, and to ameliorate the informativeness of the generated text.

Although the open-world knowledge brings improvement to the generation process in most cases, its effect is still limited to the cases involving fewer entities or abstract semantics. On the other hand, the process of generating text by humans is often grounded by more than one single type of knowledge perception. In addition to world knowledge, the task-specific knowledge also acts as an important information source, and is usually not well covered in PLMs and is hard to acquire through fine-tuning. For example, in dialogue systems, what people have said or responded before can be reused as an important knowledge source, where these utterances talked before can be retained as the task-related knowledge in the mind of an interlocutor; for question generation, what part of a document makes people curious most and then ask specific questions, can often get enlightened by the existing questions raised from their corresponding passages. Intuitively, these related task-specific examples can bring additional information associated with the given source mes-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1597 - 1609
May 22-27, 2022

sages and provide exemplary information for neural generative models, but this useful information source is neglected in previous studies.

On account of the above issues, we propose augmenting TExt Generation via Task-specific and Open-world Knowledge (TEGTOK). Specifically, the world knowledge is assumed to be *unstructured Wikipedia documents* that provide supplementary information of an entity mentioned within or background knowledge of an input sequence. The task-specific knowledge is a pre-built index that is domain-relevant and acts as an exemplary information source for guiding text generation. It can be flexibly adjusted according to different tasks or domains, e.g., context-response pairs in dialogue generation or passage-question pairs in question generation. Inspired by the success of dense retrieval methods for the task of open-domain question answering (Lee et al., 2019; Guu et al., 2020; Karpukhin et al., 2020), we use pre-trained encoders to convert input texts and knowledge entries into dense representation vectors and employ fast maximum inner-product search (MIPS) (Shrivastava and Li, 2014) to complete the retrieval, so as to ensure effectiveness and efficiency of knowledge selection. Finally, these two types of knowledge are injected into source text encoding and target text decoding stages respectively. By this means, our model can learn how and what to generate in a unified framework with the help of two types of knowledge.

To measure the effectiveness of our proposed framework, we evaluate it on the tasks of dialogue generation and question generation, which are both important research issues of text generation. Experimental results show that our proposed method outperforms the GPT-2 (Radford et al., 2019) and BART (Lewis et al., 2020a) baseline models, and can generate more informative texts including entities that do not appear in the input texts.

In summary, our contributions in this paper are three-fold: (1) A proposal of a general and unified text generation framework named TEGTOK that incorporates both task-specific and world knowledge through dense retrieval. (2) The proposed framework is verified on two text generation tasks.

2 Related Work

Knowledge-enhanced Text Generation. As knowledge can help to understand the input text and its surrounding context, many previous studies explored the leverage of knowledge bases (Speer and Havasi, 2012; Speer et al., 2017; Koncel-Kedziorski et al., 2019; Liu et al., 2021) or unstructured texts (Zhang et al., 2018; Zhou et al., 2018c; Dinan et al., 2019; Lewis et al., 2020b) for the text generation task, and they have demonstrated promising performance on generating informative and coherent texts. To incorporate unstructured knowledge from the web, retrieval-augmented text generation (Lewis et al., 2020b) has been widely explored. Besides, researchers also introduced the paradigm of retrieve-and-edit (Hashimoto et al., 2018; Wu et al., 2019; Ren et al., 2020) or exemplar-based decoding (Peng et al., 2019; Gupta et al., 2020) to enhance the generation processes with similar input-output pairs come from the specific task. More related works about knowledge-enhanced text generation can be referred to Yu et al. (2020b).

Dialogue Generation. The generation-based dialogue models synthesize a response with a NLG model by maximizing its generation probability given the previous conversation context. The pioneer researchers formulated the dialogue generation task as a sequence-to-sequence translation problem (Shang et al., 2015; Sordoni et al., 2015; Vinyals and Le, 2015; Serban et al., 2016, 2017) where encoder is designed for dialogue context modeling, and decoder is constructed to conduct the target response prediction. Expanded from the general dialogue generation problem, more interesting and challenging tasks relying on external knowledge have been explored to improve the anthropomorphic characteristic of dialogue systems. A line of work introduced personalized information into dialogue generation to help deliver better dialogue response such as emotion (Li and Sun, 2018; Zhou et al., 2018a; Song et al., 2019) and persona (Zhang et al., 2018; Zheng et al., 2020). In addition, to further enhance and enrich the response generation, researchers have studied grounding dialogue generation on knowledge graphs (Zhou et al., 2018b; Moon et al., 2019) or unstructured documents (Dinan et al., 2019; Zhang et al., 2018; Zhou et al., 2018c; Santhanam et al., 2020; Tan et al., 2021).

Question Generation. This task aims at generating a question from a given passage (Du et al., 2017) in an answer-aware or answer-unaware manner. In this paper, we work on the answer-unaware setting, encouraging diversity of generated questions. Researchers have explored statistical keyword extraction techniques to select salient words from input documents, and then incorporated the extracted keywords into question generation (Cho et al., 2019; Wang et al., 2020) Recent work has applied reinforcement learning to natural question generation (Chen et al., 2020).

Different from previous text generation models that either incorporate unstructured Wikipedia knowledge or enhance the generation with exemplar cases, to the best of our knowledge, this paper makes the first attempt to retrieve and exploit both the task-specific and world knowledge for text generation in a unified framework. Our knowledge retrieval process is conducted through dense representations which can help to capture deep and latent semantics.

3 Method Formulation

The task of text generation is to output an appropriate target text given a source text as input. Given a dataset $\mathcal{D}$, an example is represented as (s, t). Specifically, s represents a source text and t represents a target text. A source text is used as a query to retrieve task-specific and world knowledge. Technically, the retrieved task-specific and world knowledge entries can be treated as two latent variables z_1 and z_2 respectively that are marginalized to get the Seq2Seq probability $p(t|s)$ via a top-*m* approximation as

$$\begin{aligned} p(t|s) &= \sum_{z_1,z_2} p_1(z_1|s)p_2(z_2|s)p_\theta(t|s,z_1,z_2) \\ &= \sum_{z_1,z_2} p_1(z_1|s)p_2(z_2|s)\prod_{t=1}^{|y|} p_\theta(t_j|s,z_1,z_2,t_{<j}), \end{aligned} \tag{1}$$

where $z_1 \in \text{top-}m(p_1(\cdot|s))$, $z_2 \in \text{top-}m(p_2(\cdot|s))$, t_j and $t_{<j}$ stand for the j-th token and the first $(j-1)$ tokens of a target text t respectively, $|t|$ is the length of t, and the target text tokens are generated in an auto-regressive way. $p_1(\cdot|s)$ and $p_2(\cdot|s)$ are modeled with the retrieval probability that will be introduced in Eq. (2).

4 TEGTOK Model

Figure 1 shows the overview architecture of TEGTOK which consists of a *retriever* and a *generator*. The retriever uses the input source text as a query to retrieve the world knowledge and task-specific knowledge, the former of which is concatenated with the source text as additional background knowledge and the latter is fed into the decoder as exemplary information to guide the target text decoding. Details about each component are provided in the following subsections.

4.1 Knowledge Retriever

As shown in Figure 1(a), given a collection of a large number of knowledge entries (k_i^α), the goal of the retriever is to index all knowledge entries in a low-dimensional and continuous space, so that it can retrieve efficiently the top-*m* knowledge entries relevant to the input source text. Here, $\alpha \in$ {world knowledge (W), task-specific knowledge (T)}. Inspired by the dense passage retrieval (DPR) (Karpukhin et al., 2020), we adopt a bi-encoder architecture to derive the dense representations of the source text and each knowledge entry. Specifically, two independent pre-trained language models (i.e., BERT (Devlin et al., 2019)), $E_S^\alpha(\cdot)$ and $E_K^\alpha(\cdot)$ are employed as the encoders for the source text and the knowledge entry respectively. Furthermore, the representation of the `[CLS]` token is output as the dense representation. At retrieval-time, the retriever first maps the input source text to a vector, and then retrieves knowledge entries of which vectors are the closest to the source text vector. The similarity $s(s, k_i^\alpha)$ between the source text s and each knowledge entry k_i^α is defined using the dot product of their vectors as

$$s(s, k_i^\alpha) = E_S^\alpha(s)^\top \cdot E_K^\alpha(k_i^\alpha), i \in \{1, 2, ...\}. \tag{2}$$

Due to the significant difference between the two types of knowledge, we employ two independent retrievers for these two knowledge indexes.

World Knowledge Retriever World knowledge usually covers a wide variety of domains and has been proven effective in improving informativeness of the generated texts through providing the relevant background knowledge in open-domain text generation (Dinan et al., 2019; Zhao et al., 2020). Motivated by the success of open-domain question answering (QA) (Guu et al., 2020; Karpukhin et al., 2020; Lee et al., 2019), we assume the open-world knowledge as documents from the Wikipedia dump. Specifically, we adopt the Wikipedia dump provided in open-domain QA tasks as our open-world knowledge which is composed of over 21 millions of passages segmented from the Wikipedia pages. The goal of this retriever is to retrieve a small number of documents relevant

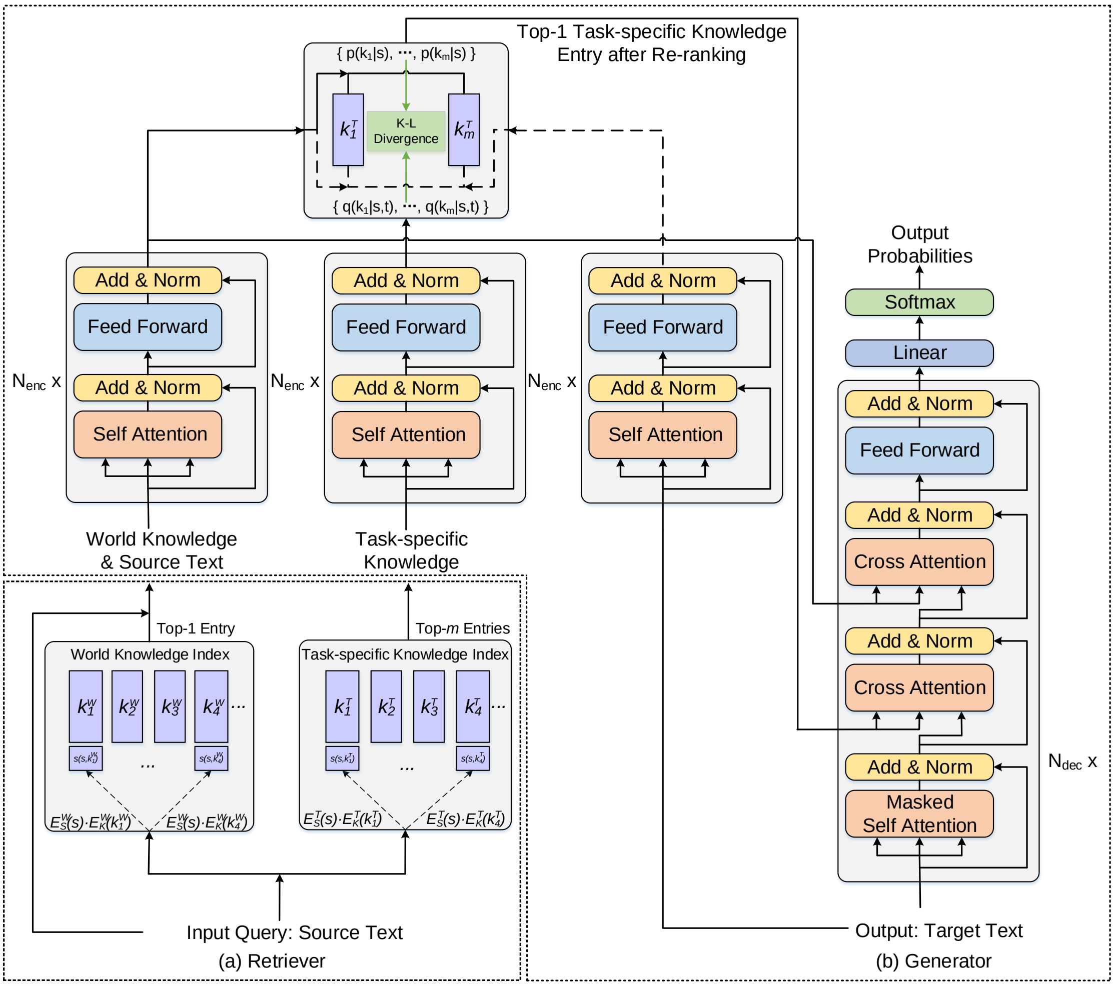

Figure 1: The overview architecture of our proposed TEGTOK model which consists of (a) a retriever and (b) a generator. Here, $E^{\alpha}_{\beta}(\cdot)$ denotes the dense representation of an input sequence, where $\alpha \in \{$world knowledge (*W*), task-specific knowledge (*T*)$\}$ and $\beta \in \{$source text (*S*), knowledge (*K*)$\}$.

to the given source text. Meanwhile, we use the DPR model which is a pre-trained bi-encoder released by Karpukhin et al. (2020) as the world knowledge retriever in our paper, since it has achieved great performance on various knowledge-intensive tasks.[1] The retrieved top-1 Wikipedia document (k^W) is employed for augmenting source text which will be described in Section 4.2.

Task-specific Knowledge Retriever In addition to the world knowledge, it would also be desirable to obtain the relevant task-specific knowledge to guide the text generation process, since open-domain texts are often grounded by more than one single type of knowledge perception. These related task-specific examples from a pre-built index can also bring additional information associated with the given source messages and provide exemplary information for guiding the target text decoding.

Formally, given a training example represented as $(s, t^+, t_1^-, ..., t_n^-)$, where each instance contains one source text s and one matched (positive) target text t^+, along with n mismatched (negative) distractors t_i^- that are randomly sampled from the whole corpus, we can define the training objective function of the task-specific knowledge retriever as

$$\begin{aligned} & L(s, t^+, t_1^-, ..., t_n^-) \\ & = -\log \frac{e^{s(s,t^+)}}{e^{s(s,t^+)} + \sum_{i=1}^{n} e^{s(s,t_i^-)}}. \end{aligned} \tag{3}$$

At testing time, the model retrieves the top-*m* knowledge entries (k^T) with the highest similarities calculated by Eq. (2).

4.2 Generator

It is based on the pre-trained Transformer-based encoder-decoder architecture, BART (Vaswani et al., 2017). To incorporate both types of knowl-

---

[1] https://github.com/facebookresearch/DPR

edge during the source text encoding and the target text decoding stages respectively, we make several modifications as follows.

Augmented Source Text Encoder In order to incorporate the world knowledge into the source text encoding stage, we concatenate the source text with the retrieved world knowledge entry. Formally, the input sequence is organized as $\{\texttt{[BOS]}, k_1^W, ..., k_{l_{kW}}^W \texttt{[EOS]}, s_1, ..., s_{l_s}, \texttt{[EOS]}\}$, where `[BOS]` and `[EOS]` denote *begin-of-sentence* and *end-of-sentence*, $k_1^W, ..., k_{l_{kW}}^W$ and $s_1, ..., s_{l_s}$ denote the knowledge and source text tokens, and l_{kW} and l_s denote the token numbers of knowledge and source text respectively. Then the input sequence is fed into the stacked attention layers (Vaswani et al., 2017; Lewis et al., 2020a) by employing itself as *query*, *key* and *value* as

$$\mathbf{S}^{l+1} = \textsc{AttenLayer}(\mathbf{S}^l), \tag{4}$$

where $l \in \{0, ..., L-1\}$ and each AttenLayer includes operations of a self-attention layer and a feed forward layer, both of which are followed by a residual connection and a layer normalization. $\mathbf{S}^l \in \mathbb{R}^{(l_{kW}+l_s+3)\times d}$ denotes the representation of the concatenated source text and world knowledge at the *l*-th encoder layer, and d denotes the dimension of the embedding vector. The outputs of each encoder layer are utilized as the inputs of the next encoder layer. In each layer of encoding, the world knowledge serves as additional background and fully interacts with the source text to incorporate the relevant information into their representations through multi-head attention operations. After stacked layers of encoding, it can help to better understand the source text and return the contextualized representations, which will be further used during the decoding stage.

Task-specific Knowledge Encoder Different from the BERT-based encoding in Section 4.1 for retrieval, another encoder that is a component of the generator, is designed to encode the task-specific knowledge to derive its contextualized representations for generation. Formally, each of the retrieved top-*m* task-specific knowledge entries is organized as $\{\texttt{[BOS]}, k_{i,1}^T, ..., k_{i,l_i^T}^T, \texttt{[EOS]}\}, i \in \{1, ..., m\}$.[2] Then the input sequence is fed into another encoder that does not share parameters with the augmented source text encoder. Finally, we denote $\mathbf{K}_i^{T,l}$ as the representation of the i-th task-specific knowledge at the *l*-th encoder layer.

Task-specific Knowledge Re-ranking Since the target text cannot be foreseen at testing time, a latent variable model (Zhao et al., 2017; Lian et al., 2019; Kim et al., 2020) is introduced to select the target text by treating it as the posterior information. However, it is inefficient to calculate the prior and posterior probabilities in a large-scale dataset. Therefore, a task-specific knowledge re-ranking is designed for the top-*m* knowledge entries output by the knowledge retriever. In general, to further calculate the similarity between each task-specific knowledge and the target text at a fine granularity, the target text is used for re-ranking the set of retrieved task-specific knowledge entries. The target text is encoded to acquire its representation, and then combined with the representation of the augmented source text to get the posterior representation, followed by a linear transformation as

$$\mathbf{c}(s,t) = \mathbf{W}_c[\mathbf{s}_{\texttt{[BOS]}}^L; \mathbf{t}_{\texttt{[BOS]}}^{L'}] + \mathbf{b}_c, \tag{5}$$

where $\mathbf{s}_{\texttt{[BOS]}}^L$ and $\mathbf{t}_{\texttt{[BOS]}}^{L'}$ denote the outputs of the augmented source encoder and the target encoder corresponding to the `[BOS]` token, $\mathbf{W}_c$ and $\mathbf{b}_c$ are parameters updated during training. The similarity between this representation and the representation of each task-specific knowledge entry is calculated to obtain the probability distribution of re-ranking,

$$q_\phi(k_i^T|s,t) = \mathrm{softmax}(\mathbf{c}(s,t) \cdot \mathbf{k}_{i,\texttt{[BOS]}}^{T,L}), \tag{6}$$

for $i \in \{1, ..., m\}$. In order to accommodate the situation where the target text is not available when testing, the prior probability is calculated as

$$p_\theta(k_i^T|s) = \mathrm{softmax}(\mathbf{s}_{\texttt{[BOS]}}^L \cdot \mathbf{k}_{i,\texttt{[BOS]}}^{T,L}), \tag{7}$$

for $i \in \{1, ..., m\}$. Finally, two probability distributions of $q_\phi(\boldsymbol{k}^T|s,t)$ and $p_\theta(\boldsymbol{k}^T|s)$ are approximated in a way optimizing KL divergence as

$$\mathcal{L}_{kl} = \mathbb{E}_{q_\phi(\boldsymbol{k}^T|s,t)} \log \frac{q_\phi(\boldsymbol{k}^T|s,t)}{p_\theta(\boldsymbol{k}^T|s)}. \tag{8}$$

The bag-of-words (BOW) loss (Zhao et al., 2017) is introduced to facilitate the training process as

$$\mathcal{L}_{bow} = -\mathbb{E}_{k^T \sim q_\phi(\boldsymbol{k}^T|s,t)} \sum_{j=1}^{l_t} \log p(t_j|k^T), \tag{9}$$

---

[2] We did study concatenating the source text with the task-specific knowledge as well, but no further improvement can be achieved.

where $p(t_j|k^T)$ denotes the estimated probability of word t_j calculated by

$$p(\cdot|k^T) = \mathrm{softmax}(\mathbf{W}_{\texttt{bow}}\mathbf{k}^{T,L}_{\texttt{[BOS]}} + \mathbf{b}_{\texttt{bow}}), \quad (10)$$

where $\mathbf{k}^{T,L}_{\texttt{[BOS]}}$ denote the outputs of the knowledge encoder corresponding to the `[BOS]` token of the selected knowledge, $\mathbf{W}_{\texttt{bow}}$ and $\mathbf{b}_{\texttt{bow}}$ are parameters updated during training.

Decoder In order to inject all the encoded information of the source text, the world knowledge and the task-specific knowledge to guide the target text decoding, two additional sub-layers are inserted into each decoder layer, which perform cross-attention over the output of the last layer of the two encoders. Particularly, after a sub-layer of masked self-attention where each token cannot attend to future tokens to avoid information leakage, the target text first attends to the output of the task-specific knowledge encoder and then attends to the output of the augmented source text encoder. Mathematically, we have

$$\begin{aligned}
\bar{\mathbf{T}}^l &= \mathrm{LN}\Big(\mathbf{T}^l + \textsc{SelfAtten}(\mathbf{T}^l)\Big), \\
\tilde{\mathbf{T}}^l &= \mathrm{LN}\Big(\bar{\mathbf{T}}^l + \textsc{CrossAtten}(\bar{\mathbf{T}}^l, \mathbf{K}^{T,L})\Big), \\
\hat{\mathbf{T}}^l &= \mathrm{LN}\Big(\tilde{\mathbf{T}}^l + \textsc{CrossAtten}(\tilde{\mathbf{T}}^l, \mathbf{S}^L)\Big), \\
\mathbf{T}^{l+1} &= \mathrm{LN}\Big(\hat{\mathbf{T}}^l + \textsc{FeedForward}(\hat{\mathbf{T}}^l)\Big),
\end{aligned} \quad (11)$$

where $l \in \{0, \cdots, L-1\}$, LN denotes the operation of layer normalization, $\mathbf{T}^l$ denotes the representation of the target text at the l-th decoder layer, $\bar{\mathbf{T}}^l$, $\tilde{\mathbf{T}}^l$ and $\hat{\mathbf{T}}^l$ are intermediate representations after each operation. In this way, the model can first learn *how to generate* and consider the retrieved task-specific knowledge as exemplary information. The model can further learn *what to say* according to the retrieved world knowledge that is used to augment the source text and enrich the exemplary information.

4.3 Learning

Given the representation of each target text token at the last decoder layer $\mathbf{T}^L = \{\mathbf{t}_j\}_{j=1}^{l_t}$ where $\mathbf{t}_j \in \mathbb{R}^d$, the probability distribution over the whole vocabulary of each target text token $\mathbf{p}_{t_j}$ can be calculated via a non-linear transformation. The learning objective of this task is to minimize the negative log-likelihood loss as

$$\mathcal{L}_{gen} = -\mathbb{E}_{k^T\sim q_\phi(\boldsymbol{k}^T|s,t)} \sum_{j=1}^{l_t} \log p(t_j|s, t_{<j}, k^T). \quad (12)$$

Finally, the parameters of our model are optimized by performing multi-task learning by minimizing the sum of all loss functions as

$$\mathcal{L}_{total} = \mathcal{L}_{gen} + \mathcal{L}_{kl} + \mathcal{L}_{bow}. \quad (13)$$

5 Experiments

We evaluated the proposed method on the tasks of dialogue generation and question generation.

5.1 Knowledge and Datasets

World Knowledge Index. For the world knowledge, all tasks and datasets shared the same English Wikipedia dump from Dec. 20, 2018 provided by Lee et al. (2019). Each Wikipedia article was split into disjoint 100-word chunks to make a total of 21M documents. Each passage was also prepended with its title, along with an `[SEP]` token.

Reddit Dataset for Dialogue Generation. To construct the task-specific knowledge index for this dataset, the Reddit dialogue corpus collected by Zhou et al. (2018b) was used. 3 millions responses were randomly sampled from the training set of the Reddit dataset. After excluding the samples used for constructing the task-specific knowledge index, the remaining dataset composed of 38.4k/10k/20k context-response pairs in the training/validation/testing sets respectively, was employed to train a generator and to evaluate the performance of our framework. Thus, there is no data overlap between that for the task-specific knowledge index and that for learning a generator.

SQuAD Dataset for Question Generation. Similarly, 45k randomly selected sentence-question pairs from the training set of the SQuAD Dataset processed by Du et al. (2017) were used to construct the task-specific knowledge index for this dataset. Also, the remaining dataset composed of 25.5k/10.5k/11.9k sentence-question pairs in the training/validation/testing sets respectively, was employed to train the generator.

5.2 Baseline Models

The following models were selected as the baseline models: **(1) RNN** (Sutskever et al., 2014) is a

Models \ Metrics	BLEU-1	BLEU-2	METEOR	ROUGE$_L$	Average	Greedy	Extrema
RNN (Sutskever et al., 2014)	7.36	2.94	7.28	10.03	0.6591	2.0585	0.3331
CVAE (Zhao et al., 2017)	7.45	2.85	7.34	9.68	0.6642	2.0853	0.3357
Transformer (Vaswani et al., 2017)	7.97	3.14	7.92	10.51	0.6693	2.0703	0.3334
GPT-2 (Radford et al., 2019)	8.43	3.04	8.33	10.65	0.6484	2.0601	0.3303

Models \ Aspects	Rel.	Flu.	Inform.	Kappa
Human	1.40	1.64	1.47	0.62
Transformer	0.86	1.07	0.71	0.42
GPT-2	1.09	1.20	0.84	0.43
BART	1.36	1.48	1.14	0.47
TEGTOK	1.44	1.51	1.23	0.46

Table 3: Human evaluation results of TEGTOK on a randomly sampled test set of the Reddit dataset. Here, Rel., Flu., and Inform. indicates relevance, fluency, and informativeness respectively.

LSTM-based sequence-to-sequence model with attention mechanism. **(2) CVAE** (Zhao et al., 2017) uses latent variables to learn a distribution over potential conversation contexts based on conditional variational autoencoders. **(3) Transformer** (Vaswani et al., 2017) uses the self-attention mechanism to build the encoder and the decoder, which has shown better performance than RNN-based Seq2Seq models in many natural language processing tasks. **(4) GPT-2** (Radford et al., 2019) is a uni-directional pre-trained language model that has shown great performance on a lot of natural language generation tasks. Following its original concatenation operation, the context and the response were concatenated with a special `[SEP]` token as input for encoding. **(5) DialoGPT** (Zhang et al., 2020) has the same architecture with GPT-2 but is trained with Reddit discussions Datasets. **(6) BART** (Lewis et al., 2020a) is a denoising autoencoder using a standard Tranformer-based neural machine translation architecture for pre-training the sequence-to-sequence models. BART is trained by corrupting text with an arbitrary noising function to reconstruct the original text.

5.3 Evaluation Metrics

To ensure all experimental results were comparable, the automated and human evaluation metrics popular used in previous work were adopted in this paper. BLEU, METEOR, ROUGE$_L$ and three embedding-based metrics including Embedding Average, Greedy Matching and Extrema Score used in Forgues et al. (2014) which can cover the weaknesses of BLEU were employed as the automated metrics. Human evaluation was also conducted to measure the quality of the generated responses of models in terms of three independent aspects: 1) relevance (Rel.), 2) fluency (Flu.) and 3) informativeness (Inform.). Each judge was asked to give three scores for a response, each of which was ranged from 0 to 2.

5.4 Training Details

Model parameters were initialized with pre-trained weights of *bart-base* released by Wolf et al. (2020). The word embedding table was shared between the encoder and decoder. The AdamW method (Loshchilov and Hutter, 2019) was employed for optimization. The learning rate was initialized as $6.25e$-5 and was decayed linearly down to 0. The max gradient norm was clipped down to 1.0. The batch size was set to 64. The maximum length of the concatenation of open-domain knowledge and context was set to 128. The maximum length of the task-specific knowledge was set to 128. The number of task-specific knowledge entries was set to 3, achieving the best performance out of $\{1, 2, 3, 4, 5\}$ on the validation set. The strategy of greedy search was performed for decoding. The maximum length of response to generate was also set to 50. All experiments were run on a single A100 GPU. The maximum number of epochs was set to 15. The validation set was used to select the best model for testing. All code was implemented in the PyTorch framework[3] and are published to help replicate our results. [4]

5.5 Evaluation Results

Automated Evaluation Table 1 and Table 2 present the evaluation results of our method and previous methods on the test sets of the Reddit dataset for dialogue generation and the SQuAD dataset for question generation respectively. Each model ran four times with identical architectures and different random initializations, and the best out of them was reported. The results show that our method outperformed all baseline models in terms of all metrics. Specifically, TEGTOK outperformed GPT-2 by 1.28% BLEU-1 and 1.20% METEOR, outperformed DialoGPT by 2.13% BLEU-1 and 1.68% METEOR, and outperformed BART by 0.47% BLEU-1 and 0.50% METEOR on the Reddit dataset. Meanwhile, TEGTOK outperformed BART by 1.41% BLEU-1 and 0.67% METEOR on the SQuAD dataset, illustrating the effectiveness of incorporating both two types of knowledge.

To further verify the effectiveness of each component in our proposed methods, ablation tests were conducted as shown in the last two rows of Table 1 and Table 2. First, the world knowledge was ablated and the results show that BLEU-1 and METEOR dropped down by 0.27% and 0.26% respectively on the Reddit dataset, along with 0.32% and 0.27% respectively on the SQuAD dataset, illustrating the effectiveness of retrieving world knowledge for text generation. On the other hand, the task-specific knowledge was ablated and only the world knowledge can be attended to during the decoding stage. The results show that BLEU-1 and METEOR dropped down by 0.24% and 0.34% respectively on the Reddit dataset, along with 0.94% and 0.58% respectively on the SQuAD dataset, illustrating the effectiveness of attending to task-specific knowledge during the decoding stage.

Human Evaluation Table 3 presents the human evaluation results on a randomly sampled test set of the Reddit dataset. 100 samples were evaluated and the order of evaluation systems were shuffled. Three judges were asked to score from 0 to 2 (2 for the best) for each human evaluation aspect and the average scores were reported. The Fleiss's kappa value (Fleiss, 1971) for each model was also reported, indicating the inter-judge moderate agreement during evaluation. In general, the results show that our method outperformed all baseline models, showing that it can generate more natural responses. Particularly, compared with BART, our method achieves the greatest improvement in terms of informativeness, illustrating the effectiveness of incorporating the task-specific and world knowledge for improving informativeness of generated texts.

5.6 Case Study

Case studies were conducted by randomly sampling an instance from the Reddit dataset in dialogue generation and an instance from the SQuAD dataset in question generation as shown in Table 4. Given the conversation context (or the passage of a question), it was used as a query to retrieve the task-specific and world knowledge in the upper block of a single case in Table 4. For case 1, as we can see that, there was no text overlap between the second task-specific knowledge entry and the conversation context, but it can be retrieved

---

Case 1
Context: whatever happened to al qaeda? **WK**: Al-Qaeda operates as a network of Islamic extremists and Salafist jihadists. The organization has been designated as a terrorist group by the United Nations Security Council, ... The Taliban provided a safe haven for Osama bin Laden and al-Qaeda officials, allowing them to plot major terrorist attacks such as the September 11 attacks (9/11). ... **TK**: isis first iteration was al - qaeda in iraq.
Transformer: i 'm not sure what you 're talking about , but i 'm not sure if you 're referring to what you 're talking about. **GPT-2**: i think he was a member of the al qaeda branch. **DialoGPT**: they're still around. **BART**: i'm not sure. i'm sure the media is talking about the death of the leader of the country. **TegTok**: they're a terrorist organization in iraq plot major attacks.
Case 2
Passage: in late summer he was invited by jane stirling to visit scotland , where he stayed at calder house near edinburgh and at johnstone castle in renfrewshire , both owned by members of stirling 's family . **WK**: ... After this, in 1860 Stirling returned to Edinburgh - his address there was 4 Laverock Bank Road, Trinity, Edinburgh - which then became his permanent residence until ... **TK**: where did victoria and her family retreat to safety during a conflict in 1848?
BART: where was johnstone castle? **TegTok**: where did stirling stay in the summer of 1860?

Table 4: Generation results of two cases from the Reddit and SQuAD datasets respectively. We kept original texts without manual corrections. WK and TK denote world knowledge and task-specific knowledge respectively. Words in the same color are related.

through semantic relevance, which shows the effectiveness of using dense representations for knowledge retrieval. Since the given context is short and contains few informative words, it is difficult for models to generate informative responses without any external knowledge, such as the generic response generated by the Transformer model. Furthermore, our generated response can capture the relevant and important information from the retrieved knowledge, such as "*terrorist*" from the world knowledge and "*in iraq*" from the task-specific knowledge, making the generated response more informative and illustrating the effectiveness of incorporating these two types of knowledge for dialogue generation. For case 2, we can see that there was little text overlap between the world knowledge and the passage, but it could be retrieved through semantic relevance, showing the effectiveness of using dense representations for knowledge retrieval. Our generated text can capture the relevant and important information from the retrieved world knowledge, such as "*1860*" and "*Stirling*" from the world knowledge, making the generated text more informative. Furthermore, since the given passage mainly focuses on narrative descriptions, it is difficult for models to generate exemplar texts without any external knowledge, such as the "*where did ... in*" question template retrieved from the task-specific knowledge index. Again, these results illustrated the effectiveness of incorporating these two types of knowledge for question generation.

6 Conclusion

In this paper, we study retrieving relevant external knowledge for enhancing text generation. Two types of knowledge, i.e., task-specific and world knowledge, are retrieved using dense representations to ensure effectiveness and efficiency of knowledge selection, and are further incorporated into the input encoding and output decoding stages respectively, providing the supplementary information to guide text generation. Experimental results on two tasks of dialogue generation and question generation show that our method achieves better performance than baseline models and can generate more informative texts. In the future, we will explore applying this framework to more text generation tasks and other modalities such as image caption, to further verify its effectiveness and generalization.

Abstract

Emotion recognition in conversation (ERC) aims to analyze the speaker's state and identify their emotion in the conversation. Recent works in ERC focus on context modeling but ignore the representation of contextual emotional tendency. In order to extract multi-modal information and the emotional tendency of the utterance effectively, we propose a new structure named Emoformer to extract multi-modal emotion vectors from different modalities and fuse them with sentence vector to be an emotion capsule. Furthermore, we design an end-to-end ERC model called EmoCaps, which extracts emotion vectors through the Emoformer structure and obtain the emotion classification results from a context analysis model. Through the experiments with two benchmark datasets, our model shows better performance than the existing state-of-the-art models.

1 Introduction

Emotion recognition in conversation (ERC) is a work that recognizes the speaker's emotion and its influencing factors in the process of conversation. Nowadays, social media such as Facebook and Twitter generate a large amount of dialogue data with various modalities of textual, audio, and video all the time. The study of speaker emotional tendency has huge potential value in the fields of public opinion analysis, shopping, and consumption. Therefore, conversation emotion recognition has attracted more and more attention from researchers and companies.

In ERC, existing research mainly focuses on the way of contextual information modeling (Majumder et al., 2019; Ghosal et al., 2019). However, These models have some shortcomings due to their inability to better extract the grammatical and semantic information of the utterance. Recent studies (Yuzhao Mao et al., 2020; Weizhou Shen et al., 2020) have introduced the transformer structure into the utterance feature extraction to solve the above problems. Li et al. (2021) proposed a new expression vector, "emotion vector" for ERC, which is obtained by mapping from sentence vector, but only for textual modality. Meanwhile, existing studies (Song et al., 2004; Dellaert et al., 1996; Amir, 1998) have shown that only textual information is not enough for emotional presentation, the tone and intonation reflect the speaker's emotions to a certain extent, and the facial expressions also express the inner feelings of the speaker in most cases. As shown in Figure 1, different modalities contain different information, and all are slightly flawed, so multi-modal based information can better identify the speaker's emotion than a single modality in ERC.

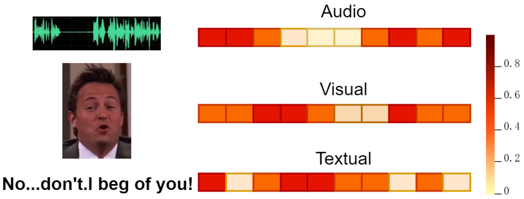

Figure 1: Visualization of the heatmap for an utterance in a conversation, with three modalities.

In order to identify the speaker's emotion in conversation effectively, it is necessary to obtain good utterance features. Also we can't ignore the role of the utterance's emotional tendency. As shown in Figure 2, the emotional tendency of the utterance itself is like an "offset vector", which makes the neutral utterance have an "emotional direction". For single-sentence emotion classification, emotional tendency is consistent with the results of emotion recognition, while in ERC, the influence of the context may cause the emotional tendency to be inconsistent with the result of emotion recognition. However, emotional tendency can provide features for the model so that model can "understand" the reason for emotional reversal.

So, we propose a new multi-modal emotional

Findings of the Association for Computational Linguistics: ACL 2022, pages 1610 - 1618

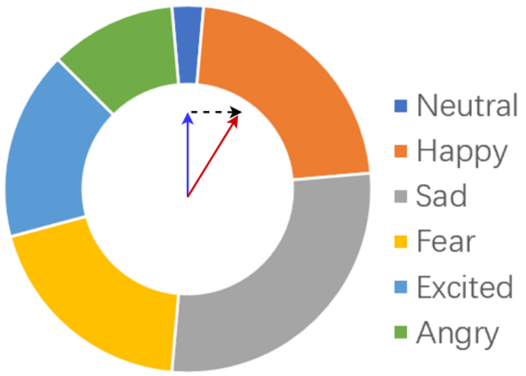

Figure 2: A map for emotion classification. The dashed arrow represent the offset vector, which is added to the neutral vector to obtain the vector with an emotional direction.

tendency extraction method called Emoformer, which is a Transformer-based model but doesn't include the decoder part. As shown in Figure 3, Emoformer extracts the emotional tendency, i.e., emotion vector, from the modal features through the multi-head self-attention layer and feed-forward layer. More details we will analysis in Section 3.

Based on the Emoformer, we further propose an end-to-end ERC model to classify the emotion based on multi-modal information, named EmoCaps. Specifically, we employ the Emoformer structure to extract emotion vectors of textual, audio, and visual features. Then, we merge the emotion vectors of the three modalities with the sentence vector to an emotion capsule. Finally, we employ a context analysis model to get the final result of the emotion classification.

In general, the contributions of this paper are as follows:

- We innovatively introduce the concept of emotion vectors to multi-modal emotion recognition and propose a new emotion feature extraction structure, Emoformer, which is used to jointly extract emotion vectors of three modalities and merge them with sentence vector to the emotion capsule.
- Based on Emoformer, we further propose an end-to-end emotion recognition model named EmoCaps to identify the emotion from multi-modal conversation.
- Our model and the existing state-of-the-art model are tested on MELD and IEMOCAP datasets. The test results show that our model has the best performance both in multi-modality and text-modality.

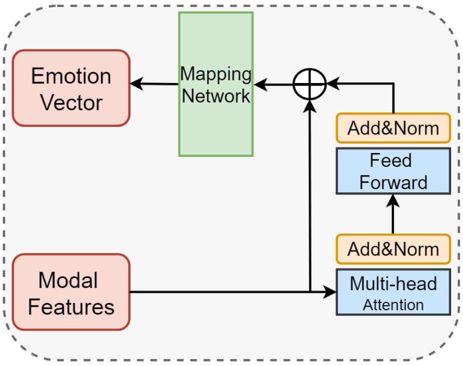

Figure 3: Schematic diagram of Emoformer. The mapping network consists of 5 fully connected layers.

The rest of the paper is organized as follows: Section 2 discusses related works; Section 3 introduces the proposed EmoCaps model in detail; Section 4 and 5 present the experiment setups on two benchmark datasets and the analysis of experiment results; Finally, Section 6 concludes the paper.

2 Related Work

2.1 Emotion Recognition in Conversation

Poria et al. (2017) use Biredectional LSTM (Hochreiter and Schmidhuber 1997) in ERC, which builds context information without differentiating among the speakers. ICON (Hazarika et al., 2018b) is an extension of CMN (Hazarika et al.,2018), which contains another GRU structure to connect the output in the CMN model to distinguish the speaker relationship. Majumder et al. (2019) use three GRUs to obtain context information and update the speaker status. Ghosal et al. (2019) construct a conversation into a graph, then use a graph convolutional neural network to convert the emotion classification task of the conversation into a node classification problem of the graph. Ghosal et al. (2020) use common sense knowledge to learn the interaction of interlocutors. Shen et al. (2021) design a directed acyclic neural network for encoding the utterances. Hu et al. (2021) propose the DialogueCRN to fully understand the conversational context from a cognitive perspective.

2.2 Multi-modal Emotion Recognition

Zadeh et al. (2017) propose the TFN model, which is a multi-modal method using the tensor outer product. Liang et al. (2018) propose the model which use a multi-level attention mechanism to extract different modal interaction information. Cai et al. (2019) propose a hierarchical fusion model to model graphic information for irony recognition. But the above models are not applied in ERC. Hazarika et al. (2018b) propose the CMN model in ERC, which uses a GRU structure to store multimodal data information and considers the role of contextual information in conversation emotion recognition. Jingwen Hu et al. (2021) propose the MMGCN model, which is a graph convolutional neural network model based on a multi-modal hybrid approach.

2.3 Transformer Models

Inspired by the self-attention mechanism (Bengio et al. 2014), the Transformer is proposed for computing representations and efficiently obtaining long-distance contextual information without using sequence (Vaswani et al. 2017), which has achieved great success in the field of computer vision and audio processing (Tianyang Lin et al. 2021). Devlin et al. (2019) use the Transformer structure to train a large-scale general-purpose text corpus to obtain a language model with syntactic and semantic information. By employing a transformer-based pretraining model, Hazarika et al. (2020) transfer the context-level weight of the generated conversation model to the conversation emotion recognition model. Yuzhao Mao et al. (2020) use Transformer to explore differentiated emotional behaviors from the perspective of within and between models. Weizhou Shen et al. (2020) use the XL-Net model for conversation emotion recognition (DialogXL) to obtain longer-term contextual information. The above-mentioned algorithms use a transformer-based structure but they are not applied for multi-modal models.

3 Methodology

3.1 Problem Definition

Given a dialogue:$u_1, u_2, u_3, \ldots, u_n$, where n is the number of utterances. The purpose of conversation emotion recognition is to input a dialogue and identify the correct emotion classification of each sentence in the dialogue from the emotion label set y:$y_1, y_2, y_3, ..., y_m$, where m is the number of emotional label.

Parameter Setting	**Dataset**	
	IEMOCAP	MELD
Epochs	80	80
Lr	0.0001	0.0001
Dr	0.1	0.1
Batch size	30	30
Dim-T	100	600
Dim-V	256	256
Dim-A	100	300

Table 1: Parameter settings detail of MELD dataset and IEMOCAP dataset. Epochs represents number of training epochs, Lr represents the learning rate, Dr represents the dropout rate. Dim-T represent the the total dimension of sentence vector and textual emotion vector, Dim-V and Dim-A represent the emotion vector dimensions of visual and audio modalities.

3.2 Unimodal Feature Extraction

We extract the features of the utterance u, represented as U. In particular, when the input data is multi-modal, features of utterance U can be expressed as:

$$U = [U_t, U_a, U_v] \tag{1}$$

where U_t means textual feature, U_a means audio feature, and U_v means visual feature.

Textual Feature Extraction: In order to obtain good utterance representation, we use a pre-trained language model, BERT, to extract text feature vectors. BERT is a large general-purpose pre-trained language model proposed by Devlin et al. (2019), which can effectively represent the grammatical and semantic features of the utterance. Specifically, we first split the dialogue into a series of individual utterances, which are used as the input of the BERT-base model. Unlike other downstream tasks, we use the transformer structure to encode the utterances without classifying or decoding; then we get the sentence vector of every utterance with 512 dimensions. It should be noted that using a larger pre-tranined BERT model did not improve the performance, and a smaller BERT model couldn't get good enough performance.

Audio Feature Extraction: Identical to Hazarika et al. (2018), we use OpenSMILE (Eyben et al. 2010) for acoustic feature extraction. Specifically, in this work, we use the IS13 ComParE config file, which extracts a total of 6373 features for each utterance video, then we use the fully connected layer to reduce the dimensionality to 512 dimensions.

Visual Feature Extraction: We use the 3D-CNN

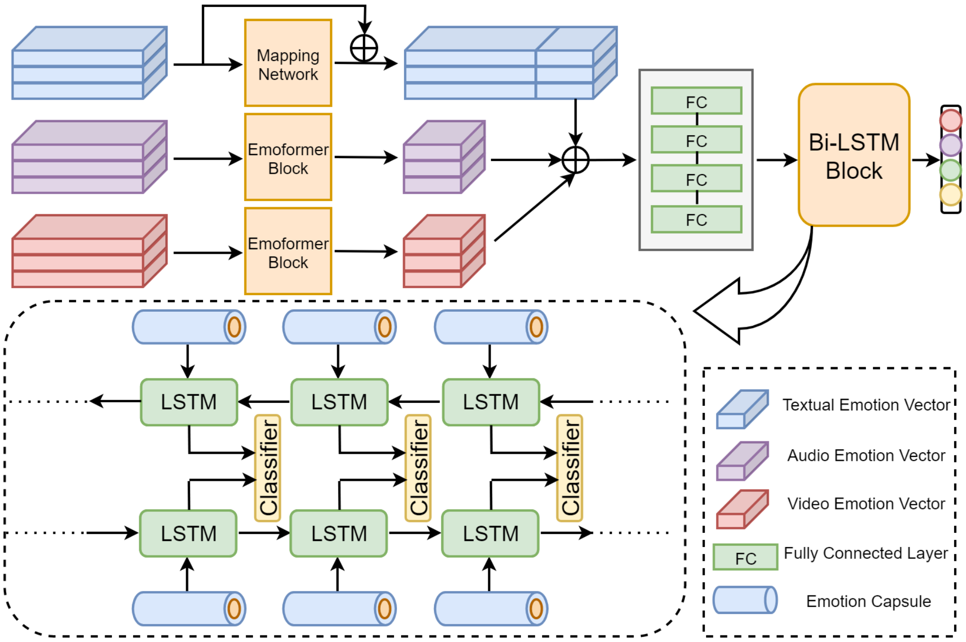

Figure 4: Framework illustration of the EmoCaps based ERC model.

model to extract video features, especially the facial expression features of the speaker. The 3D-CNN model can capture changes in the speaker's expression, which is important information in ERC. Specifically, we use 3D-CNN with three fully connected layers to get a 512-dimensional vector.

3.3 Our Method

We assume that the emotion of the utterances in the dialogue depends on three factors:

- The emotional tendency of the utterance itself.
- Emotional information contained in different modal of utterance.
- Context information

Based on the above three factors, our model EmoCaps is modeled as follows: We obtain three modal features of dialogue data: textual, audio, and visual; and input them into the Emoformer structure, then get the emotion vector of three modals and fuse them with sentence vector; finally, the context analysis model is used to obtain the emotion recognition result. The framework of the model is shown in Figure 4. It is worth noting that our text features, i.e., the sentence vector, are encoded by a transformer-based pre-trained language model, so we no longer use the self-attention mechanism but directly employ a mapping network to extract the emotion vector, then the residual structure concats sentence vector with emotion vector.

Emoformer Block Existing methods mainly use CNN, TextCNN, GRU, etc., to extract text feature vectors, which extract grammatical information weakly. At the same time, they only take the original feature vectors without emotional tendency as input. Based on this, we propose to use the Emoformer structure to extract the emotion vectors of various modalities. As shown in Figure 3, Emoformer has an Encoder structure similar to Transformer, but does not include the Decoder structure. A multi-head attention layer is used to get the emotional tendency feature from the original feature, both are connected through the residual structure, then emotion vector is obtained through a mapping network composed of 5 fully connected layers. The self-attention layer can be used to extract features that contain emotional tendencies or emotional factors effectively, and the residual structure ensures the integrity of the original information; finally the mapping network decouples features and reduces feature dimensions.

Identical to Vaswani et al. (2017), for a given input feature U, we calculate three matrix of query $Q \in \mathbb{R}^{T_Q \times d_Q}$, key $K \in \mathbb{R}^{T_K \times d_K}$ and value $V \in \mathbb{R}^{T_V \times d_V}$ by linear transformation from U:

$$[Q, K, V] = U[W^Q, W^K, W^V] \tag{2}$$

where T_Q, T_K, T_V represent the sequence length of the Q, K, V, and d_Q, d_K, d_V represent the dimensions of the Q, K, V, and $W^Q \in \mathbb{R}^{d_Q \times d_m}$, $W^K \in \mathbb{R}^{d_K \times d_m}$, $W^V \in \mathbb{R}^{d_V \times d_m}$.

Then we can express the formula of the self-attention layer as:

$$A = softmax(\frac{QK^T}{\sqrt{d_k}})V \tag{3}$$

where A is the weight of value V, d_k is equal to the dimension of u. In this way, multiple self-attention layers are concatenated to get Multi-Head Attention layer:

$$MultiHead(A) = Concat(A_1, ..., A_h)W \tag{4}$$

where $A_1, ..., A_h$ are the output of self-attention layers, h is the number of layers, and W is the weight parameter.

Then a residual connection with normalization layer is used to normalize the output of Multi-Head attention layer, and a Feed Forward layer is employed to get the output of the self-attention parts:

$$N = Norm(A + MultiHead(A)) \tag{5}$$

$$F = max(0, NW_1 + b_1)W_2 + b_2 \tag{6}$$

$$G = Norm(F + MultiHead(F)) \tag{7}$$

where W_1, W_2 are the weight parameter, b_1, b_2 are the bias parameter.

Finally, the orignal features U and the output of self-attention parts G are connected through the residual structure, and a mapping network is employed to get the final output E:

$$H = U \oplus G \tag{8}$$

$$E = Map(H) \tag{9}$$

where the Map represents the mapping network, which consists of 5 fully connected layers.

Combine the above Eq. (2) to (9), we can get different modality emotion vectors from different input channels with Emoformer:

$$[E_a, E_v, E_t] = Emoformer(U_a, U_v, U_t) \tag{10}$$

where U_a, U_v, U_t represent the original input of audio,visual and textual features, and E_a, E_v, E_t represent the emotion vectors of modalities.

Emotion Capsule For the composition of the emotion capsule, we are based on the following rules: the text feature vector of the utterance contains grammatical and semantic features, emotion vector represents the emotional tendency of the utterance. Both are the main sources of conversation emotion recognition. Textual features most intuitively represent the meaning, emotions, characteristics, etc., of the utterance. However, visual features and audio features contain a few of emotional factors and emotional features, which can provide some emotional clues when the text features do not have sufficient emotional inclination. Therefore, sentence vector concats with three modalities' emotion vector to be an emotion capsule, which just like a "capsule", the emotion vector is "wrapped" by the sentence vector and "absorbed" by the context analysis model to determine the speaker's emotion finally. Our emotion capsule O can be expressed as:

$$O = U_t \oplus E_t \oplus E_v \oplus E_a \tag{11}$$

Context Modeling Since the same emotion has different expressions, and the same expression can express different emotions in different contexts, it is very difficult to infer the true emotions from a single word (Barrett, 2017). According to Grice's theory of implicature (1957), the meaning of a sentence can be canceled, so it is necessary to integrate context to infer the true meaning of a sentence. Therefore, contextual information is an indispensable part of conversation emotion recognition. Context information is divided into two parts: the information obtained from the previous moment is named emotional clue traceability, and the information obtained from the next moment is named emotional reasoning.

In this paper, we employ a Bi-directional LSTM model as the context analysis model to extract contextual information. In a conversation, we form a batch of emotion capsules of all utterances into the Bi-LSTM model in the order of dialogue, and each LSTM cell corresponds to an emotion capsule. For the time i, in the forward propagation sequence, the contextual information C_i at this moment is composed of the hidden state output of the LSTM cells at all previous moments, that is, the emotional clue traceability; in the backpropagation sequence, the contextual information at this moment is composed of the hidden state output of the LSTM cells at all following moments, which is emotional reasoning. The two fed into an MLP with fully connected layers and get the values of the utterance u_i under each emotion label:

$$l_i = ReLU(W_l C_i + b_l) \tag{12}$$

$$P_i = softmax(W_{smax} l_i + b_{smax}) \tag{13}$$

where W_l, W_{smax} are the weight parameter, b_l, b_{smax} are the bias parameter.

	IEMOCAP						
	Happy	Sad	Neutral	Angry	Excited	Frustrated	Average
BC-LSTM	43.40	69.82	55.84	61.80	59.33	60.20	59.19
CMN	30.38	62.41	52.39	59.83	60.25	60.69	56.13

EmoCaps	**71.91**	**85.06**	**64.48**	68.99	**78.41**	66.76	**71.77**

Table 2: Experimental results (F1 score) on the IEMOCAP dataset. Average means weighted average. Some of the models only provide overall average results without results under each emotion category, so some data cells are lacking.

Finally we choose the max value as the emotion label y for the i-th utterance:

$$y_i = \arg\max_{m}(P_i[m]) \tag{14}$$

4 Experiment Setting

4.1 Dataset

IEMOCAP (Busso et al. 2008): The IEMOCAP dataset includes video data of impromptu performances or scripted scenes of about 10 actors. There are in total 7433 utterances and 151 dialogues in IEMOCAP dataset. At the same time, it contains audio and text transcription to meet the needs of multimodal data. In this data set, multiple commentators set the emotional labels of the utterances into six categories: including happy, sad, neutral, angry, excited and frustrated.

MELD (Poria et al. 2019): The MELD dataset contains 13708 utterances and 1433 conversations, which making up from TV series "Friends". It is also a multi-modal dataset containing video, audio, and text formats. In this dataset, multiple commentators set the emotional labels of the words into seven categories: including neutral, surprise, fear, sadness, joy, disgust, and angry.

4.2 Baseline Models

BC-LSTM (Poria et al. 2017): Bc-LSTM uses Bidirectional LSTM structure to encode contextual semantic information, it does not recognize the speaker relationship.

CMN (Hazarika et al. 2018): It takes a multimodal approach comprising audio, visual and textual features with gated recurrent units to model past utterances of each speaker into memories.

DialogueRNN (Majumder et al. 2019): DialogueRNN uses different GRU units to obtain contextual information and speaker relationships. It is the first conversation emotion analysis model to distinguish between speakers.

DialogueGCN (Ghosal et al. 2019): DialogueGCN constructs a conversation into a graph, transforms the speech emotion classification problem into a node classification problem of the graph, and uses the graph convolutional neural network to classify the results.

DialogXL (Weizhou Shen et al. 2020): DialogXL use XLNet model for conversation emotion recognition to obtain longer-term contextual information.

DialogueCRN (Hu et al. 2021): DialogueCRN introduces the cognitive phase to extract and integrate emotional clues from context retrieved by the perceptive phase for context modeling.

DAG-ERC (Weizhou Shen et al. 2021): DAG-ERC is a directed acyclic graph neural network for ERC, which provides a intuitive way to model the information flow between long-distance conversation background and nearby context.

MMGCN (Jingwen Hu et al. 2021): MMGCN uses GCN network to obtain contextual information, which can not only make use of multimodal dependencies effectively, but also leverage speaker information.

4.3 Implementation

For textual data, we use BERT model to obtain the sentence vector then get the textual emotion vector from a mapping network. For audio and visual data, we use Emoformer obtain the audio and visual emotion vector.

As for the hyperparameter settings, we follow

	MELD							
	Neutral	Surprise	Fear	Sadness	Joy	Disgust	Angry	Average
BC-LSTM	73.80	47.70	**5.40**	25.10	51.30	5.20	38.40	55.90
DialogueRNN	73.50	49.40	1.20	23.80	50.70	1.70	41.50	57.03
DialogueGCN	-	-	-	-	-	-	-	58.23
DialogXL	-	-	-	-	-	-	-	62.41
DialogueCRN	-	-	-	-	-	-	-	58.39
DAG-ERC	-	-	-	-	-	-	-	63.65

EmoCaps	**77.12**	**63.19**	3.03	**42.52**	**57.50**	**7.69**	**57.54**	**64.00**

Table 3: Experimental results (F1 score) on the MELD dataset. Average means weighted average. The CMN model only for two-party conversation, but MELD is a multi-party conversation dataset. Some of the models only provide overall average results without results under each emotion category, so some data cells are lacking.

Modality	**Dataset**	
	IEMOCAP	MELD
Text	69.49	63.51
Audio	33.00	31.26
Video	31.64	31.26
T+A	71.39	63.73
T+V	71.30	63.58
T+V+A	**71.77**	**64.00**

Table 4: Performance (F1 score) of EmoCaps under different multimodal settings. T represent textual modality, A represent audio modality, and V represent visual modality.

Li et al. (2021). For both of MELD dataset and IEMOCAP dataset, the epochs is set to 80, the learning rate is set to 0.0001, and the dropout rate is set to 0.1. The detailed parameter setting is shown in Table 1.

5 Results and Analysis

Our proposed model is compared with other state-of-the-art models on the IEMOCAP dataset and MELD dataset, which are under the same parameter conditions. The experimental results are shown in Table 2 and Table 3, our model has the best performance on both datasets.

5.1 Compare with Other Baseline Models

On the one hand, compared with existed methods, our model encodes sentences through a pre-trained language model to obtain a better utterance representation. On the other hand, our emotion capsule contains the emotional tendency of the utterance itself, combined with contextual information, can more effectively identify the speaker's emotion. The experimental results prove the rationality of our assumptions about the emotional factors in ERC.

Model	Dataset	
	IEMOCAP	MELD
DialogueRNN	71.08	**65.86**
Bi-LSTM	**71.77**	64.00

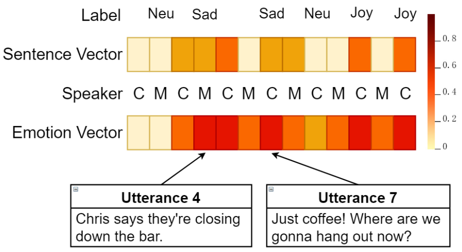
Table 5: Performance(F1 score) under the multimodal setting of different models as context modeling model.

5.2 Various Modality

Table 4 shows the performance of our model on the MELD dataset and the IEMOCAP dataset under different modality combinations. It is easy to find that the performance of multi-modal input is better than single-modal input. At the same time, among the three modalities of textual, audio, and visual, the textual modal has better performance than the other two modalities.

5.3 Error Analysis

As shown in Table 4, the performance of audio and visual modal is not good enough. For audio features, the frequency and amplitude of the sound features can only reflect the intensity of the speaker's emotions, not the specific emotional tendencies. Therefore, when certain emotions have similar frequencies and amplitudes, it is difficult to correctly distinguish the speaker's emotions only through audio data. For example, for two emotions of excited and fear, the frequency and amplitude characteristics in the audio mode are both at high values. Thus it's hard to distinguish the two emotions. For visual features, It is easy for us to judge the speaker's expression by facial features, but when the speaker hides his own expression, the video feature is not



Chris says they're closing down the bar.

Just coffee! Where are we gonna hang out now?

Figure 5: Visualization of the heatmap in the "Friends" Season 3 Dialogue 2. Speaker C refer to Chandler and Speaker M refer to Monica.

enough to judge the speaker's emotion. In addition, for a single video modality, the emotional changes in the context are unexplainable.

When the textual modality is added, the performance is significantly improved. In other words, textual modality play a major role in conversation emotion recognition, while audio and visual modalities can help improve the accuracy of recognition, which is consistent with the previous assumptions.

5.4 Impact of Speaker Embedding

In order to analyze the impact of speaker modeling on conversation emotion recognition, we use a variant of DialogueRNN as a context modeling model to test its performance on two benchmark datasets. As shown in Table 5, the performance of the DialogueRNN-based model on the MELD dataset is better than the LSTM-based model. The reason is that most of the MELD dataset belongs to multi-person dialogue situations, so the speaker modeling model (DialogueRNN-based) is more effective in identifying speaker emotions than the model not using speaker modeling (LSTM-based). However, in the IEMOCAP dataset, which is based on two-person dialogue situations, speaker modeling becomes insignificant.

Furthermore, compared with the LSTM-based model, using DialogueRNN-based or other models that include speaker modeling structures consumes more computing resources and time.

5.5 Case Study

Figure 5 shows the influence of emotion vector when emotion reversal in a conversation. At the beginning of the conversation, both speakers are in a neutral emotional state, while utterance 4 changes the situation that speakers' emotion turn into surprise and sadness. The sentence vector doesn't "understand" the reason why emotion change, but the emotion vector contains a negative emotion tendency which easier to get the correct emotion label. Utterance 7 shows that when the context is in the sad emotion, the emotion vector makes the utterance "biased" to "sad", while the sentence vector is in a neutral emotion. It proves the role of emotion vector in ERC.

6 Conclusion

In this paper, we propose a new multi-modal feature extraction structure, Emoformer, which is based on the transformer structure. Further, we design a new ERC model, namely EmoCaps. First, we use Emoformer structures to extract the emotion vectors of textual, audio, and visual modalities, then fuse the three modalities emotion vectors and sentence vectors to be an emotion capsule; finally, we employ a context analysis model to get the emotion recognition result. We conduct comparative experiments on two benchmark datasets. The experimental results show that our model performs better than the existing state-of-the-art models. The experimental results also verified the rationality of our hypothesis.

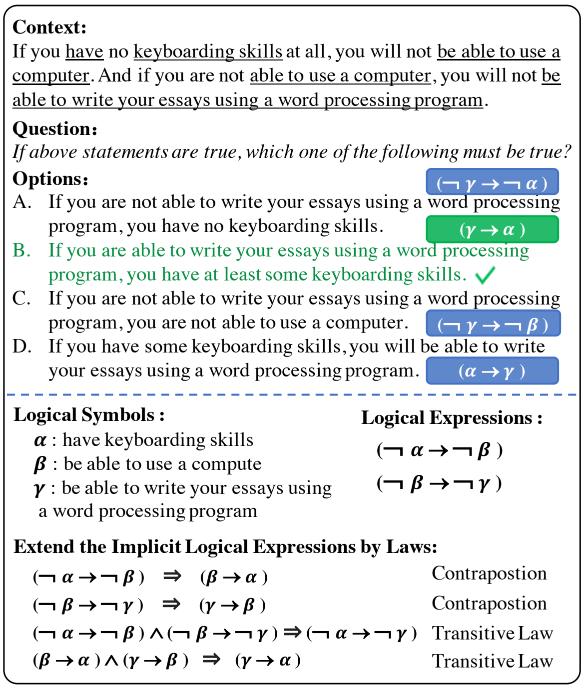
Abstract

Logical reasoning of text requires identifying critical logical structures in the text and performing inference over them. Existing methods for logical reasoning mainly focus on contextual semantics of text while struggling to explicitly model the logical inference process. In this paper, we not only put forward a logic-driven context extension framework but also propose a logic-driven data augmentation algorithm. The former follows a three-step reasoning paradigm, and each step is respectively to extract logical expressions as elementary reasoning units, symbolically infer the implicit expressions following equivalence laws and extend the context to validate the options. The latter augments literally similar but logically different instances and incorporates contrastive learning to better capture logical information, especially logical negative and conditional relationships. We conduct experiments on two benchmark datasets, ReClor and LogiQA. The results show that our method achieves state-of-the-art performance on both datasets, and even surpasses human performance on the ReClor dataset. [1]

1 Introduction

Recent years have witnessed a growing interest in logical reasoning of text, which learns to understand a given text in logical level and perform logical inference to deduce implications from asserted ones (McCarthy, 1989; Nilsson, 1991). As a significant component of human reading comprehension, it is essential in many application scenarios, such as negotiation and debate. And several datasets have been proposed as benchmarks for this task (Williams et al., 2017; Habernal et al., 2017; Yu et al., 2020; Liu et al., 2020).



Context:
If you have no keyboarding skills at all, you will not be able to use a computer. And if you are not able to use a computer, you will not be able to write your essays using a word processing program.

Question:
If above statements are true, which one of the following must be true?

Options:

A. If you are not able to write your essays using a word processing program, you have no keyboarding skills. $(\neg\gamma \rightarrow \neg\alpha)$

B. If you are able to write your essays using a word processing program, you have at least some keyboarding skills. ✓ $(\gamma \rightarrow \alpha)$

C. If you are not able to write your essays using a word processing program, you are not able to use a computer. $(\neg\gamma \rightarrow \neg\beta)$

D. If you have some keyboarding skills, you will be able to write your essays using a word processing program. $(\alpha \rightarrow \gamma)$

Logical Symbols :
α : have keyboarding skills
β : be able to use a compute
γ : be able to write your essays using a word processing program

Logical Expressions :
$(\neg\alpha \rightarrow \neg\beta)$
$(\neg\beta \rightarrow \neg\gamma)$

Extend the Implicit Logical Expressions by Laws:

$(\neg\alpha \rightarrow \neg\beta) \Rightarrow (\beta \rightarrow \alpha)$	Contrapostion
$(\neg\beta \rightarrow \neg\gamma) \Rightarrow (\gamma \rightarrow \beta)$	Contrapostion
$(\neg\alpha \rightarrow \neg\beta) \wedge (\neg\beta \rightarrow \neg\gamma) \Rightarrow (\neg\alpha \rightarrow \neg\gamma)$	Transitive Law
$(\beta \rightarrow \alpha) \wedge (\gamma \rightarrow \beta) \Rightarrow (\gamma \rightarrow \alpha)$	Transitive Law

Figure 1: A logical reasoning example from ReClor dataset (Yu et al., 2020). To find the answer, it needs to extract *logical symbols*, identify *logical expressions* and perform logical inference to extend the *implicit logical expressions*. The underlined phrases represent logical symbols. The colored rectangles are corresponding logical expressions of each option.

An example of logical reasoning problems is shown in Figure 1, which takes a context description, a question and four options as the input, and aims to identify the option that logically follows the context. The main challenge to solve such a problem is to uncover the logical propositional structure among the text and perform logical inference over them, which are beyond the capability of contextual pre-trained models (Liu et al., 2019; Yang et al., 2019; Lan et al., 2020) without such logical annotations. They usually treat logical reasoning as a traditional reading comprehension task and match the given context with candidate answers, without modeling the discrete logical inference process explicitly (Yu et al., 2020). Recently, Huang et al. (2021) utilizes discourse information to unwrap

Findings of the Association for Computational Linguistics: ACL 2022, pages 1619 - 1629
May 22-27, 2022

the logical structure and propose a discourse-aware graph network to learn discourse-based contextual embeddings for logical reasoning. However, it is still entangled in enhancing contextual representation while ignoring explicit logical inference.

In responding to these issues, we propose a three-step paradigm for logical reasoning based on symbolic logic information. Firstly, we identify the elementary components for reasoning from the context as the logical expressions, like $(\neg\alpha \rightarrow \neg\beta)$, to uncover the logical relationships between logical symbols. Then we perform logical inference following equivalence laws to extend the implicit ones from these identified logical expressions. Thirdly, candidate options can be validated by comparing themselves with all obtained logical expressions.

We propose a logic-driven context extension framework to integrate these three reasoning steps, namely logic identification to parse the context into logical expressions, logic extension to infer implicit logical expressions and logic verbalization for answer prediction. To combine the interpretability of symbolic inference with anti-noise of continuous representation, we follow a neural-symbolic paradigm (Besold et al., 2017; Garcez et al., 2019) which conducts logic identification and extension in a symbolic manner and utilizes the pre-trained model as the backbone of logic verbalization. In practice, we verbalize implicit logical expressions into natural language and feed them as an extended context into a pre-trained model to match the answer. Moreover, to encourage the pre-trained model to better capture logical information, we further propose a logic-driven data augmentation algorithm. Specifically, it constructs challenging instances with literally similar but logically different contexts by modifying logical expressions. Contrastive learning (Chen et al., 2020) is used for encouraging our model to distinguish different contexts to better capture negative and conditional relationships in logical expressions.

The experiments are conducted on two challenging logical reasoning datasets, ReClor (Yu et al., 2020) and LogiQA (Liu et al., 2020). Results show that our system achieves state-of-the-art performance on both datasets, and even surpasses human performance on ReClor. Further results also show the effectiveness of both logic-driven context extension framework and data augmentation algorithm, and demonstrate the generalizability of our system.

2 Task and Background

2.1 Task Definition

We study the problem of logical reasoning of text on a multiple-choice question answering task. The task is described as following: given a context c, a question q, and four associated options $\{o_1, o_2, o_3, o_4\}$, we aim to select the most appropriate option as the answer o_a.

2.2 Base Model

In this paper, we follow the leading methods on the leaderboards to take pre-trained models as our base model, e.g., RoBERTa (Liu et al., 2019). It concatenates the context, the question and each option as an input and encodes the sequence for calculating its score. Given four options, four concatenated sequences are constructed to calculate four scores, and the one with the highest score is chosen as the answer. Specifically, the concatenated sequence is formulated as $[CLS]\ c\ [SEP]\ q\ ||\ o\ [SEP]$, where c is the context and $q\ ||\ o$ is the concatenation of the question and each option. The representations of special token $[CLS]$ in four sequences are fed into a linear layer with a softmax function to get the probability distribution of options as $P(\{o_1, o_2, o_3, o_4\}|c, q)$. The cross entropy loss is calculated as Eq. 1, where o_a is the correct option.

$$\mathcal{L}_A = -\sum \log P(o_a|c, q) \qquad (1)$$

Although promising results have been reported (Yu et al., 2020), pre-trained models for logical reasoning directly encode the triplet of context, question and options, which mainly leverage contextual semantics but struggle to model the symbolic inference process explicitly. Thus we propose a framework on top of a pre-trained model to extract logical expressions in the text and symbolically perform logical inference to predict the answer.

3 Logic-Driven Context Extension

In this section, we present a logic-driven context extension framework for logical reasoning of text, which is illustrated in Figure 2. The framework is divided into three steps as follows. It first identifies the logical symbols and expressions explicitly mentioned in the context and options (§ 3.1). Then it performs interpretable logical inference over them to extend the logical expressions implicit in the context (§ 3.2). Finally, it verbalizes the extended logical expressions related to each option as an

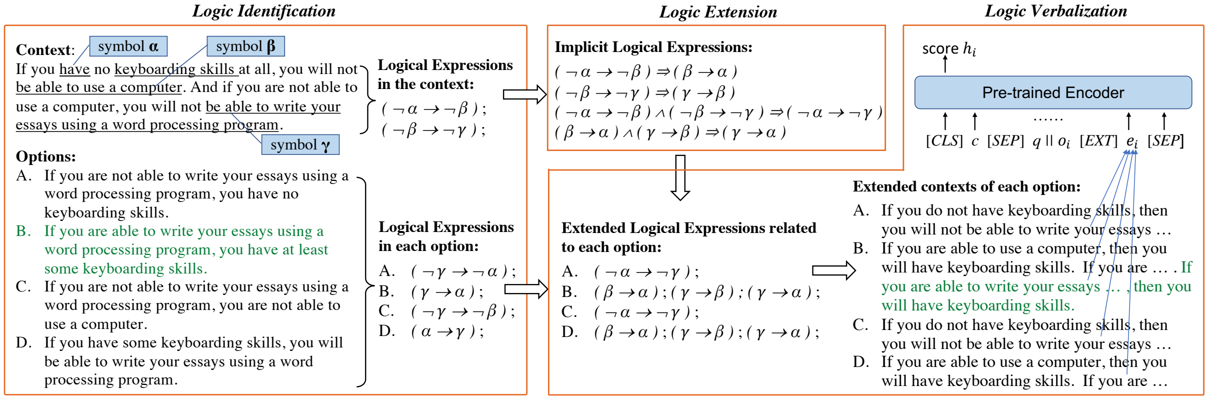

Figure 2: The overall architecture of logic-driven context extension framework. c, q, o_i and e_i are the context, question, i-th option and the extended context for i-th option, respectively. The texts in green mean that the option B is matched against its extended context which has the highest score.

extended context and utilizes it in the pre-trained model to match the answer (§ 3.3).

3.1 Logic Identification

In order to perform logical reasoning, we first need to identify the elementary reasoning components as logical expressions to uncover the logical relationships between logical symbols. We identify the existing logical expressions for each sentence in the context and each option. To show the format of the logical expression, we introduce some notations:

(1) $\{\alpha, \beta, \gamma, ...\}$: the logical symbols, which are the basic constituents in the context to constitute the logical expressions, such as the "have keyboarding skills" in Figure 2.

(2) $\{\neg, \rightarrow\}$: the logical connective set. $\neg$ means the negation operation upon a specific logical symbol and $\rightarrow$ acts as a conditional relationship between two logical symbols.

(3) $\{(\alpha \rightarrow \beta), ...\}$: the logical expressions, which are composed of logical symbols and connectives. $(\alpha \rightarrow \beta)$ means that α is the condition of β.

To ensure the generalizability of our framework without annotated logic forms, we design a fairly simple logical identification approach using an off-the-shelf constituency parser (Joshi et al., 2018) and several common keywords of logical semantics. We first employ the constituency parser to extract constituents including noun phrases and gerundial phrases as basic symbols. The logical symbols in each sentence are combined by logical connectives to constitute logical expressions as follow-up. If any negative word (e.g., "*not*", "*unable*") is in or immediately before a logical symbol α, we add the negation connective $\neg$ before α as a new symbol $\neg\alpha$. Then if there is a conditional relationship between two symbols α and β in a sentence, we construct the corresponding logical expression as $(\alpha \rightarrow \beta)$. We simply recognize the conditional relationship between α and β as $(\alpha \rightarrow \beta)$ according to conditional indicators (e.g., *"if* α*, then* β*"*, *"*β *since* α*"*) and whether an active voice occurs between α and β. The detailed negative and conditional keywords are listed in Appendix A with the whole identification procedure summarized as an algorithm. As shown in Figure 2, given the context with two sentences, we can extract three logical symbols $\{\alpha, \beta, \gamma\}$ and identify two existing logical expressions as $(\neg\alpha \rightarrow \neg\beta)$ and $(\neg\beta \rightarrow \neg\gamma)$.

3.2 Logic Extension

In addition to the logical expressions explicitly mentioned in the context, there are still some other implicit ones that we need to logically infer and extend. We combine the identified logical expressions existing in all sentences of the context as a logical expression set $\mathcal{S}$, and perform logical inference over them to further extend the implicit expressions according to logical equivalence laws. Here we follow two most applicable logical equivalence laws involving implication and negation in propositional logic, including *contraposition* (Russel et al., 2013) and *transitive law* (Zhao et al., 1997):

Contraposition :

$$(\alpha \rightarrow \beta) \implies (\neg\beta \rightarrow \neg\alpha) \quad (2)$$

Transitive Law :

$$(\alpha \rightarrow \beta) \wedge (\beta \rightarrow \gamma) \implies (\alpha \rightarrow \gamma) \quad (3)$$

Then the extended implicit logical expressions form an extension set of the current logical expression set $\mathcal{S}$ as $\mathcal{S}_E$. As in Figure 2, the set of existing logical expressions is $\mathcal{S} = \{(\neg\alpha \to \neg\beta), (\neg\beta \to \neg\gamma)\}$ and the logic extension set is $\mathcal{S}_E = \{(\beta \to \alpha), (\gamma \to \beta), (\neg\alpha \to \neg\gamma), (\gamma \to \alpha)\}$.

3.3 Logic Verbalization

After inferring the extended logical expression set $\mathcal{S}_E$, we verbalize them into natural language for better utilization of the pre-trained model considering that symbolic logic is more difficult to be encoded. We first select the related expressions from $\mathcal{S}_E$ for each option. A logical expression is regarded as related to an option if it has the same logical symbols with the option judged by the text overlapping and whether a negation connective exists. For example, $(\neg\alpha \to \neg\gamma)$ in Figure 2 is related to option C because they both contain $\neg\gamma$. Then we transform all logical expressions related to the option at symbolic space into natural language by filling them into a template and concatenate them into a sentence. We take such a sentence as an extended context for this option. For simplicity, we only adopt the If-Then statements as the verbalization template, which is one of the most common patterns of logical reasoning, but we make some adjustments according to the tense and singular/plural. Specifically, the template is designed as shown in Table 1.

Logic	$(\neg\alpha \to \neg\gamma)$
Template	If do not α, then will not γ.
Extended context	If you do not have keyboarding skills, then you will not be able to write your essays using a word processing program.

Table 1: An example of verbalizing a logical expression into text.

We feed extended contexts into the pre-trained model to match the options and predict the answer. We take an extended context as the sentence e, and introduce a special token $[EXT]$ to represent context extension. Then we reformulate the input sequence as $[CLS]\ c\ [SEP]\ q\ ||\ o\ [EXT]\ e\ [SEP]$ for encoding and feed the $[CLS]$ representation into a classification layer to get each option's score and find the most appropriate answer.

4 Logic-Driven Data Augmentation

In order to make the pre-trained model put more focus on logical information in the context, especially logical negative and conditional relationships, we further introduce a logic-driven data augmentation algorithm. Inspired by SimCLR (Chen et al., 2020), we augment challenging instances with literally similar but logically different contexts built by modifying logical expressions. It then adopts contrastive learning and encourages our model to distinguish logically correct context supporting the answer. We first introduce the background of SimCLR and then describe our logic-driven contrastive learning.

SimCLR As a paradigm of self-supervised representation learning by comparing different samples, contrastive learning (Wu et al., 2018; He et al., 2020a) aims to make the representations of similar samples be mapped close together, while that of dissimilar samples be further away in the encoding space. The goal can be described as following.

$$s(f(x), f(x^+)) \gg s(f(x), f(x^-)) \tag{4}$$

x^+ is a positive sample similar to the data point x while x^- is a negative sample dissimilar to x. $f(\cdot)$ is an encoder to learn a representation and the $s(\cdot)$ is a similarity function of two representations. Over this, SimCLR (Chen et al., 2020) builds a classifier to distinguish positive from negative samples and learns to capture what makes two samples different.

Logic-Driven Contrastive Learning In our question answering setting, we alter the score function from measuring the similarity between two representations towards calculating the score that the question can be solved by the correct answer under a given context:

$$s^{'}(c^+, q, o_a) \gg s^{'}(c^-, q, o_a) \tag{5}$$

where (c^+, q, o_a) and (c^-, q, o_a) are the positive and negative sample, c^+ and c^- are the positive and negative context, respectively, and $s^{'}$ is the score function. The contrastive loss can be formulated as a classification loss for predicting the most plausible context that supports the answer:

$$\mathcal{L}_C = -\sum \log \frac{\exp(s^{'}(+))}{\exp(s^{'}(+)) + \exp(s^{'}(-))} \tag{6}$$

where $s^{'}(+)$ and $s^{'}(-)$ are short for $s^{'}(c^+, q, o_a)$ and $s^{'}(c^-, q, o_a)$ respectively.

Aware of symbolic logical expressions, we can construct *logical negative samples* including negative contexts that are literally similar but logical dissimilar to the positive one. We take the original context to construct the positive sample. Then we generate a negative sample by modifying the existing logical expressions in the context and verbalizing the modified logical expressions into a negative context as § 3.3. During the modification operations, we randomly choose a logical expression and randomly *delete, reverse or negate* such an expression. The *delete, reverse or negate* operations are respectively to delete a logical expression in the context, reverse the conditional order of a logical expression and negate a logical symbol in a logical expression. The constructing procedure of a logical negative sample is illustrated in Figure 3. Then the model can be trained to better capture logical information, especially negative and conditional relationships in logical expressions.

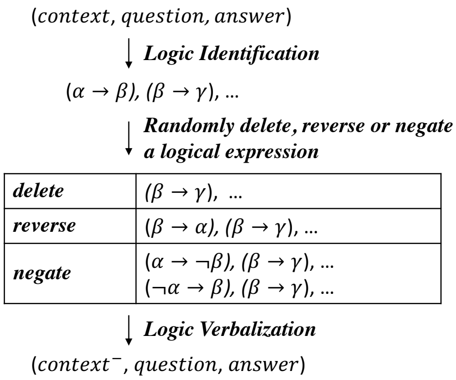

Figure 3: Procedure to construct a logical negative sample.

In the logic-driven data augmentation algorithm, our framework is trained with a combined loss as $\mathcal{L} = \mathcal{L}_A + \mathcal{L}_C$. And the classification of positive and negative context for the correct answer is also implemented in the logic-driven context extension framework.

5 Experiments

5.1 Experimental Dataset

Our experiments are conducted on two challenging datasets ReClor (Yu et al., 2020) and LogiQA (Liu et al., 2020) that cover diverse and complicated logical reasoning skills, to investigate the general effectiveness of our system. ReClor is built upon standardized exams including GMAT and LSAT. As there are some biased instances that can be solved without knowing contexts and questions, ReClor splits the unbiased instances from the test data as the HARD set to fully assess the logical reasoning ability. The other biased ones are taken as the EASY set. LogiQA comes from the National Civil Servants Examination of China and is professionally translated into an English version.

ReClor consists of $6,138$ questions and is divided into training, validation and test sets with $4,638$, 500 and $1,000$ data points. The test set is further split into EASY set and HARD set with 440 and 560 data points. LogiQA contains $8,678$ questions and is split into $7,376/651/651$ samples for training, validation and testing. Each question is collected with a context and four answer options, in which only one is correct. The implementation details of experiments are given in Appendix B.

5.2 Overall Performance

We compare our systems with several baseline models and human performance.

Baseline Models The compared baseline pre-trained models include *BERT* (Devlin et al., 2019), *RoBERTa* (Liu et al., 2019), *ALBERT* (Lan et al., 2020) and *DeBERTa* (He et al., 2020b). We also compare our model with *DAGN* (Huang et al., 2021), an available state-of-the-art method on the leaderboard which proposes a discourse-aware graph network for logical reasoning taking RoBERTa-large as the backbone.

Our Systems *LReasoner*$_{RoBERTa}$ is our proposed logic-driven **reasoner** taking RoBERTa as the backbone model, which utilizes both logic-driven context extension framework and data augmentation algorithm. We also build our *LReasoner* on top of two more powerful pre-trained models ALBERT and DeBERTa as *LReasoner*$_{ALBERT}$ and *LReasoner*$_{DeBERTa}$, respectively. Besides, *LReasoner*$_{Ensemble}$ is an ensemble of *DeBERTa*, *LReasoner*$_{ALBERT}$ and *LReasoner*$_{DeBERTa}$.

Human Performance Yu et al. (2020) and Liu et al. (2020) report human performance as the average scores of graduate or post-graduate students over randomly chosen test samples.

The evaluation results are shown in Table 2. We have several findings:

- Our systems outperform all baseline models on both datasets by a considerable margin. *LReasoner*$_{Ensemble}$ even surpasses the human performance on both EASY and HARD sets of ReClor. This indicates the effectiveness of our method for logical reasoning.
- Compared to the corresponding baseline models including *RoBERTa*, *ALBERT* and *DeBERTa*, our *LReasoner*$_{RoBERTa}$, *LReasoner*$_{ALBERT}$ and

Model	ReClor				LogiQA	
	Val	Test	EASY	HARD	Val	Test
BERT (Devlin et al., 2019)*	53.8	49.8	72.0	32.3	33.8	32.1
RoBERTa (Liu et al., 2019)*	62.6	55.6	75.5	40.0	35.9	35.3
ALBERT (Lan et al., 2020)	70.2	66.5	76.6	58.6	38.9	37.6
DeBERTa (He et al., 2020b)	74.4	68.9	83.4	57.5	44.4	41.5
DAGN (Huang et al., 2021)	65.8	58.3	75.9	44.5	36.9	39.3
$LReasoner_{RoBERTa}$	66.2	62.4	81.4	47.5	38.1	40.6
$LReasoner_{ALBERT}$	73.2	70.7	81.1	62.5	41.6	41.2
$LReasoner_{DeBERTa}$	**74.6**	**71.8**	**83.4**	**62.7**	**45.8**	**43.3**
$LReasoner_{Ensemble}$	78.0	76.1	87.0	67.5	45.8	45.0
*Human Performance**	-	63.0	57.1	67.2	-	86.0

Table 2: Experimental results (accuracy %) of different models on ReClor and LogiQA. The results in **bold** are the best performance of each column except for $LReasoner_{Ensemble}$ and *Human Performance*. * indicates that the results of ReClor and LogicQA are taken from (Yu et al., 2020) and (Liu et al., 2020).

$LReasoner_{DeBERTa}$ consistently perform better. It demonstrates that our method is robust to be effective for logical reasoning based on different pre-trained models, even the most recent state-of-the-art ones.

- Our models generate large improvement on both HARD and EASY sets of ReClor compared with baseline models. This observation verifies that our model is capable of improving logical reasoning ability on both biased and unbiased data.

5.3 Further Analysis

Ablation Study To dive into the effectiveness of different components in our logic-driven reasoner, we conduct an ablation study which takes *RoBERTa* as our backbone model on ReClor validation and test sets. As shown in Table 3, *RoBERTa+CE* and *RoBERTa+DA* both outperform the baseline model *RoBERTa* and perform worse than our final system *RoBERTa+CE+DA*. It indicates that both logic-driven context extension framework and data augmentation algorithm can boost the performance of question answering involving logical reasoning.

Model	Val	Test	EASY	HARD
RoBERTa	62.6	55.6	75.5	40.0
+ *CE*	65.2	58.3	78.6	42.3
+ *DA*	65.8	61.0	80.9	45.4
+ *CE* + *DA*	66.2	62.4	81.4	47.5

Table 3: Ablation study of our system. *CE* and *DA* are respectively our logic-driven context extension framework and data augmentation algorithm. *RoBERTa+CE+DA* is our proposed $LReasoner_{RoBERTa}$.

Comparison of Negative Sample Construction Strategies To further analyze the effectiveness of our logical negative samples in logic-driven contrastive learning, we compare several different negative sample construction strategies in contrastive learning on top of *RoBERTa* for ReClor.

Model	Test	EASY	HARD
RoBERTa (w/o CLR)	55.6	75.5	40.0
RoBERTa (w/ CLR-RS)	58.2	79.3	41.6
RoBERTa (w/ CLR-RD)	58.9	78.9	43.2
RoBERTa (w/ CLR-L)	61.0	80.9	45.4

Table 4: Comparison of different negative sample construction approaches. *CLR* represents contrastive learning. *RS* means randomly selecting a context from in-batch data while *RD* means randomly deleting a sentence from the original context. *L* denotes our logical negative sample construction method in logic-driven contrastive learning.

From Table 4, we can find that all models with contrastive learning outperform the model without it, which demonstrates that contrastive learning can help to better predict the answer. Our logic-driven contrastive learning *RoBERTa(w/ CLR-L)* performs best. It reveals that logical negative samples are more effective than negative samples constructed by other methods which make the model better capture the logical negative and conditional relationships in the context for logical reasoning.

Evaluation of Logic Identification To evaluate the performance of our symbolic logic identification method, we randomly sample 50 instances from the validation set and manually annotate the logical symbols and expressions as labels. We re-

Context : Everyone sitting in the clubhouse of the golf course today at ten o' clock had just registered for a beginner' s golf lesson. Gerald, Robert, and Shirley were sitting in the clubhouse this morning at ten o' clock. No accomplished golfer would register for a beginner' s golf lesson.

Question : If the statements above are true, which one of the following must also be true on the basis of them?

Options : (Answer : C)

A. Gerald, Robert, and Shirley were the **only** people who registered for a beginner 's golf lesson this morning. ($\gamma \rightarrow$ Others)
B. None of the people sitting in the clubhouse this morning at ten o' clock **had ever played golf**. ($\alpha \rightarrow \neg$ Others)
C. Neither Gerald nor Shirley is an accomplished golfer. ($\gamma \rightarrow \neg \eta$)
D. Everyone sitting in the clubhouse this morning at ten o' clock registered **only** for a beginner's golf lesson. ($\alpha \rightarrow$ Others)

Logical Symbols & Expressions	α : sitting in the clubhouse of the golf course today at ten o' clock; β : registered for a beginner' s golf lesson ; γ : Gerald, Robert, and Shirley; η: accomplished golfer ; $\alpha \rightarrow \beta$; $\gamma \rightarrow \alpha$; $\eta \rightarrow \neg \beta$;
Extending the Implicit Logical Expressions	$(\alpha \rightarrow \beta) \Rightarrow (\neg \beta \rightarrow \neg \alpha)$; $(\gamma \rightarrow \alpha) \Rightarrow (\neg \alpha \rightarrow \neg \gamma)$; $(\eta \rightarrow \neg \beta) \Rightarrow (\beta \rightarrow \neg \eta)$; $(\alpha \rightarrow \beta) \wedge (\gamma \rightarrow \alpha) \Rightarrow (\gamma \rightarrow \beta)$; $(\neg \beta \rightarrow \neg \alpha) \wedge (\neg \alpha \rightarrow \neg \gamma) \Rightarrow (\neg \beta \rightarrow \neg \gamma)$; $(\alpha \rightarrow \beta) \wedge (\beta \rightarrow \neg \eta) \Rightarrow (\alpha \rightarrow \neg \eta)$; $(\eta \rightarrow \neg \beta) \wedge (\neg \beta \rightarrow \neg \alpha) \Rightarrow (\eta \rightarrow \neg \alpha)$; $(\gamma \rightarrow \beta) \wedge (\beta \rightarrow \neg \eta) \Rightarrow (\gamma \rightarrow \neg \eta)$; $(\eta \rightarrow \neg \alpha) \wedge (\neg \alpha \rightarrow \neg \gamma) \Rightarrow (\eta \rightarrow \neg \gamma)$;
Implicit Logical Expressions related to each option	A. $(\gamma \rightarrow \beta)$; $(\gamma \rightarrow \neg \eta)$; B. $(\alpha \rightarrow \neg \eta)$; C. $(\gamma \rightarrow \beta)$; $(\gamma \rightarrow \neg \eta)$; ✓ D. $(\alpha \rightarrow \neg \eta)$;

Figure 4: A ReClor case of the reasoning process of *LReasoner*$_{ALBERT}$. Phrases underlined denote other symbols (called *Others*) different from the logical symbols in context and **bold** tokens make them different.

port the recall of logical symbol and logical expression identification as 65.9% and 48.9%, respectively. We can see that our generic logic parsing method which operates in an unsupervised manner achieves relatively reliable performance. Unsupervised and generic logic parsing is an essential future direction that is expected to be further studied to enhance the performance of the overall system.

Case Study A ReClor case is presented in Figure 4 to show the reasoning process of our system. At first, the logical symbols are correctly extracted from the context and the logical expressions are identified based on them considering logical negative and conditional relationships. Then we extend the logical expressions by inferring implicit ones in the context. For each option, we recognize its logical expression and find the related extended expressions. We verbalize them into the text to feed into the pre-trained model as an extended context to compute a matching score. Finally, we take option C which exactly matches an extended implicit logical expression as the most plausible answer.

Detailed Analysis of Different Reasoning Types As ReClor integrates various types of logical reasoning skills, we can detailedly investigate the performance of our system *LReasoner*$_{ALBERT}$ on different logical reasoning types compared to the baseline model *ALBERT*. We analyze the improvements brought by our system, and point out challenges to shed a light on future directions.

Reasoning Type	*Base*	*Ours*
Necessary Assumptions (11.0%)	73.7	76.3 (↑)
Sufficient Assumptions (3.6%)	70.0	70.0 (−)
Strengthen (9.0%)	69.1	70.2 (↑)
Weaken (10.6%)	64.6	59.3 (↓)
Evaluation (1.6%)	69.2	69.2 (−)
Implication (6.2%)	43.8	54.3 (↑)
Conclusion/Main Point (3.1%)	80.6	77.8 (↓)
Most Strongly Supported (6.7%)	58.9	71.4 (↑)
Explain or Resolve (8.0%)	60.7	67.9 (↑)
Principle (5.7%)	72.3	76.9 (↑)
Dispute (2.5%)	63.3	80.0 (↑)
Technique (3.8%)	75.0	80.6 (↑)
Role (3.7%)	78.1	68.8 (↓)
Identify a Flaw (11.3%)	65.0	71.8 (↑)
Match Flaws (4.9%)	61.3	61.3 (−)
Match the Structure (2.7%)	56.7	86.7 (↑)
Others (5.5%)	68.5	72.6 (↑)

Table 5: Results of different reasoning types. Numbers in parentheses are percentages of different types. *Base* is the *ALBERT* while *Ours* means our *LReasoner*$_{ALBERT}$. ↑, ↓ and − respectively mean that our performance is better, worse than and equal to the baseline *ALBERT*.

As shown in Table 5, our model is generally effective on most reasoning types compared to the baseline model, especially `Implication`, `Most Strongly Supported`. These questions emphasize the ability of inference over logical units. Specifically, `Implication` needs to infer the conclusion that logically follows a set of premises while `Most Strongly Supported` aims to find the statement that is most strongly supported by a stimulus. This observation verifies the effectiveness of our system to model logical deduction. Besides, `Implication` is precisely the reasoning ability investigated by NLI tasks, which reveals that our model would also be effective in NLI.

However, there still exists some reasoning types that are challenging for our system, such as `Match flaws` and `Weaken`. `Weaken` aims to find the opposite statement that weakens the argument. `Match flaws` is even more challenging as it requires analyzing the flaw that conflicts with the complete logical chain in the context, and finding an option exhibiting the same flaw. Therefore, how to model the different degrees of a logical statement, and abstract the complete logical chain for flaw identification, are interesting future directions.

5.4 Generalizability Discussion

Our logic-driven reasoner not only embodies its superiority in ReClor and LogiQA, but also can be generalized to other datasets and task formats. To demonstrate this, we evaluate our framework on a widely studied extractive QA task SQuAD (Rajpurkar et al., 2016), which covers diverse skills instead of just explicit logical reasoning, such as reasoning of lexical variation, commonsense and causal relations (Sugawara and Aizawa, 2016). As shown in Table 6, our framework is effective on SQuAD compared to both RoBERTa-base and RoBERTa-large, which manifests the generalizability of our logic-driven reasoner.

Model	EM	F1
*RoBERTa-base**	83.0	90.4
LReasoner$_{\textit{RoBERTa-base}}$	85.6	91.7
*RoBERTa-large**	88.9	94.6
LReasoner$_{\textit{RoBERTa-large}}$	89.3	94.8

Table 6: Dev. set results of our framework compared to RoBERTa (both base and large models) on SQuAD. * denotes the results come from (Liu et al., 2019).

6 Related Work

In recent years, there has been a surge in NLP research towards complex reasoning, such as reasoning for commonsense knowledge (Huang et al., 2019), numerical calculation (Dua et al., 2019) or multi-hop aggregation (Yang et al., 2018). Compare to these widely studied reasoning tasks, logical reasoning is also an essential and challenging capability but is relatively unexplored. Natural Language Inference (NLI) (Dagan et al., 2005; Bowman et al., 2015; Williams et al., 2018; Khot et al., 2018) is a typical task requiring logical reasoning, which aims to determine whether a hypothesis can be reasonably entailed from a premise. However, these NLI datasets mainly handle the task at sentence-level and are limited to only a few logical reasoning types, such as entailment, contradiction, and neutral. To promote a deeper passage-level logical reasoning ability, several QA datasets have been proposed. LogiQA (Liu et al., 2020) is collected from the National Civil Servants Examination of China covering 5 logical reasoning types. Yu et al. (2020) propose ReClor dataset from the GMAT and LSAT tests which examines 17 types of logical reasoning. In this paper, we take both ReClor and LogiQA as the testbed to investigate diverse and complicated logical reasoning skills.

Pre-trained language models (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019; Lan et al., 2020) have been widely adopted for various reasoning tasks and achieve promising performance. However, they directly encode the given texts to predict the output while failing to identify the symbolic logical structure and perform explicit logical inference for logical reasoning of text. Semantic parsers (Reddy et al., 2016; Singh et al., 2020) are usually employed for converting texts to logical forms, and graph neural networks (Fang et al., 2019; Huang et al., 2021) and neural module networks (Gupta et al., 2019) also have been attempted to partly imitate the human reasoning process. But these neural methods may not be easily generalized to our desired propositional logical schema without annotations and still perform an implicit inference. To circumvent these limitations and utilize the superior performance of neural models, we take inspiration from neuro-symbolic reasoning (Wang et al., 2018; Arabshahi et al., 2020) to integrate symbolic inference and neural representation. We design an explicit three-step logical reasoning paradigm and propose a logic-driven reasoning system to generically identify the logical structure and perform interpretable logical inference in a symbolic module while taking a pre-trained model as the backbone.

7 Conclusion and Future Work

In this paper, we focus on the task of logical reasoning of text. Following a three-step logical reasoning paradigm, we first propose a neuro-symbolic logic-driven context extension framework. It identifies logical expressions as elementary units of logical inference and symbolically deduces the implicitly mentioned expressions, and verbalizes them as an extended context into a pre-trained model to match the answer. We also introduce a logic-driven data augmentation algorithm, which augments literally similar but logically different instances and employs contrastive learning to help our model better capture logical information. Experimental results confirm the general effectiveness of our LReasoner, and it even surpasses human performance on the ReClor dataset. In the future, we will explore to model different logical reasoning types and directly incorporate symbolic logic into the model structure.

A Details of Logic Identification

We design a generic logic identification approach that uses an off-the-shelf constituency parser and most common keywords of logical semantics (totally no more than 20). We employ the constituency parser to extract constituents as basic symbols. We regard literally similar constituents with an overlap rate over 60% as the same symbol if they also have consistent degree modifiers, such as "*only*", "*most*", "*least*", etc.

We define a set of negative words for identifying logical negation, including {"*not*", "*n't*", "*unable*", "*no*", "*few*", "*little*", "*neither*", "*none of*"}. And the full set of conditional indicators for recognizing the logical conditional relationship between α and β as $(\alpha \rightarrow \beta)$ is {"*if* α, *then* β", "α *in order for* β", "α *thus* β", "β *due to* α", "β *owing to* α", "β *since* α", "$\neg\beta$ *unless* α"}. The detailed parsing procedure is illustrated in Algorithm 1.

Algorithm 1 Logic Identification Algorithm

```
Input: A sentence in the context or an option $t$ to be parsed, a set of logical negative keywords $\mathcal{N}$ and a set of logical conditional indicators $\mathcal{C}$.
Output: A logical expressions set $\mathcal{S}$ parsed from the input $t$.
Initializing $\mathcal{S} := \{\}$
Extracting constituents from the input $t$.
Recognizing literally similar constituents as the same symbol and obtain all logical symbols as $\{\alpha, \beta, ...\}$.
for symbol $a$ in $\{\alpha, \beta, ...\}$ do
    if $\exists\ n_i \in \mathcal{N}$ is in or immediately before the logical symbol $a$ then
        Adding the negation connective $\neg$ before $a$ as $\neg a$.
        Replacing the original symbol with the negative one as $a := \neg a$.
    end if
end for
for symbol $a$ in $\{\alpha, \beta, ...\}$ do
    for symbol $b$ in $\{\alpha, \beta, ...\}$ do
        if $a \neq b$ and ( $\exists\ c_i \in \mathcal{C}$ is between two logical symbols $a$ and $b$ or an active voice occurs between $a$ and $b$ ) then
            Obtaining a logical expression $a \rightarrow b$.
            Appending $a \rightarrow b$ to the logical expression set $\mathcal{S}$.
        end if
    end for
end for
return The logical expressions set $\mathcal{S}$.
```

B Implementation Details

We take RoBERTa-large (Liu et al., 2019), ALBERT-xxlarge-v2 (Lan et al., 2020) and DeBERTa-xlarge (He et al., 2020b) as our backbones and implement them using Huggingface (Wolf et al., 2019). We use a batch size of 8 and fine-tune for 10 epochs. The AdamW (Loshchilov and Hutter, 2017) with $\beta 1$ = 0.9 and $\beta 2$ = 0.98 is taken as the optimizer and the learning rate is 1e-5. We use a linear learning rate scheduler with 10% warmup proportion. We automatically evaluate our model on validation set to choose parameters that achieve the highest accuracy. We select at most two extended logical expressions related to each option to construct the extended context for ReClor and select at most three for LogiQA. We train our proposed systems and other comparison models on two NVIDIA Tesla V100 GPUs.

Transfer Learning and Prediction Consistency for Detecting Offensive Spans of Text

Abstract

Toxic span detection is the task of recognizing offensive spans in a text snippet. Although there has been prior work on classifying text snippets as offensive or not, the task of recognizing spans responsible for the toxicity of a text is not explored yet. In this work, we introduce a novel multi-task framework for toxic span detection in which the model seeks to simultaneously predict offensive words and opinion phrases to leverage their inter-dependencies and improve the performance. Moreover, we introduce a novel regularization mechanism to encourage the consistency of the model predictions across similar inputs for toxic span detection. Our extensive experiments demonstrate the effectiveness of the proposed model compared to strong baselines.

1 Introduction

With the proliferation of social networks, the amount of textual data posted online is also ever-increasing. This growth comes with some challenges too. One of the issues associated with social networks is the level of toxicity expressed in posts or comments shared online. The toxic/offensive languages in social networks can be realized in different forms such as insults, mockeries, threats, discrimination, or swearing. Due to their detrimental effect on users of social networks, it is desirable to identify and remove offensive text from these networks.

Since this is an important requirement, the task of offensive language detection has been extensively studied in NLP community (Schmidt and Wiegand, 2017; Feng et al., 2018; Borkan et al., 2019; Sivanaiah et al., 2020; Yasaswini et al., 2021). However, most of the existing works are limited to classifying a text snippet as offensive or not. In other words, these models fail to provide further information about what specific phrases in the text snippet contribute the most to the offensive tone of the text. This information is necessary for the moderators to decide further actions for the posts/comments flagged as offensive, especially if the text snippet is long. As such, in this work, we fill this gap by proposing a novel model for the task of offensive span detection (OSD). As an example, in the given text "*This livestreamer clearly has no brain; he is such a tool!*", the phrase "*has no brain*" and the slang word "*tool*" are two offensive spans responsible for the toxicity of the text. One of the barriers for this task is data scarcity. To address this limitation, we propose a novel model trained in multi-task setting in which the model is trained on two tasks: (1) Offensive phrase detection whose goal is to detect word(s) contributing to the toxicity of the text, (2) Opinion word extraction which is supposed to assist the main model to pinpoint word(s) conveying subjectivity. Note that the second task could help the model restrict its prediction to more likely words. As the available resources for offensive span detection do not provide any annotation for opinion words in the text, in this work, we propose to employ transfer learning to fulfill the training on the second task (i.e., opinion word extraction). In particular, a separate model is pre-trained on sentiment polarity prediction on a sentiment analysis corpus. Afterward, the pre-trained model is exerted to provide supervision for the task of opinion word extraction. In addition to the proposed multi-task setting, we also introduce a novel regularization loss in which the model is encouraged to make consistent predictions on similar inputs. Concretely, in this work, we propose to compute the similarity between samples in a mini-batch with respect to two criteria: (i) word representations (ii) prediction of offensive words. During training, the samples that have the highest similarity are encouraged to have less discrepancy with each other. In order to fulfill this goal, for the first time, we propose to employ Optimal Transport

Findings of the Association for Computational Linguistics: ACL 2022, pages 1630 - 1637
May 22-27, 2022

to compute the consistency loss between samples. We evaluate the proposed model on a recently released dataset for offensive span detection. Our extensive experiments show the effectiveness of the proposed model by outperforming the strong baselines.

2 Model

Formal Task Description: The input to the model is the document $D = [w_1, w_2, \dots, w_n]$ consisting of n words. The label provided for the document is also the sequence $Y = [y_1, y_2, \dots, y_n]$ in which y_i is the label for the word w_i in BIO format. This problem is modeled as a sequence labeling task in which the model predicts the label of every word w_i in the document D. Our proposed method is based on multi-task training with opinion word prediction as the auxiliary task. We also propose a novel regularization using Optimal Transport. The rest of this section provides details of our approach.

2.1 Main Task

For the main task of offensive span detection (OSD), we employ the BERT$_{base}$ model with fixed parameters to encode the input text. Formally, the input to the BERT model is $[CLS]w_1w_2 \dots w_n[SEP]$ and the representation of the token at the final layer of the BERT model are used to represent them, i.e., $X = [x_1, x_2, \dots, x_n]$. Since the parameters of the BERT model are fixed, to update the representations of the tokens for the offensive span detection task, we feed the representations X to a Bi-directional Long Short-Term Memory (BiLSTM) network. The hidden states of the BiLSTM network is used as the final representations of the words, i.e., $H = [h_1, h_2, \dots, h_n]$. Finally, a two-layer feed-forward network is employed to obtain the label distribution $P(\cdot|D, w_i)$ for word w_i: $P(\cdot|D, w_i) = \text{softmax}(W_1 * (W_2 * h_i + b_1) + b_2)$, where W_1 and W_2 are the weight matrices, b_1 and b_2 are biases, softmax is the softmax function, and the $P(\cdot|D, w_i)$ represent the probability distribution over different labels predicted by the feed-forward layer for the word w_i. To train this model, we use cross-entropy loss in word-level (i.e., negative log-likelihood). More specifically, the following loss function is used: $\mathcal{L}_{main} = -\sum_i^n \log(P(y_i|D, w_i))$, where y_i is the gold label for the word w_i in the document D in training data.

2.2 Auxiliary Task

One of the limitations of the existing training data for OSD is their small size which could hurt the generalization ability of the model. To alleviate this issue, we propose to train the model in a multi-task setting, thus benefiting from the interaction between the main and the auxiliary task. Specifically, we choose opinion work extraction (OWE) as the auxiliary task. In this task, the goal is to find the words conveying sentiment in text. Note that opinion words are the super-set of the toxic words, as such training on OWE could help the model to restrict its predictions to more likely words. Unfortunately, the existing OSD datasets do not annotate the opinion words. Therefore, to train the model on OWE, we resort to transfer-learning, in which a pre-trained model on another related task, i.e., Sentiment Analysis (SA), is employed to guide the OSD model on the auxiliary task OWE.

Specifically, for the pre-training of the SA model, we employ the available sentiment analysis dataset, i.e., $\mathcal{D}_{SA}$. In this dataset, every sentence $S' \in \mathcal{D}_{SA}$ is labeled as "*Positive*", "*Neutral*" or "*Negative*". To train the model SA, the sentence S', represented by the GloVe embedding of its words, is encoded by a BiLSTM network, i.e., $H' = [h'_1, h'_2, \dots, h'_m]$. Finally, a feed-forward network consumes the max-pooled representation of the sentence S' to produce the label probability distribution, i.e., $P'(\cdot|S') = FF(MAX\_POOL(H'))$. To train the model, the negative log-likelihood is employed: $\mathcal{L}_{pre} = -\log(P(l|S'))$, where l is the label of the sentence S'.

In order to employ the per-trained SA model to guide the OSD model for OWE, we posit that if the OSD model masks the opinion words of the input document D then the pre-trained model SA will predict *Neutral* label for the masked document. Note that without masking, the sentiment of the document D is always negative. To fulfill this idea, in our model, we first feed the representation of the document D, i.e., the vectors H obtained form BiLSTM of OSD model, to a feed-forward network to obtain the scores $A = [a_1, a_2, \dots, a_n]$, where $a_i = \sigma(FF(h_i))$ and σ is the sigmoid activation function. The scores a_i represent the extent to which the OSD model predicts w_i as opinion word. Next, to mask out the opinion words, the weighted vectors X' is computed: $X' = [x'_1, x'_2, \dots, x'_n]$, where $x'_i = a_i * x_i$ and x_i is the GloVe embedding of the word $w_i \in D$. The masked document representation X' is fed into the pre-trained model SA to obtain the label distribution $P'(\cdot|D)$. Note that, during training of the main model, the parameters of the pre-trained SA model are fixed. To train the main model, we use the following loss function: $\mathcal{L}_{aux} = -\log(P'(l_n|D))$, where l_n is the *Neutral* label. As the training could collapse by predicting all-zero vector for A, we use the following regularization for the auxiliary task: $\mathcal{L}_{reg} = |n - \text{SUM}(A)|$, where n is the length of the document and $SUM(X)$ is the sum of all elements of the vector X.

2.3 Prediction Consistency

In order to address the data scarcity for OSD, we also propose a novel regularization in which the model is encouraged to make consistent predictions for similar input documents. Hence, the model behavior on one sample can guide it on the other samples too. To this end, we propose to compute the consistency between model's predictions on two documents D_i and D_j by the cost of converting (D_i, Y'_i) to (D_j, Y'_j) where Y'_i and Y'_j are predictions of the model for documents D_i and D_j, respectively. This problem can be efficiently solved by Optimal Transport (OT). OT is a method to compute the lowest cost of converting a probability distribution to another one. Formally, given the probability distributions $p(x)$ and $q(y)$ over the domains $\mathcal{X}$ and $\mathcal{Y}$, and the cost function $C(x,y) : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}_+$ for mapping $\mathcal{X}$ to $\mathcal{Y}$, OT finds the optimal joint distribution $\pi^*(x,y)$ (over $\mathcal{X} \times \mathcal{Y}$) with marginals $p(x)$ and $q(y)$, i.e., the cheapest transportation from $p(x)$ to $q(y)$, by solving the following problem:

$$\pi^*(x,y) = \min_{\pi \in \Pi(x,y)} \int_{\mathcal{Y}} \int_{\mathcal{X}} \pi(x,y) C(x,y) dx dy \quad \text{s.t. } x \sim p(x) \text{ and } y \sim q(y), \tag{1}$$

where $\Pi(x,y)$ is the set of all joint distributions with marginals $p(x)$ and $q(y)$. Note that if the distributions $p(x)$ and $q(y)$ are discrete, the integrals in Equation 1 are replaced with a sum and the joint distribution $\pi^*(x,y)$ is represented by a matrix whose entry (x,y) represents the probability of transforming the data point $x \in \mathcal{X}$ to $y \in \mathcal{Y}$ to convert the distribution $p(x)$ to $q(y)$. By solving the problem in Equation 1[1], the cost of transforming the discrete distribution $p(x)$ to $q(y)$ (i.e., Wasserstein distance $Dist_W$) is defined as: $Dist_W = \Sigma_{x \in \mathcal{X}} \Sigma_{y \in \mathcal{Y}} \pi^*(x,y) C(x,y)$.

In our model, we use the Wasserstein distance $Dist_W$ between two documents to compute their consistency. In particular, for every pair of (D_k, D_l) where D_k and D_l are two documents in the same mini-batch, the domain $\mathcal{X}$ is defined over the word representations of the document D_k, i.e., H_k, and the domain $\mathcal{Y}$ is defined over the word representations of the document D_l, i.e., H_l. Moreover, in order to define the distributions $p(x)$ and $q(y)$, we take the probability of the label O for each word of the document D_k and D_l predicted by the main task model and feed that into a softmax function.

Finally, to define the cost function $C(x_i, y_j)$, we use the Euclidean distance between the two vector representation h_i and h_j for the word w_i of D_k and the word w_j of D_l: $C(x_i, y_j) = \|h_i - h_j\|$. Using these definitions, we can use OT to compute the Wasserstein distance $Dist_W^{k,l}$ between the document D_k and D_l in the same mini-batch. Finally, we select the document $D_{k'}$ as the most similar document to D_k where: $k' = \text{argmin}_l Dist_W^{k,l}$

Hence, we define the consistency loss for document D_k as its Wasserstein distance to the similar document $D_{k'}$: $\mathcal{L}_{cons} = Dist_W^{k,k'}$.

Finally, we use the following loss function with trade-off parameters α, β, and γ to train the entire model: $\mathcal{L} = \mathcal{L}_{main} + \alpha * \mathcal{L}_{aux} + \beta * \mathcal{L}_{reg} + \gamma * \mathcal{L}_{cons}$

3 Experiments

In order to evaluate the effectiveness of the proposed model, called TPOSD (Transfer learning and Prediction consistency for Offensive Span Detection), in our experiments, we use the dataset of SemEval 2021 Task 5 (John Pavlopoulos and Laugier, 2021). We use the official splits with 7939/690/2000 documents in train/development/test sets. Also, to pre-train the SA model for the sentiment analysis task to be used for auxiliary training, we employ the Amazon-2 dataset Zhang et al. (2015). In our model we use the (fixed) BERT$_{base}$ to encode data; 250 dimensions for the hidden states of LSTM and 2 layers for feed-forward neural networks with 250 hidden dimensions. The trade-off parameters α, β and γ are set to 0.1, 0.1, and 0.05, respectively. The learning rate is set to 0.3 for the Adam optimizer and the batch size of 64 is employed during training.

we compare the performance of TPOSD with

---

[1] It is worth mentioning that this problem is intractable so we solve its entropy-based approximation using the Sinkhorn algorithm (Peyre and Cuturi, 2019).

Table 2: Ablation study on the development set of the SemEval 2021 Task 5 dataset.

the following baselines: (1) **BiLSTM+CRF**: The GloVe embedded document is encoded by BiLSTM and the labels are predicted by a CRF layer; (2) **BERT+CRF**: BERT$_{base}$ parameters are fine-tuned on OSD task and the task-specific head, i.e., CRF, is employed for label prediction; (3) **IITK** (Bansal et al., 2021): This baseline is the existing SOTA model on SemEval 2021 Task 5 dataset; (4) **SANER** (Nie et al., 2020): This baseline is the SOTA model for sequence labeling on user-generated text; (5) **DUAL-MRC** (Mao et al., 2021): This is the SOTA model for opinion and aspect term extraction. Note that since there are not target annotations in SemEval dataset, we skip the aspect term extraction task in the training of this baseline.

Results: Table 1 shows the performance of the models on the test set. There are several observations from this table. First, the BiLSTM-CRF model significantly underperforms the other baselines that employ BERT embedding. It clearly shows that the background knowledge encoded in the BERT model is necessary for the task of offensive span detection. Second, both DUAL-MRC and SANER baseline outperform the BERT-CRF model. This higher performance could be attributed to their capability to augment the representation of the words obtained from the BERT model. Third, among all baselines, our proposed model achieves the highest performance. Our hypothesis for the achieved improvement is that the proposed model is able to restrict its predictions to the more probable candidate spans, i.e., opinion words, due to the training of the auxiliary task. Moreover, it performs more consistently across different documents thanks to the consistency regularization employed during the training of the model.

Analysis: To study the contribution of the proposed techniques, we conduct an ablation study on the development set of the SemEval 2021 Task 5 dataset. Specifically, we ablate the auxiliary task (**OWE**$^{-}$), the regularization in the auxiliary task (**AuxReg**$^{-}$), i.e., $\mathcal{L}_{reg}$, the consistency loss (**Cons**$^{-}$), i.e., $\mathcal{L}_{cons}$. Also, we study the performance of the model when the Wasserstein distance is computed regardless of the document representations (**Cons**$^{-sem}$) or model predictions (**Cons**$^{-pred}$). The results are shown in Table 2. This table shows that all components are necessary, as removing each will hurt the performance. Specifically, the auxiliary task has the largest effect on the final performance, indicating the importance of the proposed method. For the case study analysis, see appendices.

In the proposed approach, to simultaneously train the model on OSD and OWE, as the existing training data for OSD does not provide gold labels for OWE, we resort to transfer-learning, in which a pre-trained sentiment-analysis model is employed to supervise the main model on OWE task. However, one natural question is that why transfer-learning is the optimal approach to train the model on OWE? To answer this question, in this section, we propose a baseline, in which a model pre-trained on OWE is employed to automatically annotate the existing OSD training data with opinion words for OWE task. In particular, we first train a sequence-tagger consisting of a BiLSTM encoder followed by a feed-forward layer on the available OWE dataset. Specifically, in our experiments, we use the combinations of the four benchmark datasets presented by Fan et al. (2019) as the training data to pre-train the OWE model. Note that the original datasets by Fan et al. (2019) provide opinion words with respect to a given target mention. However, in the pre-training of the OWE model, we aim to train the model to detect all opinion words in the input text. As such, in our experiments, we combine opinion words of all samples of the same sentence in the dataset. Finally, the pre-trained OWE model is employed to annotate the opinion words in the OSD dataset, i.e., SemEval 2021 Task 5 (John Pavlopoulos and Laugier, 2021). The au-

Model	Precision	Recall	F1
Pre-Train OWE	64.11	68.83	66.39
TPOSD (Ours)	**67.78**	**71.92**	**69.79**

Table 3: Performance of the models on the test set of the SemEval 2021 Task 5 dataset.

tomatically annotated OSD dataset with opinion words is next employed to jointly train the main model on OSD and OWE. Concretely, the representations of the words obtained from the main model BiLSTM, i.e., $H = [h_1, h_2, \dots, h_n]$, are fed into two different feed-forward layers FF_{OSD} and FF_{OWE} to obtain the label probability distribution $P_{OSD}(\cdot|D, w_i)$ and $P_{OWE}(\cdot|D, w_i)$, respectively: $P_{OSD}(\cdot|D, w_i) = \text{softmax}(FF_{OSD}(h_i))$, and $P_{OWE}(\cdot|D, w_i) = \text{softmax}(FF_{OWE}(h_i))$.

Finally, the following loss functions are employed for each task: $\mathcal{L}_{OSD} = -\sum_i^n \log(P_{OSD}(y_i^{OSD}|D, w_i))$ and $\mathcal{L}_{OWE} = -\sum_i^n \log(P_{OWE}(y_i^{OWE}|D, w_i))$, where y_i^{OSD} and y_j^{OWE} are the gold labels for offensive span detection (OSD), provided in the SemEval dataset, and opinion word extraction (OWE) tasks, provided by the pre-trained OWE model, for i-th word. The overall loss to train the model jointly on both tasks is then defined by: $\mathcal{L}_{total} = \mathcal{L}_{OSD} + \alpha * \mathcal{L}_{OWE}$.

We call this baseline **Pre-Train OWE** and its performance on the test set of the SemEval dataset is reported in Table 3. This table shows that this baseline under-performs our transfer-learning approach. Our hypothesis for this inferior performance is that compared to our transfer-learning approach that utilizes soft filtering of the input text to identify the opinion words, the pre-trained model employs the discrete labels for OWE generated by the pre-trained model. As the pre-trained OWE model could be erroneous, thus the errors can more easily deflect the training of the main model. Unlike this baseline, in our proposed model, the opinion words are denoted by the scores A discussed in section 2.2. As such, the soft opinion word extraction mechanism in our proposed model has more potential to overcome errors in the OWE task.

4 Related Work

Prior works related to this task can be categorized into two groups: (i) Toxicity Detection: These works aim to classify a piece of text as toxic or non-toxic (Wulczyn et al., 2017; Borkan et al., 2019; Schmidt and Wiegand, 2017; Pavlopoulos et al., 2017a,b, 2019; Zampieri et al., 2019). The main limitation of these works is that they cannot recognize the spans in the text that are responsible for the toxicity of the text. (ii) Opinion Word Extraction: In this group, models perform a sequence labeling task to identify the spans in the text that convey the sentiment (Liu et al., 2015; Xu et al., 2018; Yin et al., 2016; Wang et al., 2016, 2017; Li and Lam, 2017; Mao et al., 2021). The major limitation of all these models is that they require the existence of the target opinion (i.e., the word or phrase that the text has a sentiment polarity toward it).

5 Conclusion

In this work, we proposed a novel model for offensive span detection. To train the model, in a novel framework, we propose to exploit the interaction with the related task of opinion word extraction. Specifically, in a multi-task learning setting, we train the model for offensive and opinion word extraction. Also, we introduce a novel regularization loss based on optimal transport which encourages the consistency of the model prediction on similar documents. Our experiments on the available benchmark dataset show the effectiveness of the proposed model and outperform strong baselines.

A Case Study

To qualitatively study the improvement achieved by the proposed model, in Table 4, we present some cases that the proposed model could successfully identify the offensive spans while the other baselines fail. Specifically, cases 1 and 2 show that the baseline *BERT-CRF* incorrectly predict non-opinion words/phrase “*gross reliance*" and “*joke*" as the offensive spans. On the other hand, TPOSD successfully predicts the offensive spans. This improvement could be attributed to the training of the main model on opinion word extraction which could restrict model decisions to more likely words. Moreover, in case 3, the baseline *BERT-CRF* incorrectly predicts the word “*strange*" as the offensive word. However, the proposed TPOSD model successfully identifies the word “*idiot*" as the only offensive word in the text. Among other reasons, the better performance of the proposed model for this case could be due to the regularization enforced during training which helps the model learns from other samples that “*strange*" is less likely to be used as the offensive word.

ID	Document	BERT-CRF	TPOSD	Gold
1	Sorry. Damn spell checker and my gross reliance on it! My humblest apologies :-)	gross reliance	Damn	Damn
2	Yeah, what a joke. They can’t confirm the gunshot wounds were inflicted by the police? Ridiculous.	joke	Ridiculous	Ridiculous
3	Hard to believe this strange comment! He is such an idiot.	strange, idiot	idiot	idiot

Table 4: Case study in SemEval 2021 Task 5 dataset. Predicted offensive words by the *BERT-CRF* and the proposed model, *TPOSD*, along with gold labels are provided.

Learning Reasoning Patterns for Relational Triple Extraction with Mutual Generation of Text and Graph

Abstract

Relational triple extraction is a critical task for constructing knowledge graphs. Existing methods focused on learning text patterns from explicit relational mentions. However, they usually suffered from ignoring relational reasoning patterns, thus failed to extract the implicitly implied triples. Fortunately, the graph structure of a sentence's relational triples can help find multi-hop reasoning paths. Moreover, the type inference logic through the paths can be captured with the sentence's supplementary relational expressions that represent the real-world conceptual meanings of the paths' composite relations. In this paper, we propose a unified framework to learn the relational reasoning patterns for this task. To identify multi-hop reasoning paths, we construct a relational graph from the sentence (text-to-graph generation) and apply multi-layer graph convolutions to it. To capture the relation type inference logic of the paths, we propose to understand the unlabeled conceptual expressions by reconstructing the sentence from the relational graph (graph-to-text generation) in a self-supervised manner. Experimental results on several benchmark datasets demonstrate the effectiveness of our method.

1 Introduction

Relational triple extraction is defined as automatically recognizing semantic relations with triple structures (*subject*, *relation*, *object*) among multiple entities in a sentence. It is a critical task for natural language processing, especially for Knowledge Graph (KG) construction from unlabeled corpus (Dong et al., 2014).

Recent work proposed several neural network methods to extract relational triples. For example, Zheng et al. (2017) proposed a sequence tagging scheme for this task but failed to extract overlapping triples. Wei et al. (2020) proposed to solve the overlapping triple problem with a binary tagging framework. Zeng et al. (2018) proposed to address this issue by generating triple element sequences with copy mechanism.

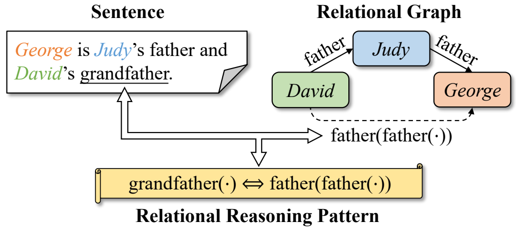

Figure 1: An example of the relational graph and the relational reasoning pattern. Solid arrows of the relational graph are golden relational triples. The dashed arrow is a two-hop reasoning path.

Existing methods achieved considerable success in learning text patterns of relational triples from explicit mentions. However, they usually suffered from the failure of extracting the relational triples which are implicitly implied in the text (Zhu et al., 2019). This is because they ignored relational reasoning patterns in natural language, which usually consist of *finding multi-hop paths* and *inferring relation types along these paths*. For example, in Figure 1, the triple ("*David*", "*father*", "*Judy*") is not explicitly expressed in the sentence and requires relational reasoning to be extracted. Unfortunately, the ignorance of relational reasoning patterns in existing methods will cause serious incompleteness of the constructed KGs and performance degradation of downstream tasks (Angeli and Manning, 2013; Jia et al., 2020).

Our work is motivated by several observations. First, the relational triples of a sentence usually have a graph structure, which is useful for finding multi-hop reasoning paths. For example, in Figure 1, the relational graph provides a two-hop reasoning path between "*David*" and "*George*". Second, the sentence usually contains supplementary relational expressions that represent the real-world

---

*Equal contribution.

Findings of the Association for Computational Linguistics: ACL 2022, pages 1638 - 1647
May 22-27, 2022

conceptual meanings of the paths' composite relations, which can help capture the relation type inference logic through the paths. For example, in Figure 1, the phrase "*'s grandfather*" helps capture the equivalence between the composite relation "*father(father(·))*" and the real-world relational concept "*grandfather*", which reflects the relation type inference logic of the two-hop path.

In this paper, we propose a unified framework to learn reasoning patterns for the relational triple extraction task. First, we construct a relational graph from the sentence, i.e. **text-to-graph** generation, to identify potential multi-hop reasoning paths. Then we utilize a multi-layer Relational Graph Convolution Network (R-GCN) (Schlichtkrull et al., 2018) to propagate node information along these paths. Next, to capture the relation type inference logic of the reasoning paths, we aim to exploit and understand the conceptual expressions in the sentence, but the absence of human annotations for these expressions poses a huge challenge. To tackle this challenge, we propose a self-supervised reconstruction of the sentence from the relational graph, i.e. **graph-to-text** generation. Our model captures the relation type inference logic by learning to recover the conceptual expressions from the symbolic relation composition, such as the recovery of "*'s grandfather*" from "*father(father(·))*" in Figure 1. Finally, we use the reasoning pattern enhanced model to extract relational triples from the sentence.

The main contributions of this paper are:

- We propose a mutual generation framework of text and graph to learn relational reasoning patterns for relational triple extraction.
- To identify multi-hop reasoning paths, we construct a relational graph from the sentence and apply a multi-layer R-GCN to the graph.
- To capture the relation type inference logic of the paths, we propose to exploit the unlabeled conceptual expressions with a self-supervised sentence reconstruction task from the graph.
- Experimental results on several datasets indicate the effectiveness of our method.

2 Related Work

Early work extracted relational triples with pipeline systems (Zelenko et al., 2003; Zhou et al., 2005; Chan and Roth, 2011; Gormley et al., 2015), but they usually suffered from error propagation problems. Also, they failed to capture the interactions between entities and relations. To address these issues, jointly extracting entities and relations with an end-to-end model has become the main paradigm of this task. Previous work proposed several feature-based models (Yu and Lam, 2010; Li and Ji, 2014; Ren et al., 2017). For example, Ren et al. (2017) proposed a joint embedding framework to map entities, relations, text features and type labels into unified low-dimensional spaces. Afterward, several neural network-based methods were proposed to eliminate hand-crafted features (Gupta et al., 2016; Miwa and Bansal, 2016; Zheng et al., 2017). For example, Zheng et al. (2017) proposed to extract relational triples directly with a sequence tagging model, whose tags contain the information of entities and the relations they hold. However, they assigned only one label to each word and failed to extract multiple triples whose entities overlap with each other.

Recent work proposed several mechanisms to address the overlapping triple problem, such as sequence tagging variations (Wei et al., 2020; Wang et al., 2020; Zheng et al., 2021) and triple element generation (Zeng et al., 2018, 2019, 2020; Sui et al., 2020; Huguet Cabot and Navigli, 2021). For example, Wei et al. (2020) proposed a cascade binary tagging framework and modeled relations as functions that map subjects to objects. Zheng et al. (2021) proposed to decompose the task into three subtasks: relation judgment, entity extraction and subject-object alignment. Zeng et al. (2018) proposed to generate the element sequence of triples with a copy-based seq2seq model, while Sui et al. (2020) proposed to generate the set of triples with a set prediction network. However, these methods mainly focused on learning text patterns of the explicitly mentioned triples. They usually ignored the relational reasoning patterns thus failed to extract the implicitly implied triples (Zhu et al., 2019). Although Chen et al. (2021) proposed a reasoning pattern enhanced model, they utilized entity type information, which requires extra supervision.

Different from previous work, we propose a mutual generation framework of text and graph to capture relational reasoning patterns. We identify multi-hop reasoning paths by generating a relational graph from the sentence. We propose to capture the relation type inference logic by incorporating supplementary conceptual expressions with self-supervised sentence generation from the graph. Experimental results on several datasets demonstrate the effectiveness of our method.

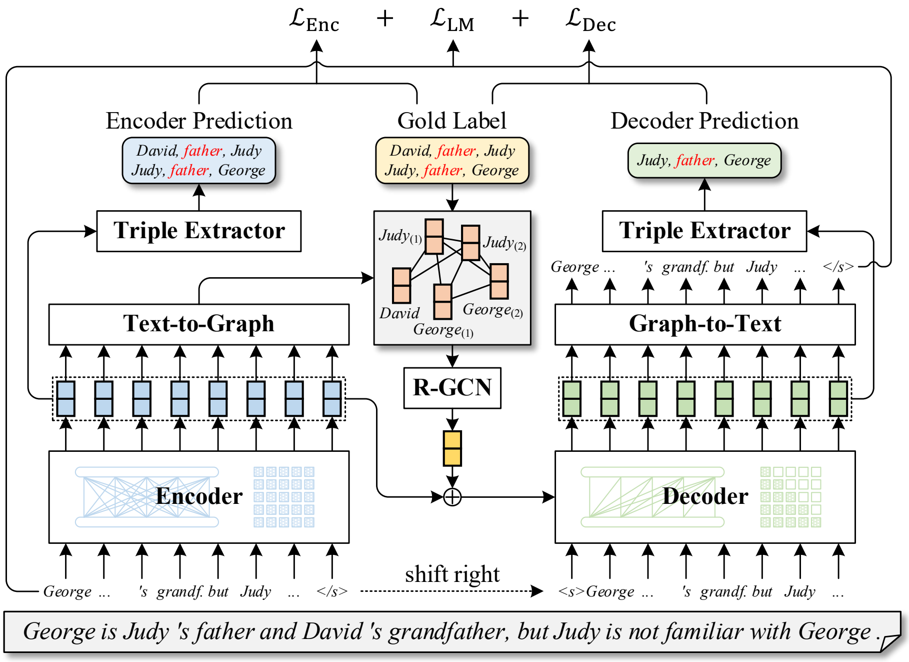

Figure 2: The overall framework of our approach. When recovering the sentence, we use the left-to-right Language Model (LM) objective, which is controlled by the lower triangular attention mask of the Transformer decoder.

3 Our Approach

The overall framework of our approach is illustrated in Figure 2. We introduce the text-to-graph and the graph-to-text generation methods in Section 3.1 and 3.2, respectively. Then we introduce the triple extractor in Section 3.3 and the details of training and inference in Section 3.4.

3.1 Text-to-Graph Generation

Relational reasoning in natural language is challenging because it usually requires reasoning for multiple hops. We observe that the graph structure of a sentence's relational triples can help identify multi-hop reasoning paths. Therefore, we construct a relational graph from the sentence to find multi-hop paths and apply multi-layer graph convolutions to propagate information along the paths.

First, we encode the words in the sentence into dense vector representations. Given the sentence $[x_1, \dots, x_n]$, we employ a bi-directional Pre-trained Language Model (PLM) based on Transformers (Vaswani et al., 2017) as the encoder to capture the context of the sentence. We use the last hidden states $[\mathbf{h}_1^E, \dots, \mathbf{h}_n^E]$ of the PLM as the contextual representations of the words.

Next, we use the word representations and the ground truth of relational triples to obtain the relational graph. We denote the graph as $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{R})$, where $\mathcal{V} = \{\mathbf{v}_1, \dots, \mathbf{v}_{|\mathcal{V}|}\}$ are the nodes with feature vectors, $\mathcal{R} = \{r_1, \dots, r_{|\mathcal{R}|}\}$ are the relation types and $\mathcal{E} = \{(\mathbf{v}_i, r_k, \mathbf{v}_j), \dots\}$ are the edges of the graph. We first utilize the text spans of the golden triples' entities to find the positions of all entity mentions in the sentence by perfect matching. We consider each entity mention $m = [x_{s_m}, \dots, x_{e_m}]$ as a graph node, where s_m and e_m are the mention's start and end positions, respectively. We average the contextual word representations of the corresponding positions to obtain the feature vector $\mathbf{v} = \text{Average}([\mathbf{h}_{s_m}^E, \dots, \mathbf{h}_{e_m}^E]) \in \mathcal{V}$. Then we add three kinds of edges to $\mathcal{E}$, as shown in Figure 3: (1) *Golden edges*, which connect all nodes (mentions) of the subject s and the object o with relation r for each golden triple (s, r, o). These edges provide the basic relation information of the golden triples. (2) *Reversed golden edges*, which are the reverse of the golden edges with new reverse relation types. These edges are added to allow sufficient bidirectional flow of node information to prevent some special graph structures from cutting off the information flow paths between nodes, such as siblings[1]. (3) *Co-reference edges*,

---

[1] For example, consider the graph B ← A → C. If reversed edges are not added, B and C will only be updated by A (and of course themselves) but A will never be updated by B or C. This will cut off the information flow path between B and C. If reversed edges are added, then each node can be updated by the other two, making the information flow more sufficient.

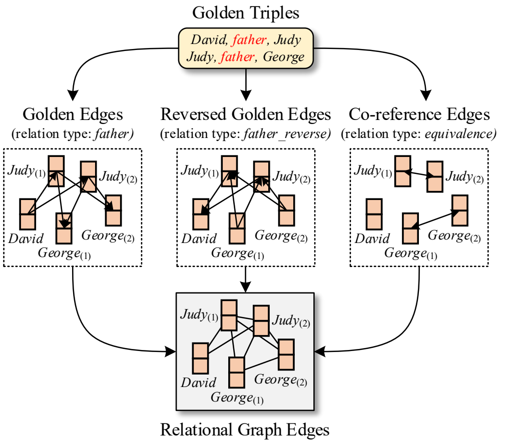

Figure 3: An example of the relational graph edges.

which connect all mentions pairs of the same entity with an equivalence relation. These edges are added to enhance entity representations (Wadden et al., 2019) because they propagate the rich information included in multiple mentions and their surrounding contexts. Therefore, the relation type set $\mathcal{R}$ contains the equivalence relation, the original relations of the dataset, and their reverse relations.

Finally, we employ an R-GCN (Schlichtkrull et al., 2018) with multiple layers to incorporate relation type information and propagate information along multi-hop paths. Following Guo et al. (2019), we add dense connections to the R-GCN. Formally, the convolution of the l-th layer is formulated as:

$$\mathbf{g}_i^{l+1} = \rho\Big(\mathbf{W}_s^l \mathbf{k}_i^l + \sum_{r \in \mathcal{R}} \sum_{j \in \mathcal{N}_i^r} \frac{1}{|\mathcal{N}_i^r|} \mathbf{W}_r^l \mathbf{k}_j^l\Big) \quad (1)$$

where ρ is an activation function (e.g. ReLU) and $\mathbf{W}_r^l$ and $\mathbf{W}_s^l$ are the transformation matrices of relation r and self-loops. $\mathcal{N}_i^r$ denotes neighbors of the i-th node under the relation r, and $\mathbf{k}_i^l = [\mathbf{g}_i^1, \ldots, \mathbf{g}_i^l]$ where $\mathbf{g}_i^1 = \mathbf{v}_i$. Then we feed the nodes' initial features and the R-GCN's output into a Multi-Layer Perceptron (MLP) and average the output to obtain the final graph representation: $\mathbf{g} = \text{Average}\big(\text{MLP}([\mathbf{v}; \mathbf{g}^L])\big)$.

3.2 Graph-to-Text Generation

Given a multi-hop reasoning path, inferring the relation type along the path is difficult because the inference logic usually reflects complicated commonsense facts. Fortunately, we observe that the sentence usually contains supplementary expressions that represent the real-world concepts of the paths' composite relations. These relational expressions can help capture the relation type inference logic. For example, in Figure 1, the symbolic composition of the two-hop relational path is "*father(father(·))*". The phrase "*'s grandfather*" in the sentence helps connect the composite relation and the real-world relational concept "*grandfather*", which reflects the fact that "*father*'s *father* is *grandfather*".

Based on this observation, we propose to exploit and understand the conceptual expressions in the sentence. However, the absence of human annotations for these concepts poses a great challenge. Inspired by self-supervised pre-training techniques of various PLMs (Devlin et al., 2019; Raffel et al., 2020; Lewis et al., 2020), we propose to reconstruct the sentence from the relational graph in a self-supervised manner to tackle this challenge. Our model learns the type inference logic by recovering the conceptual expressions from the symbolic relation compositions. For example, generating "*grandfather*" from "*father(father(·))*" represents the ability of understanding the logical equivalence between "*father*'s *father*" and "*grandfather*" (Radford et al., 2018; Tseng et al., 2020).

To reconstruct the sentence, we utilize an autoregressive PLM as the decoder with the left-to-right LM objective. Given the sentence's encoder hidden states $[\mathbf{h}_{1:n}^E]$ and the graph representation $\mathbf{g}$, the standard graph-to-text decoder takes $\mathbf{g}$ and the right-shifted sentence $[\texttt{<s>}, x_1, \ldots, x_{n-1}]$ as input. However, we discover that the sentence may have relational irrelevant contents (e.g. "*is not familiar with*" in Figure 2), which may bring corruption to the reconstruction. To address this issue, we borrow part of the contextual information by feeding the average of $[\mathbf{h}_{1:n}^E]$ and $\mathbf{g}$ instead of $\mathbf{g}$ into the decoder. We denote the decoder's last hidden states as $[\mathbf{h}_{1:n}^D]$. Finally, we use a softmax classifier to predict the reconstructed tokens: $\mathbf{p}_i^{\text{LM}} = \text{softmax}\big(\mathbf{W}_d \mathbf{h}_i^D + \mathbf{b}_d\big)$.We choose the state-of-the-art T5 (Raffel et al., 2020) model as our backbone PLM because it has the same encoder-decoder structure as ours.

3.3 Triple Extractor

We employ CASREL (Wei et al., 2020) to extract relational triples. It consists of a subject tagger and relation-specific object taggers. The subject tagger first recognizes all possible subjects with two identical binary classifiers. It assigns each token a binary tag that indicates whether the current token corresponds to a subject's start or end position:

$$\mathbf{p}^{ss/se} = \sigma\big(\mathbf{W}_{ss/se}\mathbf{h} + \mathbf{b}_{ss/se}\big), \quad (2)$$

where σ is the sigmoid function, $\mathbf{h}$ are the input representations, $\mathbf{p}^{ss/se}$ are the probabilities of identifying all the tokens as the subject start/end positions, and $(\mathbf{W}_{ss}, \mathbf{b}_{ss})$, $(\mathbf{W}_{se}, \mathbf{b}_{se})$ are parameters of the two classifiers, respectively.

Then the relation-specific object taggers identify the objects and the involved relations w.r.t. the recognized subjects. Each object tagger corresponds to a relation type and has the same structure with the subject tagger. To incorporate the subject information, the object taggers take the averaged representation of the k-th subject's start and end tokens as $\mathbf{s}_k$ and predict the objects' start and end tags:

$$\mathbf{p}_{rk}^{os/oe} = \sigma\big(\mathbf{W}_{os/oe}^{r}(\mathbf{h} + \mathbf{s}_k) + \mathbf{b}_{os/oe}^{r}\big), \quad (3)$$

where $\mathbf{p}_{rk}^{os/oe}$ denotes the position probabilities under relation r w.r.t. the k-th subject, $(\mathbf{W}_{os}^{r}, \mathbf{b}_{os}^{r})$ and $(\mathbf{W}_{oe}^{r}, \mathbf{b}_{oe}^{r})$ are the classifiers' parameters of relation r. If the probabilities exceed some threshold, we set the corresponding tags to 1 otherwise 0. We heuristically set the threshold to 0.5 in our model. Then we match the nearest start-end position pair to identify subjects and objects. If an object o is identified under relation r w.r.t. a subject s, then (s, r, o) is extracted as a relational triple. We refer readers to (Wei et al., 2020) for more comprehensive descriptions of the extractor.

3.4 Training and Inference

We calculate a binary cross-entropy $f(\mathbf{y}, \mathbf{p}) = -\frac{1}{n}\sum_{i=1}^{n} y_i \log p_i + (1 - y_i)\log(1 - p_i)$ as the loss of a triple extractor's predictions:

$$\mathcal{L}_t = \sum_{*\in\{s,e\}} \Big(f(\mathbf{y}^{s*}, \mathbf{p}^{s*}) + \sum_{r,k} f(\mathbf{y}_{rk}^{o*}, \mathbf{p}_{rk}^{o*})\Big), \quad (4)$$

where $\mathbf{y}$ are the labels corresponding to the position probabilities $\mathbf{p}$. We apply a triple extractor to the encoder hidden states $\mathbf{h}^E$ to extract triples and obtain the encoder's triple loss, denoted as $\mathcal{L}_{\text{Enc}}$. Then we formulate the sentence reconstruction loss as a cross-entropy: $\mathcal{L}_{\text{LM}} = -\frac{1}{n}\sum_{i=1}^{n} \log p^{\text{LM}}(\hat{x}_i = x_i)$,where $\hat{x}_i$ is the i-th reconstructed token. However, we observe that training the decoder only using $\mathcal{L}_{\text{LM}}$ causes serious overfitting and hurts the performance. To reduce overfitting, we apply another extractor to the decoder hidden states $\mathbf{h}^D$ and compute the decoder's loss $\mathcal{L}_{\text{Dec}}$, which is equivalent to adding an auxiliary task for decoder training. Finally, we train our model with the joint loss $\mathcal{L} = \mathcal{L}_{\text{Enc}} + \mathcal{L}_{\text{LM}} + \mathcal{L}_{\text{Dec}}$. During inference, we only use the encoder's extracted triples because the decoder requires ground truth as its input.

4 Experiments

4.1 Datasets and Evaluation Metrics

We conduct our experiments on two widely used benchmark datasets: NYT (Riedel et al., 2010) and WebNLG (Gardent et al., 2017). NYT consists of sentences from the New York Times corpus and contains 24 relation types. WebNLG was proposed for natural language generation and used by Zeng et al. (2018) for relational triple extraction, which contains 171 relation types. Following Zeng et al. (2018), we split the sentences into three categories: *Normal*, *EntitypairOverlap* (EPO) and *SingleEntityOverlap* (SEO) according to different overlapping patterns of triples, as shown in Table 1. For a fair comparison, we employ the same partial match setting as various previous work (Wei et al., 2020; Chen et al., 2021) for evaluation. An extracted triple is regarded as correct only if the relation and the heads of both subject and object are all correct. We report the standard micro precision, recall, and F_1 scores on both datasets.

Dataset	NYT		WebNLG	
	Train	Test	Train	Test
Normal	37013	3266	1596	246
SEO	9782	1297	227	457

ALL	56195	5000	5019	703

Table 1: Statistics of NYT and WebNLG datasets.

4.2 Experimental Settings

We tune the hyper-parameters on the validation sets. We choose pre-trained checkpoints[2] of two T5 variants: T5$_{\text{BASE}}$ and T5$_{\text{LARGE}}$, whose hidden dimensions are 768 and 1024, respectively. We adopt a 3-layer R-GCN and the hidden dimensions are 256. We apply the basis decomposition to regularize the R-GCN layers and the number of basis functions is 10. The MLP of R-GCN contains 2 layers and the hidden dimension is 128. We train our model using the Adam optimizer (Kingma and Ba, 2014) with the learning rate of $5e^{-4}$. We add 50% dropout (Srivastava et al., 2014) to all hidden layers of the R-GCN and the MLP. Following previous work (Chen et al., 2021), we set the max length of input sentences to 100. We train our model with

the batch size of 40 on both datasets. To prevent overfitting, we stop the training process when the validation performance gains no improvement for 5 consecutive epochs. Then we load the parameters with the best validation performance, divide the learning rate by ten, and continue training for 20 epochs. Finally, we choose the best validation model and report scores on the test set.

4.3 Performance Evaluation

We report the evaluation results on the NYT and WebNLG test sets in Table 2. We compare our **MuT**ual **G**eneration model of **T**ext and **G**raph (**MTG**) with several state-of-the-art models: (1) **NovelTagging** (Zheng et al., 2017) proposed a novel sequence tagging scheme but ignored the overlapping triples. (2) **CopyRE** (Zeng et al., 2018) proposed to generate triple sequences with an end-to-end seq2seq model based on the copy mechanism. (3) **CasRel** (Wei et al., 2020) proposed a cascade binary tagging framework. (4) **TPLinker** (Wang et al., 2020) proposed a one-stage token pair linking model with a novel handshaking tagging scheme. (5) **SPN** (Sui et al., 2020) proposed to predict triple sets with a non-autoregressive decoder. (6) **CGT** (Ye et al., 2021) proposed a novel triple contrastive training object. (7) **PFN** (Yan et al., 2021) proposed a partition filter network to capture the interactions between entity and relation representations. (8) **TDEER** (Li et al., 2021) proposed a decoding schema that regards the relation as a translating operation from subject to objects. (9) **PRGC** (Zheng et al., 2021) proposed a potential relation and global correspondence model. (10) **R-BPtrNet** (Chen et al., 2021) proposed a reasoning pattern enhanced binary pointer network to extract implicit relational triples. (11) **REBEL** (Huguet Cabot and Navigli, 2021) proposed to generate linearized triples with an encoder-decoder language model.

From Table 2 we have several observations. First, our MTG$_{T5\text{-}BASE}$ model outperforms previous BERT-based models with similar amounts of PLM parameters for inference[3]. Also, it produces competitive performance to the models that incorporate entity type information and larger PLMs than T5$_{\text{BASE}}$. It indicates that our model effectively captures the relational reasoning patterns through

---

[3] During inference, we only use the MTG encoder's predictions involving half of the T5$_{\text{BASE}}$'s 220M parameters, which is similar to BERT$_{\text{BASE}}$'s 110M parameters.

the mutual generation of text and graph and improves the performance. Second, MTG*T5-BASE* significantly outperforms CASREL*T5-BASE* and CASREL*T5-BASE-Encoder*. We also notice that the two T5-based CASREL models perform only slightly better than CASREL*BERT*. These results show that the improvements of our model come not primarily from the employment of T5, but from the mutual generation method we proposed. Finally, MTG*T5-LARGE* further outperforms MTG*T5-BASE* and other baseline methods. It indicates that the more powerful PLM brings more common-sense knowledge and conceptual facts to our model and helps capture the relation type inference logic more accurately.

4.4 Performance on Different Sentence Types

Following previous work (Wang et al., 2020; Chen et al., 2021), we split the test sets of the two datasets with the number of triples and the overlapping patterns to verify the ability of our model in handling complex sentences, as shown in Table 3. We observe that the MTG models bring significant improvements to the sentences with overlapping triples and with more than one triple. We argue that this is because these sentences have complicated interactions among their relational triples, which are more likely to require reasoning patterns to be extracted. Therefore, these sentences gain more improvements from our mutual generation model. In contrast, we observe that sentences without overlapping triples (and of course with only one triple) usually contain simple text patterns, thus receive

limited benefit. Our model effectively learns relational reasoning patterns and improves the performance on complicated overlapping triples.

4.5 Ablation Study

To study the contribution of each component of our model, we run an ablation study on the NYT test set, as shown in Table 4. Note that when removing R-GCN, we average all node features and feed it into a fully-connected layer to obtain the graph representation g. From Table 4 we observe that the R-GCN module and the sentence reconstruction task both have significant contributions to the model performance. The decoder's auxiliary loss also brings significant improvements because it prevents the model from overfitting to the sentence reconstruction task. Finally, the model without all three components (actually CASREL$_{T5\text{-}BASE\text{-}Encoder}$) produces the worst performance, which proves the effectiveness of our mutual generation method.

We also study the influence of three kinds of graph edges (Section 3.1), as shown in Table 5. We can observe that simply using the basic golden edges does not yield significant effects. Adding reversed golden edges and co-reference edges each bring more improvements to model performance because the flow of node information and the exploration of contextual information are more sufficient. Finally, the full graph yields the best performance, which demonstrates the effectiveness of our graph construction method.

To investigate the influence of each component of our model on relational reasoning, following Chen et al. (2021), we manually select 120 sentences with triples that need to be derived by relational reasoning and run the same ablation study on them. We illustrate the performance on the triples, entity pairs, and relation types in Figure 4. We can first observe that the R-GCN mainly contributes to the entity pair performance. It indicates the effectiveness of the text-to-graph generation in identifying potential multi-hop paths between the entities. Then, we observe that the sentence reconstruction mainly contributes to the performance of relation types, which shows the validity of the graph-to-text generation on capturing the type inference logic. The above observations demonstrate the effectiveness of our mutual generation method in learning relational reasoning patterns.

4.6 Case Study

Figure 5 shows the comparison of the MTG$_{T5\text{-}BASE}$ and CASREL$_{T5\text{-}BASE\text{-}Encoder}$ models on three example sentences. They have exactly the same model structures for inference and the only difference is that MTG$_{T5\text{-}BASE}$ is trained with our mutual generation method. In the first example, the including relation between "*San Francisco*" and "*Yerba Buena Island*" needs to be reasoned by understanding the geographical relationship of the three locations. The second example contains relational concepts "*great-grandfather*" and "*grandfather*", which indicate the parent-child relation chain of the persons. The third example implies that "*Cornell University*" is in "*Ithaca*" because a person of the university gives birth to a child in that place. We can observe that the CASREL model mainly concentrates on local text patterns, so it only extracts the superficial triples and even gets an error in the second example. Our MTG model effectively extracts the latent triples by capturing multi-hop interactions between entities and learning type inference logic from the relational expressions.

5 Conclusion

In this paper, we propose to learn relational reasoning patterns for relational triple extraction with mutual generation of text and graph. We construct a relational graph from the sentence and apply graph convolutions to identify multi-hop reasoning paths. We propose a sentence reconstruction task to explore the unlabeled conceptual expressions of the sentence for capturing the relation type inference logic along the paths. We conduct experiments on two benchmark datasets, and the results demonstrate the effectiveness of our method.

Abstract

Event Argument Extraction (EAE) is one of the sub-tasks of event extraction, aiming to recognize the role of each entity mention toward a specific event trigger. Despite the success of prior works in sentence-level EAE, the document-level setting is less explored. In particular, whereas syntactic structures of sentences have been shown to be effective for sentence-level EAE, prior document-level EAE models totally ignore syntactic structures for documents. Hence, in this work, we study the importance of syntactic structures in document-level EAE. Specifically, we propose to employ Optimal Transport (OT) to induce structures of documents based on sentence-level syntactic structures and tailored to EAE task. Furthermore, we propose a novel regularization technique to explicitly constrain the contributions of unrelated context words in the final prediction for EAE. We perform extensive experiments on the benchmark document-level EAE dataset RAMS that leads to the state-of-the-art performance. Moreover, our experiments on the ACE 2005 dataset reveals the effectiveness of the proposed model in the sentence-level EAE by establishing new state-of-the-art results.

1 Introduction

Event Extraction (EE) is one of the important subtasks of Information Extraction (IE). The major goal of EE is to identify events and their engaged entities (i.e., event arguments). To this end, two sub-tasks should be solved: 1) Event Detection (ED): To recognize event triggers (i.e., the words or phrases that clearly specify the occurrence of events) and their event types, 2) Event Argument Extraction (EAE): To identify participants of events (i.e., entities engaged in events) and their argument roles. Compared to ED, the EAE sub-task is relatively less explored in IE. Moreover, prior works on EAE are mainly restricted to sentence-level setting where event triggers and arguments are assumed to appear in the same sentences. This is unfortunate as a considerable portion of event arguments might not be immediately mentioned in the same sentence as their event triggers. For instance, in the EE dataset of the DARPA AIDA program (phase 1) extraction[1], 38% of arguments has been shown to be outside sentences containing the corresponding triggers, i.e., in the document-level context (Ebner et al., 2020). Thus, further research to study the more realistic setting of document-level EAE is extremely needed.

To the best of our knowledge, there are two prior works on document-level EAE (Ebner et al., 2020; Chen et al., 2020). Both works employ representation vectors for argument spans obtained from a transformer to compute likelihood scores for argument roles. Unfortunately, those prior works only exploit the sequential order of words in documents to represent the arguments and totally ignore structures of input documents. This is a limitation as in other related document-level tasks, e.g., relation extraction (RE), document structures (i.e., graphs to capture interactions between different words/sentences) have been showed to enhance representation learning (Thayaparan et al., 2019; Gupta et al., 2019; Sahu et al., 2019; Christopoulou et al., 2019; Nan et al., 2020). In addition, syntactic structures (i.e., dependency trees) have not been exploited in prior document-level EAE models. To address those limitations, we aim to devise a deep learning model to effectively employ syntactic structures of input documents to boost the performance of EAE.

Given a document, how can we efficiently induce its syntactic structure? One simple solution, as demonstrated in (Gupta et al., 2019) for document-level RE, is to employ the syntactic structure (i.e., dependency tree) of each sentence and connect their roots to each other to create a connected graph

Findings of the Association for Computational Linguistics: ACL 2022, pages 1648 - 1658
May 22-27, 2022

for an input document (called document structure). However, this approach might introduce unrelated words for the role prediction of a candidate argument for a given event trigger into the graph, thus hindering effective representation learning for document-level context. To alleviate this issue, (Gupta et al., 2019) proposes to prune the document structure by only retaining words along the dependency path (DP) between the two words of interest (i.e., event trigger and argument candidate in our case). Unfortunately, in document-level EAE, related words for role predictions might not solely reside in the dependency path between the event trigger and argument candidate. In particular, some related words that belong to sentences other than the hosting sentences of the event trigger and argument might be excluded if the document structure is pruned along the dependency path. For instance, in the document "*The primary goal of the plan is to* ***provide*** *protection to refugees. According to reports, all 8* ***countries*** *that signed the plan will congregate once a quarter to monitor the progress.*", the trigger and the candidate argument, i.e., *provide* and *countries*, appear in different sentences and the DP between them is "*provide* → *is* → *congregate* → *countries*". However, in order to predict the role of the argument, i.e., *Giver*, one should consider the word *plan* in the first sentence and the words *plan* and *signed* in the second sentence which are off the DP.

These limitations call for better methods to prune dependency-based structures of documents to better preserve important words and exclude noisy ones. Unlike prior work that resorts to simple syntax-based rules, i.e., distance to the dependency path (Zhang et al., 2018), we argue that the pruning operation should be also aware of the semantics of the words. In other words, two criteria, i.e., syntactic and semantic relevance, should be taken into account. Specifically, a word is retained in the document structure for document-level EAE if it has a small distance to the event trigger/argument words in the dependency structure (i.e., syntax-based importance) and it is semantically related to one of the words in the dependency path (i.e., semantics-based importance). Note that the semantic similarity between words can be obtained from their representations induced by the model. A key challenge for this idea is the different nature of the syntactic and semantic distances that complicates the information combination to determine the importance of a word for the structure. In addition, the retention decision for a word should also be contextualized in the potential contributions of other words in the document structure for EAE. As such, motivated by the dependency path as the anchor for document structure pruning, we propose to cast the problem of joint consideration of syntactic and semantic distances of words into finding an optimal alignment between off-the-DP and on-the-DP words. The optimal alignment will be solved via Optimal Transport (OT) methods where syntactic and semantic distances of words to those on the dependency path are simultaneously modeled in a joint optimization problem. OT is an established mechanism to efficiently find an optimal transport plan (i.e., an alignment) between two groups of points (i.e., off-the-DP and on-the-DP words in our case) based on their pairwise transportation costs and the distribution mass accumulated on the points. We propose to employ semantic similarity of words to obtain their transportation costs while syntactic distances to the event trigger/argument are leveraged to compute the mass distributions of words for OT in our document-level EAE problem. Finally, to prune the document structure, an off-the-DP word is considered important for the document structure (thus being retained) if it is aligned to one of the on-the-DP words via the OT solution. The pruned document structure will be leveraged to learn representation vectors for input documents to perform argument role predictions using Graph Convolution Networks (GCN) (Kipf and Welling, 2017).

Although the OT-based pruning method could help exclude unrelated words for EAE in the document structure, their noisy information might be still encoded in the representations of the related words due to the contextualization in the input encoder (e.g., BERT). To improve the representation learning, we thus propose to explicitly constrain the impact of unrelated words for representation learning via a novel regularization technique based on the pruned document structure. In particular, we seek to add unrelated words back to the pruned structure (thus restoring the original tree) and ensure a minimized change of representation vectors due to this addition. As such, in addition to the pruned structure, we apply the GCN model over the original dependency structure to obtain another set of representations vectors for the words. Eventually, in the final loss function, we introduce the difference between the representation vectors obtained from the pruned and original structures to achieve the contribution constraint for unrelated words. In our experiments, we evaluate our model on both sentence-level and document-level EAE benchmark datasets, demonstrating the effectiveness of the the proposed model by establishing new state-of-the-art results in both settings.

2 Model

Problem Definition: The goal of EAE task is to recognize the role of entity mentions toward a specific event trigger. We formulate this task as a multi-class classification problem. Formally, given a document $D = [w_1, w_2, \ldots, w_n]$, with the trigger word w_t and the candidate argument w_a, the goal is to predict one of the labels $L = [l_1, l_2, \ldots, l_m]$ as the role of the candidate argument w_a in the event evoked by the trigger w_t. The label set L contains a special label $None$ to indicate that the candidate argument w_a is not a participant in the event w_t.

Model Overview: The proposed model consists of four major components: 1) Input Encoder to represent the words in the document using high-dimensional vectors; 2) Dependency Pruning to employ Optimal Transport (OT) to prune unrelated words in the dependency tree; 3) Regularization to explicitly minimize the contribution of unrelated words for representation learning; and 4) Prediction to use the representations induced for the words of the document to make the final prediction.

2.1 Input Encoder

In the first step, we represent each word $w_i \in D$ using a high dimensional vector x_i. The vector x_i is constructed by concatenating the following vectors: A) Contextualized Word Embedding: We feed the input text $[CLS]w_1w_2 \ldots w_n[SEP]$ into the BERT$_{base}$ model (Devlin et al., 2019); we use the hidden state of w_i in the final layer as the contextualized word embedding. Note that for words consisting of multiple word-pieces, we take the average of its word-piece representations; and B) Distance Embeddings: We represent the relative distances of the word w_i toward the trigger and the argument words (i.e., $|i - t|$ and $|i - a|$) using high dimensional vectors obtained from a distance embedding table (initialized randomly). The distance embedding table is updated during training. Also, in our experiments, we find that fixing the BERT parameters is more helpful. As such, to tailor the vectors x_i to EAE task, we feed the vectors $X = [x_1, x_2, \ldots, x_n]$ to a Bi-directional Long Short-Term Memory network (BiLSTM). The hidden states obtained from the BiLSTM, $H = [h_1, h_2, \ldots, h_n]$, will be consumed by subsequent components.

2.2 Dependency Pruning

To employ the syntactic structure of the input document D, we leverage the dependency trees of the sentences in the document. Here, we use the undirected versions of the dependency trees generated by the Stanford CoreNLP parser. To connect the dependency trees of the sentences to form a single dependency graph for D, similar to (Gupta et al., 2019), we add an edge between the roots of the dependency trees for every pair of consecutive sentences in D. As such, the generated syntactic tree for D, called T, will contain all the words $w_i \in D$. As discussed in the introduction, the full tree T for D might contain both related and unrelated words for the argument role prediction of w_a with respect to the event trigger w_t. It is thus necessary to prune this tree to retain only the related words, thus preventing potential noises introduced by unrelated words for representation learning. Motivated by the effectiveness of dependency paths for sentence-level EAE in prior work (Li et al., 2013), we employ the dependency path (DP) between the event trigger w_t and the argument candidate w_a in T as the anchor to prune the unrelated words. In particular, besides the words along DP (that might miss some important context words for prediction), we seek to retrain only off-of-DP words in T that are syntactically and semantically close to to the words in DP (i.e., aligning off-of-DP and on-the-DP words). We propose to employ Optimal Transport (OT) to jointly consider syntax and semantics for this word alignment. In the following, we first formally describe OT. We will then provide details on how OT could be leveraged to implement our idea.

OT is an established method to find the optimal plan to convert (i.e., transport) one distribution to another one. Formally, given the probability distributions $p(x)$ and $q(y)$ over the domains $\mathcal{X}$ and $\mathcal{Y}$, and the cost/distance function $C(x, y) : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}_+$ for mapping $\mathcal{X}$ to $\mathcal{Y}$, OT finds the optimal joint alignment/distribution $\pi^*(x, y)$ (over $\mathcal{X} \times \mathcal{Y}$) with marginals $p(x)$ and $q(y)$, i.e., the cheapest transportation from $p(x)$ to

$q(y)$, by solving the following problem:

$$\pi^*(x,y) = \min_{\pi \in \Pi(x,y)} \int_{\mathcal{Y}} \int_{\mathcal{X}} \pi(x,y) C(x,y) dx dy \quad \text{s.t. } x \sim p(x) \text{ and } y \sim q(y), \tag{1}$$

where $\Pi(x, y)$ is the set of all joint distributions with marginals $p(x)$ and $q(y)$. Note that if the distributions $p(x)$ and $q(y)$ are discrete, the integrals in Equation 1 are replaced with a sum and the joint distribution $\pi^*(x, y)$ is represented by a matrix whose entry (x, y) ($x \in \mathcal{X}, y \in \mathcal{Y}$) represents the probability of transforming the data point x to y to convert the distribution $p(x)$ to $q(y)$. Note that to obtain a hard alignment between data points $\mathcal{X}$ and $\mathcal{Y}$, we can align each row of $\pi^*(x, y)$ with the column with the highest probability, i.e., $y^* = \text{argmax}_{y \in \mathcal{Y}} \pi^*(x, y)$ where y^* is the data point in $\mathcal{Y}$ aligned with the data point $x \in \mathcal{X}$.

The most important and useful characteristics of OT in our problem is that it can find a transportation (i.e., an alignment) between two groups of data points with lowest cost according to two criteria: 1) the distance between data points, and 2) the difference between their probability masses. In particular, these two criteria can be exploited to capture the semantic and syntactic similarity required in our model to find an alignment between off-the-DP and on-the-DP words. Specifically, we use the words on the DP as the data points in the domain $\mathcal{Y}$ and the words off the DP as the data points in the domain $\mathcal{X}$. To compute the distributions $p(x)$ and $q(y)$ (i.e., probability masses for data points) for $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, we use the syntax-based importance scores. Formally, for the word w_i, we compute its distance to the trigger and the candidate argument in the dependency tree (lengths of dependency paths), i.e., d_i^t and d_i^a, respectively. Afterward, the probability mass for a word $x = w_i \in \mathcal{X}$ is computed as the minimum of the two distances, i.e., $p(x) = \min(d_i^t, d_i^a)$. Note that the distribution $p(y)$ is computed similarly; $p(x)$ and $p(y)$ are also normalized with softmax over their corresponding sets to obtain distributions. In order to obtain the distance/transportation cost $C(x, y)$ between every pair of words $(x, y) \in \mathcal{X} \times \mathcal{Y}$, we propose to use their semantic information based on the Euclidean distance of their representation vectors h_x and h_y in H: $C(x, y) = \|h_x - h_y\|$.

Using this setup, solving Equation 1 returns the optimal alignment $\pi^*(x, y)$ that can be used to align each data point in $\mathcal{X}$ with one data point in $\mathcal{Y}$[2]. However, in our problem, we look for a subset of data points in $\mathcal{X}$ to be aligned with data points in $\mathcal{Y}$ for retention in the dependency structure for D. As such, we add an extra data point "*NULL*" to $\mathcal{Y}$ whose representation is computed by averaging the representations of all data points in $\mathcal{X}$ and probability mass is the average of probability masses of the data points in $\mathcal{X}$. Alignments with this data point in $\mathcal{Y}$ will serve as null alignment indicating that the aligned data point in $\mathcal{X}$, i.e., an off-the-DP word, should not be kept in the pruned tree. Other words in $\mathcal{X}$ with a non-null alignment, called $\mathcal{I}$ ($\mathcal{I} \subset \mathcal{X}$), will be preserved in the pruned tree for D. The removal of *NULL*-assigned off-of-DP words from T produces a new graph that presumably contains the most important words for argument role prediction for D. Here, to ensure the connectivity of the new graph, we also retain any words along the dependency paths between the trigger/argument words and a word in $\mathcal{I}$, leading to a new graph T' to represent D with important context words.

In the next step, we feed T' into a Graph Convolution Network (GCN) (Kipf and Welling, 2017; Nguyen and Grishman, 2018) to learn more abstract representation vectors for the words in T', leveraging BiLSTM-induced vectors in H as the inputs. We denote the hidden vectors produced in the last layer of the GCN model `GCN` by: $H' = h'_{i_1}, \ldots, h'_{i_m} = \texttt{GCN}(H, T')$ where m is the number of words in T' ($m < n$) and h'_{i_k} is the vector for the word w_{i_k} (i.e., the k-word in T').

2.3 Regularization

By using the pruned tree T' to compute the representation vectors in H', we expect to explicitly guide those vectors to: (i) encode related/important context words, and (ii) exclude potentially noisy information from unrelated words for the role prediction of w_a. However, due to the contextualization in the input encoder with BERT, the noisy information of unrelated words might still be included in the representations H for the selected words in the pruned tree T', thus being propagated by the GCN into the representations H'. As such, to further constrain the contribution of unrelated words for representation learning, we introduce a novel regularization technique that encourages

---

[2] Note that as solving the OT problem in Equation 1 is intractable, we employ the entropy-based approximation of OT and solve it with the Sinkhorn algorithm (Peyre and Cuturi, 2019).

the representations obtained from every word in D to be similar to the representations obtained only from the related words in T' (i.e., adding unrelated words does not change the representations significantly). As the output vectors from the GCN model will be used by the role prediction, we implement this regularization technique based on the representation vectors induced from GCN. Formally, we first feed the H and the full dependency tree T for D into the same `GCN` model, i.e., $H'' = \texttt{GCN}(H, T)$. Afterward, we compute the vector representation vectors $\bar{h}'$ and $\bar{h}''$ for the sets H' (based on T) and H'' (based on T) by performing a max-pooling, i.e., $\bar{h}' = MAX\_POOL(h'_{i_1}, \ldots, h'_{i_m})$ and $\bar{h}'' = MAX\_POOL(h''_1, h''_2, \ldots, h''_n)$. Finally, we enforce the similarity of $\bar{h}'$ and $\bar{h}''$ by adding their L_2 distance into the overall loss function: $\mathcal{L}_{reg} = \left\|\bar{h}' - \bar{h}''\right\|$.

2.4 Prediction

To perform the argument role prediction for w_a and w_t, we form the overall vector $V = [h'_t, h'_a, \bar{h}']$, where h'_t and h'_a are the representation vectors for w_a and w_t in H'. As such, V will be consumed by a two-layer feed-forward network to obtain the distribution $P(\cdot|D, w_t, w_a)$ over possible argument roles. To train the model, we use negative log-likelihood loss: $\mathcal{L}_{pred} = -\log P(l|D, w_t, w_a)$, where l is the gold label. The overall loss function for our model is thus: $\mathcal{L} = \mathcal{L}_{pred} + \beta\mathcal{L}_{reg}$, where β is a trade-off parameter.

3 Experiments

3.1 Datasets & Parameters

We evaluate the proposed model, i.e., Optimal Transport-based Event Argument Extraction (OTEAE), on the RAMS dataset which is recently introduced in (Ebner et al., 2020) for document-level EAE. RAMS contains 9,124 annotated event mentions across 139 event types for 65 argument roles, serving as the largest available dataset for this task. We use the official train/dev/test split and evaluation scripts for RAMS provided by (Ebner et al., 2020) for a fair comparison.

We use the development set of RAMS to fine tune the hyper parameters for the proposed model. Based on our experiments, the following hyper parameters are chosen: 50 dimensions for position embeddings; 1 layer for BiLSTM and 2 layers for GCN; 150 dimensions for the hidden states of the BiLSTM, GCN and feed-forward networks; 64 for the batch size; 0.2 for the learning rate with the Adam optimizer, and 0.1 for the trade-off parameter β.

3.2 Baselines

For the experiments on the RAMS dataset, we compare our model with two groups of baselines: (1) Prior works that report their performance on RAMS. Specifically, we compare our model with the **RAMS**$_{model}$ model in (Ebner et al., 2020), the **Head-based** model in (Zhang et al., 2020c) and the **Joint** model in (Chen et al., 2020). As such, the Joint model in (Chen et al., 2020) currently has the best reported performance on RAMS. Note that all of these baselines are sequence-based deep models that ignore the syntactic structure of the input document.; (2) To thoroughly compare OTEAE with previous works, we examine the structure-aware deep learning models proposed for another related task, i.e., document-level relation extraction, and adapt them for EAE. Concretely, we compare our model with: (i) the **iDepNN** model in (Gupta et al., 2019) that employs the syntactic structure of the document with pruning along the dependency path; (ii) the **GCNN** model in (Sahu et al., 2019) that leverages both syntactic and discourse-level (i.e., co-reference links) structures to encode the document; (iii) the **LSR** model in (Nan et al., 2020) that infers document structures by a deep reasoning module; and (iv) the **EoG** model in (Christopoulou et al., 2019) that encodes syntactic and discourse structures using high dimensional vectors to represent the edges of the structure graphs.

Following (Ebner et al., 2020), we report the performance of the models in two different settings for RAMS: (1) Standard Decoding: In this setting, the label is predicted by operating `argmax` on the probability distribution $P(\cdot|D, w_t, w_a)$; (2) Type Constrained: In this setting, the prediction of the models for a given candidate argument and event trigger is constrained to the set of permissible roles for the event type of the given event trigger. Specifically, before applying `argmax` on $P(\cdot|D, w_t, w_a)$, the probabilities of the non-permissible roles for the event type evoked by w_t are set to zero.

3.3 Performance Comparison

The performance of the models on the RAMS test set is presented in Table 1. As can be seen, the proposed model significantly outperforms both sequence-based and structure-aware baselines in both settings on the RAMS dataset (with $p < 0.01$),

Model	Standard Decoding			Type Constrained		
	P	R	F1	P	R	F1
RAMS	62.8	74.9	68.3	78.1	69.2	73.3
Head-based	71.5	66.2	68.8	81.1	66.2	73.0
Joint	-	-	-	79.6	80.2	79.9
iDepNN	65.8	68.0	66.9	77.1	67.7	72.1
EoG	71.0	71.7	71.4	82.4	69.2	75.2
GCNN	72.2	72.8	72.5	85.1	69.4	76.5
LSR	72.6	73.6	73.1	83.9	71.4	77.2
OTEAE (ours)	75.2	76.1	**75.6**	83.1	78.9	**80.9**

Table 1: Performance on the RAMS test set. All models employ BERT for the input encoder.

Model	P	R	F1
BERT-based	57.9	59.1	58.5
GTM	62.1	64.3	63.2
Joint	56.0	79.2	65.6
OTEAE (ours)	64.2	68.1	**66.1**

Table 2: Sentence-level performance on the ACE 2005 test set.

yielding to the state-of-the-art performance for document-level EAE on RAMS. Compared to the sequence-based baselines (i.e., Head-based, Joint), we attribute the success of our model to the ability to capture long-distance dependencies between words in multiple sentences (via syntactic structures) that can encode documents with richer information. Moreover, compared to the document structure-aware baselines, our hypothesis for the superior performance of OTEAE involves the OT-based component that is able to recognize the optimal trade-off between semantics-based and syntax-based importance of the words to better filter unrelated words to learn document structures for EAE. In particular, most baseline models employ human-designed rules to compute document structures that cannot flexibly prune unrelated words e.g., iDepNN (Gupta et al., 2019) to prune syntactic structures along dependency paths, and EoG (Christopoulou et al., 2019) and GCNN (Sahu et al., 2019) to employ heuristic discourse information (coreference links), thus leading to inferior performance.

3.4 Performance on ACE 2005

To provide more insight into the performance of the proposed model OTEAE, following (Chen et al., 2020), we further examine the models' performance on the well-known ACE 2005 dataset for the sentence-level EAE task. This dataset contains 599 documents, 33 event subtypes and 35 argument roles. We employ the same data split and pre-processing scripts as prior works (Lin et al., 2020; Chen et al., 2020). To be directly comparable with (Chen et al., 2020) (the current state-of-the-art model for document-level EAE), we assume golden event trigger and argument spans in this experiment. Table 2 reports the performance of the models on the ACE 2005 test set. Here in addition to OTEAE and Joint (Chen et al., 2020), we show the performance of two other models: (i) the BERT-based model that directly uses the BiLSTM vectors in H to form the overall representation vector $V = [h_t, h_a, MAX\_POOL(h_1, \ldots, h_n)]$ for predictions (i.e., the OT-based pruning and regularization are not applied here); and (ii) the GTM model in (Veyseh et al., 2020) that currently has the current state-of-the-art model for sentence-level EAE on ACE 2005.

As can be seen from the table, OTEAE still performs well even with shorter context of single sentences, leading to state-of-the-art performance for sentence-level EAE. Notably, the substantially better performance of OTEAE over BERT-based shows that the proposed dependency pruning and regularization components are also beneficial for representation learning in sentence-level EAE.

3.5 Ablation Study

OTEAE has two major components: (1) The structure generator component to infer pruned dependency structures for documents, (2) The regularization component to explicitly exclude the unrelated information. This section conducts an ablation study to analyze the effectiveness of these components for OTEAE. In particular, we evaluate the performance of the following ablated models: (1) **Reg$^-$**: This model excludes the regularization loss, i.e., $\mathcal{L}_{reg}$, from the overall loss function $\mathcal{L}$; (2) **OT$^-$**: This baseline eliminates the OT-based component for tree pruning, instead, it prunes dependency structures along dependency paths; (3) **Prune$^-$**: This model employs the full dependency tree as the structure to be consumed by the GCN model. As such, the regularization component which requires a pruned tree is also excluded from the final loss function; (4) **GCN$^-$**: This model excludes the GCN model from OTEAE. Here, we still retain the OT-based pruning and regularization components; however, instead of using GCN-based representations, the vectors for final predictions and regularization need to be computed over the BiLSTM-induced vectors in H. In particular, the final prediction vec-

Semantics$^-$	74.4	73.5	73.9
DP$^-$	74.1	73.1	73.6

Table 4: Optimal Transport analysis on the RAMS development set.

tor V is constructed as $V = [h_t, h_a, \hat{h}]$ where $\hat{h} = MAX\_POOL(h_{i_1}, \ldots, h_{i_m})$ (i.e., the max-pooling is done over the words in the pruned tree T' from OT); the regularization term in the overall loss function is replaced by: $\mathcal{L}_{reg} = \left\|\hat{h} - \tilde{h}\right\|$ where $\tilde{h} = MAX\_POOL(h_1, \ldots, h_n)$ (max-pooling is performed over all the words in D). Results of this analysis are shown in Table 3. This table demonstrates the necessity of all components for the proposed model to achieve its highest performance. In particular, the superior performance of OTEAE over OT$^-$ and Prune$^-$ suggests that using only dependency paths or full dependency structures is suboptimal to produce document structures for document-level EAE, necessitating OT to better select important context words for documents in our problem.

In order to provide more insight into the importance of OT for tree pruning, we perform another ablation study solely on the OT component. Specifically, we answer two questions: (1) Are both syntax-based and semantic-based criteria necessary to prune the dependency tree? (2) Should the dependency paths be taken into account during pruning? For the first question, we study two ablated models: (1) **Syntax**$^-$: In this model, we use uniform distribution for $p(x)$ and $q(y)$ in OT, thus excluding the syntactic distances of the words to the trigger/argument from OT computation; (2) **Semantics**$^-$: In this baseline, we use a constant cost function, i.e., $C(x, y) = 1$, for OT so the representation-based similarities between the words are not used by OT. To answer the second question, we evaluate the model **DP**$^-$ where the domain (Y) only consists of the trigger and the argument words; and the domain $\mathcal{X}$ involves all other words in D (including the ones on the dependency paths). Note that in this model, we still add the extra node "*NULL*" into $\mathcal{Y}$ to represent null alignments. Table 4 presents the performance of the models. There are several observations from this table. First, removing either syntax-based (i.e., Syntax$^-$) or semantic-based (i.e., Semantics$^-$) criterion will hurt the performance, indicating the necessity of both criteria. Second, compared to the syntax-based information, the semantic-based criterion contributes more to OTEAE as removing it will lead to larger performance reduction. This is important as the semantic-based criterion has not been used in prior methods for document structure inference with tree pruning. Finally, using only the trigger/argument words as the anchor points for positive alignment (i.e., DP$^-$) is not optimal, showing that dependency paths are critical for OT to find related words in documents for EAE.

4 Analysis

Inter- vs. Intra-sentence Performance: To shed more light on the effectiveness of the proposed model, we study the performance of the proposed model in two different settings: (1) Intra-sentence where both trigger and argument words appear in the same sentence, i.e. the number of sentences between the trigger and the argument is zero; and (2) Inter-sentence where the trigger and argument appear in different sentences, i.e., the number of sentences in between is non-zero. We compare our model with the state-of-the-art models for document-level EAE, i.e., the RAMS$_{model}$ (Ebner et al., 2020) and Joint (Chen et al., 2020) models in this analysis. All models assumes Type-Constrained decoding in this section. The results on the RAMS development set are shown in Table 6. This table shows that the proposed model significantly outperforms prior works (except for the distance of 2 where the performance is comparable). Interestingly, the obtained improvement is consistent for both inter-sentence and intra-sentence settings, suggesting the benefits of using efficient document structure for EAE in general.

Case Study: Finally, we perform a case study to explore the benefits of OTEAE compared to prior document-level methods. In particular, we analyze examples in which our model successfully predicts the argument role, while all other docu-

ID	Text	Role

2	47	**79.1**	78.7	79.0

Table 6: F1 scores on the RAMS development set for examples with different numbers of sentences between the trigger and the argument. Negative numbers imply that the argument appears before the trigger.

ment structure-aware baselines fail (i.e., iDepNN, EoG, GCNN, and LSR). Some examples of this type are shown in Table 5. In particular, for the first example (ID 1), the trigger and the argument are in two different sentences with an extra sentence in between. Due to the long distance between the trigger and the argument, using the document structure is crucial to infer the role of the argument. Specifically, a successful prediction should encode the mentions of *massive explosions* in the first sentence and *second explosion* in the second sentence, and their semantic similarity. Unfortunately, none of these phrases are on the DP between the trigger and the argument in the document's dependency graph, causing the failure of the baseline models. In contrast, the OT-based selection method in OTEAE is able to select both phrases to include in the pruned tree T' for representation learning, thus being able to make a correct prediction.

Finally, in the second example document (ID 2) of Table 5 with two sentences, to correctly predict the argument role for "*Sibreian pristine Boreal*", it is important to consider the word *fire* in the second sentence. Unfortunately this word does not belong to the dependency path between the trigger and argument, hindering the operation of prior models for this example. OTEAE, in contrast, can return a correct prediction in this case as the its OT component helps include the important word "*fire*" into consideration for the document structure.

5 Related Works

Event Argument Extraction is one of the sub-tasks of Event Extraction which is mainly approached with sentence-level models in the prior works. Early models for this task employed feature-based methods (Patwardhan and Riloff, 2009; Riedel and McCallum, 2011; Hong et al., 2011; McClosky et al., 2011; Li et al., 2013; Miwa et al., 2014; Yang and Mitchell, 2016). Later, deep learning emerged as the state-of-the-art approach for sentence-level EE (Chen et al., 2015; Zhang et al., 2019; Yang et al., 2019; Nguyen and Nguyen, 2019; Zhang et al., 2020b; Lai et al., 2020; Nguyen et al., 2021; Veyseh et al., 2021) or specifically, EAE (Wang et al., 2019). As the sentence-level models are not able to detect all arguments of an event mentioned in a document, recently the document-level setting has gained more attention; a new dataset (i.e., RAMS) has been introduced by (Ebner et al., 2020). The most similar models to our document-level EAE model involve RAMS$_{model}$ (Ebner et al., 2020), Head-based (Zhang et al., 2020c) and the Joint model (Chen et al., 2020). However, none of these models explore document structures for representation that have been shown to be critical for EAE in our work.

Document structures has been also exploited for other Information Extraction (Sahu et al., 2019; Gupta et al., 2019; Nan et al., 2020; Tran et al., 2020) and NLP tasks (Pan et al., 2020; Balachandran et al., 2020; Zhang et al., 2020a; Lu et al., 2021). In particular, for the related task of document-level relation extraction, existing works have attempted to construct document structures based on the syntax or discourse information. However, these models fail to involve semantics of the document in the constructed structure, resulting in the inferior performance. In this work, we address this limitation by exploiting optimal transport to jointly consider syntactic and semantic information for document structures. To our knowledge, OT has not been used for document structures in prior work.

6 Conclusion

In this work, we propose a new document structure-aware model for document-level EAE. Our model employs dependency trees of sentences and presents a novel technique based on optimal transport to prune dependency trees for documents in the EAE task. In addition, we introduce a novel regularization to explicitly constrain the contribution of irrelevant words for representation learning. Our extensive experiments demonstrate the effectiveness of the proposed model. In the future, we plan to apply our model for other IE tasks.

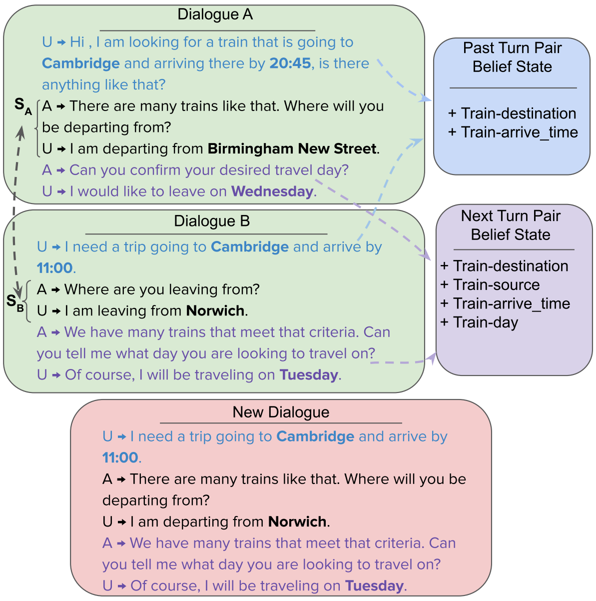
Abstract

Augmentation of task-oriented dialogues has followed standard methods used for plain-text such as back-translation, word-level manipulation, and paraphrasing despite its richly annotated structure. In this work, we introduce an augmentation framework that utilizes belief state annotations to match turns from various dialogues and form new synthetic dialogues in a bottom-up manner. Unlike other augmentation strategies, it operates with as few as five examples. Our augmentation strategy yields significant improvements when both adapting a DST model to a new domain, and when adapting a language model to the DST task, on evaluations with TRADE and TOD-BERT models. Further analysis shows that our model performs better on seen values during training, and it is also more robust to unseen values. We conclude that exploiting belief state annotations enhances dialogue augmentation and results in improved models in n-shot training scenarios.

1 Introduction

Task-oriented dialogue (TOD) agents are the next-generation user interface and are slated to replace browsing static websites. However, a key bottleneck in fielding such agents practically concerns adapting to new domains with few available data. In the light of this dependency in ample amounts of annotated data, **data augmentation** is growing in importance (Feng et al., 2021). Most augmentation methods in natural language processing (NLP) target written forms of text — passages, news articles, *etc.* — which operate with word- or sentence-level permutations of the original text data, synthesizing new text (Liu et al., 2020; Wei and Zou, 2019; Yu et al., 2018; Xie et al., 2017; Kobayashi, 2018). These methods do not exploit the structure of conversational data in its entirety. We study augmenting task-oriented dialogues, a specific form of conversational data.



U → Hi , I am looking for a train that is going to **Cambridge** and arriving there by **20:45**, is there anything like that?
A → There are many trains like that. Where will you be departing from?
U → I am departing from **Birmingham New Street**.
A → Can you confirm your desired travel day?
U → I would like to leave on **Wednesday**.

U → I need a trip going to **Cambridge** and arrive by **11:00**.
A → Where are you leaving from?
U → I am leaving from **Norwich**.
A → We have many trains that meet that criteria. Can you tell me what day you are looking to travel on?
U → Of course, I will be traveling on **Tuesday**.

U → I need a trip going to **Cambridge** and arrive by **11:00**.
A → There are many trains like that. Where will you be departing from?
U → I am departing from **Norwich**.
A → We have many trains that meet that criteria. Can you tell me what day you are looking to travel on?
U → Of course, I will be traveling on **Tuesday**.

Figure 1: Scenario with two dialogues from *train* booking domain. Dialogue snippets, $S_A \& S_B$, have the same dialogue function and the new dialogue created by replacing them and inserting proper slot values is still coherent end to end.

A TOD is a form of conversation where the aim is to accomplish a task through exchanges between a user and an agent, accounting for the user's preferences.

Within TOD, dialogue state tracking (DST) is a fundamental task, which aims to detect these preferences in a given dialogue. For this task, each pair of utterances in a dialogue is annotated with slot-label and slot-value pairs (*cf.* Figure 1: *train-destination*: "Cambridge") and a belief state. Here, a *belief state* can be equated as an attribute–value store that gives the final values of each slot label (attribute) after an utterance.

There have been several attempts to augment conversational data in the literature. Quan and Xiong (2019) up-sample the data through word or

sentence level modifications, following standard text augmentation techniques in NLP such as synonym substitution, back-translation, or paraphrasing. Kurata et al. (2016) perturb embeddings of single utterances and decode similarly functioned synthetic utterances. Gao et al. (2020) create an end-to-end pipeline that finds the utterances with similar dialogue functions and trains a paraphrasing model. CoCo (Li et al., 2021) trains a conditional user–utterance generation model, then generates synthetic turns by modifying belief states using a rule-based system and conditioning the model on the modified belief state. Gritta et al. (2021) create a working graph of TOD datasets where each edge is a dialogue act and create synthetic dialogues by traversing alternative paths; however, their framework requires user acts to work with. Critically, none of the above techniques exploit the belief state annotations of TODs within an n-shot scenario.

In contrast, dialogue belief state annotations guide our approach to an effective n-shot augmentation method. We observe that the belief state identifies the specific slots that each turn-pair discusses. As such, belief states can be used as a proxy to represent dialogue function. For example, after exchanging two turn-pairs that serve the same dialogue function in separate dialogues, coherency in both dialogues should be preserved, if discounting necessary changes to slot values (Figure 1). Motivated by this, we delexicalize and store each turn-pair with their dialogue function to effectively

construct new dialogues from scratch.

We evaluate our framework with MultiWOZ, a multi-domain dialogue dataset (Budzianowski et al., 2018). Each of its 10,000 dialogues is annotated with its turn belief states, system acts, and turn slots.

We experiment using both the previous state-of-the-art (SOTA) recurrent TRADE (Wu et al., 2019) model and the transformer-based TOD-BERT (Wu et al., 2020b) model. Our framework significantly increases n-shot performance,

both when adapting a DST model to a new domain and when adapting a language model to the DST task. A fine-grained analysis of evaluation results reveals that models finetuned on synthetic data become robust to previously unseen slot values, and recognize seen values better. The latter aspect accounts for the majority of the performance gain.

2 Related Work

2.1 Dialogue State Tracking

Previous DST models cumulatively keep track of utterances to obtain dialogue states (Williams and Young, 2007; Thomson and Young, 2010; Wang and Lemon, 2013). Lei et al. (2018) introduced Sequicity to generate belief spans as an intermediate process and improve the performance on the end task. Zhong et al. (2018) proposed to use a unique module for each slot, which improves the tracking of unseen slot values. The majority of these systems relied on an in-domain vocabulary and they were all evaluated on a single domain. Ramadan et al. (2018) proposed to jointly train the domain and state tracker using multiple bi-LSTMs and allowed the learned parameters to be shared across domains; whereas Rastogi et al. (2017) used a multi-domain approach using bi-GRU where the dialogue states are defined as distributions over a candidate set derived from dialogue history.

We use two base models in this paper. The first one, TRADE, was proposed by Wu et al. (2019). It implements an encoder–decoder architecture and applies a copy mechanism that helps to overcome out of vocabulary (OOV) challenges. The second one, TOD-BERT (Wu et al., 2020b), is a task-oriented dialogue model following the transformer paradigm. It is pretrained using 9 TOD datasets with a contrastive objective function.

2.2 Few-shot Dialogue State Tracking

Many papers focus on the low-resource scenario in the DST field aiming to generate comparable results between low- and rich-resource settings. These invariably categorize into two approaches to address the low-resource challenge: (1) optimization functions aimed to exploit the smaller amounts of data, or (2) augmentation of the target data.

Few-shot Models and Techniques. Some approaches in the first class of solutions benefit from the recent transformer trend. One such study finetunes the GPT-2 model and reports n-shot slot-filling and intent recognition results on the SNIPS dataset (Madotto et al., 2020). They achieve promising results compared to baselines with fewer shots. TOD-BERT reports results on four downstream tasks in the full- and low-resource settings (Wu et al., 2020b). Another line of research tries to address the problem without transformers. Span-ConverRT re-defines the slot-filling problem as turn-based span extraction that helps greatly in the few-shot setting (Coope et al., 2020). Huang et al. (2020) use the model agnostic meta-learning (MAML) algorithm to adapt to new domains and show that it can outperform traditional methods with fewer data. Coach (Liu et al., 2020), on the other hand, breaks the slot-filling task into two components: a first slot entity detection task, followed by an entity type prediction task.

Data Augmentation for the Few-shot Setting. Other studies, like our approach, focus on augmentation to improve few-shot performance. Quan and Xiong (2019) adopt four techniques for augmentation: synonym substitution, stop-word deletion, translation, and paraphrasing at the sentence level. Kurata et al. (2016) start by pretraining a dialogue encoder–decoder, and then perturb the dialogue representations to back-decode synthetic dialogues. Another study by Jalalvand et al. (2018) trains a logistic regression model on the small target data to detect the most informative n-grams and then find related samples from an out-of-domain corpus. Yin et al. (2020) propose a reinforcement learning setting, alternating learning between a generator and a state tracker to discover augmentation policies that benefit the end task. Two separate studies try to solve the OOV problem by enriching dialogue slot values with other values (Song et al., 2020; Summerville et al., 2020). Liu et al. (2019) train a TOD comprehension model using a synthetic data generator that simulates human-human dialogues. The transformations within the generation process are on the turn-level which limits the information flow to the rest of the dialogue. Aksu et al. (2021) on the other hand take whole dialogues states into consideration during synthetic generation, however, their augmentation method requires manual annotation for each new domain.

Campagna et al. (2020) create an abstract dialogue model by defining domain templates through manual observations and then generates augmented data using these templates. Their model improves the zero-shot performance but requires manual work for each new domain.

Three studies use dialogue annotations during the augmentation process. PARG matches turns of a task-oriented dialogue by their dialogue state to create pairs for paraphrase generation (Gao et al., 2020), they then jointly train the paraphrase generator with the end task outperforming other dialogue augmentation baselines. The low-resource setting defined by PARG is still required to be large enough to train a neural paraphrase model from scratch, thus limiting its applicability to emerging domains with little data. Moreover, they do not model the interaction of a turn-pair with the next turn-pairs; as such a paraphrased utterance may be noisy, repeating a slot on the next turn. Gritta et al. (2021) create graph representations of dialogue datasets where each edge corresponds to a dialogue act by the user or system. They then extract alternative dialogues. However, they experiment only using full data settings. Additionally, their framework presumes the dialogue states are specific to each utterance, but for MultiWOZ (among other datasets) dialogue states harbor information from a pair of system–user utterances. Lastly, Li et al. (2021) train a conditional user-utterance generation model on a large dataset, then generate synthetic dialogues by mutating the belief states through a rule-based system. This method is also limited as it requires enough data to train a conditional generation model, an unrealistic requirement for few-shot training.

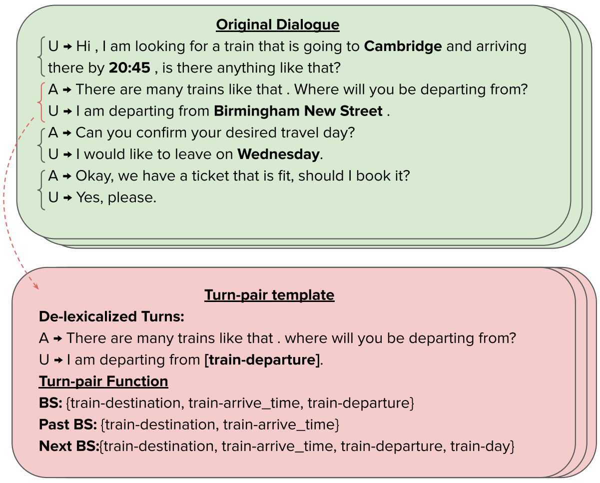
3 Method

Our method leverages a simple hypothesis, visualized in Figure 1: that the function of a pair of turns in a dialogue can be defined by its slots, and its interactions with its previous and next turn-pairs. The example has two turn-pairs: S_a from Dialogue A and S_b from Dialogue B. The turn-pair belief states that precede both S_a and S_b are composed of the same set of slot labels. The same holds for the belief states of turn-pairs following S_a and S_b.

Thus S_a and S_b have the same function in the dialogue. We hypothesize the interchange of these pairs of turns (after changing the values according to the parent dialogue state) maintains a coherent dialogue. Our observations on the MultiWOZ dataset showed that this is true to a large extent for task-oriented dialogues because the belief state history represents the ongoing topic, and slot labels of the next turn give hints about the system acts.

Our framework implements this hypothesis in three steps. In Step 1 (§ 3.1), we create turn-pair templates by delexicalizing each pair (replacing slot values with their respective slot label),

then storing each template with the previous, current, and next pair's belief states (*cf.* Figure 2). We also mine a dictionary of possible slot label–value pairs to be used in filling generated templates. In Step 2 (§ 3.2) we create dialogue templates by



Original Dialogue

U → Hi , I am looking for a train that is going to **Cambridge** and arriving there by **20:45** , is there anything like that?
A → There are many trains like that . Where will you be departing from?
U → I am departing from **Birmingham New Street** .
A → Can you confirm your desired travel day?
U → I would like to leave on **Wednesday**.
A → Okay, we have a ticket that is fit, should I book it?
U → Yes, please.

Turn-pair template

De-lexicalized Turns:
A → There are many trains like that . where will you be departing from?
U → I am departing from **[train-departure]**.

Turn-pair Function
BS: {train-destination, train-arrive_time, train-departure}
Past BS: {train-destination, train-arrive_time}
Next BS:{train-destination, train-arrive_time, train-departure, train-day}

Figure 2: Sample turn-pair template (bottom, pink) and the original dialogue it is extracted from (top, green). The subject template is composed of four elements: 1) delexicalized turn utterances, and the belief state of 2) current, 3) past, and 4) next turns in the original dialogue.

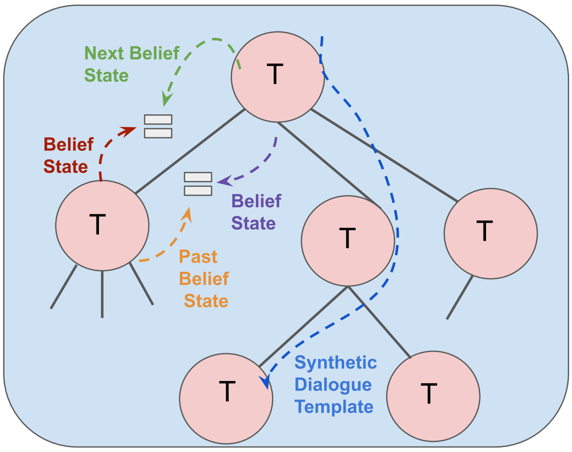


Figure 3: In our framework, dialogue templates are generated through adding proper turn-pair templates in a chain structure. The chains form a tree, which covers every possible dialogue template as a path from root to a leaf node.

combining these pairs constrained such that two consecutive pairs' dialogue functions do not break coherency. We do this combination in a breadth-first manner, best visualized as a tree where each node is a turn-pair template, and every string of nodes from root to leaf is a dialogue template (*cf.* Figure 3). Finally in Step 3 (§ 3.3), we create final synthetic dialogues by filling the slot labels in the dialogue templates (*cf.* Figure 4) using the mined dictionary.

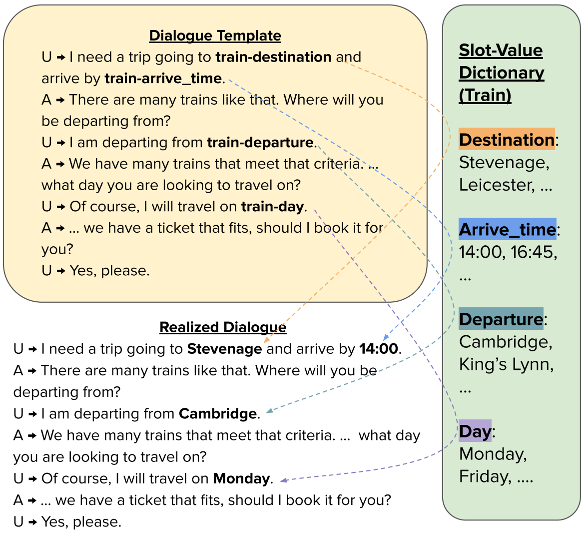
3.1 Step 1: Turn-pair Template Generation

Figure 2 depicts a sample turn-pair template that our framework generates. Each turn-pair template in our framework consists of a pair of turns: a system turn and a user turn. Our templates consist of pairs of turns, simply because consecutive turns (system–user) share the same dialogue state annotation. Each turn-pair template consists of a delexicalized pair of turns and a dialogue function formed as the combination of the previous, current, and next turn belief states.

During delexicalization we follow (Hou et al., 2018) to replace each slot value with "[slot-name]". Since MultiWOZ 2.1 does not provide indices for slot values, we manually find each value by searching in the turn-pair. This brings up several problems where two slots might have the same value or where some categorical values might not show up in the text (*e.g. hotel-internet*: {"dontcare", "yes", "no"}). We filter out templates with the same values for different labels and leave the values for the categorical labels the same, assuming that they are independent of changes in other values. However, unlike non-categorical ones, we are limited from enriching the values of such slot types through surface realization when we fill in our templates. Each dialogue in MultiWOZ usually starts with a salutation and ends with a farewell. To distinguish these starting–ending pairs, we define two exception cases: (1) If a template's turn-pair comes from the beginning of a dialogue, we set its previous belief state as *null* (start state), (2) if it comes from the ending of a dialogue we set its next belief state as *null* (end state). We use these two cases later in template generation to generate coherent dialogues from start to end.

3.2 Step 2: Dialogue Template Generation

We generate each dialogue template by combining a set of turn-pair templates. We form our dialogue templates using a tree structure where each node corresponds to a turn-pair template, and a chain of nodes starting from a root and ending with a leaf is a dialogue template (Figure 3). We start by defining a root node and setting its belief state as *null*. Initially, we ignore the next belief state condition and add every template whose previous belief state is *null* — such turns are legitimate conversation starters (roots). At each level, we mark every newly-added node as an active node. Then after each level, we iterate through active nodes



Dialogue Template

U → I need a trip going to **train-destination** and arrive by **train-arrive_time**.
A → There are many trains like that. Where will you be departing from?
U → I am departing from **train-departure**.
A → We have many trains that meet that criteria. ... what day you are looking to travel on?
U → Of course, I will travel on **train-day**.
A → ... we have a ticket that fits, should I book it for you?
U → Yes, please.

Realized Dialogue

U → I need a trip going to **Stevenage** and arrive by **14:00**.
A → There are many trains like that. Where will you be departing from?
U → I am departing from **Cambridge**.
A → We have many trains that meet that criteria. ... what day you are looking to travel on?
U → Of course, I will travel on **Monday**.
A → ... we have a ticket that fits, should I book it for you?
U → Yes, please.

Figure 4: The last step in our framework, surface realization, utilizes the dictionary of slot label and slot values obtained from the original dialogues in Step 1, populating the templates with every permutation of possible values of each slot.

and expand each node with the set of eligible templates. Two conditions need to be met to append Template B to the tail of Template A: (1) B's belief state slots should be met by A's next belief state slots and (2) A's belief state slots should be met by B's past belief state slots. We continue adding templates until there are no active nodes. Eventually, we end up with a tree structure where each connected node represents a turn-pair and each path from the root to a leaf node is a unique dialogue template. We discard paths whose leaf nodes do not have *null* as the next belief state. This ensures that the dialogue template has a valid ending.

3.3 Step 3: Surface Realization

We now fill in the delexicalized dialogue templates. Using the slot–value dictionary extracted in Step 1, we fill each dialogue with every possible slot value combination thus effectively sourcing synthetic augmented dialogues (Figure 4). This final step returns a set of task-oriented dialogues, suitable for training (or fine-tuning) a learning system (*cf.* Appendix A for sample dialogues).

4 Experiments

4.1 Dataset, Models and Evaluation

We conduct experiments on MultiWOZ, a well-known dataset in the DST field. When compared to its counterparts like WOZ (Wen et al., 2017), DSTC2 (Henderson et al., 2014) and Restaurant-8k (Coope et al., 2020), MultiWOZ is the richest, combining several domains with a variety of slot labels and values. MultiWOZ is a multi-domain dialogue dataset that covers 10,000 dialogues between clerks and tourists, each annotated with turn belief states, system acts, and turn slots. Following prior works (Wu et al., 2019, 2020a) we conduct our experiments on 5 of 7 domains leaving *hospital* and *police* domains out as their validation and test sets sample quantity is very low.

We wish to assess how fine-tuning with our augmented data affects model performance. We experiment with the TRADE and TOD-BERT models (Wu et al., 2020a, 2019) to assess whether their base performance can be improved using our augmentation framework.For both models, we follow the fine-tuning experiments done by (Wu et al., 2019): we train a base model on four domains and then fine-tune this model with small sets of randomly sampled data from the remaining left-out target domain (5- or 10-shots). We compare this against the scenario where we apply our augmentation framework on the small set before fine-tuning.

Due to space limitations, we present results only for the subset of the *restaurant*, *taxi*, and *hotel* domains in TOD-BERT. These three domains cover almost every unique slot in the MultiWOZ dataset, and is thus representative. We conduct an additional experiment for TOD-BERT, training/testing with data from all domains in several few shot settings (20-, 40-, and 80-shot).

We evaluate TRADE using the metrics proposed by Wu et al. (2019): Slot Accuracy and Joint Accuracy. *Slot Accuracy* measures the proportion of correctly predicted slot values; while *Joint Accuracy* is more coarse-grained, measuring the correctly predicted turn dialogue states. To predict a turn dialogue state correctly means that all its contained slot values are predicted correctly. Also, when a slot is not mentioned in the utterance the ground truth for that slot becomes *None*. This results in utterances having ground truth slot values which mostly consist of the value *None*. We observe that in our few-shot experiments, unlike TRADE, TOD-BERT model returns predictions consisting only of *None* values. We believe that the discrepancy is attributable to TRADE's copy mechanism, which the TOD-BERT model lacks. To better assess the contribution of our augmentation approach, we use Active Slot Accuracy (Dingliwal et al., 2021) for

	Hotel		Taxi		Restaurant		Attraction		Train

the TOD-BERT experiments, which is the accuracy of slot value predictions for all non-*None* values.

4.2 Implementation and Training Settings

We adjust our training settings to facilitate a fair comparison among the models trained on different data sizes (original versus augmented). For the TRADE model, we use the default hyperparameter settings reported in the original paper. For TOD-BERT, we change the training batch size to 4 and the evaluation batch size to 8, the development set evaluation frequency to 1 evaluation per 200 steps, set the terminating condition to early stopping bounded by a maximum number of steps. For our augmented fine-tuning model training, we fine-tune the base model on synthetic data for $N/2$ steps, followed by fine-tuning on the mixture of original and synthetic data for another $N/2$ steps. We perform this mixing of original samples in the latter part of fine-tuning to ensure that the model is exposed to a diverse set of samples, while not significantly deviating from the original distribution. This is conceptually similar to the notion of experience replay in reinforcement learning.

4.3 Results

TRADE Experiments (Table 1). We report the significance of results with 95% confidence along with averages over 10 runs. Our framework can sustain the model performance in all five domains and significantly improves over baseline (Row 1) in either the 5- (Row 4) or 10-shot (Row 6) scenarios in four of the five domains, where most results are statistically significant at the $p \geq 0.95$ level. These results also greatly improve over fine-tuning using just 5 or 10 target domain samples (compare Row 3 against 4, and Row 5 against 6). Overall, applying our augmentation framework yields a macro-averaged improvement of 3.2% slot accuracy and 1.5% joint accuracy. As a pseudo-upper bound, we compare our method against fine-tuning over 80 shots (roughly 1% of the target domain data, represented by Row 2), and see that our approach significantly closes this performance gap.

The exception is the *taxi* domain where the augmented data does not result in significant change. We believe this is due to *taxi* domain slots having a higher variety in values than in other domain slots. This results in many OOV values in the test set. The TRADE model thanks to its copy mechanism, adapts well to these OOV with fewer data. The fact that the performance of the base model fine-tuned with 1% of data is already reached by fine-tuning the same model within a 5-shot scenario (compare Row 2 and Row 1's *taxi* column) supports our claim.

TOD-BERT Experiments (Tables 2 and 3). With TOD-BERT, we examine our framework's effect on both domain and task adaptation.

· Table 2 shows results for domain adaptation, and the figures are comparable to those in Table 1 for

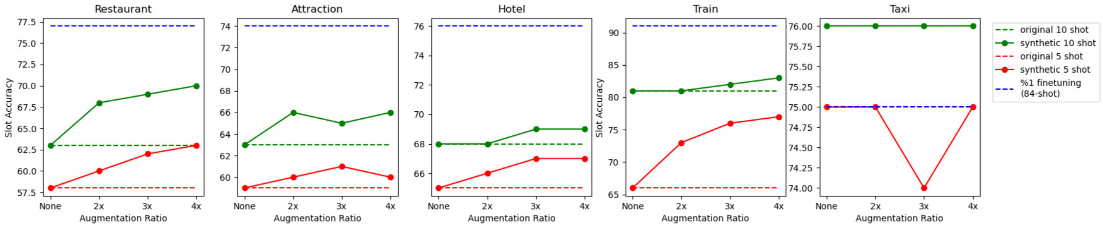

Figure 5: Effects of the augmentation ratio on TRADE model by domain. The dashed blue line represents the performance of fine-tuning with 1% of full data (∼80 dialogues) for comparison as a pseudo upper bound [Note y-axis scales differ per chart].

Recall	Unseen Values	Seen Values
All-domains		
Original	0.1 e-3	0.24
Augmented	**0.2 e-3**	**0.28**
Restaurant		
Original	1.5 e-3	0.20
Augmented	**2.3 e-3**	**0.26**
Taxi		
Original	6.3 e-3	0.16
Augmented	**6.8 e-3**	**0.21**
Hotel		
Original	0.5 e-3	0.30
Augmented	**1.0 e-3**	**0.32**

Table 4: TOD-BERT evaluation results, subdivided between on seen and unseen values, averaged over 10 runs, with best results per section in **bold.**

TRADE. We number the rows with primes (′) to imply the corresponding results from the TRADE experiments. We follow the same setting as above for TRADE (train on 4 other domains, test on target domain). We observe uniformly improved results over the few shot fine-tuning, as we did for TRADE, proving the agnostic feature of our framework.

· Table 3 shows results for task adaptation. Here, the TOD-BERT model has no familiarity with the DST task at all, thus fine-tuning is an adaptation to the task itself. This is a more challenging scenario. Again, we see uniform improvement, especially for the lower-shot scenarios (20- and 40-).

The results for both are consistent and in favor of our framework. Our framework helps in both cases: (1) LM adaptation to a new task (*e.g.* DST), and (2) LM adaptation to a new task-oriented dialogue domain (*e.g. restaurant*).

4.4 How Does Augmentation Improve Performance?

To study the reason behind the performance gain by augmentation, we dispart our test set samples into two groups: samples with unique values that do not show up during training, and samples with values seen during training. We then evaluate the TOD-BERT model trained with original and synthetic data on these two separate groups, *cf.* Table 4. The results suggest that although, augmentation increases robustness to unseen values in all domains, the largest part of the contribution is on seen values. This is expected since our framework uses the same set of values as in small original dialogue set during surface realization.

Error type	Original	Synthetic
restaurant-food	2,041	1,675
restaurant-pricerange	1,210	603
restaurant-name	1,133	1,061
restaurant-area	853	480
restaurant-book day	743	335
restaurant-book people	740	212
restaurant-book time	1,119	347

Table 5: Fine-grained *restaurant* domain errors, for the original and augmented TRADE model, classified by slot type.

Note that for the "All-domains" section in the table the improvement on unseen values is smaller compared to domain-specific sections (*Restaurant*, *Taxi*, *Hotel*), this is because, in the former, the model learns DST task from scratch thus exploiting seen-values to learn the task overweighs to generalizing over unseen values. Whereas for the latter, robustness to unseen values gets higher learning priority since the model is already familiar with the DST task from training on other 4 domains.

This analysis shows that our framework helps the model to exploit slots that have a bounded value pool with less unique values while also making it robust to unseen values for slots with broader value pools.

4.5 Effect of Augmentation Ratio

We run our framework with several different augmentation ratios in both the 5 and 10 shot cases to inspect if the synthetic data amount affects the results proportionally. Figure 5 shows the results for the TRADE model in all 5 domains. Our framework outperforms base fine-tuning steadily, and the amount of synthetic data affects the results propor-

	Hotel		Taxi		Restaurant		Attraction		Train	
	Joint	Slot	Joint	Slot	Joint	Slot	Joint	Slot	Joint	Slot
5 Shot Augmentation on Target Domain										
BM fine-tuned with CoCo	0.12	0.66	**0.60**	0.75	**0.13**	**0.62**	0.24	0.58	0.27	0.69
BM fine-tuned with our framework	0.12	**0.67**	0.58	0.75	**0.13**	**0.62**	**0.26**	**0.61**	**0.31**	**0.77**
10 Shot Augmentation on Target Domain										
BM fine-tuned with CoCo	**0.15**	0.68	**0.61**	0.75	**0.16**	0.67	0.31	0.64	**0.39**	0.82
BM fine-tuned with our framework	**0.15**	**0.69**	0.60	**0.76**	**0.16**	**0.70**	**0.32**	**0.66**	**0.39**	**0.83**

Table 6: Evaluation results of TRADE model comparing our augmentation framework to the upperbound CoCo model pre-trained on full training data (including target domain).

Active Slot F1	Restaurant	Taxi	Hotel
5 Shot			
CoCo	0.17	0.0047	0.21
Ours	**0.19**	**0.0078**	**0.22**
10 Shot			
CoCo	**0.22**	0.0114	0.21
Ours	**0.22**	**0.0132**	**0.23**

Table 7: Evaluation results of TOD-BERT model comparing our augmentation framework to the upperbound CoCo model pre-trained on full training data (including target domain).

tionally in every case except the *taxi* domain as explained before (*cf.* Section 4.3).

4.6 Fine-grained Error Analysis

4.6.1 Slot-type Errors

Apart from performance in evaluation metrics we also analyze the error rates of the TRADE model in each specific slot type in the *restaurant* domain and compare results with and without our framework. Table 5 shows the results. Our framework consistently reduces error rates in every single slot type. The drop in the error rate is least remarkable for the name and food slots, we believe this is because the challenge in these slots is most largely unknown vocabulary words. Our framework enriches the dialogue templates with values from the original set. Thus it is less helpful for those slots suffering from the unknown slot value problem and shows more significant improvements on slots with arguably more isolated vocabulary (*e.g.* Book-day: 1, 2, 3, *etc.* or price range: cheap, moderate, expensive).

To support the significance of results on fine-grained slot error types, we use McNemar's test ($\alpha = 0.01$) upon creating the confusion matrix between our framework and original fine-tuning. The results suggest that synthetic data fine-tuning shows statistically significant improvements over the original data fine-tuning, with $p < \alpha$.

4.7 Comparison against CoCo Model

To better locate the position of our framework in the literature we repeat target domain experiments using another dialogue augmentation method: CoCo (Li et al., 2021). However, CoCo is a learning-based approach that requires rich amounts of data, so it is unfair to expect it to learn from only a few shots (5/10). Instead, we use the pretrained weights that are provided by the original CoCo paper and treat it as an upper bound because it is trained on the full training data (including the target domain for leave-one-out experiments) whereas our framework uses only the provided few dialogues during augmentation.

Tables 6 and 7 give the results for TRADE and TOD-BERT, respectively. Despite the advantageous standing of CoCo, our framework outperforms CoCo in all domains for the TOD-BERT model and shows either superior or comparable results on TRADE.

4.8 Effect of Template Generation

We conduct an ablation study to see the effect of dialogue template generation by re-running the TOD-BERT target domain experiments for *hotel* and *restaurant* domains with a simpler baseline, where we use only the original n dialogues as templates and perform surface realization.

The results in Table 8 show that template generation improves results compared only surface realization in most of the cases. Our template generation strategy offers higher diversity to the samples but it might bring up noisy samples along, whereas only surface realization is less noisy but lacks the diversity that novel templates contribute.

5 Conclusion

Our framework showcases a distinct approach to dialogue augmentation, where, unlike other studies, we apply the modification not on a datum/sample

Active Slot F1	Restaurant	Hotel
5 Shot		
Full pipeline	**0.183**	**0.255**
Only SR	0.157	0.250
10 Shot		
Full pipeline	0.198	**0.258**
Only SR	**0.237**	0.243

Table 8: TOD-BERT target domain experiments comparing full pipeline (first row) against only surface realization (second row). Each number corresponds to an average of 3 runs.

level (*i.e* modifying utterances or words in an utterance) but on the data level exchanging information among different samples. We apply this concept within TODs as their dialogue states are like blueprints detailing each dialogue separately which can be used to partition and reconstruct new dialogue samples from scratch.

Experiments on MultiWOZ dataset using both the TRADE and TOD-BERT models suggest that our framework consistently improves the performance of the base-model it is applied to. This is true both when adapting the model to the DST task from scratch and also when adapting a model pre-trained on DST task to a new domain. The performance boost behind our augmentation framework comes mostly from performance increase on seen values during training although it also makes the model more robust to unseen values. Showing that our framework consistently improves the few-shot performance over the DST task we believe it can open doors for many other TOD tasks in limited data scenarios.

A Sample Synthetic Dialogues

Speaker	Turn
User	I am coming to town and looking for a good Spanish restaurant to try near the town center. Do you have any suggestions ?
Agent	The Spanish restaurant near center is Wagamama. The address is 36 saint Andrews street .
User	I'll be needing a table for 4 at 5p.m. this next Monday , can you help ?
Agent	Here is your reference number 6huyuygs is there anything else I can do for you?
User	Yes I need to find a train to Cambridge from Kings Lynn.
Agent	When would you like to travel ?
User	Tuesday morning at 9 am
Agent	train tr3447 leaves Kings Lynn at 09:11. Would you like to reserve a ticket ?
User	Yes please. Make a booking for the same number of people .
Agent	Okay, the booking was successful , the total fee is 58.8 gbp payable at the station . reference number is : fz6dqhqt. Anything else i can help you with?
User	That is all i needed today.

Speaker	Turn
User	I am looking for a train to Cambridge that departs after 10:45.
Agent	What day would you like to travel?
User	I'll be travelling on a Wednesday.
Agent	Where would you be departing from?
User	I will be leaving Norwich.
Agent	On what day will you be leaving?
User	I will be leaving on Wednesday.
Agent	It is 18.88 pounds per ticket. How many tickets would you like to purchase?
User	Just 2 tickets please and thank you.
Agent	Your ticket has been reserved . Total fee is 18.88 gbp, payable at the station. Reference number zm5k0a4q. Can i help you with anything else today?
User	Can you book Acorn guest house for 7 people starting on Wednesday for 4 nights, please ?
Agent	Thank you so much for reserving my train ticket. I have the information for Acorn guest house you requested. Would you like me to reserve it for you ?
User	Yes. I need the reference number.
Agent	The booking was successful. your reference number is dtkw11yu
User	That is all I needed today, thank you for your help.

Table 9: Sample synthetic dialogues generated by our framework. (T) Dialogue in *restaurant* domain generated by 2 different original dialogues. (B) Dialogue in *train* domain generated by 3 different original dialogues.

We showcase two synthetic dialogues generated with our framework, *cf.* Table 9, by merging templates from 2 and 3 different dialogues respectively. Our framework can generate multi-domain dialogues following the original dialogues' belief state. For instance, the first half of the first dialogue includes slots from the *restaurant* domain, while the second half has slots from the *train* domain. The second dialogue on the other hand combines slots from domains: *train* (from two different dialogues) and *hotel* (from another third dialogue). Although both dialogues seem coherent in shape, the latter has a redundancy where the system request the day information after the user already stated it. This is because of a missing annotation where the train-day slot in the belief state of the third turn is missing. These kinds of annotations are unavoidable but negligible because it recaptures a misunderstanding by the agent which is observed in real dialogues frequently.

Document-Level Relation Extraction with Adaptive Focal Loss and Knowledge Distillation

Abstract

Document-level Relation Extraction (DocRE) is a more challenging task compared to its sentence-level counterpart. It aims to extract relations from multiple sentences at once. In this paper, we propose a semi-supervised framework for DocRE with three novel components. Firstly, we use an axial attention module for learning the interdependency among entity-pairs, which improves the performance on two-hop relations. Secondly, we propose an adaptive focal loss to tackle the class imbalance problem of DocRE. Lastly, we use knowledge distillation to overcome the differences between human annotated data and distantly supervised data. We conducted experiments on two DocRE datasets. Our model consistently outperforms strong baselines and its performance exceeds the previous SOTA by 1.36 F1 and 1.46 Ign_F1 score on the DocRED leaderboard.[1]

1 Introduction

The problem of document-level relation extraction[2] (DocRE) is highly important for information extraction and NLP research. The DocRE task aims to extract relations among multiple entities within a document. The DocRE task is more challenging than its sentence-level counterpart in the following aspects: (1) The complexity of DocRE increases quadratically with the number of entities. If a document contains n entities, classification decisions must be made on $n(n-1)$ entity pairs and most of them do not contain any relation. (2) Aside from the imbalance of positive and negative examples, the distribution of relation types for the positive entity pairs is also highly imbalanced. Considering the DocRED (Yao et al., 2019) dataset as an example, there are 96 relation types in total, where the top 10 relations take up 59.4% of all the relation labels. This imbalance significantly increases the difficulty of the document-level RE task.

Most existing approaches of DocRE leverage dependency information to construct a document-level graph (Zeng et al., 2021; Zeng et al., 2020), and then use graph neural networks for reasoning. Another popular strand of this field uses transformer-only (Vaswani et al., 2017) architecture (Zhou et al., 2021; Xu et al., 2021; Zhang et al., 2021). Such models are able to achieve state-of-the-art performance without explicit graph reasoning, showing that pre-trained language models (PrLMs) are able to implicitly capture long-distance relationships. However, there are three limitations of the existing DocRE methods. Firstly, existing methods mainly focus on the syntactic features from PrLMs while neglecting the interactions between entity pairs. Zhang et al. (2021) and Li et al. (2021) have used CNN structure to encode the interaction between entity pairs, but CNN structure cannot capture all the elements within the two-hop reasoning paths. Secondly, there is no prior work that explicitly tackles the class-imbalance problem for DocRE. Existing works (Zhou et al., 2021; Zhang et al., 2021; Zeng et al., 2020) only focus on threshold learning for balancing the positive and negative examples, but the class-imbalance problem within positive examples is not addressed. Lastly, there are very few works discussing the method of adapting distantly supervised data for the DocRE task. Xu et al. (2021) has shown that distantly supervised data is able to improve the performance of document-level relation extraction. However, it only uses the distantly supervised data to pre-train the RE model in a naive manner.

To overcome the limitations of existing works, we propose a semi-supervised learning framework for document-level relation extraction. Firstly, to

Findings of the Association for Computational Linguistics: ACL 2022, pages 1672 - 1681
May 22-27, 2022

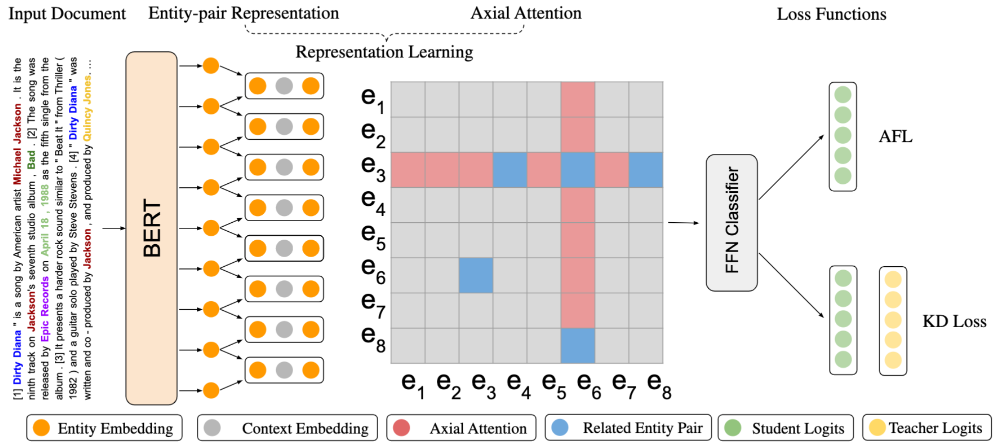

Figure 1: Model architecture of our DocRE system. We show the axial attention region for the entity pair (e_3, e_6).

improve the reasoning for two-hop relations, we propose to use an axial attention module as feature extractor. This module enables us to attend to elements that are within two-hop logical paths and capture the interdependency among the relation triplets. Secondly, we propose Adaptive Focal Loss to address the imbalanced label distribution problem. The proposed loss function encourages the long-tail classes to contribute more to the overall loss. Lastly, we use knowledge distillation to overcome the differences between the annotated data and the distantly supervised data. Specifically, we first train a teacher model with a small amount of human annotated data. The teacher model will then be used to generate predictions on a large amount of distantly supervised data. The generated predictions are used as soft labels for pre-training our student model. Finally, the pre-trained student model is further fine-tuned on the human annotated data.

We conducted experiments on two datasets – the DocRED (Yao et al., 2019) dataset and the HacRED (Cheng et al., 2021) dataset. Experimental results show that our model consistently outperforms competitive baselines. Moreover, our model significantly outperforms the existing state-of-the-art **SSAN-Adapt** (Xu et al., 2021) on the DocRED leaderboard by 1.36 in F1 score and 1.46 in Ign_F1 score.[3] Besides, we provide a thorough ablation study and error analysis to identify the bottleneck of our method.

2 Methodology

2.1 Problem Formulation

In this section, we describe the task formulation of document-level relation classification. Given a document D that contains a set of entities $\{e_i\}_{i=1}^{n}$, the document-level relation extraction task is to predict the relation types between entity pairs $(e_s, e_o)_{s,o\in\{1...n\},s\neq o}$, where the subscripts of e_s and e_o refer to subject and object. The set of relations is defined as $\mathbf{R} \cup \{\mathbf{NR}\}$, where **NR** stands for *no relation*. An entity may occur multiple times in a document, thus for each entity e_i, there can be multiple mentions $\{m_j^i\}_{j=1}^{N_{e_i}}$. If no relation exists between the entities in the pair (e_s, e_o), it will be labeled as **NR**. During test time, the relation labels for all entity pairs $(e_s, e_o)_{s,o\in\{1...n\},s\neq o}$ will be predicted. Essentially, this is a multi-label classification problem, as there can be multiple relations between e_s and e_o.

2.2 Model Architecture

As shown in Figure 1, our semi-supervised learning framework mainly consists of three parts: (1) representation learning; (2) adaptive focal loss; and (3) knowledge distillation for distant supervision pretraining. For representation learning, we first extract the contextual representation for each entity-pair by a pre-trained language model. The entity pair representations will be further enhanced by the axial attention module, which will encode the inter-dependent information between entity pairs. We then use a feedforward neural network (FFN) classifier to obtain the logits and compute their losses. We use our proposed adaptive focal loss to better learn from long-tail classes. Finally, we use

---

[3] Refer to `https://competitions.codalab.org/competitions/20717`, where our model is named *KD-Roberta*.

knowledge distillation to overcome the differences between human annotated data and distantly supervised data. Specifically, we train a teacher model with the annotated data and use its output as soft labels. We then pre-train a student model based on the soft labels and the distant labels. The pre-trained student model will be fine-tuned again with the annotated data. We will describe the details for each part in the following sections.

2.2.1 Representation Learning

Entity Representation We use a pretrained language model as the encoder. For a document D of length l, we have $D = [x_t]_{t=1}^{l}$, where x_t is the word at location t. Following prior works for relation classification, we use special token markers to represent entities. The entity mentions will be marked by a special token "*" at the start and end position. We then use a pre-trained language model (PrLM) to obtain the contextualized embeddings $\mathbf{H}$ of this document.

$$\mathbf{H} = PrLM([x_1, ..., x_l]) = [h_1, ..., h_l]) \quad (1)$$

where $\mathbf{H} \in \mathbb{R}^{l\times d}$ and d is the hidden dimension of the PrLM. If the document length exceeds the maximum position of the PrLM, the document will be encoded as multiple overlapping chunks, and the contextualized embeddings of the overlapping chunks will be averaged. We take the embedding of the special token "*" at the start of the mention as its embedding, which is denoted as h_{m_j}. Then, for each entity e_i with mentions $\{m_j^i\}_{j=1}^{N_{e_i}}$, where N_{e_i} is the number of mentions for entity e_i, its global representation is obtained by logsumexp pooling:

$$h_{e_i} = log \sum_{j=1}^{N_{e_i}} exp(h_{m_j}) \quad (2)$$

where $h_{e_i} \in \mathbb{R}^d$ is the aggregated feature of e_i.

Context-enhanced Entity Representation As prior works (Xu et al., 2021; Peng et al., 2020) have shown that contextual information is crucial for the relation classification task, our model also adapts contextual pooling method from Zhou et al. (2021). For each entity e_i, we first aggregate the attention output for its mentions by mean pooling $A_{e_i} = \sum_{j=1}^{N_{e_i}}(a_{m_j})$, where $a_{m_j} \in \mathbb{R}^{H\times l}$ is the the self-attention weight at the position of mention m_j, H is the number of attention heads, and l is the document length. Then the context query is calculated as:

$$q^{(s,o)} = \sum_{i=1}^{H}(A_{e_s}^i \circ A_{e_o}^i) \quad (3)$$

$$c^{(s,o)} = \mathbf{H}^\intercal q^{(s,o)} \quad (4)$$

where $A_{e_s} \in \mathbb{R}^{H\times l}$ is the aggregated attention output for entity e_s, likewise for e_o. $q^{(s,o)} \in \mathbb{R}^l$ is the mean-pooled attention weight for entity pair (e_s, e_o) and $\mathbf{H} \in \mathbb{R}^{l\times d}$ is the contextual embedding of the whole document. Then the context vector $c^{(s,o)} \in \mathbb{R}^d$ is fused with the entity representations.

$$z_s = tanh(\mathbf{W}_s h_{e_s} + \mathbf{W}_c c^{(s,o)}) \quad (5)$$

where $z_s \in \mathbb{R}^d$ is the context-enhanced representation of subject s for entity pair (e_s, e_o). We obtain the object representation z_o in the same manner.

Entity Pair Representation Following Zhou et al. (2021), we use a grouped bilinear function for feature combination. The entity embedding z_s will first will be split into k equal-sized groups, such that $z_s = [z_s^1, z_s^2, ..., z_s^k]$. We perform the same splitting for z_o. The value $g_i^{(s,o)}$ at each dimension of our entity pair representation is obtained by:

$$g_i^{(s,o)} = \sum_{j=1}^{k}(z_s^{j\intercal} W_{g_i}^j z_o^j) + b_i \quad (6)$$
$$g^{(s,o)} = [g_1^{(s,o)}, g_2^{(s,o)}, ..., g_d^{(s,o)}]$$

where $W_{g_i}^j \in \mathbb{R}^{d/k\times d/k}$, for $i = 1, ..., d$, $j = 1, ..., k$, is the weight matrix for dimension i. b_i is a scalar bias of dimension i. $g^{(s,o)} \in \mathbb{R}^d$ is our final entity pair representation.

For a given document D with n entities, we need to classify $n(n-1)$ number of entity pair permutations. To help us encode all the entity pairs and their positions, we used an $\mathbb{R}^{n\times n\times d}$ matrix $\mathbf{G}$ to represent all the entity pairs of document D, and the diagonal of the $n \times n$ index is neglected during training and inference.

Axial Attention-Enhanced Entity Pair Representation Instead of using only head and tail embedding for relation classification, we propose to use two-hop attention to encode the axial neighboring information of each entity pair (e_s, e_o) representation. Although there are prior works that use Convolution Neural Networks (CNNs) to encode the neighbor information for relation classification (Zhang et al., 2021), we believe that attending to the axial elements is more effective and intuitive. Given an $n \times n$ entity table, for entity pair (e_s, e_o), attending to its axial elements corresponds to attending to elements that are either (e_s, e_i) or (e_i, e_o). That is, if a two-hop relation (e_s, e_o) can be dissected into a path (e_s, e_i) and (e_i, e_o), then the most informative neighbors for classifying (e_s, e_o) are the one-hop candidates that share e_s or e_o with this entity pair. The axial attention is simply computed by self-attention along the height axis and the width axis, and each computation along the axes is followed by a residual connection. For the cell (e_s, e_o), we have:

$$\begin{aligned} r_w^{(s,o)} &= r_h^{(s,o)} + \sum_{p \in 1..n} softmax_p(q_{(s,o)}^T k_{(s,p)}) v_{(s,p)} \\ r_h^{(s,o)} &= g^{(s,o)} + \sum_{p \in 1...n} softmax_p(q_{(s,o)}^T k_{(p,o)}) v_{(p,o)} \end{aligned} \tag{7}$$

where we denote query $q_{(i,j)} = W_Q g^{(i,j)}$, key $k_{(i,j)} = W_K g^{(i,j)}$, and value $v_{(i,j)} = W_V g^{(i,j)}$, which are all linear projections of the entity pair representation g at position (i, j). $W_Q \in \mathbb{R}^{d \times d}$, $W_K \in \mathbb{R}^{d \times d}$, and $W_V \in \mathbb{R}^{d \times d}$ are all learnable weight matrices. The output of the axial attention module is $r_w^{(s,o)} \in \mathbb{R}^d$. The $softmax_p$ function denotes a softmax function that applies to all possible $p = (i, j)$ positions. The formulation of this mechanism resembles Wang et al. (2020). However, our motivation is different, as Wang et al. (2020) aim to use this mechanism to reduce the computational complexity of semantic segmentation, whereas our motivation is to attend to the one-hop neighbors for the two-hop relation triplets.

2.2.2 Adaptive Focal Loss

Finally, we have a linear layer for predicting relations:

$$l^{(s,o)} = \mathbf{W}_l r_w^{(s,o)} + b_l \tag{8}$$

where $l^{(s,o)} \in \mathbb{R}^c$ denotes the output logits for all relations, $\mathbf{W}_l \in \mathbb{R}^{d \times c}$ is the weight matrix that maps the relation embedding to the logit of each class and c is the number of classes.

Our relation extraction problem is essentially a multi-label classification problem. Traditionally, binary cross-entropy (BCE) loss is used to tackle this problem. However, this method relies on a global probability threshold for inference. Recently **Adaptive Thresholding Loss** (**ATL**, Zhou et al., 2021) has been proposed for multi-label classification. Instead of using a global probability threshold for all examples, ATL introduced a special class TH as the adaptive threshold value for each example. For each entity pair (e_s, e_o), the classes whose logits are larger than the TH class logit will be predicted as positive classes, and the rest will be predicted as negative classes.

We propose **Adaptive Focal Loss** (**AFL**) as an enhancement to **ATL** for long-tail classes. Our loss consists of two parts, the first part is for positive classes and the second part is for negative classes. During training, the label space is divided into two subsets: positive class subset $\mathcal{P}_T$ and negative class subset $\mathcal{N}_T$. The positive class subset $\mathcal{P}_T$ contains the relations that exist in entity pair (e_s, e_o), and if there is no relation between (e_s, e_o), $\mathcal{P}_T$ is empty ($\mathcal{P}_T = \varnothing$). The negative subset $\mathcal{N}_T$, on the other hand, contains the relation classes that do not belong to the positive classes, $\mathcal{N}_T = \mathcal{R} \setminus \mathcal{P}_T$. The probability of each positive class is computed as:

$$P(r_i|e_s, e_o) = \frac{exp(l_{r_i}^{(s,o)})}{exp(l_{r_i}^{(s,o)}) + exp(l_{TH}^{(s,o)})} \tag{9}$$

where the logit of r_i is ranked with the logit of threshold class TH individually. This is different from the original ATL, where all positive logits are ranked together with a softmax function. For simplicity, $P(r_i|e_s, e_o)$ is denoted as $P(r_i)$ in this section, because we are only discussing (e_s, e_o). For the negative classes, we use their logits to compute the probability of the TH class:

$$P(r_{TH}|e_s, e_o) = \frac{exp(l_{r_{TH}}^{(s,o)})}{\sum_{r_j \in \mathcal{N}_T \cup \{TH\}} exp(l_{r_j}^{(s,o)})} \tag{10}$$

Similarly, $P(r_{TH}|e_s, e_o)$ is referred to as $P(r_{TH})$ in the remainder of this section. Since the distribution of the positive labels is highly imbalanced, we leverage the idea of focal loss (Lin et al., 2017) for balancing the logits of the positive classes. We have our loss function as:

$$\mathcal{L}_{RE} = \sum_{r_i \in \mathcal{P}_T} (1 - P(r_i))^{\gamma} log(P(r_i)) + log(P(r_{TH})) \tag{11}$$

where γ is a hyper-parameter. Our loss is designed to focus more on the low-confidence classes. If $P(r_i)$ is low, the loss contribution from the relevant class will be higher, which enables a better optimization for long-tail classes.

2.2.3 Knowledge Distillation for Distant Supervison

In this section, we describe how we utilize the distantly supervised data in a more effective manner.

The distantly supervised data included in the DocRed dataset (Yao et al., 2019) was obtained by performing entity linking on the Wikidata Knowledge Base (Vrandečić and Krötzsch, 2014) and the Wikipedia data dump. It is shown that pre-training from the distantly supervised data is beneficial for document-level relation extraction (Xu et al., 2021). However, prior work only adapts the distantly supervised data in a naive manner. The key challenge for the distant supervision adaptation is to overcome the differences between probability distributions of the distantly supervised data and the human annotated data. We compare two strategies for adapting the distantly supervised data.

Naive Adaptation Adopting from (Xu et al., 2021), this method first pretrains the model with the distantly supervised data with the relation extraction loss $\mathcal{L}_{RE}$ (Eqn. 11), and then the model is fine-tuned on the human-annotated data with the same objective. We denote this method as **Naive Adaptation (NA)**.

Knowledge Distillation To further utilize the annotated data, we use a relation classification model trained on the human-annotated data (#Train in Table 1) as the teacher model. The teacher model is used to generate soft labels on the distantly supervised data. Specifically, the distantly supervised data is fed into the teacher model and the predicted logits will be the soft labels used for training the student model. The student model has the same configuration as the teacher model, but is trained with two signals simultaneously. The first signal is the supervision from the hard labels of the distantly supervised data and the second is from the predicted soft labels. We denote the loss computed on the hard labels as $\mathcal{L}_{RE}$ and the knowledge distillation loss computed on the soft labels as $\mathcal{L}_{KD}$. We use mean squared error (MSE) as the knowledge distillation loss function:

$$\mathcal{L}_{KD} = MSE(l_S^{(s,o)}, l_T^{(s,o)}) \tag{12}$$

where $l_S^{(s,o)}$ denotes the predicted logits of the student model and $l_T^{(s,o)}$ is the prediction of the teacher model. The student model is further fine-tuned with human-annotated data (#Train in Table 1) after it has been pre-trained on the distantly supervised data. The overall loss of pre-training with distantly supervised data is computed as:

$$\mathcal{L} = \mathcal{L}_{KD} + \mathcal{L}_{RE} \tag{13}$$

We denote this method as **KD** in our main experimental results section. Besides the MSE loss, we also compare different adaptation methods, such as KL-Divergence, in section 3.6.

3 Experiments

Statistics	DocRED	HacRED
# distant docs	101,873	–

Avg # mentions per entity	1.4	1.2
Avg # relations per doc	12.5	7.4

Table 1: Dataset statistics of the DocRED and HacRED datasets.

3.1 Dataset Statistics

We evaluated our model on two document-level relation extraction datasets – the DocRED (Yao et al., 2019) benchmark and the HacRED dataset (Cheng et al., 2021). DocRED is a crowd-sourced large-scale document-level relation extraction dataset. It contains 3,053/1,000/1,000 instances for training, validation, and test, respectively. HacRED is a Chinese relation extraction dataset that focuses on the hard cases of relation extraction. It contains 27 hard relations and is split into 6,231/1,500/1,500 instances for training, validation, and test. However, the test set of HacRED is not released yet. In this paper, we only provide the results on its dev set.

3.2 Implementation Details

We implemented our model with the PyTorch version of the Huggingface Transformers (Wolf et al., 2020). For experiments on DocRED, we experimented with Roberta-large (Liu et al., 2019) and Bert-base (Devlin et al., 2019) as our document encoder respectively. For experiments on HacRED, we use XLM-R base (Conneau et al., 2020) as the document encoder. AdamW (Loshchilov and Hutter, 2019) is used as the optimizer. At the knowledge distillation stage, we trained the model with the learning rate set to 1e-5 for 2 epochs. Warmup is applied on the initial 6% steps. The dropout rates between transformer layers are set to 0.1 and the maximum gradient norm is clipped at 1.0. During the fine-tuning stage, the learning rate is set

Table 2: Experimental results for the DocRED dataset. The reported metrics are F1 score and Ign_F1. We report the average of five random runs for the development set and the best checkpoint is used for the leaderboard submission for the test results. Results with * are obtained by our reproduction.

to 1e-6 and we train the model for 10 epochs. We performed grid search for $\gamma \in [0, 0.5, 1.0, 1.5, 2.0]$ and set it to 0.5. Our model is trained on a single NVIDIA V100 GPU with 32 GB memory. The main evaluation metrics are Ign_F1 and F1 score following Yao et al. (2019), where Ign_F1 refers to the F1 score that ignores the triples that appear in the annotated training data.

3.3 Compared Methods

We denote Bert-base and Bert-large encoders as **B-b** and **B-l**. The Roberta-large model is denoted as **Rb-l**. We compare our model with the state-of-the-art systems on the DocRED leaderboard as well as strong baselines by our own implementation. They are the following models: Wang et al. (2019) has proposed to fine-tune BERT for document-level RE with a two-step process (**Two-stage-B-b**). The Bert model needs to classify whether the two entities have relation and then classify their relation if the first step is positive. The **Coref-Rb-l** (Ye et al., 2020) uses a co-reference module to aggregate the mention representations of the same entity. The **SSAN** (Xu et al., 2021) model utilizes co-occurrence information between entity mentions, leverages distantly supervised data for pretraining, and achieves the state of the art on the DocRED leaderboard. Since their best model **SSAN-Adapt** is equivalent to naive adaptation in our work, we denote it as **SSAN-NA-Rb-l** in our experiments. The **GAIN** (Zeng et al., 2020) model adds a graph neural network on top of a pre-trained language model, constructs a document-level graph for each example, and uses the graphical structure to extract relations. **SIRE** (Zeng et al., 2021) uses two encoders for different types of relation — a sentence-level encoder to extract intra-sentence relations and a document encoder to extract inter-sentence relations. **ATLOP** (Zhou et al., 2021) is purely based on the transformer architecture and a novel adaptive thresholding loss to deal with the multi-label problem for DocRE. Besides, it also fuses the contextual information with the aggregated attention weights for each entity. The **DocuNet** (Zhang et al., 2021) model treats the relation extraction task in a similar way as semantic segmentation in computer vision. We also conducted an experiment that pretrained the **ATLOP-Rb-l** model with distantly supervised data, as this model is the best model by our reproduction.

3.4 Main Results

Our main results for the DocRED dataset are shown in Table 2. Knowledge distillation is able to significantly improve the performance of our model. **Ours-KD-Rb-l** achieves the best single-model performance of 67.28 test F1. Our best model significantly ourperforms the previous state of the art **SSAN-NA-Rb-l** by 1.36 on test F1 and 1.46 on test Ign_F1. As of 11th Nov 2021, our best model achieves the highest scores on the DocRED leaderboard.

	P	R	F1
GAIN*	73.38	**80.07**	76.09
ATLOP*	76.97	78.29	77.63
Ours	**78.53**	78.96	**78.75**

Table 3: Experimental results on HacRED dev set. Results with * are implemented by us. All experiments used XLM-R-base as the encoder.

The experiment results for the HacRED dataset are shown in Table 3. The main difference of our method with the ATLOP baseline is the Adaptive Focal Loss and the Axial Attention Module. Our proposed method is able to exceed the ATLOP baseline by 1.12 F1. Besides the performance of the models, it is worth noting that for each method, the absolute performance of HacRED is significantly higher than its performance on DocRED. This is counter-intuitive as HacRED focuses on the hard relations whereas DocRED is more general. This can be caused by the following: 1) The human annotated training instances of the HacRED dataset are significantly more than DocRED, leading to better generalization performance. 2) Even though HacRED claims it focuses on the hard cases for relation extraction, it only has 27 classes, and the relation type distribution within the HacRED dataset is more balanced.

3.5 Ablation Study

We first separate our label space into two subsets. The first subset consists of the 10 most frequent labels, accounting for 59.4% of the positive relations in the training data. The second subset is denoted as the long-tail labels, which includes the rest of the 86 relations (the total label space is 97 and there is one TH class). Since our Adaptive Focal loss function is mainly designed for improving the performance on the less frequent classes, we show the ablation study by frequent and long-tail classes in Table 4. When we change the AFL loss to conventional Adaptive Thresholding Loss (Zhou et al., 2021), the overall performance with KD drops by 0.89 F1, and the F1 score for the frequent labels only drops by 0.65. Meanwhile, the long-tail labels' F1 drops by 1.78, which is significantly higher than the drop in overall performance and frequent performance. This indicates that our Adaptive Focal Loss is able to balance the weight of the frequent classes and infrequent classes. The axial attention module is also more beneficial for the long-tail classes than the frequent classes, which shows that our model's performance on the frequent classes is saturated.

	Frequent F1	Long-tail F1	Overall F1
ATLOP-Rb-l	70.93	50.01	63.12
Ours-Rb-l	**71.26**	**51.97**	**64.19**
w/o **Axial**	70.86	50.77	63.56
w/o **AFL** *w* **ATL**	70.94	50.86	63.67
With Distant Supervision			
ATLOP-NA-Rb-l	73.26	52.39	65.33
Ours-KD-Rb-l	**74.15**	**56.51**	**67.12**
w/o **Axial**	73.52	54.96	66.36
w/o **AFL** *w* **ATL**	73.50	54.73	66.23

Table 4: Experiment results for frequent and long-tail type relations. Frequent types refer to the most popular 10 relation types, and long-tail relations refer to the rest of the 86 relations.

	P	R	Infer-F1
GAIN-B-b	38.71	59.45	46.89
Ours-Rb-l	**42.15**	**61.56**	**50.04**
w/o **Axial**	40.26	60.60	48.37

Table 5: Ablation study for the Infer-F1 relation triples on the development set of DocRED.

We also provide an ablation study on the multi-hop relations in Table 5. We use the same evaluation method for multi-hop relations as Zeng et al. (2020). This evaluation method ignores all the one-hop relation triples. Our axial attention module effectively improves Infer-F1 by 1.67, while its improvement for overall performance is only 0.63.

3.6 Comparison of Adaptation Methods

In this section, we directly compare the knowledge adaptation methods on the development set of DocRED (Table 6). We mainly compare three methods for adaptation: 1) Naive Adaptation (**NA**), 2) **KD**$_{KL}$ knowledge distillation with the KL divergence loss and 3) **KD**$_{MSE}$ with mean squared error loss. The adaptation performance on the development set is positively correlated with the per-

Distant Adaptation	Ign_F1	F1
NA	52.29	54.67
KD$_{KL}$	53.89	56.97

Continue-trained	Ign_F1	F1
NA	63.38	65.64
KD$_{KL}$	64.42	66.24
KD$_{MSE}$	**65.27**	**67.12**

Table 6: Development set performance of different knowledge adaptation methods for DocRED.

formance of downstream fine-tuning. In the distant adaptation setting, our best method **KD**$_{MSE}$ is able to outperform **NA** by 3.07 F1 and **KD**$_{KL}$ by 0.77 F1. Similar performance differences are observed in the continue-trained setting.

4 Error Analysis

Even though our final model significantly outperforms the previous state of the art on the DocRED leaderboard, the absolute performance of our model still does not match human performance. In this section, we provide a detailed error analysis of our model on the development set of DocRED.

	Ground Truth	
Predictions	$r \in \mathbf{R}$	**NR**
$r \in \mathbf{R}$	**C**: 8,273 (51.4%) **W**: 242 (1.5%)	**MR**: 3,814 (23.7%)
NR	**MS**: 3,761 (23.4%)	380,703

Table 7: Statistics of our error distribution. The final evaluation score is evaluated on $r \in \mathbf{R}$ triples, hence the correct predictions of **NR** are ignored when calculating the final scores.

We first construct the union of our model's predictions and the ground truth triples (without **NR** label). Then, we categorize the union into four categories: (1) **Correct (C)**, where prediction triples are in the ground truth. (2) **Wrong (W)**, where the predicted head entity and tail entity are in the ground truth but the predicted relation is wrong. (3) **Missed (MS)**, where the model predicts no relation for a pair of head entity and tail entity with some relation in the ground truth. (4) **More (MR)**, where the model predicts an extraneous relation for a pair of head entity and tail entity not related in the ground truth. From Table 7, we observe that the error percentage of the **W** category is very small. This indicates that for a pair of head entity and tail entity with some relation in the ground truth, and when our model predicts that there is a relation between these two entities, it is able to predict the correct relation rather accurately. However, we observe that most of our errors are under the **MR** and **MS** categories, and their counts are about the same. To better understand the performance bottleneck of the document-level RE task, we evaluate our model on a simplified subtask (Table 8). This subtask is binary classification, i.e., to determine whether two entities are related or not, and it is denoted as **Binary Labels**. In this subtask, we only care about predicting correctly that there is some relation between a head entity and a tail entity, but not what the exact relation is among the 97 relation classes. The performance on this simplified task is 68.64 F1 score, which is only marginally higher than the original F1 score of 67.12. This may be due to incomplete annotation of the two document-level relation extraction datasets, and we will illustrate this hypothesis in Figure 2.

	P	R	F1
Binary Labels	68.51	68.78	68.64
Original Labels	67.10	67.13	67.12

Table 8: Performance breakdown on the DocRED dev set.

"**Eivind Bolle** (**13 October 1923** – **10 June 2012**) was a **Norwegian** politician for the **Labour Party**. He was born in **Hol**. He was elected to the **Norwegian Parliament** from **Nordland** in 1973. ... On the local level he was a member of **Hol** municipality council from **1959** to **1963** , and later in Hol 's successor municipality **Vestvågøy**. He served as mayor from **1971** to **1973** , during which term he was also a member of **Nordland** county council ..."

More: (**Nordland**, *country*, **Norwegian**), (**Vestvågøy**, *country*, **Norwegian**),...

Correct: (**Labour Party**, *country*, **Norwegian**), (**Hol**, *country*, **Norwegian**),...

Figure 2: Example output of our model on the DocRED dev set.

In Figure 2, we show an example document from the dev set of DocRED and its predictions. We observe that many triples in the **MR** category are factually correct. That is, some of the pairs of entities are truly related but are labeled as **NR** throughout the dataset. For instance, from the ground truth, we can see that **Labour Party** and **Hol** are all entities from *country* **Norway**. Similarly, **Nordland** and **Vestvågøy** are all in **Norway**, but their relations with **Norway** are not present in the ground truth triples. Therefore, when our model predicts these triples, its performance would be unfairly penalized during evaluation. This observation indicates that there are some incomplete annotations in the DocRED dataset. However, this is not the focus of this paper and we would like to leave this as future work.

5 Related Work

Early works on relation extraction mainly focused on sentence-level RE (Zhang et al., 2017; Baldini Soares et al., 2019; Peng et al., 2020). However, prior works have shown that a large number of relations can only be extracted from multiple sentences (Verga et al., 2018; Yao et al., 2019; Cheng et al., 2021). Various methods have been proposed to tackle document-level relation extraction (DocRE). Graph neural networks (GNNs; Scarselli et al., 2008) have been widely used for the DocRE task. Quirk and Poon (2017) used words as nodes and dependency information as edges to construct document-level graphs. This graph will be used to extract features for each entity pair. Later works extended this idea by applying different GNN architectures (Peng et al., 2017; Verga et al., 2018; Christopoulou et al., 2019; Nan et al., 2020; Zhang et al., 2018; Zeng et al., 2020). In particular, Nan et al. (2020) proposed the latent stucture refinement (LSR) model, which used structured attention to induce the document-level graph. Zeng et al. (2020) constructed the document-level graph by entity-mention nodes and sentence edges. Besides the graph-based methods, transformer-only architectures have also proven to be highly effective for the DocRE task (Tang et al., 2020; Zhou et al., 2021). Specifically, Zhou et al. (2021) proposed adaptive thresholding loss to tackle the multi-label classification problem in DocRE.

On the other hand, learning from distant supervision is another important problem for relation extraction. Qin et al. (2018) used generative adversarial training for selecting informative examples and Feng et al. (2018) used reinforcement learning to achieve the same goal. However, there are no existing works that jointly learn from annotated data and distant data. To this end, this paper is the first to overcome the differences between the human annotated and distantly supervised data. Moreover, this paper also tackles the under-explored class imbalance problem and the two-hop logical reasoning problem with novel solutions to the shortcomings of existing approaches.

6 Conclusions

In this paper, we have proposed a novel framework for document-level relation extraction, based on knowledge distillation, axial attention, and adaptive focal loss. Our proposed method is able to significantly outperform the previous state of the art on the DocRED leaderboard. Besides, we also conducted a thorough ablation study and error analysis to identify the bottleneck of the document-level relation extraction task.

Abstract

In typical machine learning systems, an estimate of the probability of the prediction is used to assess the system's confidence in the prediction. This confidence measure is usually uncalibrated; i.e. the system's confidence in the prediction does not match the true probability of the predicted output. In this paper, we present an investigation into calibrating open setting machine reading systems such as open-domain question answering and claim verification systems. We show that calibrating such complex systems which contain a discrete retrieval and deep reading components is challenging and current calibration techniques fail to scale to these settings. We propose simple extensions to existing calibration approaches that allow us to adapt these callibrators to these settings. Our experimental results reveal that the joint callibration of the retriever and the reader outperforms the reader calibrator by a significant margin. We also show that the callibrator can be useful for selective prediction, e.g., when question answering systems are posed with unanswerable or out-of-the-training distribution questions.

1 Introduction

With recent advances in machine reading, there has been a surge of interest in practical applications of the technology such as open-domain question answering (Karpukhin et al., 2020; Lee et al., 2019) and claim verification (Thorne et al., 2018b). Due to various scale limitations in practical settings, these systems are seldom trained end-to-end. Such systems typically make use of a RETRIEVER alongside a READER – the evidence is first retrieved from a large corpus and is then used by a machine reading model to provide an answer.

As these systems are increasingly being deployed in the real world, it is important that they are not only accurate but also trustworthy. A way to make these systems trustworthy is to indicate when they are likely to be incorrect by providing a calibrated `confidence` measure in addition to the prediction. A naive solution for this is to use the system's output probability as the confidence. However, this confidence score is often `uncalibrated` (Kuleshov and Liang, 2015; Guo et al., 2017); i.e. it is not representative of the true correctness likelihood.[1]

Previous work (Jiang et al., 2020; Jagannatha and Yu, 2020; Desai and Durrett, 2020) has shown that large language models especially suffer from miscalibration. Thus, several methods have been proposed to calibrate language models based on gradient-based calibration methods such as temperature scaling (Guo et al., 2017) and feature-based forecasters (Kuleshov and Liang, 2015). While gradient-based calibration is intuitive and easy to implement, feature-based forecasters require manual feature engineering.

In this work, we contribute a simple method to calibrate practical RETRIEVER - READER machine reading pipelines. These systems typically include a hard retrieval step which makes gradient-based calibration infeasible. Thus, we make use of the Gumbel machinery (Jang et al., 2017; Maddison et al., 2017); specifically the Gumbel top-K procedure of Vieira (2014); Xie and Ermon (2019) to obtain a differentiable sampling routine for the retrieval step. This sampler can then be combined with any gradient-based calibration technique such as Platt's scaling.

We conduct experiments on three different models – a generative and extractive open-domain question answering model and a claim verification model. We find that calibrating the RETRIEVER and the READER jointly is better than calibrating only the READER or the RETRIEVER . We also show that our approach can produce calibrated

---

[1] For a perfectly calibrated system, given 100 answer predictions, each with a confidence of 0.7, we expect that 70 should be correct.

Findings of the Association for Computational Linguistics: ACL 2022, pages 1682 - 1693

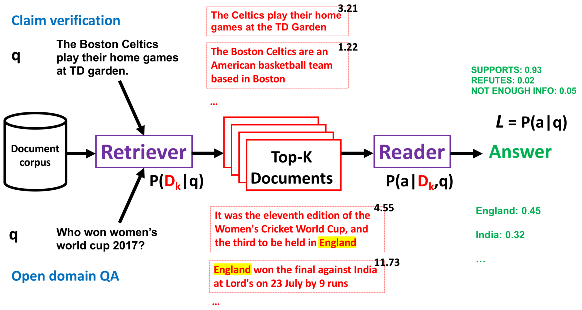

Figure 1: General architecture of the two machine reading systems considered in this paper. a) Claim verification (top half) and b) Open-domain QA (bottom half). The systems follow the same architecture and are composed of a retriever and a reader. Given the query, the retriever retrieves a set of K documents from the corpus along with scores for each of them. The reader then takes these as input and produces the output: a veracity label for claim verification and an answer span for the QA model. This can be seen as a probabilistic model with latent retrieval (D_k shown in red). The goal of this paper is to calibrate the final output probabilities $P(a|q)$.

scores that can be used to selectively abstain from answering questions that are contrived or ill-posed or questions that are out-of-the-training distribution. Finally, we also demonstrate how the calibration of such a system works – the calibration techniques lower the confidence of the predicted answer when the question is unanswerable or when the retriever is not able to retrieve any relevant evidence for answering the question. We perform our analysis on different types of unanswerable questions and show that incorporating the confidence of the RETRIEVER along with the READER can improve the confidence estimate of the answer.

2 Preliminaries

2.1 Machine Reading at Scale

Practical real-world machine reading systems such as open-domain question answering systems (Chen et al., 2017) (Karpukhin et al., 2020) (Izacard and Grave, 2020b) or claim verification systems (Hanselowski et al., 2018) rely on an information retrieval (IR) component called a RETRIEVER to reduce the search space over a large corpus of documents. This smaller set of documents is then passed to a READER model that reasons over the text and produces an answer. This setting, where the READER is not given labeled documents is referred to, in the literature, as an open-domain setting. We now proceed to formally define the pipeline for a machine reading system in the open-domain setting.

Let $\mathscr{D} = \{d_1, \dots, d_N\}$ denote the given corpus of documents. Let q denote the user query (a question or a claim). We denote the answer to the question or the veracity label of the claim as a. The retreiver model takes in q and scores all the documents $d \in \mathscr{D}$ to produce a set of scores:

$$\textsc{Retriever}(d_1, \dots, d_N|q) \longrightarrow S_{d_1}, \dots, S_{d_N} \tag{1}$$

This formulation of the RETRIEVER is generic. This allows our method to work with any IR model such as the traditional BM25 model (Wikipedia contributors, 2004) to more modern methods such as Dense Passage Retrieval (DPR) by Karpukhin et al. (2020).

The documents are then sorted based on the scores and the k top-scoring documents are chosen. We call this set of top-K documents D_k. D_k is then given to a READER model which extracts the answer or predicts a veracity label for the claim, a. The READER can vary depending on the task. For extractive QA, the READER produces a score for each span (s_i) in the documents provided to it.

$$\textsc{Reader}\ (q, D_k) \longrightarrow S^{Read}(s_i), s_i \in D_k \tag{2}$$

In claim verification, the READER produces a score for each veracity label: SUPPORTED, REFUTED or NOT ENOUGH INFO, which indicate whether the claim can be verified by the given set of documents.

$$\begin{aligned}\textsc{Reader}\ (D_k, q) \longrightarrow & S_{\text{SUPPORTED}}, \\ & S_{\text{REFUTED}}, \\ & S_{\text{NOT ENOUGH INFO}},\end{aligned}$$

2.2 Calibration

We summarize below the calibration framework (Kuleshov and Liang, 2015) in the context of machine reading. Given a query q, true output a, model output $\hat{a}$, and probability $P(\hat{a}|q)$ calculated over this output, a perfectly calibrated model satisfies the following condition:

$$\mathbb{P}(\hat{a} = a | P(\hat{a}|q) = p) = p \quad \forall p \in [0, 1] \tag{3}$$

In simple words, for the confidence estimate $P(\hat{a}|q)$ to be calibrated, we require that $P(\hat{a}|q)$ follows the unknown true probability distribution $\mathbb{P}$.

In a multi/binary class setting, a calibrator can be learned to map the output distribution to a calibrated confidence score. However, in a machine reading setting, the space of possible documents retrieved and answers contained in them is usually very large. Thus, we only focus on a specific event set $I(q)$ of interest. The event set $I(q)$ can be defined using the outputs relevant to the deployment requirements of the machine reading model. In our work, we consider all answer candidates in the retrieved set of documents D_k: $I(q) = \{a | a \in \arg\max_{D_k} P(\hat{a}|D_k, q)\}$

2.3 Measuring Calibrated-*ness*

Calibration can be measured by computing the difference in expectation between confidence scores and accuracies.

$$\mathbb{E}_{P(\hat{a}|q)}\Big[\mathbb{P}(\hat{a} = a | P(\hat{a}|q) = p) - p\Big] \quad (4)$$

This is known as expected calibration error (ECE) (Naeini et al., 2015). Practically, ECE is estimated by partitioning the predictions in M equally spaced bins $(B_1 \ldots B_M)$ and taking the weighted average of the difference between the average accuracy and average confidence of the bins.

$$\text{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{n} |acc(B_m) - conf(B_m)| \quad (5)$$

Reliability Diagrams

Another common tool to visualize model calibration is a reliability diagram. A reliability diagram plots sample accuracy as a function of confidence for each bin. If a model is perfectly calibrated, the confidence and accuracy bars should be identical.

2.4 Calibration methods

The general algorithm used for calibrating classification models involves transforming the logits produced by the model. The parameters for this transformation are trained on a held-out calibration set $C = \{(q_i, a_i)\}_{i=1}^{N}$. This method has been shown to improve the model's ECE without a significant loss in accuracy. In our work, we use negative log-likelihood (NLL) to tune a model $P(a|q)$ to be a good probability estimate of the output answers:

$$l_\theta = -\sum_{i=1}^{N} log(P(a_i|q_i)) \quad (6)$$

ML theory guarantees that NLL is minimized if and only if $P(a_i|q_i)$ recovers the ground-truth conditional distribution $\mathbb{P}(a|q)$. In the following part of this section, we describe some of these key methods.

Temperature Scaling

Temperature scaling (Guo et al., 2017) is one of the simplest methods for calibration and has been shown to be very effective. Temperature scaling allows the logits of the system's output (Z) to be scaled by a single temperature value τ. This scaling is done before the computation of the softmax.

$$Y = \texttt{softmax}(Z/\tau) \quad (7)$$

We optimize τ by maximizing $\mathscr{L}_\theta$ on the dev set.

Temperature prediction

The temperature prediction approach (Kumar and Sarawagi, 2019) extends temperature scaling to a gradient-based approach. The output logits of the classifier are featurized and passed through an MLP which predicts a temperature value. This temperature value is used to scale the logits. In contrast to temperature scaling which learns one temperature parameter for each example, in this approach, a new temperature value can be learned for each example.

$$\frac{1}{\tau_i} = \sigma(\texttt{MLP}(Z_i))$$
$$Y_i = \texttt{softmax}(Z_i/\tau_i)$$

Forecasters

Forecasters were introduced to calibrate structured prediction models (Kuleshov and Liang, 2015; Jagannatha and Yu, 2020). The forecaster approach introduces a feature-rich calibration model that uses various features of the model such as its logits and various uncertainties estimated to predict the confidence score. This approach generally only produces a calibrated score over a smaller set of candidate predictions referred to as the interest set $I(.)$ Previous work has successfully used gradient boosted decision trees **(XGB)** as forecasters.

3 Calibration of Machine Reading Systems

Previous work has looked at calibration in the aspect of machine reading (Jagannatha and Yu, 2020; Jiang et al., 2020). However, these works do not consider the open setting in which the evidence document for each query is not provided. We are interested in determining the calibrated probability distribution of the system, $\mathbb{P}(a|q)$. In the first set of methods, we do this by calibrating the confidence of the model $P(\hat{a}=a|q)$. For a machine reading system,

$$P(\hat{a}=a|q) = \sum_{D_k \in \mathscr{D}} \underbrace{P(D_k|q)}_{\text{conf of RETRIEVER}} \times \underbrace{P(\hat{a}=a|q,D_k)}_{\text{conf of READER}} \tag{8}$$

We discuss three possible ways to calibrate $P(\hat{a}=a|q)$

ONLY READER One way to calibrate $P(\hat{a}=a|q)$ is to assume that the RETRIEVER is perfectly accurate and perfectly calibrated. We refer to his approach in our results as ONLY READER. In this approach, we only calibrate $P(\hat{a}=a|q,D_k)$. We can use all the previously mentioned calibration approaches for this task. Indeed, this is the approach taken by (Jagannatha and Yu, 2020; Jiang et al., 2020). For extractive QA, the output logits lie over all the possible text spans, while for fact verification we have a single logit per class. In our experiments, we show that this leads to subpar calibration.

INDIVIDUALLY CALIBRATED We explore another possible approach where we calibrate $P(D_k|q)$ and $P(\hat{a}=a|q,D_k)$ indivdually using the objectives of the RETRIEVER and READER individually. We refer to this approach as INDIVIDUALLY CALIBRATED.

This happens in two steps, first the confidence of the retriever, $P(D_k|q)$, is calibrated. The confidence of the retriever is then fixed and the we calibrate the only the confidence of the reader, $P(\hat{a}=a|q,D_k)$. Finally, the confidence of the systems is computed as $P(\hat{a}=a|q)$ in Equation 8.

We posit that this method results in subpar calibration owing to the RETRIEVER not having gold labels and is calibrated using the less accurate distance supervision objective.

JOINTLY CALIBRATED Finally, we discuss our approach to calibrate the entire system using the final objective of the system. We refer to this approach as JOINTLY CALIBRATED. In this approach, we treat the documents retrieved by the retriever as a latent variable D_k.

We define our calibration likelihood in eqn. 6 as:

$$\mathscr{L}_\theta = \sum_q \sum_{D_k \in \mathscr{D}} P(D_k|q) P(\hat{a}=a|q,D_k) \tag{9}$$

Clearly, it is infeasible to marginalize over all possible D_k (subsets of the corpus of size k). Thus, we propose a diffentiable sampler for D_k:

$$\mathscr{L}_\theta = \sum_{D_k \sim P_\theta(D_k|q)} P(\hat{a}=a|q,D_k) \tag{10}$$

To make our calibrator differentiable, we apply the Gumbel–softmax trick (Maddison et al., 2017) and, in particular, its extension to top-K subset selection (Vieira, 2014; Xie and Ermon, 2019). The Gumbel-top-K trick generalizes Gumbel–softmax and essentially repeats the Gumbel trick K times until we have a set of the desired size. We describe the approach further in Appendix A.

4 Experimental Details

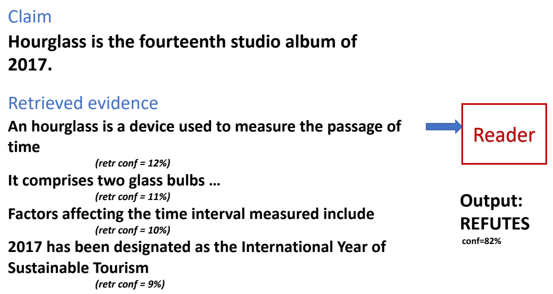
Open Domain Question Answering

Extractive We test the described calibration techniques on the open domain QA, using the pretrained models from (Karpukhin et al., 2020). We perform our experiments on the Natural Questions (NQ) dataset (Kwiatkowski et al., 2019). We randomly split our validation set into two equal parts which we will call `calib` and `valid`. We use these splits for training and tuning our calibration models respectively. We use the test set of NQ as our test set (`test`). During inference, we use the RETRIEVER to retrieve top 10 documents which are passed to the READER to extract the answer.

Generative We use the FiD model proposed by (Izacard and Grave, 2020b) for our calibration experiments. As generative models don't produce a confidence over multiple answers, we use the approach described by (Jiang et al., 2020) to generate an interest set. First we calculate the probabilities of the first generated tokens. We mask out any tokens not in the retrieved passages. Next we, select the top R tokens we find their location in the passages and calculate the probability of all continuing spans up to a certain length (of 10 tokens). We then keep the top-10 scoring spans in our candidate set.

Claim Verification

For the claim verification task, we experiment on the FEVER dataset (Thorne et al., 2018a). We use a recently published state-of-the-art model, (Liu et al., 2020), in our calibration experiments. For every test example, we retrieve 5 sentences that are provided to the claim verification model to ascertain the veracity of the claim.



Hourglass is the fourteenth studio album of 2017.

An hourglass is a device used to measure the passage of time

It comprises two glass bulbs ...

Factors affecting the time interval measured include

2017 has been designated as the International Year of Sustainable Tourism

Figure 2: The READER is highly confident about its prediction, but when we incorporate the confidence of the evidence from the RETRIEVER which can identify that the sentences are irrelevant to the claim, the confidence of the prediction can be better calibrated.

Temperature based methods

For the READER -RETRIEVER setup we require two temperature parameters `t1` and `t2` for the RETRIEVER and READER respectively. We use gradient descent to optimize `t1` and `t2` by maximizing $\mathscr{L}_\theta$ on the `valid` set. For temperature prediction we add a 2-layer MLP that predicts `t1` and `t2` for each example. Once again, the optimization is performed on `valid`.

Forecaster

For our forecaster, we use gradient boosted decision trees. We train the model to perform binary classification with the model's accuracy as the objective, i.e., if the model's prediction was correct, we assign a positive label to the example. We do not experiment extensively with various features as previous work has done and instead just use the raw logit scores. Similar to Jagannatha and Yu (2020), we create the interest set of the forecaster by choosing the top-3 predictions of the model, i.e., we choose the top-3K choices of the RETRIEVER over which we evaluate our READER and choose the top-3 choices.

Gumbel top-K

For the Gumbel top-K approach required to train the vector scaling and temperature prediction models, we start out with a high temperature value T_0 which we linearly decrease to T_∞. We treat these parameters as hyperparameters.

5 Results

We now present the results of the various calibration techniques in Table 1. We also plot the reliability diagrams in Figure 3. We compare all the described calibration algorithms in the three settings discussed. As can be seen, in all the cases there is a benefit to JOINTLY calibrate the RETRIEVER and READER . We give some reasons for why this setting works best in the discussion section below.

5.1 Discussion

Calibrating only the READER

In all our experiments we show that calibrating the READER alone performs worse. We believe that this is because, at train time, the READER is only trained on positive documents. This makes the READER *overconfident* on documents that don't have the answer. This phenomenon has been also been discussed in Clark and Gardner (2017). We show an example in Fig 2. We also notice that adding the RETRIEVER helps more in the QA task than for claim verification. We posit that this is because in the open-domain setting, the QA passage RETRIEVER has a lower accuracy than the sentence RETRIEVER for claim verification.[2]

Calibrating INDIVIDUALLY

Our experimental results show that in almost all cases, it is detrimental to individually calibrate the READER and RETRIEVER . We believe that this is due to the RETRIEVER 's accuracy being misaligned with the final objective. In several cases, such as in QA, supervision for the RETRIEVER is not provided, and instead a distant supervision objective is used where the document is marked as positive when it contains the answer string. We show an example in Figure 1 where, for the question "Who won the women's worldcup in 2017", a document saying "world cup to be held in *England*" would be assigned a positive label as it contains the answer string "England". This mismatch in accuracy for the RETRIEVER can result in an incorrectly calibrated system. This problem has been well discussed in the literature and more recently by Izacard and Grave (2020a)

Reliability plots As can be seen from Figure 3, miscalibration results from the model being overconfident. This is evident with the blue bars being lower than the red – model accuracy is less than model confidence for several bins. We also notice that all calibration techniques address this overconfidence by rescaling the output distribution.

	JOINTLY		**1.15**	**1.30**	**0.98**

Table 1: Values in % ECE, (↓ is better). **INDIVIDUALLY** denotes the retriever and reader have been calibrated separately, while **JOINTLY** indiciates that calibration on a joint objective.

6 Analysis

Next, we attempt to verify the following claims:

C1: The existing approach for calibrating only the reader doesn't result in a good calibration of the overall system. Jointly calibrating the reader and the retriever model is better.

C2: Calibrated ODQA systems do better selective prediction when they are allowed to not provide answers to some questions.

C3: Calibrated ODQA systems are better at handing domain shifts in questions at test time.

C4: Calibrated ODQA systems are better at handling unanswerable questions at test time.

6.1 Selective Prediction for Machine Reading

One key use of confidence estimation is selective prediction. The selective prediction setting allows the model to decide whether it wants to make a prediction or abstain on each given test point. Selective prediction has been a long-standing research area in machine learning (Chow, 1957; El-Yaniv et al., 2010).

We investigate how different calibration methods perform on the task of selective prediction. There have been some recent efforts to understand selective prediction for QA models with regard to domain shift; Kamath et al. (2020) investigate how forecasters can be effectively used as calibrators to predict when a model should abstain from providing an answer. We further this investigation in the open-domain setting to see if different calibration techniques can improve the model's performance on the selective prediction task. The evaluation metric used to judge a model's effectiveness in learning to abstain is the area under the risk-coverage curve.

Given an input q, the model's prediction $\hat{a}$ along with the confidence of the prediction $P(\hat{a} = a|q)$ and a threshold τ, our model predicts the the answer $\hat{a}$ if $P(\hat{a} = a|q) \geq \tau$. For the test set and a value of τ there is an associated *risk*: the fraction of the test set that the model answers incorrectly, and *coverage*: the fraction of the test set the model makes a prediction on. As τ increases, so do the risk and coverage. We plot risk vs coverage as τ varies and report the area under the risk-coverage curve (AURC). Our results are shown in table 2. We can infer from the results that all calibration

Task	Setting	AURC
Extractive QA	Uncalibrated	47.39
	Forecaster	44.21
	Temp scaling	43.68
	Temp prediction	42.64
	Best possible	26.71
Generative QA	Uncalibrated	53.57
	Forecaster	39.10
	Temp scaling	44.85
	Temp prediction	43.21
	Best possible	22.25
Claim Verification	Uncalibrated	11.04
	Forecaster	3.53
	Temp scaling	10.96
	Temp prediction	9.99
	Best possible	2.76

Table 2: Area under Risk-Coverage curve. ↓ is better

methods help reduce the AURC to some extent however the Temperature predictor is able to perform the best on extractive QA while the forecaster is the best on claim verification and generative QA indicating that improving model calibration can also help for the task of selective prediction in the setting of machine reading.

Domain Adaptation With the increasing use of machine reading systems in the wild, a common problem encountered by them is that they are not resilient to inputs that do not come from the distribution of the data they were trained on. A method of selective prediction is often employed, where the model the model can abstain from answering the question. (Kamath et al., 2020) show that training a seperate model to distinguish between in- and out-of- domain helps in doing selective prediction. We show that a well calibrated model is able to perform better on the selective prediction setting even when the calibration step has no access to an out of distribution dataset. In our experiments, we calibrate a trained on NQ FiD model on the FiD dev set. We then evaluate the performance on different splits which contain varying percentages of out-of-distribution data (TriviaQA) (Joshi et al., 2017). We plot the AURC with different splits containing different percentages of OOD questions in figure 4. We notice that an uncalibrated model gets significantly worse when the amount of OOD samples are added. However calibation techniques are able to mitigate this and are able to maintain a steady AURC with increasing OOD samples. We found that the Forecaster (XGB) performing the best in this evaluation.

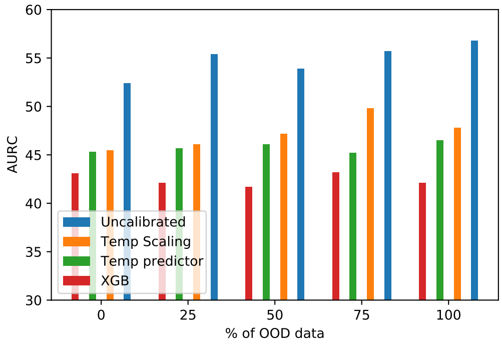

Figure 4: Area under risk coverage curves (AURC) using different calibration techniques

6.2 Effect of K on Calibration

We analyze how the ECE values are affected by increasing the number of documents the reader model consumes. We run this experiment on the open-domain extractive QA task. Along with $K = 10$, we evaluate on $K = 20$ and $K = 50$. As can be seen in Table 4 all our methods scale well when we increase the value of K. Platt's scaling and temperature scaling are able to maintain low ECE scores even when the Reader collates the answer over multiple documents. We believe that owing to the simplicity of the approach, these calibration methods are able to adapt well to different settings while in contrast, the forecaster and temperature predictor being more complex models struggle with this. The forecaster stands at a disadvantage here owing to the fact that the number of features given to the forecaster scales with K and we believe that this could also have an impact on its inability to scale to larger values of K.

Unanswerable Questions Another challenge that a user facing QA system can encouter is malformed questions. These include questions that were not probably questions, for example a user query containing a named entity which is a question or a question that cannot be answered because it contains a false premise. To investigate if a calibrated model can be used to abstain from answering such questions, we evaluate our approaches on the set of unanswerable questions proposed by (Asai and Choi, 2020). We plot Risk-Coverage curves for different calibration techniques in Figure 5. We find all calibration techniques help in performing selective prediction when compared to an uncalibrated model. However, the Forecaster outperforms all other methods. To exemplify how calibration techniques can help the model abstain

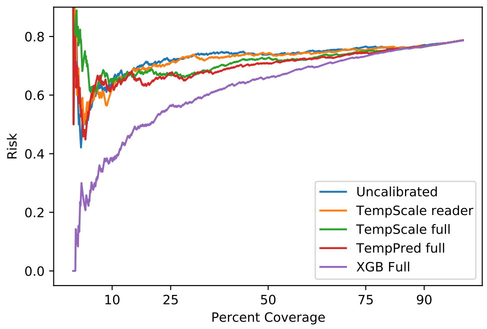

Figure 5: Risk coverage curve for unanswerable questions

we provide a few examples in table 3. These results come from running an extractive QA model on the set of unanswerable questions. We only evaluate using the top passage for simplicity. It can be seen that all calibration techniques are able to lower the confidence of the predicted answer in cases when the question is unasnwerable. The first two questions provide examples of questions containing a false premise: No Harry Potter movie came out in 2008 and there was no Joker character in The Dark Knight Rises. In these cases, both the READER and RETRIEVER are confident about their prediction. The third question exemplifies a query that is not a question. Here it can be seen that the READER still places a high confidence in its provided answer, however, the RETRIEVER assigns a very low score to its retrieved passage. This provides a great insight into examples where using the retriever score can further help in calibration. The last two questions are examples of types of questions generally not part of the dataset. They either require more sophisticated reasoning or are non-factoidal. Here we can observe that eventhough the READER is confident, the retrieved passages are assigned a much lower score. We find that by using the forecaster on generative QA we reduce the confidence of an incorrectly answered question by 46% while decreasing the confidence of a correctly answered question by 38%.

RETRIEVER mistakes Another common seen scenario in an open domain setting is when the RETRIEVER is not able to provide any relevant passages. In such cases, because the READER is generally trained on only correct passages, it still produces a high confidence for the incorrect answer. We show that calibration methods that take into account the RETRIEVER confidences can mitigate this by lowering the confidence of the answer. We provide two such examples in table 5

Table 5: Examples of questions where the RETRIEVER fetches the wrong passages

and Yu (2020) and Jiang et al. (2020) study how forecasters can be used and what features can be useful to calibrate the confidence of QA models. Kamath et al. (2020) study calibration in the context of selective answering, i.e., learning when QA models should abstain from answering questions. They show that training a forecaster to predict the model's confidence can perform well when facing a distributional shift. Su et al. (2019) also investigate selective answering using a probe in the model to determine the model's confidence.

Also related to our work is *uncertainity estimation* (Gal and Ghahramani, 2016; Lakshminarayanan et al., 2017) as model uncertainities can be seen as confidence scores. In NLP, Xiao and Wang (2019) propose an approach to characterize model and data uncertainties for various NLP problems. Wang et al. (2019) use uncertainty estimation for confidence estimation in MT. Dong et al. (2018) study confidence estimation for semantic parsing. We are the first to study calibration of open-domain machine reading systems.

Our Gumbel-topk inspired approach of jointly calibrating the READER and RETRIEVER together is interesting in the light of recent open domain QA methods such as Lewis et al. (2020) and Sachan et al. (2021) that train the entire system jointly. As a future work we would also want to compare our approach with these other end-to-end training approaches for the task of calibration.

8 Discussion and Conclusion

In this paper, we analyzed how various calibration techniques can be adopted to open-domain machine reading systems which are now being used in user-facing scenarios. We showed that in such systems that include a retriever, calibrating the system's confidence is not trivial and we proposed a technique that allows calibration of the system *jointly*. Finally, we also provide an analysis on how the calibration techniques can help the model abstain from answering a question especially in settings where the model's prediction can be incorrect due to malformed or out-of-domain questions. While we do not find evidence to prove that one calibration method (e.g. a gradient-based method) is better that the other (e.g. a forecaster approach), it would be important to investigate these questions with more nuanced human studies.

Ethical Considerations

In recent years, deep learning approaches have been the main models of choice for practical machine reading systems. However, these systems are often overconfident in their predictions. A calibrated confidence score would help system users better understand the system's decision making. Our work introduces a simple and general way for calibrating these systems. While our models are not tuned for any specific application domain, our methods could be used in sensitive contexts such as legal or healthcare settings, and it is also essential that any work using our method undertake additional quality assurance and robustness testing before using it in their setting. The datasets used in our work do not contain any sensitive information to the best of our knowledge.

A Details on the Gumbel Top-K Solution

The Gumbel-top-K trick is a generalization the Gumbel–softmax. It essentially repeats the Gumbel trick K times until we have a set of the desired size.

In order to sample a subset of size K according to the categorical distribution given by $P(D_k|q)$, the method use the well-known two-step process to massage categorical sampling into a differentiable sampling procedure which includes: 1) reparameterization of the categorical using Gumbels and 2) softening the argmax into a softmax. We formally describe the procedure below:

Gumbel top-K: We first perturb the logits S_{d_i} with Gumbel noise $n_i \sim \mathit{Gumbel}(0;1)$ such that $\tilde{S}_{d_i} = S_{d_i} + n_i$. Then, sampling from a categorical is equivalent to taking an argmax:

$$d^* = \arg\max_i \tilde{S}_{d_i} \tag{11}$$

In the top-K case, we start by sampling the first document using the gumbel pertubation and taking the argmax:

$$d_1^* = \arg\max_i \tilde{S}_{d_i} \tag{12}$$

Then we remove d_1^* from the pool of documents under consideration and repeat the same procedure:

$$d_2^* = \arg\max_{i \in \mathscr{D} \setminus \{d_1^*\}} \tilde{S}_{d_i} \tag{13}$$

$$\vdots$$

$$d_k^* = \arg\max_{i \in \mathscr{D} \setminus \{d_1^*, \ldots, d_{k-1}^*\}} \tilde{S}_{d_i} \tag{14}$$

Now, we can construct a fully differentiable procedure by replacing the argmax with a softmax (the Gumbel softmax trick (Jang et al., 2017)). We begin by relaxing the one-hot vector of the first document:

$$d_i^{(1)} = \frac{\exp\left(\tilde{S}_{d_i}^{(1)}\right)}{\sum_j \exp\left(\tilde{S}_{d_j}^{(1)}\right)} \tag{15}$$

Next, we continue relaxing the successive argmaxes with successive softmaxes (Plötz and Roth, 2018) as follows:

$$d_i^{(2)} = \frac{\exp\left(\tilde{S}_{d_i}^{(2)}\right)}{\sum_j \exp\left(\tilde{S}_{d_j}^{(2)}\right)} \tag{16}$$

$$\vdots$$

$$d_i^{(k)} = \frac{\exp\left(\tilde{S}_{d_i}^{(k)}\right)}{\sum_j \exp\left(\tilde{S}_{d_j}^{(k)}\right)} \tag{17}$$

where we define the $\tilde{S}_{d_i}^{(k)}$ recursively

$$\tilde{S}_{d_i}^{(1)} = \tilde{S}_{d_i} \tag{18}$$

$$\tilde{S}_{d_i}^{(k)} = \tilde{S}_{d_i}^{(k-1)} + \log\left(1 - d_i^{(k-1)}\right) \tag{19}$$

Xie and Ermon (2019) have shown that this procedure is a reasonable relaxation of the Gumbel-top-K. We refer the interested reader to their paper for more details. Finally, we sum over all the relaxed one-hot vectors $d_i^{(k)}$ to arrive at our softened K-hot retrieval:

$$D_K = \sum_{k=1}^{K} d_i^{(k)} \tag{20}$$

This allows us to train the calibration parameters in $P(D_k|q)$ using the objective $\mathscr{L}_\theta$.

Towards Adversarially Robust Text Classifiers by Learning to Reweight Clean Examples

Abstract

Most of the existing defense methods improve the adversarial robustness by making the models adapt to the training set augmented with some adversarial examples. However, the augmented adversarial examples may not be natural, which might distort the training distribution, resulting in inferior performance both in clean accuracy and adversarial robustness. In this study, we explore the feasibility of introducing a reweighting mechanism to calibrate the training distribution to obtain robust models. We propose to train text classifiers by a sample reweighting method in which the example weights are learned to minimize the loss of a validation set mixed with the clean examples and their adversarial ones in an online learning manner. Through extensive experiments, we show that there exists a reweighting mechanism to make the models more robust against adversarial attacks without the need to craft the adversarial examples for the entire training set.

1 Introduction

Even though deep neural networks have achieved impressive performance on many natural language processing (NLP) tasks, they are vulnerable to adversarial examples intentionally crafted under certain semantic and syntactic constraints (Jia and Liang, 2017; Ebrahimi et al., 2017; Gao et al., 2018a; Zhao et al., 2018; Cheng et al., 2019; Zheng et al., 2020). The existence and pervasiveness of adversarial examples raise serious concerns, especially when deploying such NLP models to security-sensitive applications.

Recently, many methods have been proposed to defend against adversarial attacks for neural NLP models (Miyato et al., 2017a; Sato et al., 2018a; Jiang et al., 2020; Li and Qiu, 2020; Zhu et al., 2020; Zhou et al., 2021; Dong et al., 2021; Si et al., 2021). Existing defense methods usually augment the clean training examples with the adversarial ones in one way or another in the training stage and fit the models on the augmented training set. However, the introduced adversarial examples may not be natural, which may even hurt the distribution of original training examples, resulting in lower performance on both clean and adversarial test sets. Besides, these methods usually need to generate the adversarial examples for an entire training set, which is computationally intensive. We hypothesize that one of the reasons that NLP models are not robust is because they overfit to training data biases (Bras et al., 2020) — the training data is biased towards a certain distribution, so the resulting model can be broken under some perturbations. Despite augmenting training set by adversarial examples can partially mitigate this problem, are there better and more direct ways to calibrate the training distribution without introducing additional training samples? This motivates us to investigate whether there exists a reweighting mechanism to calibrate the training distribution and lead to robust models.

We propose to train adversarially robust text classifiers by a sample reweighting method, named WETAR (Weighting Examples Towards Adversarial Robustness), in which the example weights are learned to minimize the loss of a validation set mixed with the clean examples and their corresponding adversarial ones. We explore two ways to add adversarial samples to a validation set. A static way is to generate the adversarial examples from the clean data in the validation set before the training begins, and the generated examples remain unchanged throughout the entire training process. The other way is to dynamically craft adversarial examples at every iteration to test the robustness of models against test-time attacks.

Compared with exiting defense methods, our approach can achieve competitive performance without the need to perturb the training set. We show that there indeed exists a reweighting mechanism to

make the models robust without enlarging the clean training set with any adversarial examples. We determine the example weights of the current batch at every training iteration by an online reweighting method that performs validation at an additional small size. This study is among the first ones to improve the adversarial robustness of NLP neural models by reweighing training examples under the guidance of a relatively small validation set. Through extensive experiments on three different text classification benchmark datasets, we show that our method can significantly increase the robustness to adversarial examples crafted by three representative adversarial attack algorithms.

2 Related Work

2.1 Text Adversarial Defense

The goal of adversarial defenses is to learn a model capable of achieving high test accuracy on both clean and adversarial examples. Recently, many defense methods have been proposed to defend against text adversarial attacks which can roughly be divided into two categories: *empirical* (Miyato et al., 2017b; Sato et al., 2018b; Zhou et al., 2021; Dong et al., 2021) and *certified* (Jia et al., 2019; Huang et al., 2019; Ye et al., 2020) methods.

Adversarial data augmentation is one of the most effective empirical defenses (Ren et al., 2019a; Jin et al., 2020; Li et al., 2020) for NLP models. During the training time, they replace a word with one of its synonyms to create adversarial examples. By augmenting these adversarial examples with the original training data, the model is robust to such perturbations. Zhou et al. (2021) and Dong et al. (2021) relax a set of discrete points (a word and its synonyms) to a convex hull spanned by the word embeddings of all these points, and use a convex hull formed by a word and its synonyms to capture word substitutions. Adversarial training (Miyato et al., 2017b; Zhu et al., 2020) is another one of the most successful empirical defense methods by adding norm-bounded adversarial perturbations to word embeddings and minimizes the resultant adversarial loss. The downside of existing empirical methods is that failure to discover an adversarial example does not mean that another more sophisticated attack could not find one. To address this problem, some certified defenses (Jia et al., 2019; Huang et al., 2019; Ye et al., 2020) have been introduced to guarantee the robustness to certain specific types of attacks. However, the existing certified defense methods make an unrealistic assumption that the defenders can access the synonyms used by the adversaries. They would be broken by more sophisticated attacks by using synonym sets with large sizes (Jin et al., 2020) or generating synonyms dynamically with BERT (Li et al., 2020).

Most of the existing defense methods improve the robustness by making the models adapt to the training set augmented with adversarial examples crafted by adding adversarial perturbations to discrete tokens or distributed embeddings. In contrast, our method does not need to generate adversarial examples for the entire training set and only requires a relatively small validation set to be augmented with the adversarial instances. Besides, we improve the adversarial robustness by learning to assign weights to training examples based on the loss estimated on a validation set instead of exposing the models to certain perturbations during the training process.

2.2 Weighting Examples towards Robustness

Various methods of weighting examples have been proposed to train robust models against training set bias including class imbalance (Lin et al., 2017; Cui et al., 2019) or noisy data (Shin et al., 2020; Wang et al., 2021) or both (Ren et al., 2018). In response to these problems, different weights are assigned to examples in order to match one distribution to another, and the models are trained to optimize the weighted training loss encouraging learning the examples with more weights.

Recently, incorporating the weighting method to improve the robustness against adversaries also have been investigated in the image domain. However, they all use the weighting method to assign weights to the adversarial examples instead of the clean examples. Wang et al. (2020) weight training examples in order to reduce the KL-divergence between the predicted logits of each clean example and that of the adversarial one. Zhang et al. (2021) take into account the geometric distance from data points to the decision boundary and reweight training data based on the difficulty of attacking these data points. To better defend against targeted adversarial attacks, Kim et al. (2021) proposed to reweight training examples based on the entropies of their class softmax probabilities and suggested giving more weights to the examples with higher entropies whose labels could be easily flipped.

Different from existing reweighting methods, we argue that in order to train a model that performs well in both clean accuracy and adversarial robustness, it only needs to construct a small validation set augmented with adversarial examples to guide training. In addition, we show that the adversarial examples can be added to the original validation set in a static or dynamic way. The constructed validation also can be used for the model selection. This study is among the first ones to improve the adversarial robustness of neural models by reweighing training examples in the language domain.

3 Method

We design a weighting method to improve the adversarial robustness of text classifiers by learning to reweight examples, partly inspired by the meta-learning algorithm proposed by Ren et al. (2018) from the image domain. In particular, we consider both clean accuracy and adversarial robustness by reweighting the training examples according to their similarity to the gradient descent of the validation loss, where the validation set is augmented with the adversarial examples. During the training, we ensure that a clean example and its corresponding adversary are present in the same mini-batch, which teaches the models how to balance the two training objectives. We also show how to make model selection based on the learned weight distribution over the training examples.

For text classification, a neural network-based classifier $f(x)$ with a set of learnable parameters $\boldsymbol{\theta}$ maps an input text $x \in \mathcal{X}$ to a label $y \in \mathcal{Y}$. Given a training set $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N}$, we assume there is a validation set $\mathcal{D}^v = \{(x_i^v, y_i^v)\}_{i=1}^{M}$ that consists of two parts: a set of clean examples $\mathcal{D}^c$, and a set of adversarial examples $\mathcal{D}^a$ generated by a certain attack algorithm from $\mathcal{D}^c$. The adversarial validation set $\mathcal{D}^a$ can be generated for $\mathcal{D}^c$ statically or dynamically (see Subsection 3.2). We consider a loss function $L_{\boldsymbol{\theta}}(x, y)$, and the goal of regular training is to find a solution of $\boldsymbol{\theta}$ that minimizes the expected loss $\frac{1}{N}\sum_{i=1}^{N} L_{\boldsymbol{\theta}}(x_i, y_i)$ for the training set, where each instance is equally weighted.

3.1 Learning to Reweight Examples

In this study, we guide the training by a relatively small validation set $\mathcal{D}^v$ mixed with clean and adversarial examples through a weighted loss. Thus, each training example x_i would be assigned with a weight w_i, and we learn to reweight the examples by minimizing the following weighted loss:

$$\boldsymbol{\theta}^*(\boldsymbol{w}) = \arg\min_{\boldsymbol{\theta}} \sum_{i=1}^{N} w_i L_{\boldsymbol{\theta}}(x_i, y_i), \tag{1}$$

where $\boldsymbol{w} = \{w_i\}_{i=1}^{N}$ can be viewed as training hyperparameters whose values are unknown from the beginning and can be optimized based on the validation set $\mathcal{D}^v$:

$$\boldsymbol{w}^* = \arg\min_{w_i \geq 0} \frac{1}{M} \sum_{i=1}^{M} L_{\boldsymbol{\theta}^*(\boldsymbol{w})}(x_i^v, y_i^v), \tag{2}$$

where we use superscript v to denote validation set and subscript i to denote the i-th example.

Determining the optimal $\boldsymbol{w}^*$ is a special case of the bilevel optimization problem where one problem is nested within another, and every single optimization can be very expensive. It could be worse when the adversarial validation set is created in a dynamic way, which is necessary to enhance the models in their ability to defend against test-time attacks. We use an online meta-learning algorithm (Ren et al., 2018) for reweighting training examples. At every training step, a mini-batch $\{x_i, y_i\}_{i=1}^{n}$ is sampled from the training set $\mathcal{D}$, and n is the mini-batch size $(n \ll N)$. At the same time, another mini-batch $\{x_i^v, y_i^v\}_{i=1}^{m}$ is also sampled from the validation set $\mathcal{D}^v$. We examine the gradient descent of n sampled training examples on the loss surface and reweight them according to their similarity to the descent direction of m validation data.

We need to determine the importance of each training sample (x_i, y_i) at every training step for a mini-batch sampled from $\mathcal{D}^v$. Following (Koh and Liang, 2017), we assume the weight of each training sample (x_i, y_i) is perturbed by ϵ_i, and correspondingly the parameters are updated to $\boldsymbol{\theta}_t'$ according to the descent direction of the loss on the mini-batch at step t as follows:

$$\boldsymbol{\theta}_t' = \boldsymbol{\theta}_t - \tau \nabla_{\boldsymbol{\theta}_t} \sum_{i=1}^{n} \epsilon_i L_{\boldsymbol{\theta}_t}(x_i, y_i), \tag{3}$$

where τ is the learning rate. To get a cheap estimate of w_i at step t, we calculate the gradient g_{ϵ_i} of ϵ_i by taking a single gradient descent step on a mini-batch of validation samples [1] :

$$g_{\epsilon_i} = \frac{\partial}{\partial \epsilon_i} \frac{1}{m} \sum_{i=j}^{m} L_{\boldsymbol{\theta}_t'}(x_j^v, y_j^v)|_{\epsilon_i=0}. \tag{4}$$

---

[1] We use a meta-learning paradigm in this step to calculate the gradient g_{ϵ_i} for each ϵ_i. Specifically, we use the *higher* library (Grefenstette et al., 2019) released by Facebook.

We then estimate that the importance value $\tilde{w}_i$ of sample (x_i, y_i) at step t by comparing the opposite direction of gradient g_{ϵ_i} accumulated at ϵ_i when take adversarial validation mini-batch $\{x_i^v, y_i^v\}_{i=1}^m$ into account:

$$\begin{aligned} \tilde{w}_i &= max(-g_{\epsilon_i}, 0), \\ w_i &= \frac{\tilde{w}_i}{\sum_i \tilde{w}_i + \delta}. \end{aligned} \tag{5}$$

where $\delta = 1$ if $\sum_i \tilde{w}_i = 0$, and $\delta = 0$ otherwise. We consider normalizing the weights of all training examples in a mini-batch so that they sum up to one unless all of them are 0. Once each training example is assigned with a weight under the guidance of the gradients calculated on the validation samples, we can update the parameters with the gradient accumulated through the reweighted loss at step t as follows:

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \tau \nabla_{\boldsymbol{\theta}_t} \sum_{i=1}^{n} w_i L_{\boldsymbol{\theta}_t}(x_i, y_i). \tag{6}$$

We refer to Algorithm 1 in Appendix A for details.

3.2 Adversarial Validation Set Construction

We here describe two ways to construct a validation set whose subset of adversarial examples can be generated in a static or dynamic manner. If a clean example (x_i^c, y_i^c) is sampled to be included in a validation mini-batch, we would add into the same mini-batch its adversarial example (x_i^a, y_i^a), where $y_i^c = y_i^a$, crafted by some attack algorithms .

In the static construction method, for every clean example in the validation set, its corresponding adversarial one is generated before the training begins, and the generated adversarial examples remain unchanged throughout the training process. If a clean example is randomly selected to appear in a mini-batch, its adversary generated in advance will be retrieved and included in the same mini-batch.

Although generating the adversarial examples in a static way can speed up the training process, it is questionable whether the resulting models can still perform well under test-time attacks since they should be evaluated on the adversarial examples crafted on the fly against the robustly trained models rather than the original ones. Therefore, we propose to use another dynamic strategy to generate adversarial examples, in which we apply an attack algorithm to craft the adversarial examples for randomly selected clean ones against the current model at every iteration. In practice, we generate all required adversarial examples every one or two epochs to reduce the computational cost.

Some previous studies show that the models tend to overfit the adversarial examples, and their performance on the clean data will drop if too many adversarial examples are used. Therefore, we use a similar training strategy. In a mini-batch, we randomly select ρ percent (say 50%) of the clean data in the validation set and generate their adversarial examples from them using a certain attack algorithm. We then merge these adversarial examples with the clean ones to form a final validation set.

If the static method is used to construct the validation set, the weight distribution of training examples will stabilize to some equilibrium distribution as the number of training epochs increases. Such a weight distribution is calculated for each epoch by accumulating the weights assigned to the sampled examples in every mini-batch and then normalizing the weights of all training examples to sum up to one. To compute the difference between two weight distributions before and after an epoch, we use the Wasserstein distance instead of the popular KL-divergence since the weights of many training examples will be assigned to zeros and the former is more suitable for this situation than the latter. As the training progresses, we can obtain a series of weight distributions and their differences. If such a difference does not reduce significantly for multiple epochs, we say that the distribution has stabilized. The first model obtained with its weight distribution stabilized is chosen as the final model. When the dynamic construction method is used, there will be a "spear-and-shield" battle between defender and attacker. Although the difference in weight distribution fluctuates more with the dynamic construction method than the static one, the trend of the overall decline in the distribution difference still can be used for model selection.

4 Experiments

In the following, we first evaluate the proposed method of WETAR by comparing it to four baseline methods both in clean accuracy and adversarial robustness on three text classification benchmarks. Then, we would like to study how the choice of an attack algorithm to construct the validation sets at the training stage impact the adversarial robustness of resulting models under different attacks. Finally, we investigate whether our method combined with adversarial data augmentation can further improve

Table 1: The experimental results of our WETAR and baselines on SST-2, AGNEWS, and MR datasets. We use WETAR-S to denote the setting where the adversarial examples are constructed by the static method and WETAR-D to that by the dynamic method. The best results are highlighted in bold font.

the robustness of text classifiers.

We conducted experiments on two different tasks on three widely-used datasets: Stanford Sentiment Treebank (SST-2) (Socher et al., 2013), AG-News corpus (AGNEWS) (Zhang et al., 2015) and Movie Reviews (MR) (Pang and Lee, 2005). SST-2 consists about $67,000$ training sentences for binary classification and MR contains about $9,000$ movie reviews for training. AGNEWS has four categories pertaining about $30,000$ new articles. For each dataset, we randomly select one-tenth examples from the training set to form a validation set from which the adversarial examples will be generated to guide the training and select the model. In Section 4, all experimental results are obtained over three runs with different initialization. We refer to Appendix B for more implementation details.

4.1 Attack Algorithms

The following three adversarial attack methods are used to evaluate the robustness of models, reimplemented by TextAttack toolkit (Morris et al., 2020).

TextFooler (Jin et al., 2020) uses a greedy searching method, ranking the words in an input sequence based on the predicted changes before and after deleting them. Counter-fitted embeddings are used to find synonyms to replace the selected words.

BERT-Attack (Li et al., 2020) uses a BERT-based model to estimate an importance score of each subword for the prediction, and generate the top-K candidate sub-words by the masked language model to replace the word with the highest score.

TextBugger (Li et al., 2019) locates the vulnerable words by calculating the changes in predictions before and after removing them from a text. Different from TextFooler and BERT-Attack, both character-level perturbation and word-level perturbation will be applied to generate adversarial examples.

When investigating how the choice of an attack algorithm to construct the validation set impact the performance of models, we also take two other attack methods of PWWS (Ren et al., 2019b) and DeepWordBug (Gao et al., 2018b) into consideration for comprehensive assessment.

Following (Li et al., 2021), four different metrics are used to evaluate the generation and robustness of the models: (1) Clean accuracy, denoted as *Clean*%, is defined as the model's classification accuracy on a clean test set; (2) Accuracy under attacks, denoted as *Aua*%, is the model's accuracy under some adversarial attack; (3) Attack success rate, denoted as *Suc*%, is calculated as the number of texts successfully perturbed by an attack algorithm divided by the number of all texts attempted; (4) The number of queries, denoted as *Query*%, is the average number of times the attacker queries the model to form a successful attack.

4.2 Baseline methods

We evaluate the proposed method by comparing it with several representative methods. We primarily compare with the following recently proposed defense methods,

Base fine-tunes a pre-trained BERT on a training set consisting of clean examples.

FreeLB (Zhu et al., 2020) adds norm-bounded adversarial perturbations to the input's word embeddings using a gradient-based method, and enlarges the batch size with diversified adversarial samples under such norm constraints.

FreeLB++ is a variant of FreeLB, which increases the number of ascent steps to further improve the adversarial robustness of models (Li et al., 2021). They demonstrated through extensive experiments that FreeLB and its variant of FreeLB++ outperforms other defense methods including TAVAT (Li and Qiu, 2020) and DNE (Zhou et al., 2021). Therefore, we only report the results produced by FreeLB and FreeLB++ for comparison.

Adversarial Data Augmentation (ADA) is one of the widely used methods (Dong et al., 2021; Si et al., 2021; Zhou et al., 2021). During the training, they replace a word with one of its synonyms that maximizes the prediction loss. By augmenting these adversarial examples with the original training data, the model is robust to such perturbations.

4.3 Results

Table 1 shows the clean accuracy and adversarial robustness achieved by different defense methods under three attack algorithms. We use TextFoolor as the attack algorithm to generate the adversarial examples for validation set construction because it was reported that TextFoolor can generate high-quality, semantics-preserved adversarial examples (Hauser et al., 2021). For a fair comparison, ADA also use TextFoolor to craft the adversarial examples for data augmentation. Unless otherwise specified, we set to 50% the percent of the clean data in the validation set from which the corresponding adversarial examples will be generated. We use WETAR-S to denote the setting where the adversarial examples are constructed by the static method and WETAR-D to that by the dynamic method.

From these numbers, a handful of trends are readily apparent: (1) The proposed WETAR achieved the highest robustness across three text classification datasets under different adversarial attacks over all the baseline methods while suffering little to no performance drop on the clean input data; (2) The models trained with FreeLB++ achieved the better performance than others in clean accuracy. However, the improvement in adversarial robustness is relatively small compared to WETAR; (3) The models trained with ADA method outperformed those trained with other baseline methods in adversarial robustness, but they suffer a significant drop in clean accuracy, especially on SST-2 and MR datasets[2].

WETAR-D performed better than WETAR-S on SST-2 and AGNEWS datasets while the latter outperformed the former on MR dataset. One possible explanation is that the size of MR training set is much smaller than those of SST-2 and AGNEWS. For a given maximum number of training epochs, the number of mini-batches is relatively small when the models are trained on MR dataset. It would be hard for WETAR-D to tune the models sufficiently within a limited number of epochs since WETAR-D introduces the dynamics into the training process and requires more training epochs to converge.

4.4 Impact of the Types of Augmented Adversarial Examples

To better understand the impact of different attack algorithms used to construct the adversarial validation examples on the performance, we report in Table 2 accuracy achieved by WETAR and ADA methods under different attacks on the MR dataset. We found that both WETAR-D and WETAR-S perform better than ADA under almost all attack algorithms. Besides, WETAR is not sensitive to the choice of the attack algorithm used to construct validation set at the training stage, whereas ADA shows to be more sensitive to the type of attack algorithm applied to generate adversarial examples for data augmentation. Although the choice of attack algorithm has little impact on the adversarial robustness, the models trained by WETAR integrated with BERT-Attack achieved slightly better performance on MR dataset.

4.5 Impact of the Proportion of Adversarial Examples in the Validation Set

We conducted some experiments on SST-2 dataset to investigate the impact of different proportions of adversarial examples in the validation set. Figure 1 shows the clean accuracy and accuracy under attack of our WETAR where BERT-Attack was used to generate adversarial examples for validation set construction. We evaluated the adversarial robustness of the resulting models with TextFooler.

---

[2] In our experiments, we found our implemented ADA can achieve higher robustness than that reported in Li et al. (2021).

Method	Clean	TFL	BTA	TBG	PWWS	DWB
ADA-TFL	85.1	14.3	11.3	34.0	34.1	23.9

WETAR-D-BTA	86.6	26.0	28.0	45.6	38.2	38.6
WETAR-D-TBG	86.5	29.8	32.1	48.3	40.8	41.2

Table 2: Accuracy achieved with various training methods under different attacks on the MR dataset. Those listed in the rows are training methods, and those in the columns are attacking algorithms. “Clean” denotes the clean accuracy. “TFL”, “BTA”, “TBG”, and “DWB” denotes TextFooler, BERT-Attack, TextBugger and DeepWordBug respectively.

As shown in Figure 1, we found that WETAR in general can provide a great increase in robustness only with little sacrifice in clean accuracy. WETAR is also insensitive to the proportions of adversarial examples that are added into the validation set. However, adding too many adversarial examples to the validation set will hurt the performance of models in both clean accuracy and adversarial robustness. We do get surprised that our method using a validation set that only contains clean examples can make the models more robust against the word substitution-based attacks. We believe that our training method can prevent the models from overfitting to a pre-defined training set, which leads to more robust models.

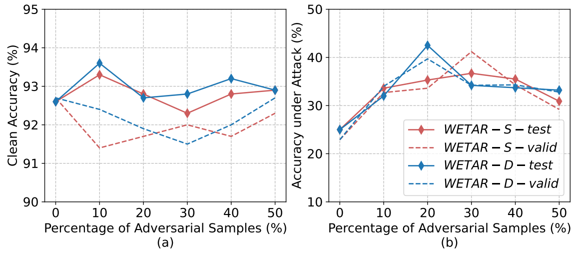

Figure 1: The impact of the proportion of adversarial samples in the validation set on MR dataset. (a) clean accuracy versus various proportions of adversarial samples. (b) the accuracy under attack versus various proportions of adversarial samples.

4.6 Combined Approach

We carried out some experiments to study whether the robustness of models can be further improved by combining WETAR with the data augmentation method. In this combination approach, we add some adversarial examples to the training set as the adversarial data augmentation. During the training process, WETAR will assign the weights to both the clean and adversarial examples based on the gradient direction of a small validation set.

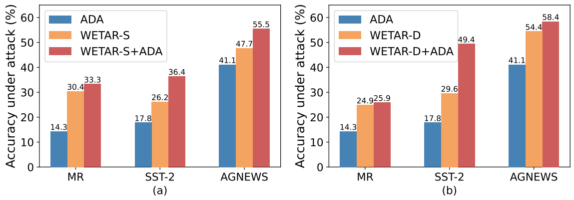

Figure 2: The robustness results achieved by WETAR combined with adversarial data augmentation. (a) WETAR with the static construction method. (b) WETAR with the dynamic construction method.

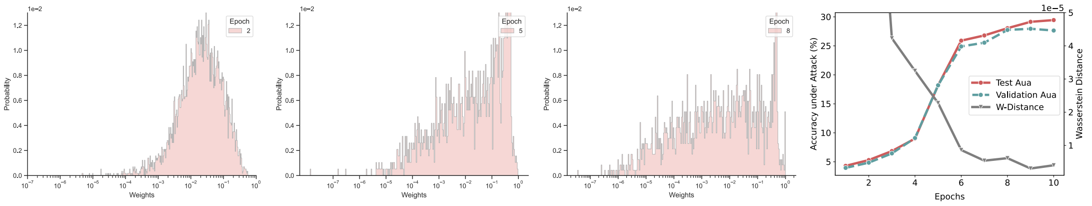
We show in Figure 2 the experimental results achieved by WETAR with validation set generated statically and dynamically under TextFooler attack on three datasets. Augmenting the training set with adversarial examples can further improve the robustness of models no matter WETAR-S or WETAR-D is used for training. Like the results reported in Section 4.3, WETAR-D outperformed WETAR-S on SST-2 and AGNEWS while the latter performed better than the former on MR dataset.

5 Analysis

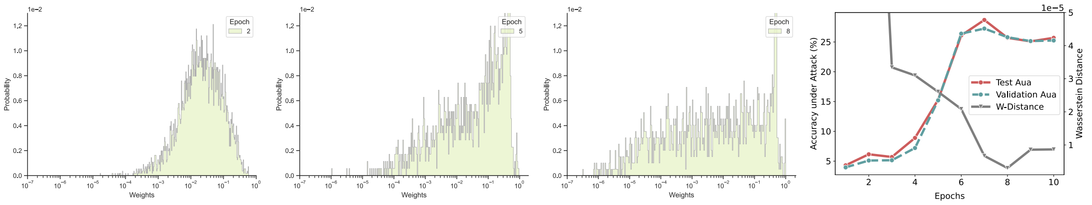
We in this section give some analyses on the interpretability of the proposed reweighting method. First, we experimentally analyze the changes in the weight distributions over the training samples produced by our reweighting method. Base on this analysis, we propose an empirical method for model selection. Second, we visualize the weights obtained by the proposed method.

5.1 Weight Distribution

To better understand the changes in the weight distributions over the training examples, we show in Figure 3 the weight distributions produced by WETAR at different epochs. Those weight distributions are obtained by normalizing the weights of all training samples at each epoch. To show whether and how those weight distributions will converge to some distribution, we use the Wasserstein distance to compute the difference between two weight distributions before and after each epoch. We remove all examples with zeros weights when visualizing the distributions.



(a) Epoch 2 (b) Epoch 5 (c) Epoch 8 (d) WETAR-S



(e) Epoch 2 (f) Epoch 5 (g) Epoch 8 (h) WETAR-D

Figure 3: The weight distributions produced by WETAR-S and WETAR-D on MR datasets. Sub-figures (a), (b), and (c) show the weight distributions produced by WETAR-S at epoch 2, 5, and 8 respectively. Sub-figures (e), (f), and (g) give the same distributions produced by WETAR-D at epoch 2, 5, and 8. Sub-figures (d) and (h) plot the curves of accuracy under attack and the Wasserstein distance between two weight distributions at every two epochs yielded by WETAR-S and WETAR-D respectively.

As shown in Figure 3, we found that the performance of robustness generally increases when the differences in the weight distributions shrink as the number of epochs grows. For examples, the weight distribution starts to converge after 8 epochs when WETAR-S is used to train the model. Therefore, we select the model as the final one when the distance between two weight distributions is small (e.g., less than a given threshold). When WETAR-D is applied, there are some drops at the end of training process in adversarial robustness. One possible explanation is that after a long "spear-and-shield" battle, it is hard for any attack algorithm to generate good adversarial examples for a robust model, and the generated adversarial examples after that will go too far from the original ones, which hurts the decision boundary of the model and results in inferior performance in robustness. We give more experimental results about the weight distributions on AGNEWS and SST-2 in Appendix C.

5.2 Visualization

Learning to reweight scheme assigns different weights to examples in a mini-batch under the guidance of the adversarial validation set during the training phase. We illustrate the proposed reweighting process in Figure 4 to provide a better understanding of our method.

In the Figure 4, we plot the representations using t-SNE visualization by analyzing the final hidden states corresponding to `[CLS]` token of the model in the last training epoch. Visualization of more epochs are provided in Appendix D. In the t-SNE analysis, we use the average weights of data points during training as a measure of its importance. We normalized the average weights by the maximum weight this weight distribution could achieve. In Figure 4, the darker the color, the more larger weight this sample point is calculated into the loss function during training, and the more important it is in the training process.

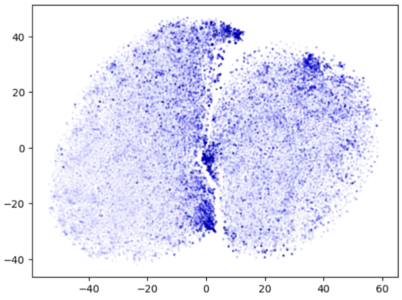


Figure 4: t-SNE visualization of the final hidden states corresponding to `[CLS]` token of SST-2 training examples produced by the model in trained via WETAR.

We found that the samples distributed in one category, while close to the other one have greater non-zero weight values, which indicates they are relatively more important than the others, coinciding with the finding mentioned by Zhang et al. (2021); Kim et al. (2021). We can also observe that more weights will be given to some samples during the training process, making the whole weight distribution sparse. Through the analysis of visualization, we found the proposed mechanism can prevent the model from being overfitted to some training samples by assigning small weights to them. Guiding the training process via these sparse weight distributions leads to a significant increase in adversarial robustness with no or little drop in clean accuracy.

6 Conclusion

In this study, we propose a defense method against text adversarial attacks by reweighting examples automatically. The algorithm learns to weight training examples in proportion to their contributions to minimize the loss evaluated on a validation set augmented with adversarial examples. The proposed method can directly be applied to any deep learning architecture without any additional hyperparameter search. We showed through extensive experiments that there indeed exists a reweighting mechanism to make the model robust without generating adversarial examples for the entire training set, and our reweighting algorithm performs better than existing defense methods across three different text classification datasets.

A Algorithm

Algorithm 1 Weighting Examples Towards Adversarial Robustness Algorithm

```
Input: $\mathcal{D}$:training dataset $\{(x_i, y_i)\}_{i=1}^N$, $\mathcal{D}^v$: adversarial validation set $\{(x_i^v, y_i^v)\}_{i=1}^M$, $\boldsymbol{\theta}$:model parameters, $\tau$:learning rate, $\boldsymbol{\epsilon}$: weights for perturbation, $\boldsymbol{w}$: weights for updating
Output:$\boldsymbol{\theta}$:model weights
 1: Initialize $\boldsymbol{\theta}$
 2: for Iterative step $t = 1, ..., T$ do
 3:     for minibatch $\{x_i, y_i\}_{i=1}^n \subset \mathcal{D}$ do
 4:         // Initialize $\boldsymbol{\epsilon}$ and minibatch from $\mathcal{D}^v$
 5:         Sample minibatch $\{x_i^v, y_i^v\}_{i=1}^m \subset \mathcal{D}^v$
 6:         $\boldsymbol{\epsilon} \leftarrow \mathbf{0}$
 7:         // Calculate $\nabla\boldsymbol{\theta}_t'$ and update meta model
 8:         $g_{\boldsymbol{\theta}_t'} \leftarrow \nabla_{\boldsymbol{\theta}_t} \sum_{i=1}^n \epsilon_i L_{\boldsymbol{\theta}_t}(x_i, y_i)$
 9:         $\boldsymbol{\theta}_t' = \boldsymbol{\theta}_t - \tau g_{\boldsymbol{\theta}_t'}$
10:         // Calculate $g_{\boldsymbol{\epsilon}}$ and weights $\boldsymbol{w}$
11:         $g_{\boldsymbol{\epsilon}} \leftarrow \nabla_{\boldsymbol{\epsilon}} \frac{1}{m} \sum_{j=1}^m L_{\boldsymbol{\theta}_t'}(\boldsymbol{x}_j^v, y_j^v)$
12:         $\tilde{\boldsymbol{w}} \leftarrow \max(-g_{\boldsymbol{\epsilon}}, \mathbf{0})$
13:         $\boldsymbol{w} \leftarrow \frac{\tilde{\boldsymbol{w}}_j}{\sum_j \tilde{\boldsymbol{w}}_j + \delta(\boldsymbol{w}_j)}$
14:         // Update model with reweighted examples
15:         $\nabla\boldsymbol{\theta}_t \leftarrow \nabla_{\boldsymbol{\theta}_t} \sum_{i=1}^n w_i L_{\boldsymbol{\theta}_t}(x_i, y_i)$
16:         $\boldsymbol{\theta}_{t+1} \leftarrow \boldsymbol{\theta}_t - \tau\nabla\boldsymbol{\theta}_t$
17:     end for
18: end for
19: return $\boldsymbol{\theta}$
```

In this section, we provide the algorithm for training process of METAR and describe the whole algorithm process in detail. We would construct an adversarial validation set first and then proceed to the next step of training. In case of METAR-D method, we reconstruct our adversarial validation set after every 1-2 epochs.

As shown in Algorithm 1, we sample a minibatch from the adversarial validation set and initialize weight perturbation $\boldsymbol{\epsilon}$ in line 5-6. In line 8-9, we calculate $\boldsymbol{\theta}_t'$ in order to obtain the gradient $g_{\boldsymbol{\epsilon}}$ of $\boldsymbol{\epsilon}$ by meta-learning algorithm in line 11. We obtain the relative importance $\tilde{\boldsymbol{w}}$ of samples by comparing the magnitude of $-g_{\boldsymbol{\epsilon}}$. Note that we use the opposite direction of $g_{\boldsymbol{\epsilon}}$ to evaluate the relative importance because we do a gradient descent operation in line 9. We then normalize this importance weight $\tilde{\boldsymbol{w}}$ to $\boldsymbol{w}$ and use $\boldsymbol{w}$ to weight training samples in the regular training. In general, the theoretical computational complexity of our algorithm is about three times greater than the regular training method.

B Implementation Details

Table B shows the implementation details about the hyper-parameters we used to train models. "Adversarial Learning Rate" is the parameter setting for standard adversarial training methods. "Proportion ρ for WETAR" means that there are 50% of samples are clean samples in validation batch in each training iteration. In order to make the guidance function of adversarial validation set more obvious, we use relatively larger adversarial validation batch.

Hyper-parameters	**SST-2**	**AGNEWS**	**MR**
Learning Rate	2×10^{-5}	2×10^{-5}	2×10^{-5}
Weight Decay	1×10^{-6}	1×10^{-6}	1×10^{-6}
Batch Size	32	32	8
Epochs	10	10	10
Adversarial Learning Rate	0.03	0.06	0.03
FreeLB Ascent Step	2	3	3
FreeLB++ Ascent Step	10	10	10
Proportion ρ for WETAR	50%	50%	50%
Validation Batch Size	256	256	64

Table 3: The training hyperparameters we selected to train models across three datasets in Table 1.

C Weight Distribution

In the section, we first provide the experimental basis for our empirical model selection method with respect to the Wasserstein distance of weight distribution at every two epochs. We also provide detailed weight distributions in this section.

Figure 5 shows the weight distribution of WETAR-D on AGNEWS and SST-2 datasets. We can draw the similar conclusion that our empirical model selection method based on Wasserstein distance could select a relatively robust model.

We provide more weight distributions in this section in addition to the above distributions. Figure 6 and 7 show the weight distribution provided by WETAR-D on AGNEWS dataset and SST-2 dataset respectively. Figure 10 and 9 show the weight distribution on MR dataset provided by WETAR-D and WETAR-S respectively.

D Visualization

Figure 8 shows t-SNE results of training examples in the SST-2 dataset. For each sub-figure, the dots are outputs of the last layer of the model for the corresponding epoch, and the relative importance of dots is calculated by the average weights.

`salam.khalifa@stonybrook.edu`

Abstract

We present state-of-the-art results on morphosyntactic tagging across different varieties of Arabic using fine-tuned pre-trained transformer language models. Our models consistently outperform existing systems in Modern Standard Arabic and all the Arabic dialects we study, achieving 2.6% absolute improvement over the previous state-of-the-art in Modern Standard Arabic, 2.8% in Gulf, 1.6% in Egyptian, and 8.3% in Levantine. We explore different training setups for fine-tuning pre-trained transformer language models, including training data size, the use of external linguistic resources, and the use of annotated data from other dialects in a low-resource scenario. Our results show that strategic fine-tuning using datasets from other high-resource dialects is beneficial for a low-resource dialect. Additionally, we show that high-quality morphological analyzers as external linguistic resources are beneficial especially in low-resource settings.

1 Introduction

Fine-tuning pre-trained language models like BERT (Devlin et al., 2019) has achieved great success in a wide variety of natural language processing (NLP) tasks, e.g., sentiment analysis (Abu Farha et al., 2021), question answering (Antoun et al., 2020), named entity recognition (Ghaddar et al., 2022), and dialect identification (Abdelali et al., 2021). Pre-trained LMs have also been used for enabling technologies such as part-of-speech (POS) tagging (Lan et al., 2020; Khalifa et al., 2021; Inoue et al., 2021) to produce features for downstream processes. Previous POS tagging results using pre-trained LMs focused on core POS tagsets; however, it is still not clear how these models perform on the full morphosyntactic tagging task of very morphologically rich languages, where the size of the full tagset can be in the thousands. One such language is Arabic, where lemmas inflect to a large number of forms through different combinations of morphological features and cliticization. Additionally, Arabic orthography omits the vast majority of its optional diacritical marks which increases morphosyntactic ambiguity.

A third challenge for Arabic is its numerous variants. Modern Standard Arabic (MSA) is the primarily written variety used in formal settings. Dialectal Arabic (DA), by contrast, is the primarily spoken unstandardized variant. MSA and different DAs, e.g., Gulf (GLF), Egyptian (EGY), and Levantine (LEV), vary in terms of their grammar and lexicon to the point of impeding system usability cross-dialectally (Habash et al., 2012). Furthermore, these variants currently differ in the degree of data availability: MSA is the highest resourced variant, followed by GLF and EGY, and then LEV.

In this paper, we explore different training setups for fine-tuning Arabic pre-trained language models in the complex morphosyntactic tagging task for four Arabic variants (MSA, GLF, EGY, and LEV) under controlled experimental settings.

We aim to answer the following questions:

- How does the size of the fine-tuning data affect the performance?
- What kind of tagset scheme is suitable for modeling morphosyntactic features?
- Is there any additional value of using external linguistic resources?
- How can we make use of annotated data in some dialects to improve performance in another low-resourced dialect?

Our system[1] achieves state-of-the-art (SOTA) performance in full morphosyntactic tagging accuracy in all the variants we study, resulting in 2.6% absolute improvement over previous SOTA in MSA, 2.8% in GLF, 1.6% in EGY, and 8.3% in LEV.

---

Table 1: This is an example of multiple readings of the word حفيدك *Hfydk* in the different variants of Arabic. The table also shows the full range of morphological features: part-of-speech (**pos**), aspect (**asp**), mood (**mod**), voice (**vox**), person (**per**), gender (**gen**), number (**num**), case (**cas**), state (**stt**) and clitics: proclitics (**prc3, prc2, prc1, prc0**) and enclitic (**enc0**). In addition to the lemma (**lex**), fully diacritized form (**diac**), and English gloss (**gloss**).

2 Arabic Language and Resources

2.1 Arabic and its Dialects

MSA is the primarily written form of Arabic used in official media communications, official documents, news, and education. In contrast, the primarily spoken varieties of Arabic are its dialects. Arabic dialects vary among themselves and can be categorized at different levels of regional classifications (Salameh et al., 2018). They are also different from MSA in most linguistic aspects (namely phonology, morphology, and syntax). Moreover, dialects have no official status despite being widely used in different means of daily communication – spoken as well as increasingly written on social media. In this work, we focus on MSA, Gulf Arabic (GLF), Egyptian Arabic (EGY), and Levantine Arabic (LEV).

2.2 Orthography

In this paper, we focus on Arabic written in Arabic script for MSA and DA. An important feature of Arabic orthography is the omission of diacritical marks which are mostly used to indicate short vowels and consonantal doubling. This omission introduces ambiguity to the text, e.g., the word كتب *ktb*[2] could mean 'to write' (كَتَب *katab*) or 'books' (كُتُب *kutub*) among other readings.

Unlike MSA, Arabic dialects have no official standard orthography. Depending on the writer, words are sometimes spelled phonetically or closer to an MSA spelling through cognates or a mix of both. It has been found that in extreme cases a word can have more than 20 different spellings (Habash et al., 2018). This results in highly inconsistent and sparse datasets and models. The Conventional Orthography for Dialectal Arabic (CODA) (Habash et al., 2018) has been proposed and used in manual annotations of many datasets including some of those used in this paper. Ideally, the process of morphological disambiguation should take raw text as input, as this is more authentic than conventionalized spelling. We follow this principle for EGY and LEV where analyses are paired with the raw text. However, the GLF dataset analyses are linked to the CODA version only, since orthographic conventionalization was applied as an independent step during manual data annotations and there are no simple direct mappings between the raw text and the analyses (Khalifa et al., 2018).

2.3 Morphology

Arabic is a morphologically rich language where a single lemma inflects to a large number of forms through different combinations of morphological features (gender, number, person, case, state, mood, voice, aspect) and cliticization (prepositions, conjunctions, determiners, pronominal objects, and possessives). As some of the morphological features are primarily expressed with optional diacritical marks, orthographic ambiguity results in different morphological analyses, e.g., MSA can have up to 12 analyses per word (out-of-context) on average (Pasha et al., 2014). MSA and DA differ in the degree of morphological complexity, for example, MSA retains nominal case and verbal mood features; but these are absent in DA. On the other hand, many dialects take more clitics than MSA, e.g., the

---

[2] Arabic transliteration is presented in the HSB scheme (Habash et al., 2007).

Variant	Resource	Size	Orthography	Analyzer
MSA	PATB	629k	Standard	Manual
GLF	Gumar	202k	CODA	Automatic
EGY	ARZTB	175k	Spontaneous	Manual
LEV	Curras	57k	Spontaneous	Automatic

Table 2: An overview of the current status of the data and morphological analyzers used in this work.

ما+ +ش *mA+ +š* negation circumclitic structure found in EGY and not MSA (Habash et al., 2012).

Table 1 shows different possible readings for the word حفيدك *Hfydk* among MSA, EGY, GLF, and LEV. Rows (a) to (i) are different inflections for case or possessive pronouns or both of the lemma حَفِيد *Hafiyd* ‘grandchild’ for all variants. Rows (j) and (k) show different readings that are inflections of the verb lemma فَاد *fAd* ‘to benefit’, the inflections are for different object pronouns. Note that even between the different POS inflections words can sound and look exactly the same, this shows the degree of morphological complexity and ambiguity in Arabic and its dialects.

2.4 Resources

In this work, we use datasets that have been fully annotated for morphological features and cliticization among other lexical features such as lemmas. We use the Penn Arabic Treebank for MSA (Maamouri et al., 2004), ARZTB (Maamouri et al., 2012) for EGY, the Gumar corpus (Khalifa et al., 2018) for GLF, and the Curras corpus (Jarrar et al., 2014) for LEV. We also use morphological analyzers that provide out-of-context analyses for a given word, those analyzers provide the same set of features that are seen in the annotated data. For MSA we use the SAMA database (Graff et al., 2009), and for EGY we use CALIMA (Habash et al., 2012). Both GLF and LEV do not have morphological analyzers, instead, we use automatically generated analyzers from their training data using paradigm completion as described in Eskander et al. (2013, 2016) and Khalifa et al. (2020). The quality and coverage of analyzers, in general, can differ depending on how they were created. Manually created analyzers (MSA and EGY in this work) tend to have a better quality and lexical coverage over automatically created ones (GLF and LEV in this work). The quality of automatically generated analyzers is also highly dependent on the quality and size of the training data used to create them.

Table 2 shows the overall state of the resources for each dialect studied in this work. In terms of the size of fully annotated corpora in tokens, MSA is approximately three times larger than GLF and EGY and 11 times larger than LEV. Both MSA and GLF have consistent orthography whereas EGY and LEV are more noisy. When it comes to external morphological analyzers, only MSA and EGY have manually created and checked morphological analyzers, while both GLF and LEV have analyzers created automatically. This contrast of resource availability allows us to study how challenging the morphosyntactic tagging task can be in different real-world situations.

3 Related Work

Arabic morphological modeling proved to be useful in a number of downstream NLP tasks such as machine translation (Sadat and Habash, 2006; El Kholy and Habash, 2012) speech synthesis (Halabi, 2016), dependency parsing (Marton et al., 2013), sentiment analysis (Baly et al., 2017), and gender reinflection (Alhafni et al., 2020). We expect all of these applications and others to benefit from improvements in morphosyntactic tagging.

There have been multiple approaches to morphological modeling for Arabic. Those approaches differ depending on the target tagset (POS vs full morphology) and the availability of linguistic resources. When it comes to MSA and DA full morphological tagging, MADAMIRA (Pasha et al., 2014) trained separate SVM taggers for each morphological feature (including cliticization) and selected the most probable answer provided by an external morphological analyzer all in one step for both MSA and EGY. AMIRA (Diab et al., 2004) on the other hand used a cascading approach where it performed POS tagging after automatically segmenting the text.

A more recent similar approach to MADAMIRA was introduced by Zalmout and Habash (2017) but using a neural architecture instead. Inoue et al. (2017) presented a multitask neural architecture that jointly models individual morphological features for MSA. Zalmout and Habash (2019) extended Zalmout and Habash (2017)’s work using multitask learning and adversarial training for full morphological tagging in MSA and EGY. Similarly, Zalmout and Habash (2020) proposed an approach where they jointly model lemmas, diacritized forms, and morphosyntactic features, providing the current state-of-the-art in MSA. The same approach was used in Khalifa et al. (2020), where they focused on the effect of the size of the data and the available linguistic resources and the impact on the overall performance on morphosyntactic tagging for GLF. Zalmout (2020) provides the current state-of-the-art performance in LEV by extending Khalifa et al. (2020)'s work to LEV.

Another line of research that works with DA includes Darwish et al. (2018), where they presented a multi-dialectal CRF POS tagger, using a small set of 350 manually annotated tweets for each of EGY, GLF, LEV, and Maghrebi Arabic (Samih et al., 2017). We do not evaluate on their data because their task is defined as shallow morpheme segmentation and tagging; this is quite different from, and not easily mappable to, our task, where we disambiguate morphosyntactic features of the whole word without identifying its morpheme segments. Additionally, their tagset includes social media specific tags, such as HASH, EMOT, and MENTION, which are not in any of the large standard dataset and analyzers we study in this paper.

Pre-trained LM-based efforts in Arabic morphosyntactic tagging are relatively limited and either assume gold segmentation or only produce core POS tags. Kondratyuk (2019) leveraged the multilingual BERT model with additional word-level and character-level LSTM layers for lemmatization and morphological tagging, assuming gold segmentation. They reported the results for the SIGMORPHON 2019 Shared Task (McCarthy et al., 2019), which includes MSA. Inoue et al. (2021) reported POS tagging results in MSA, GLF, and EGY using BERT models pre-trained on Arabic text with various pre-training configurations. They do not assume pre-segmentation of the text, however, they only consider the core POS tag, rather than the fully specified morphosyntactic tag. Khalifa et al. (2021) proposed a self-training approach for core POS tagging where they iteratively improve the model by incorporating the predicted examples into the training set used for fine-tuning.

In this paper, we work with full morphosyntactic modeling on unsegmented text in four different variants of Arabic: MSA, GLF, EGY, and LEV. Furthermore, we explore the behavior of the pre-trained LM with respect to fine-tuning data size under different training setups. Given the available resources, we recognize our results' limitations in terms of applicability to different genres and styles, as well as noisy social media text and Roman script Arabic text (Darwish, 2014).

4 Methodology

4.1 Morphosyntactic Tagging with Pre-trained LMs

To obtain a fully specified morphosyntactic tag sequence, we build a classifier for each morphosyntactic feature independently, inspired by MADAMIRA. Unlike MADAMIRA where they use an SVM classifier, we use two pre-trained LM based classifiers: CAMeLBERT-Mix for DA and CAMeLBERT-MSA for MSA (Inoue et al., 2021). In selecting these pre-trained language models, we considered the results from Inoue et al. (2021) who showed that CAMeLBERT-Mix, their largest Arabic BERT model by training data size, gives the best results on DA tasks. CAMeLBERT-MSA, which outperforms CAMeLBERT-Mix on MSA tasks, is only second to AraBERT (Antoun et al., 2020), but since it was created under the same setting as CAMeLBERT-Mix, it minimizes experimental variations in our study.[3] Following the work of Devlin et al. (2019), fine-tuning the CAMeLBERT models is done by appending a linear layer on top of its architecture. We use the representation of the first sub-token as an input to the linear layer.

4.2 Factored and Unfactored Tagset

One of the challenges of the morphosyntactic tagging is the large size of the full tagset due to morphological complexity of the language, where a complete single tag is a concatenation of all the morphosyntactic features. For example, MSA and EGY data have approximately 2,000 unique complete tags in the training data, whereas GLF and LEV have around 1,400 and 1,000 tags, respectively. These are not the full tagsets as there are many feature combinations that are not seen in the data.

MADAMIRA's basic approach is to use a factored feature tagset that comprises multiple tags, each representing a corresponding morphosyntactic category.[4] This approach remedies the issue of the large tagset size by dividing it into multiple sub-tagsets of small sizes, however, it may produce inconsistent tag combinations.

Alternatively, one can combine the individual tags into a single tag. This approach has the advan-

---

[3] We leave engineering optimization using other pre-trained language models to future work.

[4] For example, the tagset for MSA comprises POS (34 tags), per (4), gen (3), num (5), asp (4), vox (4), mod (5), stt (5), cas (5), prc3 (3), prc2 (9), prc1 (17), prc0 (7), enc0 (48).

tage of guaranteeing the consistency of morphosyntactic feature combinations. However, it may not be optimal in terms of tag coverage due to a large number of unseen tags in the test data in addition to the large space of classes.

To determine which approach is most suitable for modeling, we build morphosyntactic taggers with both the factored tagset and the unfactored tagset for each variant. Additionally, we explore the effect of the training data size for both settings.

4.3 Retagging via Morphological Analyzers

In previous efforts (Zalmout and Habash, 2017; Khalifa et al., 2020), it has been shown that lexical resources such as morphological analyzers can boost the performance of morphosyntactic tagging through an in-context ranking of out-of-context answers provided by the analyzer.

In this work, we follow their approach, where we use the morphological analyzers as a later step after tagging with the fine-tuned pre-trained model. We use the analyzers described in Section 2.4 to provide out-of-context analyses. For each word, the analyzer may provide more than one answer.[5] The analyses are then ranked based on the unweighted sum of successful matches between the values of the predictions from the individual taggers and those provided by the analyzer. To break ties during the ranking, we take the weighted sum of the probability of the *unfactored* feature tag and the product of the probabilities of all the individual tags as follows:

$$\frac{1}{2}P(t_{unfactored}) + \frac{1}{2}\prod_{m \in M} P(t_m) \qquad (1)$$

where t is the tag for the feature m and M is the set of morphosyntactic features. The probabilities are obtained through unigram models based on the respective training data split.

4.4 Merged and Continued Training

Morphosyntactic modeling for DA is especially challenging because of data scarcity. Among the datasets that we use, LEV is the least resourced variant, having 11 times less training data than MSA. Therefore, we want to investigate an optimal approach to utilize data from other variants to improve upon the performance of morphosyntactic tagging for LEV.

Split	MSA	GLF	EGY	LEV
TRAIN	478k	154k	127k	43k
TUNE	26k	8k	7k	2k
DEV	63k	20k	21k	6k
TEST	63k	20k	20k	6k
ALL	629k	202k	175k	57k

Table 3: Statistics on TRAIN, TUNE, DEV, and TEST for each variant in terms of number of words.

In this work, we experiment with the following two settings: (a) we merge all the datasets together and fine-tune a pre-trained LM on the merged datasets in a single step; and (b) similar to Zalmout (2020), we start fine-tuning a pre-trained LM on a mix of high-resource datasets (MSA, GLF, and EGY), and then continue fine-tuning on a low-resource dataset (LEV).

5 Experiments

5.1 Experimental Settings

Data To be able to compare with previous SOTA (Zalmout and Habash, 2020, 2019; Khalifa et al., 2020; Zalmout, 2020), we follow the same conventions they used for data splits: MSA and EGY (Diab et al., 2013), GLF (Khalifa et al., 2018), and LEV (Eskander et al., 2016). In Table 3, we show the statistics of our datasets.

Fine-tuning We fine-tuned the CAMeLBERT models (Inoue et al., 2021) on each morphosyntactic tagging task. Following their recommendation, we used CAMeLBERT-MSA for MSA and CAMeLBERT-Mix for the dialects. We used Hugging Face's transformers (Wolf et al., 2020) for implementation. We trained our models for 10 epochs with a learning rate of 5e-5, a batch size of 32, and a maximum sequence length of 512. We pick the best checkpoint based on TUNE and report results on DEV and TEST from a single run.

Learning Curve To investigate the effect of fine-tuning data sizes, we randomly sample training examples on a scale of 5k, 10k, 20k, 40k, 80k, 120k, and 150k tokens. We use 150k, 120k, and 40k since they are comparable to the number of tokens in GLF, EGY, and LEV datasets, respectively. This allows us to measure the performance difference across different dialects in a controlled manner. This also gives us insight into the amount

---

[5] Both the MSA and EGY analyzers provide backoff modes. We use the recommended setting by Zalmout and Habash (2017). For GLF and LEV analyzers we keep the original predictions if no answer is returned.

Table 4: DEV results on a learning curve of the training data size. Morph refers to the model with an additional step of retagging using a morphological analyzer. We bold the best score for each variant. Underlined scores denote that the differences between those scores and the best scores are statistically insignificant with McNemar's test ($p < 0.05$).

of annotated data required to achieve a certain performance, which is useful when creating annotated resources for new dialects. We use this setup in all the reported experiments.

Pre-processing for Merged and Continued Training Although the different datasets provide the same set of morphosyntactic features, there exist some inconsistencies between them. The datasets were annotated by different groups using slightly different annotation guidelines, therefore, we need to bring all the feature values into a common space with LEV. We performed the following steps to address those inconsistencies: (a) we drop the *stt, cas, mod, vox, enc1*, and *enc2* features; (b) we remove the diactization from the lexical parts of the proclitic features, e.g., the conjunction و+ *w*+ realized as *wa_conj* in MSA and *wi_conj* in EGY both maps to *w_conj* in LEV; and (c) for certain POS classes some features have default values in case they are not present, those default values were different for different datasets. Thus, we mapped those default values to match whatever was specified as default in LEV. We only performed these modifications for the experiments on merged and continued training.

Evaluation Metrics We compute the accuracy in terms of the core POS and the combined morphosyntactic features (**ALL TAGS**). For MSA, we use 14 features, which are *pos, per, gen, num, asp, vox, mod, stt, cas, prc3, prc2, prc1, prc0*, and *enc0*. For dialects, we use 16 features, where we include *enc1* and *enc2* in addition to the 14 features used in MSA. In the merged and continued training setup, we use a reduced set of 10 features, *pos, per, gen, num, asp, prc3, prc2, prc1, prc0*, and *enc0*, which we refer to as **ALL TAGS 10**.

5.2 Results

Factored vs Unfactored Models Table 4 shows the DEV results for the models trained with the factored and unfactored tagset (henceforth, factored and unfactored models, respectively) on a learning curve of the training data size. In the extremely low-resource setting of 5k tokens in the ALL TAGS metric, we observe that factored models consistently outperform unfactored models across all the variants (15.9% absolute increase on average). In particular, MSA benefited most with a 32.1% absolute increase, followed by EGY (12.5%), GLF (12.0%), and LEV (7.1%).

However, this gap shrinks as the data size increases. For instance in MSA, the differences between the scores of the factored model and the unfactored model become statistically insignificant by McNemar's test (McNemar, 1947) with $p < 0.05$ when trained on the full data. This is presumably due to the decrease in the number of unseen unfactored tags in DEV. In fact, 3.9% of the unfactored tags in DEV are not seen in TRAIN in the 5k setting, whereas only 0.1% of tags are unseen in DEV when we use the full data.

The factored model performs better than the unfactored model across all the data sizes in MSA and LEV. The EGY and GLF models follow a similar pattern in the low resourced settings, however, the unfactored models begin to perform better than the factored ones from 20k for EGY and 40k for GLF. Our results suggest that the factored tagset is optimal compared to the unfactored tagset, especially in low-resource settings.

Retagging with Morphological Analyzer We observe that the use of a morphological analyzer consistently improves the performance of both unfactored and factored models across all the different training data sizes in MSA and EGY in ALL TAGS. The value of a morphological analyzer is especially apparent in the very low resourced setting (5k), with an increase of 20.2% (MSA) and 11.8% (EGY) in the unfactored model and 11.2% (MSA) and 9.2% (EGY) in the factored model. However, the effect of retagging with a morphological analyzer diminishes as the data size increases, yet providing a performance gain of 0.4% in the unfactored model with the analyzer and 0.5% in its factored counterpart in the high resourced setting in MSA.

Similarly, we observe an increase in performance when we include a morphological analyzer in the very low-resourced settings in GLF and LEV. However, as we increase the training data size, the use of a morphological analyzer starts to hurt the performance at 40k in GLF and 10k in LEV in the unfactored model and 20k in GLF and 10k in LEV in the factored model. We observe here that the quality of the analyzer has direct implications on the performance. The analyzers used for MSA and EGY are of higher quality since they were manually created and checked, whereas GLF and LEV analyzers are impacted by the quality and size of the annotated data used to create them. This is also consistent with the findings of Khalifa et al. (2020).

Comparison with Previous SOTA Systems Table 5 shows DEV and TEST results for our models and a number of previously published state-of-the-art morphosyntactic tagging systems. For our models, we use the best systems in terms of ALL TAGS metric, namely, the factored model with a morphological analyzer for MSA and EGY, the unfactored model for GLF, and the factored model for LEV. For existing models, we report the best results from Zalmout and Habash (2020) (ZH'20) for MSA, Khalifa et al. (2020) (K'20) for GLF, Zalmout and Habash (2019) (ZH'19) for EGY, and Zalmout (2020) (Z'20) for LEV.

Since some of these systems do not report on all of the features that we report on, but rather on different subsets of them, we include in the table our results when matched with their features (ALL TAGS* in Table 5). There is no difference for MSA; however the ALL TAGS* setting for EGY and LEV excludes *enc1* and *enc2*. As for GLF, ALL TAGS* consists of only 10 features: *pos, asp, per, gen, num, prc0, prc1, prc2, prc3,* and *enc0*.

We observe that our models consistently outperform the existing systems in all variants. Our model achieves 2.6% absolute improvement over the state-of-the-art system in MSA, 2.8% in GLF, 1.6% in EGY, and 8.3% in LEV.

Merged and Continued Training Table 6 shows the results on LEV for the merged and the continued training setups. We use the factored model without the analyzer as it was the best setup in the experiments presented so far. The results for merged training are consistently below those for the baseline across different data sizes, even though they have access to more data. This is most likely a result of the disproportionately small size of the LEV dataset when compared to the other variants.

In contrast, the results for continued training show consistent improvements over the LEV-only baseline model. Continued training provides a substantial increase in performance, especially in the very low resourced setting with only 5k tokens, giving 3.6% absolute improvement over the baseline on the DEV set. Our results show that continued training from the model trained on high-resourced dialects is very beneficial with lower amounts of training data. These results are not directly comparable to the previous SOTA because of the different training data and metric used.

5.3 Error Analysis

OOV To better understand the effect of different training setups, we examine the performance of our models on out-of-vocabulary (OOV) tokens alone. Here, we observe a stronger and more consistent pattern. The *average* difference between the best model and the weakest model in ALL TAGS across

Table 6: DEV and TEST results on LEV for the merged training setup (MERGED) and the continued training setup (CONTINUED). SINGLE refers to the model trained only on LEV.

variants is larger in OOV tokens (6.7%) than in all tokens (2.3%). On OOV tokens, the factored model with a morphological analyzer consistently performs best in all the data sizes for all the variants except for LEV. In LEV, however, the same model without the morphological analyzer outperforms the one with the analyzer. This is presumably due to the orthographic inconsistency in the data along with the quality of the morphological analyzer as discussed in Section 2.4.

Error Statistics Table 7 presents the number and percentage of specific feature errors among the ALL TAGS errors in the best systems on the DEV set. On average, there are two feature prediction failures within an unfactored tag across the different variants. We observe that MSA and DA exhibit different error patterns: In MSA, case is the largest error contributor among other features, which is consistent with the previous findings along the line (Zalmout and Habash, 2020), whereas in dialects, POS is the largest error contributor.

Among the POS errors, the most common error type is mislabeling a nominal tag with a different nominal tag, at 44.2% of the errors in GLF, 67.3% in EGY, and 57.8% in LEV, while this type of error is more dominant in MSA (80.8%). Mislabeling nominals with verbs is more common in DA at 23.1% in GLF, 13.0% in EGY, and 20.1% in LEV, compared to MSA (7.7%).

The core morphological features such as *per, gen, num*, and *asp* have a higher percentage of errors in DA than in MSA. Another noticeable difference is *enc0* feature (MSA ∼2% vs DA on average ∼17%). This is likely due to label distribution differences in pronominal enclitics: MSA has a highly skewed distribution with 90%, 1%, and 9% ratio for 3rd, 2nd and 1st persons as expected in MSA news genre. In comparison, DA has less skew with 50%, 17%, and 32% respectively, which increases the likelihood of error.

Among the three dialects, we observe similar patterns in terms of feature error contribution, especially for GLF and LEV with a correlation coefficient of 0.93. However, in EGY specifically, we observe a high percentage of errors in *mod, vox, stt*, and *cas*, partly due to the difference and inconsistency in annotation schemes.

We also found some gold errors which affect all of the systems we compared (previous SOTA and ours). For example, there are cases where genitive diptotes are annotated as accusative,[6] e.g., the word إيران *ĂyrAn* ‘Iran’ in the context في إيران *fy ĂyrAn* ‘in Iran’. As the results on Arabic morphosyntactic disambiguation are reaching new heights, it may be useful for the community using these resources to revisit their annotations.

6 Conclusion and Future Work

In this paper, we presented the state-of-the-art results in the morphosyntactic tagging task for Modern Standard Arabic and three Arabic dialects that differ in terms of linguistic properties and resource availability. We conducted different experiments to examine the performance of pre-trained LMs under different fine-tuning setups. We showed that the factored model outperforms the unfactored model

Table 7: The number and percentage of specific feature errors among the ALL TAGS errors in the best systems on the DEV set.

in low-resource settings; however, this gap diminishes as the data size increases. Additionally, high-quality morphological analyzers proved to be helpful, especially in low-resource settings. Our results also show that fine-tuning using datasets from other dialects followed by fine-tuning using the target dialect is beneficial for low-resource settings. Our systems outperform previously published SOTA on this task.

In the future, we plan to investigate continued training further and find other ways where we can utilize resources and datasets for low-resourced dialects. We also intend to explore other architectures for morphosyntactic tagging using multi-task learning in the context of pre-trained LMs, as well as work on the task of automatic lemmatization. We also plan to integrate some of our best models as part of the Python open-source Arabic NLP toolkit CAMeL Tools (Obeid et al., 2020).

7 Ethical Considerations

The experiments reported in this work rely on previously published datasets described in Section 2.4. We used the CAMeLBERT models along with morphosyntactically annotated datasets to build our morphosyntactic taggers, which is in line with their intended use. Our work is on core and generic NLP technologies that can be potentially used with malicious intent, for example, as part of the pipeline. To ensure reproducibility, we make our code publicly available. The details on the datasets and training are described in Appendix A. Given the focus of this paper and the available resources, we recognize the limitations of our findings in terms of applicability to different genres, styles, and other languages.

Acknowledgment

This work was carried out on the High Performance Computing resources at New York University Abu Dhabi. We thank anonymous reviewers for their insightful suggestions and comments. We thank Bashar Alhafni and Ossama Obeid for their assistance with the codebase and the helpful discussions.

A Replicability

A.1 Resources

Pretrained transfromer models We fine-tuned CAMeLBERT-MSA for the morphosyntactic tagging task in MSA and CAMeLBERT-Mix (Inoue et al., 2021) for EGY, GLF, and LEV.

Fine-tuning Data We used the Penn Arabic Treebank for MSA (Maamouri et al., 2004), ARZTB (Maamouri et al., 2012) for EGY, the Gumar corpus (Khalifa et al., 2018) for GLF, and the Curras corpus (Jarrar et al., 2014) for LEV. The preprocessing of the data includes fixing inconsistent annotations and removing diacritics through CAMeL Tools (Obeid et al., 2020). This preprocessing was followed in all the previous work we compared with Zalmout and Habash (2019, 2020); Khalifa et al. (2020); Zalmout (2020).

Data Sampling For the learning curve experiment in Section 5.1, we sampled the training data up to 5k, 20k, 40k, 80k, 120k, 150k tokens after shuffling the entire dataset. Each sample after 5k is inclusive of the smaller samples.

Morphological Analyzers The morphological analyzers used in our experiments are the following: For MSA we use the SAMA database (Graff et al., 2009), and for EGY we use CALIMA (Habash et al., 2012). For GLF and LEV, we use automatically generated analyzers from their training data using paradigm completion as described in Eskander et al. (2013, 2016) and Khalifa et al. (2020).

Data Accessibility MSA and EGY related resources need a license from the Linguistic Data Consortium (LDC). The GLF data is available at `http://resources.camel-lab.com/` and the LEV data is available at `https://portal.sina.birzeit.edu/curras/`. We provide conversion scripts to generate our preprocessed datasets from legally accessed third-party datasets at `https://github.com/CAMeL-Lab/CAMeLBERT_morphosyntactic_tagger`.

A.2 Implementation

We used Hugging Face's transformers (Wolf et al., 2020) for implementation. Fine-tuning is done by adding a fully connected linear layer to the last hidden state. We release our code including the hyperparameters used in the experiments at `https://github.com/CAMeL-Lab/CAMeLBERT_morphosyntactic_tagger`.

For the experiments in Section 5, we use the following hyperparameters: a random seed of 12345, training for 10 epochs, saving the model for every 500 steps, a learning rate of 5e-5, a batch size of 32, and a maximum sequence length of 512. We pick the best checkpoint based on TUNE and report results on DEV and TEST from a single run.

The number of parameters of the factored model for MSA is about 1.5 billion, while the factored model for GLF, EGY, and LEV has 1.8 billion parameters in total. The unfactored model has about 110 million parameters for MSA, GLF, EGY, and LEV.

The factored model is the most computationally expensive model to train, which took about 21 hours for MSA, 16 hours for GLF, 13 hours for EGY, and five hours for LEV on a single NVIDIA-V100 card. The unfactored model took about 90 minutes to train for MSA, 60 minutes for GLF, 50 minutes for EGY, and 20 minutes for LEV on the same machine.

How Pre-trained Language Models Capture Factual Knowledge? A Causal-Inspired Analysis

Abstract

Recently, there has been a trend to investigate the factual knowledge captured by Pre-trained Language Models (PLMs). Many works show the PLMs' ability to fill in the missing factual words in cloze-style prompts such as "Dante was born in [MASK]." However, it is still a mystery how PLMs generate the results correctly: relying on effective clues or shortcut patterns? We try to answer this question by a causal-inspired analysis that quantitatively measures and evaluates the word-level patterns that PLMs depend on to generate the missing words. We check the words that have three typical associations with the missing words: *knowledge-dependent*, *positionally close*, and *highly co-occurred*. Our analysis shows: (1) PLMs generate the missing factual words more by the positionally close and highly co-occurred words than the knowledge-dependent words; (2) the dependence on the knowledge-dependent words is more effective than the positionally close and highly co-occurred words. Accordingly, we conclude that the PLMs capture the factual knowledge ineffectively because of depending on the inadequate associations.

Knowledge-Dependent:
Columbus born between 25 August and 31 October 1451, **died** **20 May 1506** was an Italian explorer.

Positionally Close:
Columbus born between 25 August and 31 October 1451, **died** **20 May 1506** **was** an Italian explorer.

Highly Co-occurred:
Columbus born between 25 August and 31 October 1451, died **20 May 1506** was an Italian **explorer**.

Figure 1: The associations we investigated. The underlined words are the missing words that need to be generated. The bold words, which hold specific associations with the missing words, are considered as the word-level patterns that PLMs may use to generate the missing words.

1 Introduction

d Do Pre-trained Language Models (PLMs) capture factual knowledge? LAMA benchmark (Petroni et al., 2019) answers this question by quantitatively measuring the factual knowledge captured in PLMs: query PLMs with cloze-style prompts such as "Dante was born in [MASK]?" Filling in the mask with the correct word "Florence" is considered a successful capture of the corresponding factual knowledge. The percentage of correct fillings over all the prompts can be used to estimate the amount of factual knowledge captured. PLMs show a surprisingly strong ability to capture factual knowledge in such probings (Jiang et al., 2020; Shin et al., 2020; Zhong et al., 2021), which elicits further research on a more in-depth question (Cao et al., 2021; Elazar et al., 2021a): How do PLMs capture the factual knowledge? In this paper, we try to answer this question with a two-fold analysis:

Research Question 1 *Which association do PLMs depend on to capture factual knowledge?*

Research Question 2 *Is the association on which PLMs depend effective in capturing factual knowledge?*

We use *association* to refer to the explicit association between the missing words and the remaining words in the context. We define three typical associations between words. Figure 1 illustrates these associations in a mask-filling sample.

Definition 1 ***Knowledge-Dependent (KD)****: According to a Knowledge Base (KB), the missing words can be deterministically predicted when providing the remaining words.*

Definition 2 ***Positionally Close (PC)****: The remaining words are positionally close to the missing words.*

(a) Dependence measure.

(b) Effectiveness measure.

Figure 2: The overview of the proposed analysis framework. The dependence measure quantifies how much the PLMs depend on each association to capture factual knowledge when per-training. The effectiveness measure evaluates whether the dependence on an association is good for the factual knowledge performance in probing.

Definition 3 *Highly Co-occurred (HC): The remaining words have a higher co-occurrence frequency with the missing words.*

Question 1 investigates how much PLMs depend on a specific group of remaining words to predict the missing words in pre-training samples. We select the remaining words to be investigated according to their association with the missing words. We propose a causal-inspired method to quantify the word-level dependence in each sample. The average dependence on the remaining words that hold the same association with the missing words over all the samples indicates how PLMs rely on this association to predict the missing words. We refer to this average dependence as dependence on the association. The above analysis is named dependence measure.

In Question 2, we reveal the effectiveness of dependence by the correlation between the quantified dependence on associations and the factual knowledge capturing performance. The performance is probed with additionally crafted cloze-style prompts(Elazar et al., 2021a). The more the dependence on an association positive correlates with the probing performance, the more effective this association is. We refer to the second analysis as effectiveness measure. According the experiment results, we have the following observations:

Observation 1 *The PLMs depend more on the positional close and highly co-occurred associations than the knowledge-dependent association to capture factual knowledge.*

Observation 2 *Depending on the knowledge-dependent association is more effective for factual knowledge capture than positional close and highly co-occurred associations.*

By connecting the two observations, we can answer the question of "*how PLMs capture factual knowledge*" as: **The PLMs are capturing factual knowledge ineffectively since the PLMs depend more on the PC and HC association than the KD association.**

The contribution of this paper can be summarized as follows: (1) We quantify the word-level dependence for mask filling with a causal-inspired method, revealing the word-level patterns that PLMs use to predict the missing words quantitatively. (2) We compare the effectiveness of the dependence on different associations, which provides direct insights for improving PLMs for factual knowledge capture. (3) This paper introduces causal theories into PLMs by formulating the effect measurement process in mask language modeling. It paves the path to measure the causal effects between entities or events described in natural language.

2 Method

2.1 Overview

We take a quick overview of our two-fold analysis with a running example in Figure 2. Figure 2a illustrates how to measure the dependence on the remaining words "Columbus" and "died" when predicting the missing words "20 May 1506." We let the PLM generate the missing words based on the original input first, then mask the remaining words in the input and let PLMs generate again. The difference between these two predictions is quantified and used to measure the dependence. The remaining and missing words hold the knowledge-dependent association in this sample. We repeat this measure on all the samples whose remaining and missing words have the KD association. Then the dependence on the KD association can be estimated by the average of the quantified difference.

Figure 2b measures the effectiveness of the dependence on each association by calculating the correlation coefficient between the dependence and

Association	Knowledge-Dependent	Positionally Close	Highly Co-occurred
Input	W_t born between 25 August and 31 October 1451, W_t $\underline{W_o}$ was an Italian explorer.	Columbus born between 25 August and 31 October 1451, W_t $\underline{W_o}$ W_t an Italian explorer.	W_t born between 25 August and 31 October 1451, died $\underline{W_o}$ was an Italian W_t.

Table 1: To analyze the dependence of associations, we do interventions on treatment words to reveal their causal effects on the outcome words.

the probing performance. Following (Petroni et al., 2019; Elazar et al., 2021a), the probing performance is indicated by the prediction accuracy and consistency when querying on the same fact with different prompts. Since the dependence on associations are quantified in the dependence measure, we can calculate the correlation coefficient between the dependence and performance over all the samples. Their correlation measures whether the dependence on an association is harmful or beneficial to the performance, showing the effectiveness of the dependence on an association quantitatively.

Section Outline We organize the rest of this section as follows. In Section 2.2.1, we formalize how we quantify the dependence with the causal effect estimation. Section 2.2.2 gives detail about how we build the probing samples for different associations. Section 2.3.1 introduces the metrics we used to indicate the performance of factual knowledge capture. Section 2.3.2 describes the details about the effectiveness measure of associations.

2.2 Quantify the Dependence on Associations

2.2.1 Causal Effect Estimation for PLMs

To study the causal effect of the different input words, we build a Structured Causal Model (SCM) for the missing words generation process and apply interventions on some input words to estimate their effect quantitatively. We consider the missing words as **outcome words** and the remaining words that hold a certain association (e.g. positionally close) with the outcome words as **treatment words**. Then, we can formally represent the word generation process with SCM, as the following structural equations:

$$\begin{aligned} w_c &= f(\mathbb{I}), w_t = \mathrm{PLM}(w_c) \\ w_o &= \mathrm{PLM}(w_c, w_t). \end{aligned} \tag{1}$$

Separate the words in a sentence into three groups: treatment words W_t, outcome words W_o, and context words W_c (specified by w_t, w_o, and w_c respectively). Equation 1 formulates the following data generation process: (1) Sample a sentence from the natural text space $\mathbb{I}$ and get the context words w_c using function f. (2) Generate the treatment words w_t by the PLM based on w_c only. (3) Generate outcome words w_o based on both the w_c and w_t.

To obtain the quantitative causal effect of treatment words W_t on outcome words W_o, we apply the do-calculus $do()$ (Pearl, 2009) on treatment words W_t to introduce interventions for estimating the causal effect. $do()$ denotes the operation of forcibly setting the value of W_t. Then the causal effect of W_t on W_o can be estimated by the Average Treatment Effect (ATE) (Rubin, 1974):

$$\begin{aligned} &\mathbb{E}\left[P(W_o|do(W_t = \hat{w}_t))\right] \\ -&\mathbb{E}\left[P(W_o|do(W_t = w_m))\right]. \end{aligned} \tag{2}$$

Accordingly, we define ATE for PLMs as:

$$\begin{aligned} \tau = &\sum_{\mathbb{I}} \mathrm{PLM}\left(do(W_t = \hat{w}_t), w_c\right) P(s) \\ &- \sum_{\mathbb{I}} \mathrm{PLM}\left(do(W_t = w_m), w_c\right) P(s), \end{aligned} \tag{3}$$

where $\hat{w}_t$ is the ground truth of the treatment words W_t (the original value of W_t without intervention). w_m is the intervention value (several [MASK]s) for W_t, and we use it to simulate removing the ground-truth value $\hat{w}_t$ from the input. $P(s)$ denotes the probability of selecting the sample s that consists of w_t, w_o, and w_c from $\mathbb{I}$. $\mathrm{PLM}(\cdot, \cdot)$ denotes the output of PLMs with certain input. Table 1 illustrates the interventions on the SCM for different associations.

The raw output of PLMs is a probability distribution over fixed vocabulary. We transform the output into reciprocal rank to quantify the differences:

$$\mathrm{PLM}_k(w_t, w_c) = \begin{cases} \frac{1}{rank_{\hat{w}_o}}, & \text{if } rank_{\hat{w}_o} \leq k \\ 0, & \text{otherwise} \end{cases}. \tag{4}$$

$\hat{w}_o$ is the ground-truth outcome words. $rank_{\hat{w}_o}$ is the rank position of $\hat{w}_o$ according to the generation probability of $\hat{w}_o$ output by $\mathrm{PLM}(w_c, w_t)$. We set k to 100 and use PLM_{100} to replace PLM in Equation 3 to calculate ATE. The ATE reflects the effect of W_t on the prediction of W_o, it can be regarded as a quantitative estimation of how much PLMs depend on W_t when generating W_o.

2.2.2 Mark words by Associations

Wikipedia is a rich source of knowledge (Thom et al., 2007; Hassanzadeh, 2021), and most of the PLMs nowadays have been pre-trained on Wikipedia (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2019), so we take Wikipedia sentences as pre-training samples to construct the probing samples for dependence measure. We probe the mask-filling on these sentences to analyze what PLMs based on when capturing factual knowledge in pre-training.

The outcome we want to observe is the predictions of factual words in the sentences. In order to locate the factual words, we align each sentence with a triplet (*subject*, *predicate*, *object*) in the KB. The words that correspond to the *object* serve as outcome words W_o for observation, and the remaining words that hold an explicit association with W_o are marked as treatment words W_t for intervention. For different associations, the W_t is identified as:

1. *Knowledge-Dependent*: all the remaining words correspond to the *predicate* and *object* in the same triplet with the W_t.
2. *Positionally Close*: the remaining words closest to W_o.
3. *Highly Co-occurred*: the remaining words that have higher Pointwise Mutual Information (PMI) (Church and Hanks, 1990) with W_o. The PMI is calculated over all the Wikipedia sentences using the following equation:

$$\mathrm{PMI}(w_i; \hat{w}_o) = \frac{P(w_i|\hat{w}_o)}{P(w_i)}, \tag{5}$$

   where $\hat{w}_o$ is a group of words (a span) and w_i is a single word.
4. We further define a *Random* (**R**) association, where the W_t are randomly selected remaining words. It provides some empirical support for how much the modifications in the context affect the mask-filling output.

Accordingly, one sentence yields four probing samples for the four associations, respectively. The four probing samples share the same W_o but use different words as W_t to show the dependence on different associations when predicting the same W_o. We preserve that the number of words in W_t is the same among different associations. For example, if there are two words used as W_t by the KD association, we select the top two closest words with W_o as W_t for PC, and the words have the top two PMI with W_o for HC. We can obtain a set of probing samples for each association. The sample sets for different associations source from the same set of sentences and have the same size.

2.3 Measure the Effectiveness of Associations

This section investigates which association can lead to better performance on factual knowledge capture. We first define the metrics to evaluate the performance, then we measure the effectiveness of an association by relating the dependence on this association with probing performance.

2.3.1 Metrics for Factual Knowledge Probing

Section 2.2 uses the original Wikipedia sentence as pre-training samples to quantify the dependence PLMs used to capture the corresponding fact in pre-training. The performance of capturing the corresponding fact is probed by having PLMs fill masks on crafted quires. We construct these queries by instantiating templates on triplets (Petroni et al., 2019). $T_i(s)$ denotes the i-th query for the fact corresponds to s. The accuracy mrr of capturing this fact is obtained by averaging over all the predictions obtained with different queries:

$$\mathrm{mrr}\,(s) = \frac{1}{n} \sum_{i}^{n} \mathrm{PLM}_k(T_i(s)), \tag{6}$$

$\mathrm{PLM}_k(T_i(s))$ denotes the reciprocal rank of the ground truth in the PLM's output for query $T_i(s)$, it is defined in Equation 4.

The consistency of the capture is indicated by the percentage of the pairs of queries that have the same result (Elazar et al., 2021a):

$$\operatorname{con}(s) = \frac{\sum_{i \neq j} \mathbb{1}_{\mathrm{PLM}(T_i(s))=\mathrm{PLM}(T_j(s))}}{n(n-1)}. \quad (7)$$

There are n different queries on every fact, and we can get $\binom{n}{2} = n(n-1)$ pairs of predictions in total. $\mathrm{PLM}(T_i(s))$ denotes the top-1 output for the query $T_i(s)$. The value of $\mathbb{1}_{\mathrm{PLM}(T_i(s))=\mathrm{PLM}(T_j(s))}$ is an indicator function that takes the value 1 if the PLMs returns identical at top-1 for $T_i(s)$ and $T_j(s)$ and 0 otherwise. The PLMs are better on the consistency metric if they keep the predictions consistent when queries only vary on the surface forms. *E.g.*, the two queries "Dante was born in [MASK]" and "The birthday of Dante is [MASK]" should return the same results.

Finally, we evaluate the factual knowledge capture performance by jointly examining the accuracy and consistency (Elazar et al., 2021a):

$$\operatorname{test}(s) = \operatorname{mrr}(s) \cdot \operatorname{con}(s) \quad (8)$$

$\operatorname{test}(s)$ measures the probing performance on template-based queries. We also define a metric to measure how well the PLMs memorize the missing words in pre-training samples (Wikipedia sentences):

$$\operatorname{train}(s) = \mathrm{PLM}_k(s). \quad (9)$$

2.3.2 Correlate Performance with Dependence

We have quantified the dependence on each association and defined the metrics for probing performance in the above sections. We then calculate the Pearson correlation coefficient (Kirch, 2008) between dependence and probing performance to reveal the effectiveness of different associations. An association is considered more effective if the probing performance positively correlates with its dependence more.

Because only part of the facts has available templates, the samples in the dependence measure without templates are ignored in the calculation. The factual knowledge captured by different PLMs may vary significantly due to the differences in model scale, pre-training data, or other settings. To make the correlation coefficient comparable between different PLMs, we calculate the correlation only on the factual knowledge gathered correctly by the PLM. *I.e.*, only the pre-training samples with $\operatorname{train}(s) = \mathrm{PLM}_k(s) = 1$ are involved.

Sample in Dependence Measure	
# Wikipedia sentences	4,779,753
# Different triplets	3,795,229
# Different predicates	565
# Sentences with synthetic templates	1,119,875
Queries in Effectiveness Measure	
# Template-based queries	7,645,635
# Different triplets	654,112
# Different predicates	38
# Different templates	328

Table 2: Statistics of the probing data.

3 Experiments and Discussions

3.1 Probing Data and PLMs

We use the TREX dataset (Elsahar et al., 2018), which aligns KB triplets with Wikipedia sentences, to construct the samples for the dependence measure following the definition in Section 2.2.2. We employ the templates from (Elazar et al., 2021a) to construct the queries to probe the factual knowledge for the effectiveness measure. Table 2 shows the statistics for the data in the dependence measure and the effectiveness measure. The PLMs we analyzed include BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), SpanBERT (Joshi et al., 2020), and ALBERT (Lan et al., 2019).

3.2 Dependence on Associations

The dependence on an association is the average ATE over the probing samples whose treatment words hold that association with the outcome words. Table 3 shows the quantified dependence of different associations. The accuracy in Table 3 represents the accuracy of recovering the masked factual words in pre-training samples, revealing how well does PLMs memorize the pre-training samples. It is calculated by Equation 9 with $k = 1$.

We find a general trend over all the picked PLMs: the Positionally Close (PC) association takes the dominant effect on the prediction results, the Highly Co-occurred (HC) association comes second, and the least for the Knowledge-Dependent (KD) association. The trend does not change much as increasing the model scale (*large vs. base*), using additional training data (RoBERTa *vs.* BERT), or improving the masking strategy (SpanBERT *vs.* BERT). Consequently, the accuracy drops the most when perturbing the positionally close words but least on knowledge-dependent words[1].

---

[1] Table 6 in the Appendix shows the accuracy decrease

Model	Accuracy	Dependences on Associations ($k = 100$)			
		KD	PC	HC	R
BERT-*base-cased*	0.3623	0.1585	0.4085	0.1779	0.1081
BERT-*large-cased*	0.3692	0.1603	0.4113	0.1791	0.0996

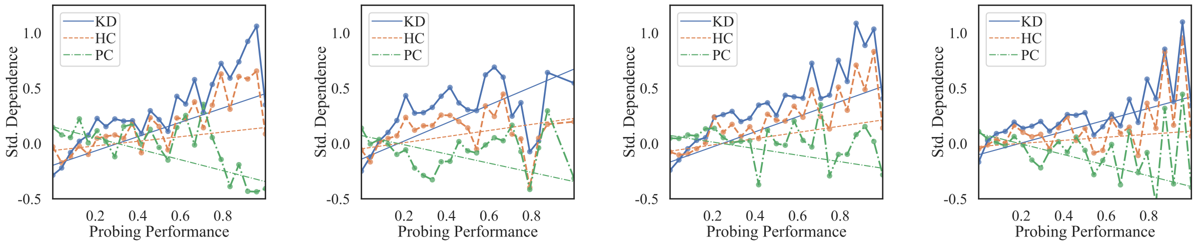
Table 3: The quantified dependence on associations. **Accuracy** denotes the performance of filling in the masks in pre-training samples. The PLMs use cased and uncased vocabularies are separated.



(a) BERT-*large-cased-wwm* (b) RoBERTa-*large* (c) SpanBERT-*large* (d) ALBERT-*xxlarge-v2*

Figure 3: The correlations between the dependence on associations and the probing performance on factual knowledge capture.

The results provide quantitative evidence for Question 1 of "*Which association do PLMs depend on to capture factual knowledge?*:" **PLMs prefer the associations founded with positionally close or the highly co-occurred words to the knowledge-based clues.** It is different from how a conventional KB works, e.g., an object can be retrieved by the corresponding subject and predicate.

3.3 Correlations between Dependence and Performance

We show the correlation between association's dependence and the probing performance in Figure 3. Each point in the figure represents a piece of factual knowledge s. We refer to it as a fact for convenience. The horizontal axis indicates $\mathrm{test}(s)$ for the fact, showing the probing performance of the fact with effectiveness measure. The vertical axis shows the dependence of associations when capturing this fact, which is quantified by the causal effect estimation defined in Section 2.2.1. The straight lines are the regression lines and different associations are shown in different line styles[2].

As we can see from the results, the dependence on the KD association positively correlates with the probing performance. The dependence on the HC association has a slightly positive correlation or almost has no correlations sometimes (such as ALBERT in Figure 3d). The PC association holds a negative correlation with the performance.

These results can give an empirical answer to "*Is the association on which PLMs depend effective in capturing factual knowledge?*:" **the more PLMs depend on the Knowledge-Dependent (KD) association, the better PLMs can capture the corresponding factual knowledge.** Meanwhile, **relying much on the positionally close association is harmful to the probing performance.**

The dependence measure results reveal that the PLMs depend most on the positionally close but least on the knowledge-dependent association. However, in effectiveness measure, we find that the positionally close association is the most ineffective for factual knowledge capture while the knowledge-dependent association is the most effective. By connecting the two results, we can conclude the answer to the question in the title: **The PLMs do not capture factual knowledge ideally,**

---

when perturbing the different associations.

[2] We standardize the quantified value of dependence (denoted as Std. Dependence) and plot a bucket of facts as a single point to show the trends clearly. The correlations without standardization for more PLMs are in Table 8

since they depend more on the ineffective associations than the effective one.

3.4 Case Study

To illustrate the analysis result intuitively, we show two cases with SpanBERT-*large* in Table 4. The MRR shows the probing performance on the template-based query (calculated by Equation 6). In Case 1, the knowledge-dependent association gains the biggest effect, and the predictions are robust in all the template-based probing. However, the positionally close association takes the main effect in Case 2, while the PLM fails to recall the word "England" with the template-based queries.

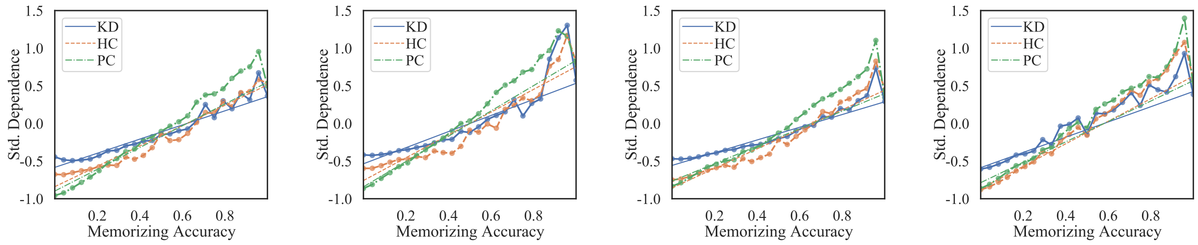
3.5 Discussions

Generality of the Proposed Probing Method Generally, the dependence measure offers a way to measure how much the word-level patterns cause the prediction of missing words in Mask Language Model (MLM). Because words are readable, directly visible, and can be manipulated from the input side directly, the word-level patterns can provide more intuitive interpretations than numeric representation vectors (Elazar et al., 2021b) or neurons (Vig et al.). We use the proposed method to estimate the causal effect of three typical associations in this paper, while this method can be easily adapted to quantify the dependence on any word-level patterns.

Reconsidering "*PLM as KB*" If we want to use a PLM like a KB, whether the PLM has the same inner workflow as KBs deserves to be considered. The prevalent KBs index knowledge as subject-predicate-object triplets and can infer with triplets (Speer et al., 2017; Bollacker et al., 2008; Vrandečić and Krötzsch, 2014). However, we find out that the knowledge-dependent association, which represents the process of inferring a missing object based on the given subject and predicate, has the lowest dependence in the PLMs. It provides evidence that the PLMs work quite differently with KBs and can not serve stably as KBs for now.

Overfiting and Generalization Figure 4 shows the correlations between the dependence on associations and the mask-filling accuracy on pre-training samples (referred to as memorizing accuracy). The memorizing accuracy increases most as the dependence of the PC association increases, demonstrating that the more PLMs depend on the positionally close words, the better PLMs can recover the pre-training samples. However, there is an opposite trend in probing performance as shown in Figure 3. The additionally crafted queries used to evaluate the probing performance are mostly unseen in per-training. If we consider these queries as the test set and the pre-training samples as the train set, we can conclude that the dependence on the PC associations makes the PLMs tend to overfit the training data and degrade the generalization on the test set.

Factual Knowledge Capture in Pre-training We want to focus on the pre-training samples that help PLMs to capture factual knowledge. So we reconstruct the pre-training samples that predict some missing factual words (object) based on the factual clues (subject, predicate). We conduct the dependence measure on these samples to investigate how the factual knowledge is captured in pre-training. The mask-filling accuracy on these pre-training samples denotes how well PLMs memorize them



(a) BERT-*large-cased-wwm* (b) RoBERTa-*large* (c) SpanBERT-*large* (d) ALBERT-*xxlarge-v2*

Figure 4: The correlations between the dependence on associations and the mask-filling accuracy on the pre-training samples (Wikipedia sentences).

in pre-training. We name it as "train" in Equation 9 and "Memorizing Accuracy" in Figure 4.

Overlap between Associations The clues for different associations overlap sometimes, e.g., some remaining words may hold the KD and PC associations with the missing words at the same time. The overlaps do not impair the estimations because we use a set of samples to estimate the effect of each association. The samples that hold the same association stay in the same set, and the average causal effect in all these samples is the quantified dependence of this association. The sample sets are quite different for different associations. Table 5 shows the corresponding statistics of the overlaps.

4 Related Works

Probing Factual Knowledge in PLMs Factual Knowledge Probing in PLMs has attracted much attention recently. LAMA (Petroni et al., 2019) propose a benchmark that probes the factual knowledge in the PLMs with cloze-style prompts and shows PLMs' ability to capture factual knowledge. This ability can be further explored by tuning the prompts for probing Jiang et al. (2020); Shin et al. (2020); Zhong et al. (2021).

Motivated by the probing results, some recent works analyze the captured factual knowledge from more perspectives. Cao et al. (2021) analyze the distribution of predictions and the answer leakage in probing. Poerner et al. (2020) propose that the PLMs could predict based on some correlation between surface forms rather than infer according to facts. Elazar et al. (2021a) reveal that the PLMs' outputs are inconsistent as querying the same fact with different prompts.

This paper proposes a more fine-grained inspection of word-level patterns in the input. In addition to constructing more challenging probing data as input or analyzing the outputs more detailedly, we try to reveal the inner mechanism of PLMs by conducting intervention on the input and then observing the change in the output.

Causal-inspired Interpretations in NLP A causal-inspired approach to explanation is to generate counterfactual examples and then compare the predictions (Feder et al., 2021a). Feder et al. (2021b) propose a framework for producing explanation for NLP models using counterfactual representation. Vig et al. analyze the effect of neurons (or attention heads) on the gender bias using causal mediation analysis. In this paper, we revisit the word-level post-hot interpretation (Sun et al., 2021; Li et al.) from a causal-effect perspective: intervene on some specified words in the input and measure the difference in the output to estimate the causal effect of these words. Furthermore, we evaluate the effectiveness of different causes by calculating correlations between their effects and performance. As far as we know, our work is the first study to probe and evaluate word-level patterns in the factual knowledge capture task.

5 Conclusion

In this paper, we try to answer the question of *How Pre-trained Language Models Capture Factual Knowledge* by measuring and evaluating different associations that PLMs use to capture factual knowledge. We present three word-level associations, knowledge-dependent, positionally close, and highly co-occurred in the analysis. The analysis results show that the PLMs rely more on the ineffective positionally close and highly co-occurred associations when capturing factual knowledge, and somewhat ignore the effective knowledge-dependent clues. These findings indicate that we should pay more attention to the knowledge-dependent association to let PLMs capture factual knowledge better.

Appendix

A Probing Sample Construction for the Dependence Measure

We detail how we construct the probing samples for the dependence measure as follows. We take a subject-predicate-object triplet in Wikidata[3] as a piece of factual knowledge (Petroni et al., 2019; Cao et al., 2021; Kassner et al., 2021; Elazar et al., 2021a). A subject-predicate-object triplet is aligned with a Wikipedia sentence by matching the subject, predicate, and object with their corresponding spans, respectively. A subject-predicate-object triplet is aligned with a Wikipedia sentence by matching the subject, predicate, and object with their corresponding spans, respectively. The words that correspond to the object are the factual words that are masked and need to be predicted, and we investigate how the different remaining words contribute to the prediction.

The remaining words that have three typical associations with the masked words are considered in the analysis. The rules to identify the remaining words that have the *Knowledge-Dependent* (**KD**) association are:

1. The W_o and the W_t describe the same subject-predicate-object triplet in KB.

2. The W_t are the natural language description of the subject and predicate, the W_o are that for the object.

3. If the subject and predicate corresponding to W_t are given correctly (*i.e.*, $W_t = \hat{w}_t$), the ground-truth value of the object is *unique* in the KB.

The first rule makes the W_t and W_o grounded in the same piece of factual knowledge. The second rule makes predicting the outcome words similar to inferring the object using a KB when giving the subject and predicate. The third rule means if the treatment words are given correctly, there should be one and only one ground-truth value for the object. The third rule is similar to the N-1 relationship (Cao et al., 2021) in KB and lets the ground-truth treatment words can be regarded as a sufficient condition to predict the unique outcome words deterministically.

We use the T-REx[4] dataset to provide the initial alignment between KB triplets and the Wikipedia sentences. We use the aliases in KB as keys for fuzzy string match (Levenshtein distance is less than 2, stemming before matching, etc.) to align more subjects, predicates, and objects with spans in the sentence. The sentences that have no aligned triplet are filtered out.

Sometimes, the outcome words in a single sentence relate to multiple triplets that satisfy the rules for KB. E.g., there are two groups of remaining words that can infer the outcome words deterministically based on KB. We select them all as the W_t when probing the KB association and keep the number of the masked words be the same in interventions for the other associations. D_{KD}, D_{PC}, and D_{HC} denote the sample sets for the Knowledge-Dependent (KD), Positionally Close (PC), and Highly Co-occurred (HC) associations, respectively.

For the *Highly Co-occurred* association (**HC**), the remaining words that are top-k in PMI with the ground-truth outcome words $\hat{w}_o$ are selected as W_t. The k is the number of words with the KD associations for the same sentence. The PMI between words is calculated by all the Wikipedia sentences. If the $\hat{w}_o$ consists of multiple words, occurring with all the words in $\hat{w}_o$ altogether are taken as co-occurring. The order of the words in $\hat{w}_o$ are ignored for efficiency. Table 5 shows more details about the probing samples.

B More Probing Results

The Pearson correlation coefficients between the dependence on associations (raw value without standardization) and the performance are shown in Table 8. The three metrics, accuracy (defined in Equation 6), consistency (defined in Equation 7), and the overall performance metric (defined in Equation 8), are reported respectively. The correlation coefficients between the dependence and the performance are consistent with the slopes of the regression lines in Figure 3. Table 6 shows the accuracy decreasing results after masking the treatments words when generating the missing words in Wikipedia sentences.

Metadata Shaping: A Simple Approach for Knowledge-Enhanced Language Models

Simran Arora **Sen Wu** **Enci Liu** **Christopher Ré**
Department of Computer Science, Stanford University
{simran, senwu, jesslec, chrismre}@cs.stanford.edu

Abstract

Popular language models (LMs) struggle to capture knowledge about rare *tail* facts and entities. Since widely used systems such as search and personal-assistants must support the long tail of entities that users ask about, there has been significant effort towards enhancing these *base LMs* with factual knowledge. We observe proposed methods typically start with a base LM and data that has been annotated with entity metadata, then *change the model*, by modifying the architecture or introducing auxiliary loss terms to better capture entity knowledge. In this work, we question this typical process and ask to what extent can we match the quality of model modifications, with a simple alternative: using a base LM and only changing the data. We propose *metadata shaping*, a method which inserts substrings corresponding to the readily available entity metadata, e.g. types and descriptions, into examples at train and inference time based on mutual information. Despite its simplicity, metadata shaping is quite effective. On standard evaluation benchmarks for knowledge-enhanced LMs, the method exceeds the base-LM baseline by an average of 4.3 F1 points and achieves state-of-the-art results. We further show the gains are on average 4.4x larger for the slice of examples containing tail vs. popular entities.

1 Introduction

Recent language models (LMs) such as BERT (Devlin et al., 2019) and its successors are remarkable at memorizing knowledge seen frequently during training, however performance degrades over the long tail of rare facts. Given the importance of factual knowledge for tasks such as question-answering, search, and personal assistants (Bernstein et al., 2012; Poerner et al., 2020; Orr et al., 2020), there has been significant interest in injecting these *base LMs* with factual knowledge about entities (Zhang et al., 2019; Peters et al., 2019, inter alia.). In this work, we work we propose a simple and effective approach for enhancing LMs with knowledge, called *metadata shaping*.

Existing methods to capture entity knowledge more reliably, typically use the following steps: first annotating natural language text with entity metadata, and next modifying the base LM model to learn from the tagged data. Entity metadata is obtained by linking substrings of text to entries in a knowledge base such as Wikidata, which stores entity IDs, types, descriptions, and relations. Model modifications include introducing continuous vector representations for entities or auxiliary objectives (Zhang et al., 2019; Peters et al., 2019; Yamada et al., 2020; Wang et al., 2020; Xiong et al., 2020; Joshi et al., 2020a; Su et al., 2021). Other methods combine multiple learned modules, which are each specialized to handle fine-grained reasoning patterns or subsets of the data distribution (Chen et al., 2019; Wang et al., 2021).

These *knowledge-aware LMs* have led to impressive gains compared to base LMs on *entity-rich tasks*. That said, the new architectures are often designed by human experts, costly to pretrain and optimize, and require additional training as new entities appear. Further, these LMs may not use the collected entity metadata effectively — Wikidata alone holds over $\sim$ 100M unique entities, however many of these entities fall under similar categories, e.g., “politician” entities. Intuitively, if unseen entities encountered during inference share metadata with entities observed during training, the LM trained with this information may be able to better reason about the new entities using patterns learned from similar seen entities. However, the knowledge-aware LMs learn from *individual entity occurrences* rather than learning these shared reasoning patterns. Implicitly learning entity similarities for 100M entities may be challenging since 89% of the Wikidata entities do not appear in Wikipedia, a popular source of unstruc-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1733 - 1745
May 22-27, 2022

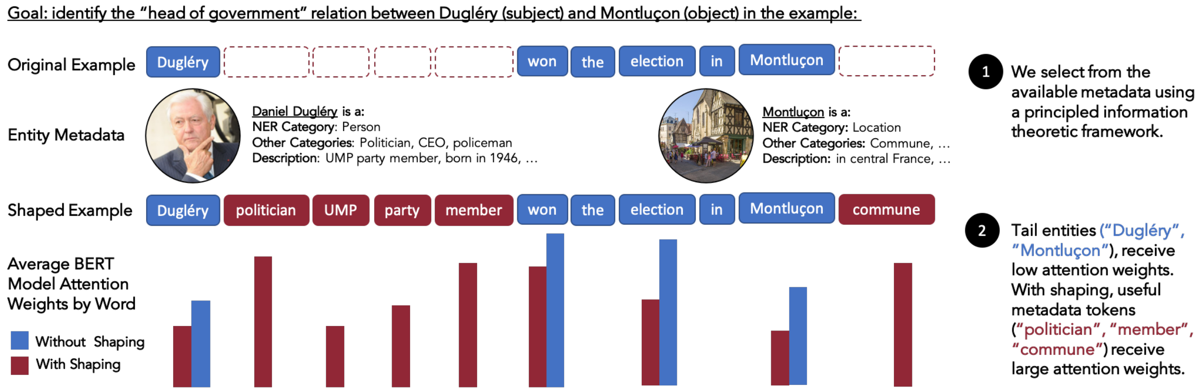

Figure 1: Metadata shaping inserts metadata (e.g., entity types and descriptions) strings into train and test examples. The FewRel benchmark involves identifying the relation between a subject and object string. The above subject and object are unseen in the FewRel training data and the tuned base LM reflects low attention weights on those words. A base LM trained with shaped data reflects high attention weights on useful metadata words such as "politician". Weights are shown for words which are not stop-words, punctuation, or special-tokens.

tured training data for the LMs, at all. [1]

We thus ask, **to what extent can we match the quality of knowledge-aware LM architectures using the base LM itself?** We find that applying some simple modifications to the data at train and test time, a method we call *metadata shaping*, is surprisingly quite effective. Given unstructured text, there are several readily available tools for generating entity metadata at scale (e.g., Manning et al. (2014); Honnibal et al. (2020)), and knowledge bases contain entity metadata including type tags (e.g., Barack Obama is a "politician") and descriptions (e.g., Barack Obama "enjoys playing basketball"). Our method entails explicitly inserting retrieved entity metadata in examples as in Figure 1 and inputting the resulting *shaped examples* to the LM. Our contributions are:

Simple and Effective Method We propose metadata shaping and demonstrate its effectiveness on standard benchmarks that are used to evaluate knowledge-aware LMs. Metadata shaping, with simply an *off-the-shelf* base LM, exceeds the base LM trained on unshaped data by by an average of 4.3 F1 points and is competitive to state-of-the-art methods, which do modify the LM. Metadata shaping thus enables re-using well-studied and optimized base LMs (e.g., Sanh et al. (2020)).

Tail Generalization We show that metadata shaping improves tail performance — the observed gain from shaping is on average 4.4x larger for the slice of examples containing tail entities than for the slice containing popular entities. Metadata establish "subpopulations", groups of entities sharing similar properties, in the entity distribution (Zhu et al., 2014; Cui et al., 2019; Feldman, 2020). For example on the FewRel benchmark (Han et al., 2018), "Daniel Dugléry" (a French politician) appears 0 times, but "politician" entities in general appear $>$ 700 times in the task training data. Intuitively, performance on a rare entity should improve if the LM has the explicit information that it is similar to other entities observed during training.

Explainability Existing knowledge-aware LMs use metadata (Peters et al., 2019; Alt et al., 2020), but do not explain when and why different metadata help. Inspired by classic feature selection techniques (Guyon and Elisseeff, 2003), we conceptually explain the effect of different metadata on generalization error.

We hope this work motivates further research on addressing the tail challenge through the data. [2]

2 Method

This section introduces metadata shaping, including the set up and conceptual framework.

2.1 Objective

The goal of metadata shaping is to improve tail performance using properties shared by popular and rare examples (e.g., the unseen entity "Daniel Dugléry" and popular entity "Barack Obama" are

---

[1] Orr et al. (2020) finds that a BERT based model needs to see an entity in on the order of 100 samples to achieve 60 F1 points when disambiguating the entity in Wikipedia text.

[2] We release our code: `https://github.com/simran-arora/metadatashaping`

both "politicians"). This work explores how to effectively provide these properties to popular transformer models. Tail entities are those seen < 10 times during training and head entities are seen ≥ 10 times, consistent with Orr et al. (2020); Goel et al. (2021).

Metadata are easily and scalably sourceable using off-the-shelf models such as those for named entity (NER, NEL) or part-of-speech (POS) tagging (Manning et al., 2014; Honnibal et al., 2020), heuristic rules, and knowledge bases (KBs) (e.g., Wikidata, Wordnet (Miller, 1995), domain-specific KBs (Bodenreider, 2004), and product KBs (Krishnan, 2018)). KBs often provide high tail coverage — e.g., a product KB will contain metadata for both popular and unpopular products.

Many prior works annotate text with metadata and in our setting, instead of using predefined feature schemas (Marcus et al., 1993; Mintz et al., 2009, inter alia.), we consider using an unrestricted set of metadata, including entity unstructured descriptions. Importantly, knowledge-aware LMs have attracted significant recent interest and data-oriented approaches have not been demonstrated as a compelling alternative, the aim of this work.

2.2 Set Up

Let input $x \in \mathcal{X}$ and label $y \in \mathcal{Y}$, and consider the classification dataset $\boldsymbol{D} = \{(x_i, y_i)\}_{i=1}^n$ of size n. Let $m \in \mathcal{M}$ denote a metadata tag and let $\boldsymbol{M(x_i)}$ be the set of metadata collected for example x_i. A shaping function $f_s : \mathcal{X} \rightarrow \mathcal{X}_s$ accepts an original example $x_i \in \mathcal{X}$ and produces a shaped example $s_i \in \mathcal{X}_s$ by inserting a subset of $\boldsymbol{M(x_i)}$ into x_i (see Figure 1). The downstream classification model $\hat{p}_\phi$ is learned from shaped train examples and infers y_i from the shaped test examples.

This work uses the following representative metadata shaping functions for all tasks to insert a range of *coarse-grained* signals associated with groups of examples to *fine-grained specific* signals associated with individual examples:

Categorical tokens establish subpopulations of entities (e.g., *Dugléry* falls in the coarse grained category of "person" entities, or finer grained category of "politician" entities). NER and POS tags are coarse grained categories, and knowledge bases contain finer-grained categories (i.e., entity types and relations). Categories are consistent and frequent compared to words in the original examples.

Description tokens give cues for rare entities and alternate expressions of popular entities (e.g., *Dugléry* is a "UMP party member"). Descriptions are likely unique across entities, and can be viewed as the finest-grained category for an entity.

2.3 Conceptual Framework

Next we want to understand if inserting $m \in \boldsymbol{M(x_i)}$ for $x_i \in \boldsymbol{D}$ can improve tail performance. We measure the generalization error of the classification model $\hat{p}_\phi$ using the cross-entropy loss:

$$\mathcal{L}_{\text{cls}} = \mathbb{E}_{(x,y)}\big[- \log(\hat{p}_\phi(y|x))\big]. \tag{1}$$

Let $\Pr(y|x_i)$ be the true probability of class $y \in Y$ given x_i. Example x_i is composed of a set of patterns $\boldsymbol{K_i}$ (i.e., subsets of tokens in x_i). We make the assumption that a pattern $k \in \boldsymbol{K_i}$ is a useful signal if it informs $\Pr(y|x_i)$. We thus parametrize the true distribution $\Pr(y|x_i)$ using the principle of maximum entropy (Berger et al., 1996):

$$\Pr(y|x_i) = \frac{1}{Z(x_i)} \exp(\sum_{k \in \boldsymbol{K_i}} \lambda_k \Pr(y|k)). \tag{2}$$

where λ_k represents learned parameters weighing the contributions of patterns (or events) k and $Z(x_i)$ is a partition function that ensures $\Pr(y|x_i)$ represents a probability distribution. Therefore when evaluating $\hat{p}_\phi$, achieving zero cross-entropy loss between the true probability $\Pr(y|k)$ and the estimated probability $\hat{p_\phi}(y|k)$, for all k, implies zero generalization error overall.

Unseen Patterns Our insight is that for a pattern k that is unseen during training, which is common in entity-rich tasks,[3] the class and pattern are independent ($y \perp k$) under the model's predicted distribution $\hat{p}_\phi$, so $\hat{p}_\phi(y|k) = \hat{p}_\phi(y)$. With the assumption of a well-calibrated model and not considering priors from the base LM pretraining stage,[4] this probability is $\hat{p}_\phi(y) = \frac{1}{|\mathcal{Y}|}$ for $y \in \mathcal{Y}$.

Plugging in $\hat{p}_\phi(y) = \frac{1}{|\mathcal{Y}|}$, the cross-entropy loss between $\Pr(y|k)$ and $\hat{p}_\phi(y|k)$ is $\Pr(k) \log |Y|$. Our idea is to effectively replace k with another (or multiple) *shaped* pattern k', which has non-uniform $\hat{p}_\phi(y|k')$ and a lower cross-entropy loss with respect to $\Pr(y|k')$, as discussed next.

---

[3] For example, on the FewRel benchmark used in this work, 90.7%/59.7% of test examples have a subject/object span which are unseen as the subject/object span during training.

[4] We ignore occurrences in the pretraining corpus and learned similarities between unseen k and seen k'. Future work can use these priors to refine the slice of unseen entities.

Algorithm 1 Metadata Token Selection

```
**Precompute Train Statistics**
**Input**: training data $\boldsymbol{D_{train}}$, metadata $M$
**for** each category $m \in M$ over $\boldsymbol{D_{train}}$ **do**
    Compute $\text{pmi}(y, m)$ for $y \in \mathcal{Y}$.
**end for**
**for** each class $y \in \mathcal{Y}$ over $D_{train}$ **do**
    Compute frequency $f_y$.
**end for**

**Select Metadata for Sentence**
**Input**: $x_i$ from $\boldsymbol{D_{train}}$ and $\boldsymbol{D_{test}}$, integer $n$.
Collect metadata $\boldsymbol{M(x_i)}$ for $x_i$.
**for** $m \in \boldsymbol{M(x_i)}$ **do**
    Compute $r_y = 2^{\text{pmi}(m,y)} f_y$ for $y \in \mathcal{Y}$.
    Normalize $r_y$ values to sum to 1.
    Compute entropy $H_m$ over $r_y$ for $y \in \mathcal{Y}$.
**end for**
Rank $m \in \boldsymbol{M(x_i)}$ by $H_m$.
**Return** $\min(n, |\boldsymbol{M(x_i)}|)$ tokens with lowest $H_m$.
```

Inserting Metadata Consider the shaped example, $s_i = f_s(x_i)$, which contains new tokens from $\boldsymbol{M(x_i)}$, and thus contains a new set of patterns $\boldsymbol{K_i^s}$. Let $k_m \in \boldsymbol{K_i^s}$ be a pattern containing some $m \in \boldsymbol{M(x_i)}$. For a rare pattern (e.g., a mention of a rare entity in x_i) k, if an associated pattern k_m (e.g., a metadata token for the rare entity) occurs non-uniformly across classes during training, then the cross-entropy loss between $\hat{p}_\phi(y|k_m)$ and $\Pr(y|k_m)$ is lower than the cross-entropy loss between $\hat{p}_\phi(y|k)$ and $\Pr(y|k)$. If k_m shifts $\hat{p}_\phi(y|x_i)$ usefully, performance of $\hat{p}_\phi$ should improve.

We can measure the non-uniformity of k_m across classes using the conditional entropy $\hat{H}(\mathcal{Y}|k)$. When k is unseen and $\hat{p}_\phi(y|k) = \hat{p}_\phi(y,k) = \hat{p}_\phi(y) = \frac{1}{|\mathcal{Y}|}$ (uniform), $\hat{H}(\mathcal{Y}|k)$ is maximized:

$$\hat{H}(\mathcal{Y}|k) = -\sum_{y \in \mathcal{Y}} \hat{p}_\phi(y,k) \log \hat{p}_\phi(y|k) = \log(|\mathcal{Y}|). \quad (3)$$

For non-uniform $\hat{p}_\phi(y|k_m)$, the conditional entropy decreases. Broadly, we connect the benefit of using different metadata, which are inputs both to existing knowledge aware LMs and our approach, to classical methods (Guyon and Elisseeff, 2003) — we seek the metadata providing the largest information gain. Next we discuss the practical considerations for selecting metadata.

Metadata Selection Entities are associated with large amounts of metadata $\boldsymbol{M(x_i)}$ — categories can range from coarse-grained (e.g., "person") to fine-grained (e.g., "politician" or "US president") and there are intuitively many ways to describe entities. Since certain metadata may not be helpful for a task, and popular base LMs do not scale very well to long sequences (Tay et al., 2020; Pascanu et al., 2013), it is important to understand *which* metadata to use for shaping.

We want to select k_m with non-uniform $\hat{p}_\phi(y|k_m)$ across $y \in \mathcal{Y}$, i.e. with lower $\hat{H}(\mathcal{Y}|k_m)$. Conditional probability $\Pr(y|k_m)$ is defined as:

$$\Pr(y|k_m) = 2^{\text{pmi}(y,k_m)} \Pr(y), \quad (4)$$

where we recall that the pointwise mutual information $\text{pmi}(y, k_m)$ is defined as $\log\left(\frac{\Pr(y,k_m)}{\Pr(y)\Pr(k_m)}\right)$. The pmi compares the probability of observing y and k_m together (the joint probability) with the probabilities of observing y and k_m independently. Class-discriminative metadata reduce $\hat{H}(\mathcal{Y}|k)$.

Directly computing the resulting conditional probabilities after incorporating metadata in $\boldsymbol{D}$ is challenging since the computation requires considering all patterns contained in all examples, generated by including m. Instead we use simplistic proxies to estimate the information gain. In Algorithm 1, we focus on the subset of $\boldsymbol{K_i^s}$ containing individual metadata tags m, and compute the entropy over $\hat{p}_\phi(y|m)$ for $y \in \mathcal{Y}$. Simple extensions to Algorithm 1, at the cost of additional computation, would consider a broader set of k_m (e.g., n-grams containing m for $n > 1$), or *iteratively* select tokens by considering the correlations in the information gain between different metadata tags.

3 Experiments

In this section, we demonstrate that metadata shaping is general and effective.

3.1 Datasets

We evaluate on standard entity-typing and relation extraction benchmarks used by baseline methods. **Entity typing** involves predicting the the applicable *types* for a given substring in the input example from a set of output types. We use OpenEntity (9 output types) (Choi et al., 2018) for evaluation. **Relation extraction** involves predicting the relation between the two substrings in the input example, one representing a subject and the other an

Model	FewRel			TACRED			OpenEntity		
	P	R	F1	P	R	F1	P	R	F1
BERT-base	85.1	85.1	84.9	66.3	78.7	72.0	76.4	71.0	73.2
K-BERT	83.1	85.9	84.3	-	-	-	76.7	71.5	74.0
ERNIE	88.5	88.4	88.3	74.8	77.1	75.9	78.4	72.9	75.6
E-BERT$_{concat}$	88.5	88.5	88.5	-	-	-	-	-	-
KnowBERT$_{Wiki}$	89.2	89.2	89.2	**78.9**	**76.9**	**77.9**	78.6	71.6	75.0
CokeBERT	89.4	89.4	89.4	-	-	-	78.8	**73.3**	75.6
Ours (BERT-base)	**90.4**	**90.4**	**90.4**	77.0	76.3	76.7	**79.3**	**73.3**	**76.2**

Table 1: Test scores on standard relation extraction and entity-typing tasks. "Ours (Base LM)" is metadata shaping. All methods use the same base LM (BERT-base) and external information (Wikipedia) for consistent comparison. A dash ("-") indicates the baseline method did not report scores for the task.

object. We use FewRel (80 output relations) and TACRED Revisited (42 output relations) for evaluation (Han et al., 2018; Zhang et al., 2017; Alt et al., 2020). While metadata shaping is generally applicable to classification tasks, our objective in this work is to compare architectural versus data-oriented methods of injecting knowledge, so we focus on benchmarks that are popular in the literature on knowledge-aware LMs.

3.2 Experimental Settings

Model We fine-tune a BERT-base model on metadata shaped data for each task, taking the pooled [CLS] representation and using a linear prediction layer for classification (Devlin et al., 2019). We use cross-entropy loss for FewRel and TACRED and binary-cross-entropy loss for OpenEntity. All test scores are reported at the epoch with the best validation score and we use the scoring implementations released by (Zhang et al., 2019). Additional training details are provided in appendix A.

Metadata Source We collect entity metadata from Wikidata for our evaluations, a compelling choice as several works successfully improve tail performance in *industrial workloads* using the knowledge base (e.g., Orr et al. (2020)) We use the state-of-the-art pretrained entity-linking model from Orr et al. (2020) to link the text in each task to an October 2020 dump of Wikidata. We use Wikidata and the first sentence of an entity's Wikipedia page to obtain descriptions. Additional details are in Appendix A. For certain examples in the tasks, there are no linked entities in the text (e.g., several subject or object entities are simply pronouns or dates). Table 3 gives statistics for the number of examples with available of metadata for each task. Metadata tags are selected by Algorithm 1.

While the metadata annotation methods have their own failure rates, our baselines also use entity linking as the first step (Zhang et al., 2019, inter alia.) with the same exposure to failures. All the same, we seek methods that are flexible to errors that arise in natural data.

3.3 Baselines

Prior work proposes various knowledge-aware LMs, which are currently the state-of-the-art for the evaluated tasks. **ERNIE**, (Zhang et al., 2019) **LUKE** (Yamada et al., 2020), **KEPLER** (Wang et al., 2020), **CokeBERT** (Su et al., 2021), and **WKLM** (Xiong et al., 2020) introduce auxiliary loss terms and require additional pretraining. Prior approaches also modify the architecture for example using alternate attention mechanisms (**KnowBERT** (Peters et al., 2019), **K-BERT** (Liu et al., 2020), **LUKE**) or training additional transformer stacks to specialize in knowledge-based reasoning (**K-Adapter** (Wang et al., 2021)). **E-BERT** (Poerner et al., 2020) does not require additional pretraining and uses entity embeddings which are aligned to the word embedding space. In Table 1, we compare to methods which use the same base LM, BERT-base, and external information resource, Wikipedia, for consistency.

3.4 End-to-End Benchmark Results

We simply use an *off-the-shelf* BERT-base LM (Wolf et al., 2020), with no additional pretraining and fine-tuned on shaped data to exceed the BERT-base LM trained on unshaped data by 5.3 (FewRel), 4.7 (TACRED), and 3.0 (OpenEntity) F1 points. Metadata shaping is also competitive with SoTA baselines which *do* modify the BERT-base LM. Results are shown in Table 1. Table 3 reports the availability of metadata for each task.

We observe that metadata shaping is effective both when most task examples have available metadata (e.g., FewRel) and when metadata tags are sparse (e.g., on OpenEntity only 30% of examples have available metadata), analyzed further in Section 4. We further note that the performance of our method is not sensitive to grammatical choices around how the metadata tags are inserted through ablations provided in Appendix B.

For the baselines, we give reported numbers when available, Su et al. (2021) reports two of the KnowBERT-Wiki and all K-BERT results, and we obtain remaining numbers using the code released by baseline work as detailed in Appendix A.

4 Analysis

Here we study the following key questions for effectively using metadata shaping: **Section 4.1** What are the roles of different varieties of metadata? **Section 4.2** What are the effects of metadata shaping on slices concerning tail versus popular entities?

4.1 Framework: Role of Metadata Types

Metadata Effects *Class-discriminative metadata correlates with reduced model uncertainty. High quality metadata, as found in Wikidata, results in improved classification performance.*

To investigate the effects of metadata on model uncertainty, we compute the entropy of $\hat{p}_\phi$ softmax scores over the output classes as a measure of uncertainty, and compute the average across test set examples. Lower uncertainty is correlated with improved classification F1 (See Figure 2 (Left)).

We compute pmi scores for inserted metadata tokens as a measure of class-discriminativeness. We rank individual tokens k by pmi(y, k) (for task classes y), computed over the training dataset. On FewRel, for test examples containing a top-20 pmi word for the gold class, the accuracy is 27.6% higher when compared to the slice with no top-20 pmi words for the class. Notably, 74.1% more examples contain a top-20 pmi word for their class when pmi is computed on shaped data vs. unshaped training data.

Metadata Selection *Simple information theoretic heuristics are effective for selecting metadata, despite the complexity of the underlying contextual embeddings.*

We apply Algorithm 1, which ranks metadata tags by their provided information gain, to select metadata tags for the tasks. Given x_i with a set $\boldsymbol{M(x_i)}$ of metadata tags, our goal is to select n to use for shaping. We compare four selection approaches: using the highest ("High Rank") and lowest ("Low Rank") ranked tokens by Algorithm 1, random metadata from $\boldsymbol{M(x_i)}$ ("Random"), and the most popular metadata tokens across the union of $\boldsymbol{M(x_i)}, \forall x_i \in \boldsymbol{D_{train}}$ ("Popular"), selecting the same number of metadata tags per example for each baseline. We observe that High Rank consistently gives the best performance, evaluated over three seeds, and note that even Random yields decent performance vs. the BERT-baseline, indicating the simplicity of the method (Table 2).

Benchmark	Strategy	Test F1
FewRel	BERT-base	84.9
	Random	87.2 ±0.8
	Popular	87.9 ±0.1
	Low Rank	87.8 ±0.4
	High Rank	**88.9** ±0.6
OpenEntity	BERT-base	73.2
	Random	74.3 ±0.7
	Popular	74.5 ±0.4
	Low Rank	74.1 ±0.4
	High Rank	**74.8** ±0.1
TACRED	BERT-base	72.0
	Random	73.8 ±1.6
	Popular	73.6 ±0.9
	Low Rank	73.3 ±1.0
	High Rank	**74.7** ±0.5

Table 2: Average and standard deviation over 3 random seeds. Each method selects up to n metadata tokens per entity. For FewRel, TACRED, $n = 3$ per subject, object. For OpenEntity $n = 2$ per main entity as 33% of OpenEntity train examples have ≥ 2 categories available (80.7% have ≥ 3 categories on FewRel). Note we use larger n for the main results in Table 1.

Considering the distribution of selected category tokens under each scheme, the KL-divergence between the categories selected by Low Rank vs. Popular is 0.2 (FewRel), 4.6 (OpenEntity), while the KL-divergence between High Rank vs. Popular is 2.8 (FewRel), 2.4 (OpenEntity). Popular tokens are not simply the best candidates; instead, Algorithm 1 selects discriminative metadata.

For OpenEntity, metadata are relatively sparse, so categories appear less frequently in general and it is reasonable that coarse-grained types have more overlap with High Rank. For e.g., "business" is in the top-10 most frequent types under High Rank,

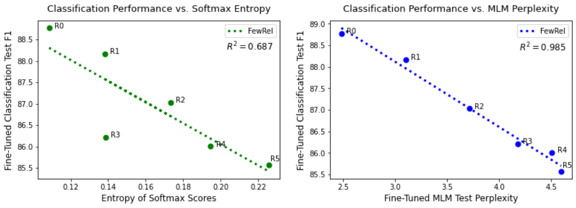

Figure 2: Test F1 for $\hat{p}_\phi$ (no additional pretraining) vs. average entropy of $\hat{p}_\phi$ softmax scores (Top) and vs. perplexity of a model $\hat{p}_\theta$ (w/ pretraining) (Bottom). $\hat{p}_\phi$ and $\hat{p}_\theta$ use the same shaped training data. Each point is a different metadata shaping scheme (median over 3 Random Seeds): for *R0* all inserted tokens are true tokens associated with the entity in the KB. For *RX*, X true metadata tokens are replaced by random (noise) tokens from the full vocabulary. For each point, the total number of metadata tokens is constant per example.

while "non-profit" (occurs in 2 train examples) is in the top-10 most frequent types for Low Rank. Metadata tokens overall occur more frequently in FewRel (See Table 3), so fine-grained types are also quite discriminative. The most frequent category under Low Rank is "occupation" (occurs in 2.4k train examples), but the top-10 categories under High Rank are finer-grained, e.g. "director" and "politician" (each occurs in > 300 train examples).

Task Agnostic Metadata Effects *Using metadata correlates with reduced task-specific LM uncertainty. We observe shaping also correlates with reduced LM uncertainty in a task-agnostic way.*

We perform additional masked language modeling (MLM) over the shaped task training data using an off-the-shelf BERT-MLM model to learn model $\hat{p}_\theta$. We minimize the following loss function and evaluate the model perplexity on the task test data:

$$\mathcal{L}_{\text{mlm}} = \mathbb{E}_{s\sim D, m\sim M, i\sim I}\big[-\log(\hat{p}_\theta(s_{m_i}|s_m/i))\big]. \quad (5)$$

where I is the masked token distribution and s_{m_i} is the masked token at position i in the shaped sequence s_m.[5] Through minimizing the MLM loss, $\hat{p}_\theta$ learns direct dependencies between tokens in the data (Zhang and Hashimoto, 2021). In Figure 2 (Right), we observe a correlation between reduced perplexity for $\hat{p}_\theta$, and higher downstream performance for $\hat{p}_\phi$ across multiple tasks, both using the same training data. Overall, shaping increases the likelihood of the data, and we observe a correlation between the intrinsic perplexity metric and the extrinsic downstream metrics as a result of the same shaping scheme. Table 4 (Appendix B) reports the same correlations for all benchmarks.

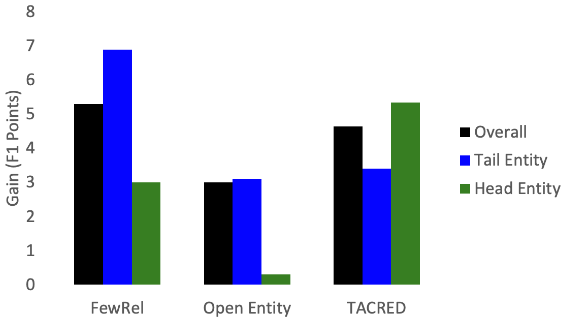

Figure 3: The gain from training the BERT-base LM with metadata shaped data over training with unshaped data, split by the popularity of the entity span in the test example.

Metadata Noise *We hypothesize that noisier metadata can provide implicit regularization. Noise arises from varied word choice, word order, and blank noising.*

Feature noising (Wang et al., 2013) is effective to prevent overfitting and while regularization is typically applied directly to model parameters, Xie et al. (2017); Dao et al. (2019) regularize through the data. We hypothesize that using metadata with diverse word choice and order (e.g., entity descriptions) and blank noising (e.g., by masking metadata tokens), can help reduce overfitting, and we provide initial empirical results in Appendix B.

4.2 Evaluation: Tail and Head Slices

Section 3 shows the overall gain from shaping. We now consider fine-grained slices of examples containing head vs. tail entities and observe gains are 4.4x larger on the tail slice on average (Figure 3).[6]

Subpopulations *Metadata are helpful on the tail as they establish subpopulations.*

We hypothesize that if a pattern is learned for an entity-subpopulation occurring in the training data, the model may perform better on rare entities that also participate in the subpopulation, but were not individually observed during training. On FewRel, we take the top-20 TF-IDF words associated with each category signal during training as linguistic

---

[5] We use the Hugging Face implementation for masking and fine-tuning the BERT-base MLM (Wolf et al., 2020).

[6] A consideration for TACRED is that 42% of these head spans are stopwords (e.g., pronouns) or numbers; just 7% are for FewRel. This is based on unseen object spans for FewRel and TACRED, as $> 90\%$ of subject spans are unseen.

cues captured by the model for the category subpopulation, consistent with Goel et al. (2021). For example, "government" is in the top-20 TF-IDF words for the "politician" entity category. At test time, we select the slice of examples containing any of these words for any of the categories inserted in the example. The performance is 9.0/3.5 F1 points higher on examples with unseen subject/object entities with vs. without a top-20 TF-IDF word for a subject/object category.

Metadata Effects on Popular Entities *For popular entities the LM can learn entity-specific patterns well, and be mislead by subpopulation-level patterns corresponding to metadata.*

Although we observe overall improvements, here we examine the effect of metadata on the popular entity slice within our conceptual framework.

Let p be a popular pattern (i.e., entity mention) in the training data, and let m be a metadata token associated with p. Intuitively, the LM can learn entity-specific patterns from occurrences of p, but coarse-grained subpopulation-level patterns corresponding to m. If m and p are class-discriminative for different sets of classes, then m can mislead the LM. To evaluate this, consider subject and object entity spans $p \in P$ seen ≥ 1 time during training. For test examples let $\mathcal{Y}_p$ be the set of classes y for which there is a $p \in P$ in the example with $\text{pmi}(y, p) > 0$, and define $\mathcal{Y}_m$ as the classes y for which there is a metadata token m with $\text{pmi}(y, m) > 0$ in the example. The examples where $\mathcal{Y}_p \neq \emptyset$, $\mathcal{Y}_m \neq \emptyset$, and $\mathcal{Y}_p$ contains the true class, but $\mathcal{Y}_m$ does not, represents the slice where metadata can mislead the model. On this slice of FewRel, the gain from the shaped model is 2.3 F1 points less than the gain on the slice of all examples with $\mathcal{Y}_p \neq \emptyset$ and $\mathcal{Y}_m \neq \emptyset$, supporting our intuition.

An example entity-specific vs. subpopulation-level tension in FewRel is: $p =$ "Thames River" is class-discriminative for $y =$"located in or next to body of water", but its m ="river" is class-discriminative for $y =$"mouth of the watercourse".

5 Related Work

Incorporating Knowledge in LMs Discussed in Section 3.2, significant prior work incorporates knowledge by changing the base LM architecture or loss function. Peters et al. (2019); Alt et al. (2020) also use NER, POS Wikpedia, or Wordnet metadata, but do not conceptually explain the benefit or selection process. Orr et al. (2020) demonstrates that category metadata improves tail performance for NED. We do not modify the base LM.

Prior work inserts metadata for entities in the data itself. Joshi et al. (2020b); Logeswaran et al. (2019); Raiman and Raiman (2018) each uses a single form of metadata (either descriptions or types) for a single task-type (either QA or NED) demonstrating empirical benefits. Metadata shaping combines different varieties of metadata and applies generally to classification tasks, and we provide conceptual grounding.

Feature Selection This work is inspired by techniques in feature selection based on information gain (Guyon and Elisseeff, 2003). In contrast to traditional feature schemas (Levin, 1993; Marcus et al., 1993), metadata shaping annotations are expressed in natural language to flexibly include arbitrary metadata. The classic methods (Berger et al., 1996) are not used to explain design decisions in the line of work on knowledge-enhanced LMs, which we connect in this work. In our setting of entity-rich tasks, we explain how metadata can reduce generalization error.

Prompting Prompting can serve similar goals, but often requires human-picked prompt tokens (Keskar et al., 2019; Aghajanyan et al., 2021) or task-specific templates (Han et al., 2021; Chen et al., 2022), while metadata shaping provides a flexible baseline across metadata-types and task-types. Prompting typically aims to better elicit *implicit* knowledge from the base LM (Liu et al., 2021), while metadata shaping focuses on *explicitly* incorporating retrieved signals not found in the original task. Shaping is applied at train and test time and does not introduce new parameters, as required by methods which use learned prompts.

Data Augmentation One approach to tackle the tail is to generate additional examples for tail entities (Wei and Zou, 2019; Xie et al., 2020; Dai and Adel, 2020). However, this can be sample inefficient since augmentations do not explicitly signal that different entities are in the same subpopulation (Horn and Perona, 2017), so the model would need view each entity individually in different contexts. Metadata shaping and prompting (Scao and Rush, 2021) may be viewed as implicit augmentation.

6 Conclusion

We propose metadata shaping to improve tail performance. The method is a simple and general baseline that is competitive with SoTA approaches for entity-rich tasks. We empirically show that the method improves tail performance and explain why metadata can reduce generalization error. While this work focused on entity-rich tasks, metadata shaping is not limited to this setting. Broadly, we hope this work motivates further research on understanding how to effectively *program* LMs with useful and readily available side information. While modifying the LM architecture to encode the information has been a popular approach, modifying the data is a simple and effective alternative.

A Appendix

A.1 Dataset Details

Benchmarks We download the raw datasets from: `https://github.com/thunlp/ERNIE`.

Metadata We tag original dataset examples with a state-of-the-art pretrained entity-linking model from (Orr et al., 2020),[7] which was trained on an October 2020 Wikipedia dump with train, validation, test splits of 51M, 4.9M, and 4.9M sentences. FewRel includes entity annotations. The types we use as category metadata for all tasks are those appearing at least 100 times in Wikidata for entities this Wikipedia training data used bh Orr et al. (2020). Descriptions are sourced from Wikidata descriptions and the first 50 words of the entity Wikipedia page. Table 3 reports the availability of metadata for examples across the benchmark tasks.

A.2 Training Details

We use the pretrained BERT-base-uncased model for each task to encode the input text. We take the hidden layer representation corresponding to the [CLS] token and use a linear classification layer for prediction. All models are trained on 1 Tesla P100 GPU (1.5 min/epoch for OpenEntity, 7.5 min/epoch for FewRel, 28 min/epoch for TACRED). For all tasks, we select the best learning rate from {1e-6, 2e-6, 1e-5, 2e-5, 1e-4} and use the scoring implementations released by Zhang et al. (2019).

Entity Typing Hyperparameters include 2e-5 learning rate, no regularization parameter and 256 max. sequence length, batch size of 16 and no gradient accumulation or warmup. We report the test score for the epoch with the best validation score within 20 epochs.

Relation Extraction Hyperparameters include 2e-5 learning rate and no regularization parameter. For FewRel, we use batch size of 16, 512 maximum sequence length, and no gradient accumulation or warmup. For TACRED, we use a batch size 48, 256 maximum sequence length, and no gradient accumulation or warmup. We report the test score for the epoch with the best validation score within 15 epochs (FewRel) and 8 epochs (TACRED).

---

Benchmark	Train	Valid	Test
TACRED	68124	22631	15509
Category	54k/46k	16k/15k	9k/10k
Description	50k/43k	15k/14k	8k/9k
FewRel	8k	16k	16k
Category	8k/8k	16k/15k	16k/15k
Description	7k/8k	15k/16k	15k/16k
OpenEntity	1998	1998	1998
Category	674	674	647
Description	655	672	649

Table 3: We show the benchmark split sizes (row 1), and the # of examples tagged with category and description metadata (rows 2 and 3). We give numbers for the subject and object entity-span on relation extraction and the main entity-span for entity-typing. The tasks have represent a range of proportions of shaped examples (e.g., essentially all FewRel examples have metadata, while metadata is sparsely available for OpenEntity).

A.3 Metadata Implementation Details

We report the test score at the epoch with the highest validation score. For the results in Table 1, we evaluated the number of metadata tokens to insert, whether place the tokens directly following or at the end of the example, and whether to use blank noising on the metadata tokens. Metadata tokens are ranked by Algorithm 1.

We use up to 20 metadata categories per subject and object on FewRel, up to 25 metadata categories per subject on OpenEntity, and up to 5 metadata categories per subject and object on TACRED. Note that categories (e.g., "United States federal executive department") can include multiple tokens, selecting these maximum values by grid search. For FewRel and OpenEntity, we insert metadata tokens directly after the corresponding entity mention, and for TACRED, we inserted all metadata at the end of the example. For OpenEntity we randomly mask 10% of metadata tokens at training time as implicit regularization, and for relation extraction, we use no blank noising. The impact of position and blank noising are further discussed in Appendix B.3.

A.4 Baseline Implementations

We produce numbers for key baselines which do not report for the benchmarks we consider, using provided code.[8] [9]

- We produce numbers for KnowBERT-Wiki on TACRED-Revisited using a learning rate of $3e-5$, $\beta_2 = 0.98$, and choosing the best score for epochs $\in$ 1, **2**, 3, 4 and the remaining provided configurations.
- We produce numbers for ERNIE on TACRED-Revisited using the provided training script and configurations they use for the original TACRED task.

B Additional Experiments

B.1 Task Agnostic Metadata Effects

In Table 4 we report the same experiment conducted in Section 4.1, for all benchmark tasks considered in this work. Each point represents the median test score over 3 random seeds.

B.2 Metadata Noise

Noisier metadata appear to provide implicit regularization. Noise arises from varied word choice and order, as found in entity descriptions, or blank noising (i.e. random token deletion).

Here we provide initial empirical results.

Blank noising (Xie et al., 2017) by randomly masking 10% of inserted metadata tokens during training leads to a consistent boost on OpenEntity: 0.1 ("High Rank"), 0.5 ("Popular"), 0.5 ("Low Rank") F1 points higher than the respective scores from Table 2 over the same 3 random seeds. We observe no consistent benefit from masking on FewRel. Since metadata are sparsely available for OpenEntity examples, we hypothesize that blank noising of the category tokens can prevent over-reliance on the signal. Future work could investigate advanced masking strategies, for example masking discriminative words in the training data.

Descriptions use varied word choice and order vs. category metadata.[10] To study whether shaping with description versus category tokens lead the model to rely more on metadata tokens, we consider two shaping schemes that use 10 metadata tokens: 10 category tokens and 5 category, 5 description, where the categories are randomly selected. We observe both give the ~same score

---

[8] `https://github.com/allenai/kb`

[9] `https://github.com/thunlp/ERNIE`

[10] Over FewRel training data: on average a word in the set of descriptions appears 8 times vs. 18 times for words in the set of categories, and the description set contains 3.3x the number of unique words vs. set of categories.

Benchmark	R^2
FewRel	0.985
TACRED	0.782*
OpenEntity	0.956

Table 4: Correlation (R^2) between test F1 of $\hat{p}_\phi$ (no additional pretraining) vs. perplexity of the independent model $\hat{p}_\theta$ (w/ additional pretraining) for three tasks, using the procedure described in Figure 2. *Without one outlier corresponding to shaping with all random tokens ($R^2 = 0.02$ with this point).

on FewRel, 89.8 F1 and 89.5 F1, and use models trained with these two schemes to evaluate on test data where 10% of metadata tokens per example are randomly removed. Performance drops by 1.4 F1 for the former and 1.0 F1 for the latter.

B.3 Implementation Choices

We also analyze the degree of sensitivity of metadata shaping to how the metadata are inserted in examples (e.g., special tokens, the number of metadata tokens, and position).

Boundary Tokens *Designating the boundary between original tokens in the example and inserted metadata tokens improves model performance.*

Inserting boundary tokens (e.g., "#") in the example, at the start and end of a span of inserted metadata, consistently provides a boost across the tasks. Comparing performance with metadata and boundary tokens to performance with metadata and no boundary tokens, we observe a 0.7 F1 (FewRel), 1.4 F1 (OpenEntity) boost in our main results. We use boundary tokens for all results in this work.

Task Structure Tokens designate relevant entities in the examples (e.g., "[START_SUBJECT]" and "[END_SUBJECT]"). With no other shaping, inserting these tokens provides a 26.3 (FewRel), 24.7 (OpenEntity) F1 point boost vs. training the BERT model without task structure tokens. These tokens are already commonly used.

Token Insertion *We observe low sensitivity to increasing the context length and to token placement (i.e., inserting metadata directly-following the entity-span vs at the end of the sentence).*

We evaluate performance a the maximum number of inserted tokens per entity, n, increases. [11] We insert metadata tokens in a random order (to control for the effect of different metadata having different levels of class-discriminativeness) and observe that for FewRel, $n \in \{1, 5, 10, 20\}$ gives $\{85.4, 86.4, 87.6, 88.5\}$ test F1. On OpenEntity, $n \in \{1, 5, 10, 20, 40\}$ gives $\{74.9, 75.7, 74.8, 74.5, 75.8\}$ test F1. Overall performance changes gracefully with n and we observe low sensitivity to longer contexts.

The benefit of inserting metadata directly-following the entity span vs at the end of the example differed across tasks (e.g., for TACRED, placement at the end performs better, for the other tasks, placement directly-following performs better), though the observed difference was small. In Section 4, tokens are inserted directly-following the relevant entity span for all tasks.

---

[11] Per subject and object entity for FewRel, and per main entity for OpenEntity. I.e., $n = 10$ for FewRel yields a maximum of 20 total inserted tokens for the example.

Enhancing Natural Language Representation with Large-Scale Out-of-Domain Commonsense

Wanyun Cui, Xingran Chen
Shanghai University of Finance and Economics
`cui.wanyun@sufe.edu.cn, xingran.chen.sufe@gmail.com`

Abstract

We study how to enhance text representation via textual commonsense. We point out that commonsense has the nature of domain discrepancy. Namely, commonsense has different data formats and is domain-independent from the downstream task. This nature brings challenges to introducing commonsense in general text understanding tasks. A typical method of introducing textual knowledge is continuing pre-training over the commonsense corpus. However, it will cause catastrophic forgetting to the downstream task due to the domain discrepancy. In addition, previous methods of directly using textual descriptions as extra input information cannot apply to large-scale commonsense.

In this paper, we propose to use large-scale out-of-domain commonsense to enhance text representation. In order to effectively incorporate the commonsense, we proposed OK-Transformer (Out-of-domain Knowledge enhanced Transformer). OK-Transformer effectively integrates commonsense descriptions and enhances them to the target text representation. In addition, OK-Transformer can adapt to the Transformer-based language models (e.g. BERT, RoBERTa) for free, without pre-training on large-scale unsupervised corpora. We have verified the effectiveness of OK-Transformer in multiple applications such as commonsense reasoning, general text classification, and low-resource commonsense settings. [1]

1 Introduction

Although unsupervised language models have achieved big success on many tasks (Devlin et al., 2019), they are incapable of learning low-frequency knowledge. For example, in the masked language model task in Fig. 1, even if we replace "Kevin was" (left) with "Jim was" (right), BERT (Devlin et al., 2019) still predicts the masked word as sick, crying, dying, etc. This is because similar texts in its training corpus rarely describe the subject of "comforted". To improve the model's ability to generalize and understand low-frequency knowledge, we propose to incorporate commonsense into language models. In Fig. 1, to make correct predictions, we need to enhance the language model with the commonsense c_1.

However, commonsense has the nature of *domain discrepancy*. The downstream task and the commonsense knowledge have distribution discrepancies. Taking the commonsense knowledge base we use (i.e. ATOMIC2020 (Hwang et al., 2020)) as an example, the distribution discrepancy is specifically manifested in (1) their data formats. The format of a commonsense description usually belongs to some specific patterns (e.g. "... As a result ...", "... Because ..."), while the downstream tasks can have arbitrary patterns. (2) The commonsense belongs to the domain of event causality, while the downstream tasks may belong to arbitrary domains.

Here we highlight the challenges caused by the domain discrepancy. To introduce external textual knowledge to a pre-trained language model, a common practice is to continue pre-training the language model on the corpus of the external knowledge (Gururangan et al., 2020; Sun et al., 2019). However, the study (Gururangan et al., 2020) also found that continuing pre-training requires external knowledge and downstream tasks to have similar domains. Due to its domain discrepancy, introducing commonsense through continuing pre-training will cause catastrophic forgetting to downstream tasks, thereby injuring the effectiveness. We have verified this empirically in Sec 6.3. Therefore, the domain discrepancy prevents us from introducing commonsense by continuing pre-training.

To enhance the representation of the target text with external commonsense, we propose to directly use its candidate commonsense as an extra input.

---

[1] The code is available in `https://github.com/chenxran/ok-transformer`

Findings of the Association for Computational Linguistics: ACL 2022, pages 1746 - 1756
May 22-27, 2022

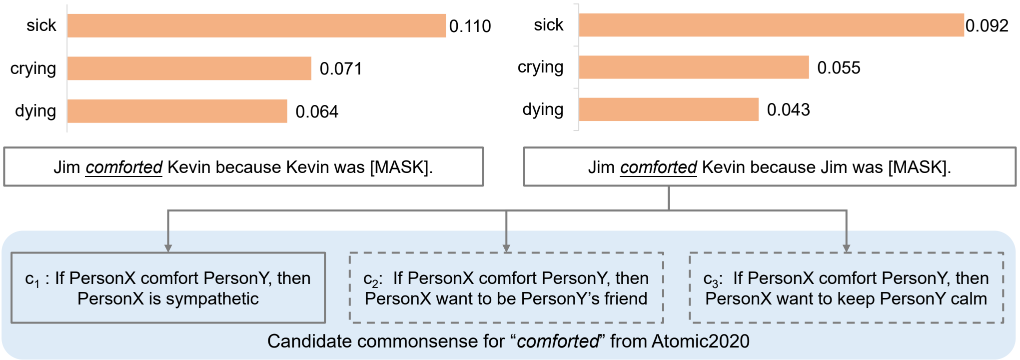

Figure 1: The prediction of [MASK] by BERT. BERT cannot distinguish between *Jim* and *Kevin* in *Jim comforted Kevin because*.

Our setup is different from a typical natural language understanding setup since the latter one only takes the target text as the input (Devlin et al., 2019). We argue that our setup – where the commonsense is introduced explicitly as input – is a more practicable setup to introduce out-of-domain commonsense that cannot be learned through pre-training. As far as we know, ExpBERT (Murty et al., 2020) is the closest setup to us. It also uses external knowledge (manually constructed templates) as the input.

Another challenge is the **scale** of the commonsense. Although ExpBERT also allows extra textual commonsense as input, it only captures small-scale commonsense with a fixed size. In addition, when we introduce commonsense from a large-scale knowledge base for general purpose (i.e. ATOMIC2020), unrelated commonsense (e.g. c_2 and c_3 in Fig. 1) will certainly occur. However, ExpBERT lacks the ability to distinguish related and unrelated commonsense. Therefore, the power of large-scale commonsense knowledge was restricted in ExpBERT. We will verify this empirically in Sec 6.3.

In order to incorporate the large-scale out-of-domain commonsense, we propose the OK-Transformer (Out-of-domain Knowledge enhanced Transformer) on the basis of Transformer (Vaswani et al., 2017). OK-Transformer has two modules. The knowledge enhancement module is used to encode the target text with commonsense, and the knowledge integration module is used to encode and integrate all candidate commonsense. OK-Transformer has two advantages. First, it fully represents the contextual information of the textual commonsense. Second, it can be adapted to existing pre-trained language models (e.g. BERT and RoBERTa) for free. That is, we are able to adapt OK-Transformer to the pre-trained language models, without pre-training OK-Transformer over large-scale unsupervised corpora from scratch.

Some other methods are related to our work, such as introducing *structured* knowledge (Peters et al., 2019; Zhang et al., 2019; Guan et al., 2020; Zhou et al., 2018) and *plain text* knowledge (Guu et al., 2020) in language models. These methods do not represent the specific inductive bias of commonsense knowledge and therefore are not suitable to introduce commonsense. We will compare these studies with more details in Sec 2.

2 Related work

In this section, we compare different ways to introduce knowledge into language models. We divide the knowledge introduction methods into (1) continuing pre-training method (Gururangan et al., 2020; Sun et al., 2019) and (2) explicit introduction in the downstream task (Guu et al., 2020; Murty et al., 2020).

Continuing pre-training the language model is effective when the external knowledge is similar to the downstream task (Gururangan et al., 2020; Sun et al., 2019). However, commonsense and downstream tasks have domain discrepancies, so continuing pre-training is unsuitable for introducing commonsense. We have empirically verified this in Sec 6.3.

Introducing explicit knowledge in downstream tasks We classify the knowledge into structured knowledge, plain text, and semi-structured knowledge, depending on its form. The entries of **structured knowledge** are represented as individual embeddings (Peters et al., 2019; Zhang et al., 2019; Guan et al., 2020; Zhou et al., 2018), while commonsense descriptions in this paper can be represented more accurately by the contextual information of their word sequences.

3 Problem Setup: Commonsense as the Extra Input

We consider a text classification task where the text x and its label y are provided for training. Assuming that the candidate commonsense descriptions for enhancing x come from a large-scale commonsense knowledge base (i.e. ATOMIC2020), we retrieve candidate commonsense for x as the extra input. We denote the commonsense descriptions for x as $cs(x) = \{c_1 \cdots c_n\}$, where each c_i is a commonsense description. The retrieval process will be shown in Sec 6. The model takes both x and $cs(x)$ as the input. Since ATOMIC2020 contains if-then knowledge for general purposes, the problem setup can be expanded to a broad range of text understanding tasks. The goal of training is to find parameter θ that minimizes the loss of training examples given the texts and candidate commonsense descriptions:

$$\arg\min_{\theta} \mathbb{E}_{(\mathrm{x},\mathrm{y})\in \mathrm{train}} \mathcal{L}(\mathrm{f}(\mathrm{x}, \mathrm{cs}(\mathrm{x})|\theta), \mathrm{y}) \tag{1}$$

where $\mathrm{f}(\cdot|\theta)$ is the model taking x and $cs(x)$ as inputs, $\mathcal{L}$ is the loss function.

4 OK-Transformer

In this section, we propose OK-Transformer based on Transformer to introduce extra commonsense descriptions. We first show OK-Transformer on an abstract level in Sec 4.1. Then we elaborate two modules within it, i.e. knowledge enhancement and knowledge integration, in Sec 4.2 and Sec 4.3, respectively.

4.1 Framework

In this subsection, we show how our OK-Transformer works at an abstract level. For the target sentence x, OK-Transformer takes both x and $cs(x)$ as inputs. To incorporate all the information of x and $cs(x)$, the OK-Transformer contains three vanilla Transformers, denoted by $\mathrm{Transformer}^{(1)(2)(3)}$. The knowledge enhancement module uses $\mathrm{Transformer}^{(1)}$ to encode the target text. Compared with the vanilla Transformer, $\mathrm{Transformer}^{(1)}$ leverages a new knowledge token to represent the commonsense that interacts with other words. The knowledge integration module encodes each individual commonsense description by $\mathrm{Transformer}^{(2)}$, and then integrates all candidate commonsense descriptions by $\mathrm{Transformer}^{(3)}$. This is shown in Fig. 2.

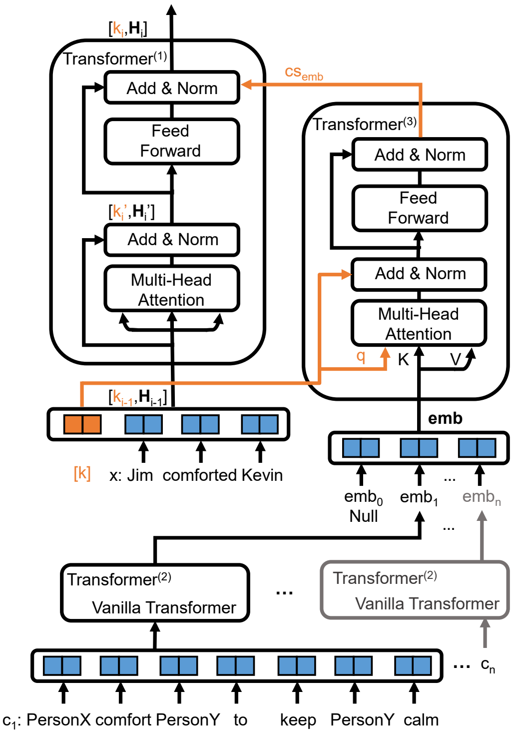

Figure 2: OK-Transformer. $\mathrm{Transformer}^{(1)}$ encodes the target text x with enhanced commonsense k_i. $\mathrm{Transformer}^{(2)}$ encodes each individual commonsense description. $\mathrm{Transformer}^{(3)}$ integrates all candidate commonsense descriptions and transfers knowledge to $\mathrm{Transformer}^{(1)}$.

4.2 Knowledge Enhancement Module

The knowledge enhancement module allows commonsense knowledge to enhance the representation of the target text.

Interaction between words and commonsense. We use $\mathrm{Transformer}^{(1)}$ to represent the interaction between words of the target text x. In addition, we introduce a special token $[k]$ to represent the commonsense knowledge. We denote it as the knowledge token. $\mathrm{Transformer}^{(1)}$ encodes all words and the knowledge token together via multi-head attention. Formally, given word sequence $\mathrm{x} = \mathrm{w}_1, \cdots, \mathrm{w}_\mathrm{n}$, $\mathrm{Transformer}^{(1)}$ accepts a sequence of $n+1$ word-piece tokens: $[\mathrm{k}], \mathrm{w}_1, \cdots \mathrm{w}_\mathrm{n}$. We denote the knowledge embedding and word embeddings produced by the i-th layer of $\mathrm{Transformer}^{(1)}$ as $k_i \in \mathbb{R}^d$ and $\mathbf{H_i} \in \mathbb{R}^{\mathbf{n}\times\mathbf{d}}$, respectively. The $\mathrm{Transformer}^{(1)}$ block first uses a multi-head self-attention layer followed by a residual connection and a layer normalization to model their interactions:

$$\begin{aligned}&\mathrm{k}_\mathrm{i}', \mathbf{H}_\mathrm{i}' = \mathrm{LayerNorm}([\mathrm{k}_{\mathrm{i}-1}, \mathbf{H}_{\mathrm{i}-1}] + \\ &\mathrm{MultiHeadAttn}([\mathrm{k}_{\mathrm{i}-1}, \mathbf{H}_{\mathrm{i}-1}], [\mathrm{k}_{\mathrm{i}-1}, \mathbf{H}_{\mathrm{i}-1}], [\mathrm{k}_{\mathrm{i}-1}, \mathbf{H}_{\mathrm{i}-1}]))\end{aligned} \tag{2}$$

where $[\mathrm{k_{i-1}}, \mathbf{H}_{\mathrm{i-1}}] \in \mathbb{R}^{(\mathrm{n}+1)\times \mathrm{d}}$ means appending k_{i-1} at the front of $\mathbf{H}_{i-1}$. $[\mathrm{k_{i-1}}, \mathbf{H}_{\mathrm{i-1}}]$ is used as the query, key, and value in the multi-head attention.

Knowledge update The vanilla Transformer projects $\mathrm{k'_i}$, $\mathbf{H}'_\mathrm{i}$ in Eq. (2) to the output space with a multi-layer perceptron neural network (MLP). Compared to the vanilla Transformer, we use an extra update operation to update the knowledge token by the integrated commonsense knowledge after the MLP. As in the vanilla Transformer, the update layer is followed by a residual connection and a layer normalization. This can be formulated by:

$$\begin{aligned} \mathrm{k_i} &= \mathrm{LayerNorm}(\mathrm{k'_i} + \mathrm{MLP}(\mathrm{k'_i}) + \mathrm{cs_{emb}}) \\ \mathbf{H}_\mathrm{i} &= \mathrm{LayerNorm}(\mathbf{H}'_\mathrm{i} + \mathrm{MLP}(\mathbf{H}'_\mathrm{i})) \end{aligned} \tag{3}$$

where cs_{emb} is the embedding of the commonsense computed by the knowledge integration module in Sec 4.3.

4.3 Knowledge Integration Module

The knowledge integration module encodes all candidate commonsense descriptions and integrates them. We first use $\mathrm{Transformer}^{(2)}$ to represent each candidate commonsense description. Then, we use $\mathrm{Transformer}^{(3)}$ to integrate all candidate commonsense, and transfer the integrated knowledge to the knowledge enhancement module.

Representing single commonsense We use a vanilla Transformer as $\mathrm{Transformer}^{(2)}$ to model each candidate commonsense description. For all the retrieved commonsense $cs(x) = \{c_1, \cdots, c_n\}$, we compute the embedding emb_j of each commonsense description c_j by:

$$\mathrm{emb_j} = \mathrm{Transformer}^{(2)}(\mathrm{c_j}) \tag{4}$$

Knowledge integration We integrate all candidate commonsense by $\mathrm{Transformer}^{(3)}$. Since not all the candidate commonsense leads to high confidence prediction as we have discussed in Sec 1, we need to select relevant commonsense and ignore irrelevant commonsense. Transformer is adequate to conduct this selection. Specifically, in the query-key-value mechanism in Transformer, we use the embedding of the knowledge token in $\mathrm{Transformer}^{(1)}$ as the query of $\mathrm{Transformer}^{(3)}$. and the commonsense embeddings by $\mathrm{Transformer}^{(2)}$ as keys and values of $\mathrm{Transformer}^{(3)}$. Then, we integrate representations of all different commonsense descriptions based on their similarities with the knowledge token.

$\mathrm{Transformer}^{(3)}$ also uses multi-head attention to allow the knowledge token to interact with the candidate commonsense in multiple ways. The output of multi-head self-attention is followed by a residual connection and a layer normalization.

$$\begin{aligned} \mathrm{cs_{emb}} =& \mathrm{LayerNorm}(\mathrm{k_{i-1}} \\ & + \mathrm{MultiHeadAttn}(\mathrm{k_{i-1}}, \mathbf{emb}, \mathbf{emb})) \end{aligned} \tag{5}$$

where $\mathbf{emb} = [\mathrm{emb_1}, \cdots, \mathrm{emb_n}]$ denotes the sequence of embeddings of all candidate commonsense descriptions. We then apply a residual connection and a layer normalization to it.

Null Commonsense Some target texts may not have valid commonsense from ATOMIC2020 to enhance their representations. Therefore, we refer to the settings of REALM (Guu et al., 2020) to add a null commonsense into the candidate commonsense of all target texts. We denote the null commonsense as c_0. Matching to the null commonsense indicates that the commonsense knowledge base cannot help enhance the target text.

5 Adaptation to Pre-trained Language Models

In this section, we take BERT as an example to illustrate how we adapt OK-Transfomer to existing pre-trained language models. We denote the adapted model as OK-BERT. An important manifestation of the effectiveness of the Transformer structure is its applications in large-scale pre-trained models (e.g. BERT, RoBERTa). In order to introduce external knowledge, many other studies conduct training over large-scale unsupervised corpus (Peters et al., 2019; Xiong et al., 2019). However, OK-Transformer is able to directly adapt to the existing pre-trained language models for free. In other words, when adapting OK-Transformer to OK-BERT, we directly use the parameters of each Transformer layer of BERT to initialize the OK-Transformer layers of OK-BERT. This property greatly improves the applicability of OK-BERT. In the rest of this section, we will describe how $\mathrm{Transformer}^{(1)}$, $\mathrm{Transformer}^{(2)}$, and $\mathrm{Transformer}^{(3)}$ are adapted respectively in Sec 5.1, and how to fine-tune OK-BERT in Sec 5.2.

5.1 Layer-by-Layer Adaptation

The OK-BERT we designed uses two original BERTs to serve as $\mathrm{Transformer}^{(1)}$ and $\mathrm{Transformer}^{(2)}$, respectively. We denote them as BERT1 and BERT2. We connect the

Transformer$^{(1)}$ and Transformer$^{(2)}$ in the corresponding layer of each BERT by Transformer$^{(3)}$. Therefore, OK-BERT makes full use of the multi-layer structure of BERT, while allowing commonsense in the knowledge token to fully interact with the target text in each layer. The architecture is shown in Fig. 3.

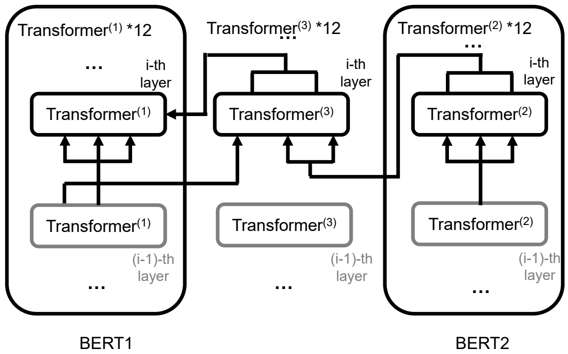

Figure 3: The architecture of OK-BERT. We only draw edges that connect to the i-th layer.

Transformer$^{(1)}$ We adapt the Transformer of BERT1 to Transformer$^{(1)}$ in the knowledge enhancement module of OK-Transformer. Note that the original BERT's tokens are [CLS] $\mathrm{w}_1 \cdots \mathrm{w}_\mathrm{L}$ [SEP] (for a single sentence) or [CLS] $\mathrm{w}_1 \cdots \mathrm{w}_\mathrm{m}$ [SEP] $\mathrm{w}_{\mathrm{m}+1} \cdots \mathrm{w}_\mathrm{L}$ [SEP] (for a sentence pair). We follow (Wang et al., 2020) and use a special token $[k]$ as the knowledge token. When tokenizing sentences, we insert the $[k]$ token after the $[CLS]$ token for each given text. In this way, the input tokens become [CLS] [k] $\mathrm{w}_1 \cdots \mathrm{w}_\mathrm{L}$ [SEP] or [CLS] [k] $\mathrm{w}_1 \cdots \mathrm{w}_\mathrm{m}$ [SEP] $\mathrm{w}_{\mathrm{m}+1} \cdots \mathrm{w}_\mathrm{L}$ [SEP] , respectively. This simple modification allows us to use $[k]$ as the knowledge token in the knowledge enhancement module.

Transformer$^{(2)}$ We adapt each Transformer layer of BERT2 to the Transformer$^{(2)}$ layer. The adaptation is straightforward since Transformer$^{(2)}$ uses the vanilla Transformer structure. We use the encoding of the $[CLS]$ token in each corresponding layer as the commonsense representation emb_j to enhance the representation of the corresponding layer in BERT1.

Transformer$^{(3)}$ For each pair of corresponding Transformer$^{(1)}$ and Transformer$^{(2)}$ from the same layer, we use one Transformer$^{(3)}$ to connect them to transfer the information from BERT2 to BERT1.

In summary, when adapting to BERT-base with 12 Transformer layers, OK-BERT contains 12 Transformer$^{(1)}$ layers for BERT1, 12 Transformer$^{(2)}$ layers for BERT2, and 12 Transformer$^{(3)}$ layers for layer-wise knowledge integration.

5.2 Parameter Initialization and Model Training

In our implementation, BERT1 and BERT2 have independent parameters. We use the parameters of BERT to initialize both BERT1 and BERT2. The parameters of Transformer$^{(3)}$ layers are randomly initialized. For downstream tasks, we then fine-tune all the parameters in the fashion of end2end.

6 Experiments

We evaluate the effectiveness of our proposed models in three scenarios: cloze-style commonsense reasoning, text classification, and low-resource commonsense settings. All the experiments run over a computer with 4 Nvidia Tesla V100 GPUs.

Models We consider adapting OK-Transformer to BERT and RoBERTa, which are denoted as OK-BERT and OK-RoBERTa, respectively. We use the BERT-base and RoBERTa-large from the HuggingFace Transformer library (Wolf et al., 2020).

Implementation details for candidate knowledge retrieval For a given text x, we retrieve candidate commonsense from ATOMIC2020. We use the if-then descriptions in ATOMIC2020 (e.g. Fig. 1). Since these descriptions cover 173k different verb phrases – one of the fundamental elements of language – the retrieval is applicable to a broad range of downstream text understanding tasks.

We use a simple retrieval method. We simply consider word segments with window size 5 of the input text x. All the commonsense descriptions matching one of these text segments will be regarded as the candidate commonsense descriptions $c_i \in cs(x)$.

6.1 Commonsense Reasoning

6.1.1 Setup

Datasets We consider the following commonsense reasoning benchmarks: WSC273 (Levesque et al., 2012), PDP (Morgenstern et al., 2016), Winogender (Rudinger et al., 2018), WinoGrande (Sakaguchi et al., 2019), CommonsenseQA (Talmor et al., 2019) and PhysicalQA (Bisk et al., 2020).

Model details Due to the different implementations between (Kocijan et al., 2019b) and (Sakaguchi et al., 2019), in this paper, we also follow their settings to compare with them, respectively. For (Kocijan et al., 2019b), we conduct disambiguation tasks directly through masked language modeling in OK-BERT. For the latter one, we convert cloze-style problems to multiple-choice classification problems in OK-RoBERTa. In particular, we replace the target pronoun of one query sentence with each candidate reference, then put the new sentences into the language model. We use a single linear layer and a softmax layer over the encoding of its $[CLS]$ token to compute the probability of each new sentence, and select the one with the highest probability as the pronoun disambiguation result.

Hyperparameters of pre-training We follow (Kocijan et al., 2019b; Sakaguchi et al., 2019) to first pre-train models for 30 and 3 epochs over WSCR (Kocijan et al., 2019b) or WinoGrande (Sakaguchi et al., 2019), respectively. Then we fine-tune models over specific tasks. We use AdamW as the optimizer with learning rate 5e-6, which is selected from $\{2e-5, 1e-5, 5e-6\}$. We set the batch size to 8.

Model	WSC	PDP
KEE(Liu et al., 2016)	52.8	58.3
WKH (Emami et al., 2018)	57.1	-
MAS (Klein and Nabi, 2019)	60.3	68.3

6.1.2 Results

We compare our models with state-of-the-art commonsense reasoning models in Table 1, 2, and 3. It can be seen that our models outperform other models in most settings. This verifies the effectiveness of our proposed models for commonsense reasoning.

Model	CommonsenseQA	PhysicalQA
BERT	55.86	68.71
OK-BERT	**56.27**	**69.09**
RoBERTa	73.55	79.76
OK-RoBERTa	**75.92**	**80.09**

Table 3: Results on CommonsenseQA and PhysicalQA.

Ablations In Table 1, 2, and 3 we also compare OK-BERT with BERT. We found that OK-BERT with OK-Transformers effectively improved the accuracy of BERT with Transformers. Similar results can be found between OK-RoBERTa and RoBERTa. This shows that the proposed OK-Transformer improves pre-trained language models by adapting to them for free, i.e. without retraining on large-scale unsupervised corpora.

6.2 General Text Classification

We use MRPC, CoLA, RTE, STS-B, SST-2, and QNLI in the GLUE dataset (Wang et al., 2018) to verify the effectiveness of the proposed models on general text classification tasks. We did not evaluate over MNLI, because our model needs to represent the corresponding n commonsense for each sentence, which is too costly for MNLI. We believe that this efficiency problem can be solved by further applying model compression (Iandola et al., 2020), but this is beyond the scope of this paper. It can be seen from Table 4 that OK-BERT and OK-RoBERTa outperform their baselines.

6.3 Commonsense Introduction Methods

Continue pre-train In the introduction section, we mentioned that a typical method of introducing textual knowledge is continuing pre-training (Gururangan et al., 2020; Sun et al., 2019). However, due to the domain discrepancy of commonsense, this method will cause catastrophic forgetting. To verify this intuition, in this subsection we compare with the continuing pre-trained model. We first continue pre-training the language model over ATOMIC2020, then fine-tune it over the target task.

ExpBERT (Murty et al., 2020) We also compare our OK-Transformer with ExpBERT, another model that is able to introduce textual knowledge. In Sec 1, we mentioned that ExpBERT is not appli-

GLUE Task	MRPC	CoLA	RTE	QNLI	STS-B	SST-2
BERT	86.27/90.21	**59.50**	71.43	91.20	89.35/88.93	91.97
OK-BERT	**87.25/90.84**	58.29	**73.65**	**91.58**	**89.82/89.46**	**93.69**
RoBERTa	90.44/93.15	66.57	84.11	94.00	91.83/91.95	95.70
OK-RoBERTa	**91.91/94.24**	**66.89**	**86.28**	**94.41**	**92.41/92.20**	**96.10**

Table 4: Results on text classification tasks. Models are evaluated by the dev split from GLUE.

cable to large-scale commonsense knowledge bases for its disability to select related commonsense and ignore unrelated commonsense. To verify this, we use the retrieved candidate commonsense descriptions from ATOMIC2020 as the additional explanations for ExpBERT. ExpBERT concatenates all the embedding of a fixed number of commonsense, which is inflexible for ATOMIC2020. For this reason, we fix the number of commonsense to 48. If there are more than 48 candidate commonsense descriptions for one sample, we will randomly select 48 of them. Otherwise, we will pad null commonsense to it. In our experiments, we also apply ExpBERT to RoBERTa (Liu et al., 2019) (i.e. ExpRoBERTa).

We show the results in Table 5. We do not report the results of ExpBERT on WSC273, as ExpBERT cannot solve the cloze-style problems. It can be seen that the performance of language models was suffered when we simply continue pre-training the models on the commonsense knowledge base. This verifies that the continuing pre-training on the out-of-domain commonsense will cause catastrophic forgetting and injure the effectiveness. On the other hand, using OK-Transformer to introduce commonsense as the extra input significantly improves the accuracy. The results also suggest that ExpBERT is not applicable to large-scale commonsense knowledge bases.

6.4 Why is OK-Transformer effective?

We now analyze why OK-Transformer can effectively introduce out-of-domain commonsense without pre-training. We are inspired by an observation of language model fine-tuning LMs (Radiya-Dixit and Wang, 2020), i.e., the parameters after fine-tuning are close to those before fine-tuning. Therefore, we argue that the key to effective introduction is whether the parameters of the meta LM is good initialization for the commonsense-enhanced LM, that the parameters do not change much before and after fine-tuning.

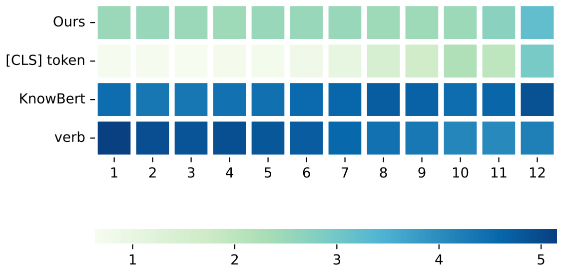

Figure 4: L_1 distances in parameter space between pre-trained and fine-tuned meta LMs. We show the metrics of W_I across the 12 Transformer layers.

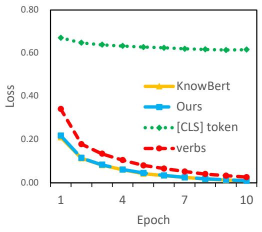

Figure 5: Losses of different knowledge integration methods in SST-2. The [CLS] token method does not converge.

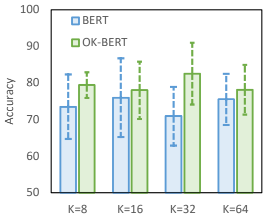

Figure 6: Effect in low-resource commonsense settings with different ks over SST-2.

To verify this, we compare the parameter changes of different knowledge integration methods. These methods include (1) OK-Transformer, (2) KnowBERT (Peters et al., 2019), (3) using the original $[CLS]$ token instead of the proposed knowledge token, and (4) abandoning the knowledge token and instead calculating the cs_{emb} of each verb phrase of the target sentence separately, and adding them to these verb phrases' hidden states in $\mathbf{H}_{i-1}$. We follow (Radiya-Dixit and Wang, 2020) to use the $L1$ as the distance metric. (Radiya-Dixit and Wang, 2020) found that the main change in parameters occurs on the W_I matrix of the Transformer. Our experimental results also follow this phenomenon. Therefore, for greater clarity, we only show the distances of the W_I matrices after fine-tune. We show the distances of different methods in Fig. 4, and their training losses in Fig. 5.

	MRPC	CoLA	RTE	QNLI	STS-B	SST-2	WSC273
BERT	86.27/90.21	**59.50**	71.43	91.20	89.35/88.93	91.97	66.30
BERT-continue	83.58/88.81	54.70	62.09	90.24	87.41/87.46	91.74	63.00
ExpBERT	85.78/89.79	58.29	62.82	87.06	84.78/84.67	91.51	–
OK-BERT	**87.25/90.84**	58.29	**73.65**	**91.58**	**89.82/89.46**	**93.69**	**67.40**
RoBERTa	90.44/93.15	66.57	84.11	94.00	91.83/91.95	95.70	90.10
RoBERTa-continue	87.01/90.38	61.74	74.01	93.61	89.57/89.66	95.99	87.91
ExpRoBERTa	89.46/92.22	**66.90**	83.39	93.78	89.81/89.94	95.99	–
OK-RoBERTa	**91.91/94.24**	66.89	**86.28**	**94.41**	**92.41/92.20**	**96.10**	**91.58**

Table 5: Comparison of different commonsense introduction approaches. Continuing pre-training even injures the effectiveness. On the other hand, using OK-Transformers to introduce external knowledge achieves better results than using Transformer.

It can be seen that the distances of OK-Transformer are much smaller than other methods, except the [CLS] token method, which does not converge as shown in Fig. 5. This fits our intuition of reducing the parameter variations to introduce external knowledge more effectively.

6.5 Effect in Low-Resource Commonsense Settings

Since there is a large number of commonsense descriptions in ATOMIC2020, a large portion of descriptions only occur a few times in the training set. In this subsection, we want to verify for these rare descriptions, can the model still benefit from it? If so, we think it means that the model uses the contextual information of the commonsense to improve the understanding of the commonsense.

To do this, we proposed a low-resource commonsense setting. We evaluate the effect of the model if the training dataset only contains $k = 8/16/32/64$ samples. Therefore the frequency of the appeared commonsense descriptions is low. In order to exclude the influence of other samples, we only use test samples whose candidate commonsense descriptions have already occurred in the k training samples. For example, when $k = 8$, we randomly select 8 samples from the training set for training, and use all samples in the test set which contains the commonsense of the 8 training samples for evaluation. We show the results over the SST-2 dataset in Fig. 6. It can be seen that our models still benefit from low-frequency commonsense.

6.6 Does OK-Transformer Provide Interpretability?

In this subsection, we try to answer if the integration of candidate commonsense descriptions by OK-Transformer is interpretable. To answer this question, we calculate the influence of different commonsense descriptions on the model's predictions. We follow (Wu et al., 2020) to quantify the influence of a commonsense description c_i as: If c_i is removed from $cs(x)$, how much will the prediction change? This change is measured by the Euclidean distance between the prediction by $cs(x) - c_i$ and by $cs(x)$. The greater the change in the prediction, the greater the influence of this commonsense.

John promised Bill to leave, so an hour later [John] left.
PersonX promises PersonY. 1. ··· As a result, PersonX wants to fulfill his promise. 2. ··· PersonX is seen as truthful 3. ··· PersonX is seen as trustworthy. 4. ··· Before, PersonX needed to talk to PersonY. 5. ··· Before, PersonX needed to go to PersonY's house.

Table 6: A case study of top 5 commonsense descriptions.

Through the case studies of the samples in WSC273, we found that although commonsense with higher influence is somewhat interpretable for people, the interpretability is not significant. We show some examples in Table 6. We believe that this is because some commonsense for people has been learned in pre-training. Therefore, the out-of-domain commonsense that these pre-trained language models need to incorporate for downstream tasks is inconsistent with human understanding.

7 Conclusion

In this paper, we study how to use commonsense to enhance the general text representation. We first analyzed the challenges brought by the domain discrepancy of commonsense. Then, we propose OK-

Transformer to allow commonsense integration and enhancement. In the experiments, we verified the effectiveness of our proposed models in a variety of scenarios, including commonsense reasoning, general text classification, and low-resource commonsense. Our models consistently outperform the baselines. We have also empirically analyzed other properties (e.g. interpretability) of the model.

A Experimentation Details

When **continuing pre-training** BERT-continue/RoBERTa-continue in Table 5, we follow (Kocijan et al., 2019b) and set learning rate to $1e-5$, batch size to 64, and train the model for only one epoch.

When **fine-tuning** the models in Sec 6.2 and Sec 6.3, we train the models for 10 epochs. We use grid search to select their learning rates and batch sizes from $\{1e-5, 2e-5, 5e-5\}$ and $\{8, 16, 32, 64\}$, respectively.

Dataset	WSC	PDP	WinoGender	WinoGrande

Table 8: Statistical results on sentence classification datasets.

B Statistics of Commonsense Descriptions

In Table 7 and Table 8, we report statistics about down-stream tasks and their commonsense descriptions. Our report includes the size of the train/test splits for the downstream tasks, the proportion of samples that matched to at least one commonsense description (*Matched proportion*) in each task, the average number of matched commonsense descriptions per sample (*Average* $|cs(x)|$), and the average length of each matched commonsense description (*Average length of* c).

From the results, we found that more than half of the samples matched to at least one commonsense description in most of the datasets. This indicates that the OOD commonsense used in this paper is generalizable to different datasets. Also, the average length of the matched commonsense descriptions is short (about 17), thus encoding them via Transformer is efficient.

Weighted self Distillation for Chinese word segmentation

Abstract

Recent researches show that multi-criteria resources and n-gram features are beneficial to Chinese Word Segmentation (CWS). However, these methods rely heavily on such additional information mentioned above and focus less on the model itself. We thus propose a novel neural framework, named Weighted self Distillation for Chinese word segmentation (WeiDC). The framework, which only requires unigram features, adopts self-distillation technology with four hand-crafted weight modules and two teacher models configurations. Experiment results show that WeiDC can make use of character features to learn contextual knowledge and successfully achieve state-of-the-art or competitive performance in terms of strictly closed test settings on SIGHAN Bakeoff benchmark datasets. Moreover, further experiments and analyses also demonstrate the robustness of WeiDC. Source codes of this paper are available on Github[1].

1 Introduction

Chinese is written without explicit word delimiters, while numerous Natural Language Processing (NLP) applications are word-based. Moreover, CWS is always a fundamental and essential step for processing most language tasks.

Following the pace of many researchers (Sun and Xu, 2011; Chen et al., 2015; Ke et al., 2021), we also choose [B, I/M, E, S] tags (Beginning, Inside/Middle, End, Single character), which represent the precise position of a character in one word. Figure 1 gives a simple example.

Char:	我	喜	欢	大	自	然	。
Tag:	S	B	E	B	I	E	S

Figure 1: The [B, I, E, S] tagging scheme. "我喜欢大自然。" ("I love nature.")

Generally, a CWS task usually consists of three important parts: Embedding, Encoder and Decoder. Google published two papers, Mikolov et al. (2013a) and Mikolov et al. (2013b), and distributed representation has been widely used in NLP due to its low dimensions and efficiency in semantic similarity. Most researchers keep a close eye to the encoder part which includes Maximum Entropy (ME) (Berger et al., 1996), feed-forward neural network (Zheng et al., 2013), recursive neural network (Wang and Xu, 2017) , long-short-term memory (LSTM) (Chen et al., 2015), Pre-training of Deep Bidirectional Transformers such as BERT (Tian et al., 2020) and other models. As for the decoder part, in addition to softmax, Conditional Random Fields (CRF) (Lafferty et al., 2001) usually plays a vital role because it can use the rich contextual feature in the annotation process.

With the prevalence of pre-training and fine-tuning, transformer-based pre-trained models have dominated the field of CWS in recent years. Given sufficient training data, the pre-trained models (Nakkiran et al., 2020; Xu et al., 2020) have achieved remarkable results. However, these works may suffer from poor predicting accuracy when rare words or OOV (out-of-vocab) words exist. What's more, Huang and Zhao (2007) confirm that the loss of word segmentation accuracy, caused by OOV words, is at least 5 times greater than word segmentation ambiguity. We believe that improving the accuracy of the OOV words is worthy of further exploration.

Unlike traditional Knowledge Distillation (KD) methods, self distillation teaches a student network by itself instead of a separate teacher (Xu and Liu, 2019; Zhang et al., 2019) . Specifically, during one training epoch, the best student model or the student model from the last iteration will be saved as the teacher model for the next training epoch to teach the student itself.

Moreover, we believe that the student model

May 22-27, 2022 ©2022 Association for Computational Linguistics

should study knowledge selectively according to the importance of information, so it is a practical solution to add an weight matrix to the training process. Different from the temperature distillation technology proposed by Hinton et al. (2015), we subtly utilize the information gap between pseudo labels, predicted by the teacher model or student model, and real labels to obtain the hand-crafted weight matrix. From another perspective, the process of acquiring weight matrices can also be seen as a kind of communication between teachers and students. Finally, to more precisely demonstrate the impact of WeiDC, we will temporarily ignore all external information.

Our contributions are summarized below. We proposed WeiDC, which only requires unigram features and adopts self-distillation technology with four hand-crafted weight modules and two teacher models configurations. Considering there are few choices of weight measures, it is also a challenge to design a feasible method to obtain a rational weight value. We also performed various experiments, such as testing its robustness in some low-resource settings, and explored the efficiency of our framework by combining different encoders and decoders. Experimental results from four widely used benchmark datasets confirm that WeiDC can achieve state-of-the-art or competitive performance, especially in OOV recall.

2 Related Work

Xue and Converse (2002) first treat CWS as a sequence labeling task and use a maximum entropy tagger to train the data set. Xu (2003) shows a unique charm of the sequential labeling method in the CWS bakeoffs (Sproat and Emerson, 2003), especially its results on R$_{OOV}$ (Recall of Out Of Vocabulary). People thus turn their attention to the research of sequence labeling method (Peng et al., 2004; Zhao et al., 2006; Zhao and Kit, 2008). And Huang and Zhao (2007) conclude that treating the word segmentation process as a character labeling problem can balance the recognition of vocabulary words and unregistered words, because all words are realized through one unified character marking process. In general, our research is related to the following works.

Pre-trained Frameworks Transformer-based pre-trained models, such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) , and ZEN (Diao et al., 2020), have demonstrated excellent performance in CWS tasks. Qiu et al. (2020) propose one unified model for multi-criteria CWS by leveraging the powerful ability of the Transformer encoder. Huang et al. (2020) also use BERT to capture various annotation criteria among datasets. Ke et al. (2021) propose a CWS-specific pre-trained model METASEG. Tian et al. (2020) and Liu et al. (2021) consider the combination of lexicon features and BERT for CWS. Huang et al. (2021) propose a semi-supervised neural method based on RoBERTa encoder through pseudo labels.

Knowledge Distillation Hinton et al. (2015) first propose knowledge distillation, using a larger network to teach a smaller network. Tang et al. (2019) choose to distill knowledge from BERT, a state-of-the-art language representation model, into a simple heterogeneous model. Huang et al. (2020) also extract knowledge from BERT to a truncated (3 or 6 layers) BERT to balance computational cost and segmentation accuracy on CWS tasks. Jiao et al. (2020) adopt multiple distilling strategies to reduce the number of parameters of the pre-trained language models. Huang et al. (2021) collect massive unlabeled data and distill knowledge from the teacher model to the student model by generating pseudo labels. Zhang et al. (2019) put forward self-distillation, which has recently been used in computer vision, but not commonly used in NLP.

To summarize, for further improving word segmentation accuracy, many researchers make use of lexicon information (Tian et al., 2020; Liu et al., 2021), multi-criteria label data (Chen et al., 2017; Huang et al., 2020; Qiu et al., 2020; Ke et al., 2020) and even unlabeled data (Sun and Xu, 2011; Zhang et al., 2013; Huang et al., 2021).

3 The WeiDC Framework

Huang and Zhao (2007) point out that CWS is the first step of most Chinese information processing systems, which usually relies on the shallow information of the text content, such as character features, which is distinct from the idea, "understand first and then segment words". As shown in Figure 2, we adopted the traditional word segmentation scheme, but added self distillation and weight modules to the training phase.

3.1 The Sequential Part

The traditional word segmentation scheme consists of the Embedding layer, Encoder layer, and Decoder layer. Formally, x is always seen as all

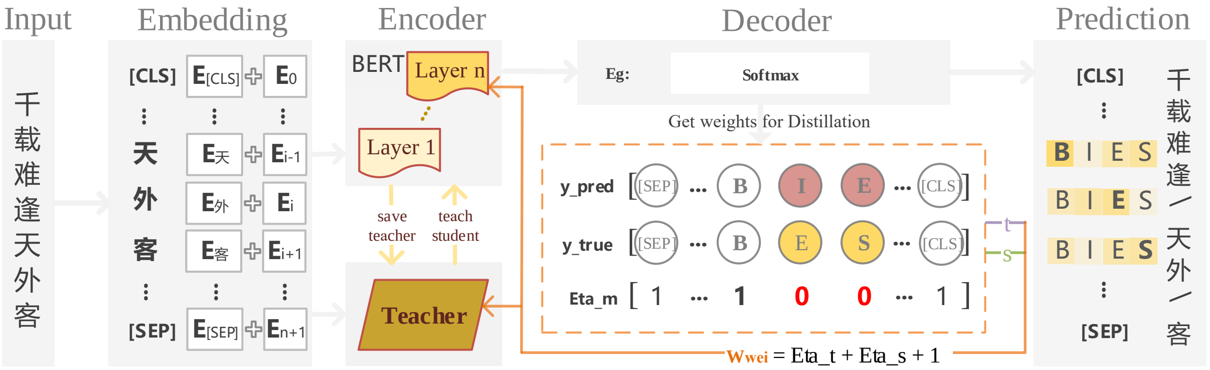

Figure 2: The WeiDC framework. The sentence, "千载难逢天外客" ("A once-in-a-lifetime visitor from outside the sky"), is from the MSR testing corpus. And it's difficult to split "天外客" ("A visitor from outside the sky").

marked data sequences and $x = [x_1, x_2, ..., x_n]$, and y is over corresponding label sequences and $y = [y_1, y_2, ..., y_n]$. We choose the BERT model to get character embeddings and encode these embeddings. After that, the encoder's outputs are fed into the decoder layer to obtain predicted tags.

Embedding layer We use BertTokenizer to obtain our input embeddings. Each character embedding consists of token embedding and position embedding. We don't need to consider the Next Sentence Prediction problem and remove token_type embedding. Additionally, to easily explore various weight mechanisms, WeiDC ignores unlabeled data or n-gram features.

Encoder layer Once obtaining character embeddings, they will be fed into an encoder, such as BERT or its derivative models. We choose `bert-base-chinese`[2] version and only need `config.json`, `pytorch_model.bin`, and `vocab.txt` to train linguistic data. Vaswani et al. (2017) give BERT, based on Transformer, an abundant description. We decide to omit its background description here. Furthermore, we also take RoBERTa[3] as our encoder to explore the impact of various pre-trained models on the CWS experiments.

Decoder layer Compared with Hidden Markov Models, Lafferty et al. (2001) present CRF for building probabilistic models to mark and segment the sequence data with weak independence assumptions.

$$p(y_i|x_i) = \frac{\exp(W_c \cdot z_i + b_c)}{\sum_{y_{i-1}y_i} \exp(W_c \cdot z_i + b_c)} \tag{1}$$

In addition, softmax is also a frequent decoder, which can efficiently convert logit to probability regardless of intrinsic correlation.

$$p(y_i|x_i) = \log \frac{\exp(z_i^d)}{\sum_d^{\mathcal{D}} \exp(z_i^d)} \tag{2}$$

where $z_i \in \mathbb{R}^{|\mathcal{D}|}$ is logits and z_i^d is the value at dimension d in z_i. $p(y_i|x_i)$ is the corresponding probability value. $W_c \in \mathbb{R}^{|\mathcal{D}|\times|\mathcal{D}|}$ and $b_c \in \mathbb{R}^{|\mathcal{D}|}$ are trainable parameters of CRF. $y_{i-1}y_i$ models the state from y_{i-1} to y_i.

We continue to operate on the probability $(p(y|x))$ to get the predicted label $(\hat{y})$.

$$\hat{y} = argmax\ p(y|x) \tag{3}$$

Through comparative experiments, Qiu et al. (2020) conclude that with or without CRF does not make much difference. Since CRF is more complex and the training cost is higher, we mainly try softmax to decode logits to make full use of computing resources.

3.2 Weight Mechanism

During one training epoch, the pseudo labels $(\hat{y})$ from t or s are compared with corresponding true labels (y), which can be expressed by formula 4. t and s indicate that $\hat{y}$ come from the teacher model or student model, respectively. η refers to the information difference between $\hat{y}$ and y.

$$\eta_m = |\hat{y}_m - y|, m = t, s \tag{4}$$

In the process of executing equation 4, we use absolute value operations. When one pseudo label is equal to the corresponding true label, we get 0, otherwise we get a positive number. Since the

---

[3] `https://github.com/brightmart/roberta_zh` (RoBERTa_zh_L12 PyTorch)

result is the opposite of what we want, we have to perform 5 and 6.

$$F(j) = \begin{cases} 0, & j = 0 \\ 1, & j \neq 0 \end{cases} \tag{5}$$

$F(j)$ converts all positive numbers to 1 and j is a variable symbol. Then, the intermediate value is processed by equation 6 to get the final result.

$$\eta_m = 1 - F(\eta_m) \tag{6}$$

We hope there will be enough communication between the teacher and student to obtain a reasonable weight value, so we designed equation 7. w^1_{wei} is the first type of weight vector.

$$w^1_{wei} = \eta_t + \eta_s + 1 \tag{7}$$

The meaning of equation 7 is very concise. During distillation, samples with higher accuracy are given more attention, while samples with lower accuracy are given less attention. Moreover, to avoid losing the basic information carried by each sample, we need to make sure that the minimum value of w^1_{wei} is 1, we thus add 1.

We also notice that η_t and η_s may contain various amounts of knowledge. Therefore, we multiply η_t or η_s by 2 to get equations 8 and 9, respectively. Certainly, other coefficients can also be selected according to actual needs.

$$w^2_{wei} = 2 \cdot \eta_t + \eta_s + 1 \tag{8}$$

$$w^3_{wei} = \eta_t + 2 \cdot \eta_s + 1 \tag{9}$$

From another perspective, if the teacher model is correct and the student model is wrong, this kind of knowledge should be more valuable. We thus get another calculation method, which is described in equation 10, to obtain the weight vector.

$$w^4_{wei} = 2 \cdot \eta_t - \eta_s + 2 \tag{10}$$

We must add 2 to ensure that the minimum value of w^4_{wei} is 1.

Finally, according to different weight modules, all possible values of a single character (marked as k) are shown in Table 1. The above four weight mechanisms show that different key factors affect the weight value. In other words, for the same pseudo label, different reference factors will lead to various weight values.

η_{t_k}	η_{s_k}	$w^1_{wei_k}$	$w^2_{wei_k}$	$w^3_{wei_k}$	$w^4_{wei_k}$
1	1	3	4	4	3
1	0	2	3	2	4
0	1	2	2	3	1
0	0	1	1	1	2

Table 1: All possible weight values of character k.

For example, if we consider that words with low frequency can better reflect the models' performance, we can increase their weights to penalize the loss of misclassifying these words. As a result, the student model will pay more attention to low-frequency words.

According to different distillation scenarios or learning needs, it is necessary to choose appropriate reference factors to design weight calculation methods. Here, we take the segmentation difficulty of words as a reference standard.

3.3 Distillation

Unlike self-training, self-distillation takes a fully supervised way to dig the potential of the model itself, requiring no auxiliary models or data. In this paper, the teacher model comes from two sources, either the student model from the last iteration (D_{last}) or the student model with the best historical performance (D_{best}) .

The student also learns from two sources of information, predicted probabilities from the teacher and one-hot ground-truth label. Hence, the final loss ($\mathcal{L}_{KD}$) consists of two parts, cross-entropy loss ($\mathcal{L}_{CE}$) and distillation loss ($\mathcal{L}_{Distill}$) :

$$\mathcal{L}_{KD} = (1 - \alpha) \cdot \mathcal{L}_{CE} + \alpha \cdot \mathcal{L}_{Distill} \tag{11}$$

To balance the above two losses, we need a coefficient α, which is also set to a fixed value during the training phase.

$\mathcal{L}_{CE}$ is to penalize the cross-entropy loss between the predicted label ($\hat{y}$) against the true label (y):

$$\mathcal{L}_{CE} = -\sum_{x} y \log \hat{y}_{(x)} \tag{12}$$

$\mathcal{L}_{Distill}$ is to reduce the mean-squared-error loss between the teacher's logits ($z^{(T)}$) and the student's logits ($z^{(S)}$), and w_{wei} can be any of the above four weight types.

$$\mathcal{L}_{Distill} = ||w_{wei} \cdot z^{(T)} - w_{wei} \cdot z^{(S)}||^2_2 \tag{13}$$

To better verify the effect of WeiDC, the temperature distillation technology is not considered here.

Dataset	MSR		PKU		AS		CITYU

Table 2: Corpus details of four CWS datasets

Distinct from previous studies on knowledge distillation, our framework adds the weight mechanism, allowing the teacher and the student to communicate fully to focus on more valuable knowledge. Furthermore, the teacher is not a static model but dynamically evolves as training proceeds. Hence, the weight vector will also alter as the teacher model changes so that the student model can learn richer knowledge.

4 Experiments

4.1 Dataset and Evaluation Metric

The second SIGHAN international Chinese word segmentation bakeoff (Emerson, 2005), which includes **MSR**, **PKU**, **AS** and **CITYU** datasets, is frequently used in CWS tasks. Since AS and CITYU are traditional Chinese characters, we convert these data into simplified ones by following previous studies (Chen et al., 2015; Qiu et al., 2020; Tian et al., 2020) . We will use these datasets in the following experiments and corpus details are listed in Table 2.

We also choose precision (P), recall (R), F-score, and R_{OOV}, which is the recall for out-of-vocabulary (OOV) words, to evaluate segmentation performance. Specifically, we first record the word information in the complete training corpus and then divide the corpus into a training set and validation set. Besides, we take no extra resources but only training corpus to train our model.

4.2 Baselines

According to whether to use a pre-trained model such as BERT as the encoder, we have selected two types of baselines, Non-pretrained Models and Pre-trained Models.

Non-pretrained Models Chen et al. (2017) propose adversarial multi-criteria learning for CWS tasks by exploiting the underlying shared knowledge across multiple heterogeneous criteria. Ma et al. (2018) also point out that using external knowledge can improve the CWS accuracy. Gong et al. (2019) provide a more flexible solution to transfer the learned information to new criteria. They all use the bidirectional LSTM encoder. Qiu et al. (2020) propose one unified model for multi-criteria CWS based on the Transformer encoder. Through the Gaussian-masked Directional (GD) Transformer, Duan and Zhao (2020) try to further strengthen the model itself to perfect CWS tasks.

Pre-trained Models Huang et al. (2020) propose a domain adaptive segmenter to exploit various open-domain knowledge. Tian et al. (2020) use key-value memory networks to incorporate wordhood information with BERT or ZEN as the encoder. Ke et al. (2021) put forward a CWS-specific pre-trained model to alleviate the discrepancy between pre-trained models and downstream CWS tasks. Nguyen et al. (2021) propose a span labeling approach to model n-gram features for word segmentation.

4.3 Training Details

All experiments are implemented on the hardware with Intel(R) Xeon(R) Gold 6240 CPU @ 2.60GHz and NVIDIA Tesla V100. Following previous works (Ma et al., 2018; Qiu et al., 2020), we randomly select 10% training data for development and only use its testing set at the end of the training phase. Similar to the previous work (Tian et al., 2020), we performed other preprocessing measures on all data sets.

During fine-tuning, we use Adam with the learning rate of 2e-5. Both train_batch_size and eval_batch_size are 16. As for the trade-off hyperparameter (α), we randomly select 1% of the training set to explore the influence of various α on WeiDC. We observe that when α is 0.3, WeiDC performs better.

Besides, we train all models up to 50 with some early stopping strategies, such as "patient epochs"

patient epochs	3	learning_rate	2e-5
train : eval	9 : 1	alpha (α)	0.3

Table 4: Hyper parameters of WeiDC.

We take [B, I, E, S] tagging scheme in our experiments. To explore the influence of diverse weight modules on CWS, we will only try BERT and RoBERTa as our encoder. As for BERT, we follow the default settings in their paper (Devlin et al., 2019). In addition to combining four weight modules and two types of teacher models, we also plan to conduct some exploratory experiments, such as testing the performance of WeiDC on a small amount of training data.

5 Results and Analysis

In this section, we firstly report the results of WeiDC and its comparison with the state-of-the-art works available. Then we explore the robustness of WeiDC through lots of experiments in different low-resource settings. We also analyze the impact of OOV words on the model. Finally, we perform various NER tasks to test WeiDC's effectiveness.

5.1 Main Results

Several observations are drawn from Table 3 and Table 5, where the overall F-score and OOV recall are all reported.

First, Table 3 demonstrates that pre-trained models, with lots of prior knowledge, perform better than non-pretrained models, especially in OOV recall. Compared with baselines listed in Table 3, the results in these experiments not only confirm that self distillation and weight mechanism are effective methods to benefit CWS without any auxiliary data or CWS-specific pre-trained models, but also fully illustrate that the design of WeiDC can enhance the model learning ability.

Second, as shown in Table 5, WeiDC achieved exciting results on R$_{OOV}$ with maintaining competitive performance on F-score. For instance, when we took BERT as our encoder, WeiDC improved the F-score by 0.16% on average, from 97.2% to 97.36%, and the R$_{OOV}$ score by 1.71% on average, from 83.64% to 85.35%.

Third, in most cases, D_{best} outperforms D_{last}, and we speculate that updating the teacher model too frequently will be detrimental to the learning process of the student model. Besides, different CWS tasks need various weight modules, so it is essential to choose reasonable weight mechanisms according to the characteristics of datasets.

Fourth, with BERT as the encoder and softmax as the decoder, our base model is powerful, but the improvement of WeiDC on R$_{OOV}$ scores is still very decent. Specifically, under the current

Table 6: Scores on PKU test set in low-resource settings.

experimental conditions (listed in table 4), w_{wei}^4 has the best overall performance on all data sets, while w_{wei}^3 has the worst performance.

Last, RoBERTa outperforms BERT when we deal with the CWS task. If CRF is used as the decoder, the CWS model seems to be more prone to overfitting, resulting in worse word segmentation.

5.2 Low-Resource Settings

In real life, the training corpus is usually insufficient, and it is valuable to measure the performance of CWS models in some low-resource settings. The partition criterion of our training sets follows Ke et al. (2021), whose sampling rates are 0.01, 0.05, 0.1, 0.2, 0.5, 0.8, and 1.0. For easy operation, we will obtain the above training datasets after randomizing the original training dataset but finally test on the same original testing dataset.

We decided to perform the above experiment on PKU without changing any parameters in Table 4. We first took BERT as the base model and gradually added D_{best} and w_{wei}^2. Related results of the experiment are shown in Table 6.

We notice that the performance of all models is greatly affected by sampling rates, especially at a low ratio such as 1% and 5%. In addition, self distillation can significantly improve the effect of CWS, and weight mechanisms can further increase the R_{OOV} scores.

Specifically, when the sampling rate drops from 100% to 5%, "$BERT + D_{best}$" and "$BERT + D_{best} + w_{wei}^2$" have better F1 scores than "$BERT$". For R_{OOV} scores, "$BERT$" decreases by 7.95% while that of "$BERT + D_{best}$" only decreases by 4.71%. Surprisingly, "$BERT + D_{best} + w_{wei}^2$" almost always maintains high R_{OOV} scores, fluctuating between 87% and 88%. We do not pay too much attention to 1%, because the sample size may be too small to reflect the real performance of the model.

Generally speaking, the above results confirm that WeiDC has strong robustness when manual annotation resources are insufficient.

5.3 OOV Words

From the above experiments, WeiDC worked well in R_{OOV}. To verify the performance of each model on OOV words, we operated the PKU training corpus to train all models but took other testing data sets to evaluate these models.

We first digitized the discrepancy between the training set of PKU and the test sets of MSR, AS and CITYU. For visual comparison, we also listed the distribution of OOV words in the PKU test set. See Table 7 for more details. It should not be ignored that both AS and CITYU are traditional Chinese datasets, where words may be slightly different, such as "铁公路" ("iron road") on CITYU while "铁路" ("railway") on PKU.

As shown in Table 8, WeiDC almost performs better than the base model on all three testing tasks, especially in R_{OOV}. According to table 7 and Table 8, the effect of WeiDC on the test set with a higher

OOV$_{word}$	**PKU**		**MSR**		**AS**		**CITYU**	
	Type	Freq	Type	Freq	Type	Freq	Type	Freq
NotInPKU_Train	2863	6006	4100	8110	8386	18006	3099	6726
All Test Word	13148	104372	12923	106873	18759	122610	8993	40936
OOV Rate	21.78	5.75	31.73	7.60	44.70	14.69	34.46	16.43

Table 7: OOV words for the four CWS test sets. "NotInPKU_Train" represents words that appear in the test set while not in the PKU training set. Column "Type" only includes the type of OOV word, but column "Freq" considers the frequency.

Model	MSR		AS		CITYU	
	F	R$_{OOV}$	F	R$_{OOV}$	F	R$_{OOV}$
BERT(base)	86.95	20.51	90.05	71.82	90.77	73.51
$+D_{best}$	+0.0	**+0.88**	+0.45	+2.38	**+0.52**	+2.2
$+D_{best}+w^2_{wei}$	-0.08	+0.81	**+0.47**	**+2.41**	+0.51	**+3.06**

Table 8: Train on PKU, but test on other three datasets.

frequency of OOV words is more distinct. However, the number of types of OOV words seems to be less beneficial.

We finally checked the PKU and MSR datasets to find out why all models performed poorly on MSR. The word segmentation standards of the above two corpora are very different, such as "最大" ("biggest") on MSR while "最 大" ("most" and "big") on PKU, which directly causes all models to perform better on AS and CITYU, but poorly on MSR.

5.4 NER Tasks

Similar to CWS tasks, Named Entity Recognition (NER) tasks can also be performed in the form of sequence annotations. To further explore the effectiveness of the weight mechanism and compare which weight mechanism performs better, we conduct some NER experiments. All hyperparameters are the same as the CWS task. The relevant results are shown in Appendix Table 13.

We can get the following suggestions. First, the hand-crafted weight module can improve sequence labeling tasks, whether CWS or NER. Second, w^4_{wei} has the best overall performance among all weight mechanisms and is also a good choice when the features of the training dataset are unclear.

Moreover, the labeling rules of various datasets vary widely, so it is almost impossible to design a general weight mechanism. This also explains that our chosen parameters do not always yield the best results. To focus our attention on experimental exploration, we did not spend much time on parameter tuning.

6 Case Study

For CWS tasks, it is very hard to get the right segmentations if two adjacent words, such as "天外" ("outside the sky") and "客" ("guest"), both appear for the first time, as shown in Table 9. Unfortunately, WeiDC can't handle this problem properly either. However, we find that if we add some valuable context, our model can still get rational results.

Gold	千载难逢 天外 客
Original	$text$: 千载难逢天外客 $BERT$: 千载难逢 **天外客** $+D_{best}+w^2_{wei}$: 千载难逢**天外客**
Replace 1	天外的人，千载难逢天外客 天 外 的 人，千载难逢 **天外 客** 天外 的 人 , 千载难逢 **天外客**
Replace 2	天外的客，千载难逢天外客 天外 的 客 ， 千载难逢 **天外 客** 天外 的 客 ， 千载难逢 **天外 客**
Replace 3	天外的流星，来做客，千载难逢天外客 天外 的 流星 ， 来 做客 ， 千载难逢 **天外 客** 天外 的 流星 ， 来 做客， 千载难逢 **天外客**
Replace 4	客人说，见到了天外来的流星，千载难逢天外客 客人 说 ， 见 到 了 天 外 来 的 流星 ， 千载难逢 **天外 客** 客人 说 ， 见 到 了 天外 来 的 流星 ， 千载难逢 **天外 客**

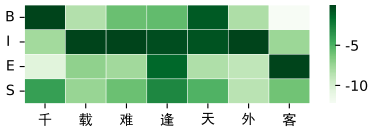
Table 9: "千载难逢天外客" ("A once-in-a-lifetime visitor from outside the sky"). In each block, the first line is a raw text, and the last two lines are segmentation results of BERT and WeiDC, respectively. Both models are trained on PKU.

Although in some cases both "天外客" ("A visitor from outside the sky") and "天外 客" ("outside the sky" and "guest") are rational representations, here we assume that "天外 客" ("outside the sky" and "guest") is correct one and let these models learn it by enhancing the semantic environment.

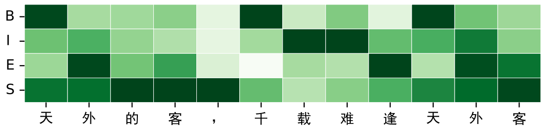
First, according to "Replace 1" and "Replace 4", if only "天外" ("outside the sky") appears in the previous text, BERT obtains "天外 客" ("outside the sky" and "guest") at the cost of inconsistent segmentation criteria in "天外" ("outside the sky"). For WeiDC, "天外客" ("A visitor from outside the sky") is regarded as a derivative of "天外" ("outside the sky"), as shown in "Replace 1". After semantic information gets enriched, the possibility of "天外" ("outside the sky") becoming an independent word increases, so the correct result is obtained. We also notice that when text content is rich, WeiDC will get desired results even if there is interference information such as "外来" ("outside") in the added semantic knowledge.

Second, from "Replace 2", when "的" ("of") locates between "天外" ("outside the sky") and "客" ("guest"), both BERT and WeiDC learn the right segmentation position by treating "的" ("of") as a single word. We analyzed the PKU training set for further exploration and found that "的" ("of") is a high-frequency single-character word. When we blur the semantic information, as shown in "Replace 3", WeiDC treats "天外客" ("A visitor from outside the sky") as a word, while BERT can still obtain the correct segmentation. We speculate that the added interference information hurts the small text content. From another perspective, WeiDC has a strong ability to learn contextual knowledge from different semantic environments to assist CWS tasks.

Last but not least, we make heatmaps to visualize the word segmentation process in Figure 3.



(a)"A once-in-a-lifetime visitor from outside the sky"



(b) "A visitor from outside the sky, a once-in-a-lifetime visitor from outside the sky"

Figure 3: Heatmaps of the label probability.

7 Conclusion

In this paper, we proposed a novel framework named WeiDC, which could make good use of the knowledge in teacher models through self-distillation. The framework also follows the sequence labeling paradigm but first applies self distillation and weight mechanism to CWS, combining four hand-crafted weight modules and two types of teacher models. Experimental results show that WeiDC could achieve higher performance on four CWS datasets, with the average F-score ranking second and the average R_{OOV} score ranking first.

However, for non-sequential labeling problems, such as text classification, a paragraph only corresponds to one tag, so the number of labels is too small, which may render the method in this paper ineffective. How to solve such a dilemma deserves more exploration. Besides, it is also promising to consider whether more efficient weight methods exist.

Table 11: Take RoBERTa as the base model.

A CWS Appendix

Combining two encoders and two decoders, the final results on the four datasets are included in Tables 10 and 11. All experiments adopted the same hyperparameters, as shown in Table 4.

We speculate that RoBERTa benefits from longer training time and larger batches of training data than BERT. In addition, some training tricks used in RoBERTa may also improve the performance of the pre-trained model, such as removing the next sentence prediction target, training longer sequences, and dynamically changing the mask pattern to be applied to the training data.

To our surprise, if CRF is used as the decoder, the CWS model seems to be more prone to overfitting, resulting in worse word segmentation. However, we also notice that CRF performs well on the AS dataset when using BERT as the encoder, suggesting that Softmax may not really outperform CRF. We consider that the current parameters are more suitable for Softmax. More detailed analysis is available from Section 5.

B NER Appendix

Corpus details of MSRA (Levow, 2006), WEIBO (Peng and Dredze, 2015), and RESUME (Zhang and Yang, 2018) are summarized in Table 12. We have no access to OntoNote 4, so didn't test it. All experiments adopted the same hyperparameters, as shown in Table 4. We did not list the latest performance of existing NER tasks, as we only explored whether WeiDC works for NER tasks and which weight mechanism is more robust.

As shown in Table 13, w_{wei}^4 performs the best on the WEIBO and MSRA datasets, while the worst on the RESUME dataset, indicating that it is difficult, if not impossible, to design a general weight mechanism. The overall performance of w_{wei}^4 is still higher than other weight mechanisms. How to more naturally integrate weight mechanisms and knowledge distillation into NER tasks requires more exploration and research.

In addition to such NER tasks, non-sequence annotation tasks, such as text classification, usually have only one label per sentence, which may limit the application of WeiDC.

Sibylvariant Transformations for Robust Text Classification

Abstract

The vast majority of text transformation techniques in NLP are inherently limited in their ability to expand input space coverage due to an implicit constraint to preserve the original class label. In this work, we propose the notion of *sibylvariance (SIB)* to describe the broader set of transforms that relax the label-preserving constraint, knowably vary the expected class, and lead to significantly more diverse input distributions. We offer a unified framework to organize all data transformations, including two types of SIB: (1) *Transmutations* convert one discrete kind into another, (2) *Mixture Mutations* blend two or more classes together. To explore the role of sibylvariance within NLP, we implemented 41 text transformations, including several novel techniques like `Concept2Sentence` and `SentMix`. Sibylvariance also enables a unique form of adaptive training that generates new input mixtures for the most confused class pairs, challenging the learner to differentiate with greater nuance. Our experiments on six benchmark datasets strongly support the efficacy of sibylvariance for generalization performance, defect detection, and adversarial robustness.

1 Introduction

Automatically generating new data is a critical component within modern machine learning pipelines. During training, data augmentation can expose models to a larger portion of potential input space, consistently leading to better generalization and performance (Simard et al., 1998; Krizhevsky et al., 2012; Perez and Wang, 2017). After training, creating effective test instances from existing data can expose specific model failure modes and provide actionable corrective feedback (Zhang et al., 2019; Ribeiro et al., 2020).

While many techniques can artificially expand labeled training sets or test suites, nearly all of them are class-preserving. That is to say, the model outputs are invariant (INV) with respect to the transformations. This cautious constraint ensures the new data does not lie in an out-of-distribution null class which might impede the learning objective. However, it also requires more conservative transforms that inherently limit the degree of diversification.

In this work, we propose and extensively investigate the potential of *sibylvariant (SIB)* transformations that *knowably* vary the expected class. From the Greek *sibyls*, or oracles, the term parallels the oracle construction problem in software testing (Barr et al., 2015). In a nutshell, sibylvariants either fully transmute a datum from one class c_i to another c_j, or mix data from multiple classes together to derive a new input with a soft label that reflects the mixed membership. In this way, SIB can more strongly perturb and diversify the underlying distribution. Moreover, SIB makes possible a new type of adaptive training by synthesizing data from frequently confused class pairs, challenging the model to differentiate with greater refinement.

In the following sections, we position SIB within a broader conceptual framework for all data transforms (Section 2) and highlight several newly proposed techniques (Section 3). To support a comprehensive evaluation of how SIB may complement or even surpass its INV counterparts, we implemented 41 new and existing techniques into an open source tool called `Sibyl`. Equipped with the framework and tool, we evaluate 3 central research questions:

- **RQ1. Generalization Performance.** Does training on SIB-augmented data improve model accuracy on the original test set?
- **RQ2. Defect Detection.** For models trained on the original dataset, how effective are SIB tests at inducing misclassifications?
- **RQ3. Adversarial Robustness.** Are models trained on SIB-augmented data more robust to existing adversarial attack algorithms?

Findings of the Association for Computational Linguistics: ACL 2022, pages 1771 - 1788

Our comprehensive evaluation encompasses 6 text classification datasets, 11 transformation pipelines, and 3 different levels of data availability. In total, we trained 216 models and generated over 30 million new training inputs, 480,000 testing inputs, and 3,300 adversarial inputs. In the generalization study, SIB attained the highest accuracies in 89% (16 out of 18) of experimental configurations, with the adaptive mixture mutations being the most consistently effective. SIB also revealed the greatest number of model defects in 83% (5 out of 6) of the testing configurations. Lastly, of all the experimental configurations where adversarial robustness was improved over the no-transform baseline, 92% (11 out of 12) of them involved SIB. Overall, our findings strongly support the efficacy of sibylvariance for generalization performance, defect detection, and adversarial robustness.

Lastly, we describe how SIB may operate theoretically and discuss potential threats to validity (Section 5) before contrasting it with related work (Section 6). The source code for `Sibyl` and our experiments is available at: `https://github.com/UCLA-SEAL/Sibyl`.

2 Sibylvariance

All data transformations in the classification setting can be categorized into one of two types:

- ***Invariant (INV)*** preserves existing labels.

$$\{T_{INV}(X_i), y_i\} \rightarrow \{X_j, y_i\} \\ \text{where } X_i \neq X_j \tag{1}$$

  For example, contracting "What is the matter?" to "What's the matter?"should preserve a model behavior for sentiment analysis.

- ***Sibylvariant (SIB)*** changes an existing label in a knowable manner.

$$T_{SIB}(\{X_i, y_i\}) \rightarrow \{X_j, y_j\} \\ \text{where } X_i \neq X_j \text{ and } y_i \neq y_j. \tag{2}$$

  SIB transforms both the input X_i to X_j and the output label from y_i to y_j label, corresponding to the new X_j; such transformation is analogous to mutating an input and setting a corresponding oracle in metamorphic testing (Chen et al., 2020b). For example, performing a verb-targeted antonym substitution on "I love pizza." to generate "I hate pizza." has the effect of negating the original semantics and will knowably affect the outcome of binary sentiment analysis

It is important to note that transformation functions are not inherently INV nor SIB. The same exact transformation may have a different effect on expected model behavior depending on the particular classification task. For example, random word insertions generally have an INV effect on topic classification tasks, but would be SIB with respect to grammaticality tasks (Warstadt et al., 2018).

2.1 Sibylvariant Subtypes

SIB can be further refined based on the types and degree of semantic shift in newly generated data:

- ***Transmutation*** changes one discrete kind into another, excluding the existing label, $L \backslash \{y_i\}$,

$$T_{SIB}(\{X_i, y_i\}) \rightarrow \{X_j, y_j\} \\ \text{where } X_i \neq X_j \text{ and } y_j \in L \backslash \{y_i\}. \tag{3}$$

  Critically, the newly created data points retain stylistic and structural elements of the original that help boost diversity.

- ***Mixture Mutation*** mixes inputs from multiple classes and interpolates the expected behavior into a mixed label distribution (i.e. *soft label*). Equivalently, we have:

$$T_{SIB}(\{X_i, y_i\}) \rightarrow \{X_j, y_j\} \\ \text{where } X_i \neq X_j \text{ and } y_j \in \bigcap_{l}^{|L|} \lambda_l \tag{4}$$

  where the final term indicates a λ-degree of membership in each label l belonging to the expected input space and is normalized as a probability distribution (i.e. $\sum_l \lambda_l = 1$). For example, a document with topic 'surfing' can be combined with another document with topic 'machine learning' to yield a new label with probability mass placed on both topics. While mixture mutations may seem unnatural, the intuition is that humans can recognize mixed examples and adjust their predictions accordingly. Models ought to do the same.

2.2 Adaptive Sibylvariant Training

One unique and promising aspect of SIB is to target specific class pairings dynamically during training. In much the same way that a human teacher might periodically assess a students' understanding and alter their lesson plan accordingly, `Sybil` computes a confusion matrix and constructs more examples containing classes for which the model has the most difficulty differentiating. For example, if a topic model most frequently misclassifies ‘science’ articles as ‘business,’ *adaptive* SIB (denoted as αSIB) will generate new blended examples of those classes in every mini-batch until the next evaluation cycle. At that point, if the model confuses ‘science’ for “health,” αSIB will construct new mixtures of those classes and so on. `Sybil` supports built-in runtime monitoring for αSIB training.

3 Transformations

In `Sybil`, we defined 18 new transforms and adapt 23 existing techniques from prior work (Ribeiro et al., 2020; Morris et al., 2020; Wei and Zou, 2019) to expand the coverage of SIB and INV text transformations. At a high level, Table 1 shows these 41 transforms organized into 8 categories: `Mixture` (i.e., blending text), `Generative` (i.e. concept-based text generation), `Swap` (e.g., substituting antonyms, synonyms, hypernyms, etc.), `Negation` (e.g., adding or removing negation), `Punctuation` (e.g., adding or removing punctuation), `Text Insert` (e.g., adding negative, neutral, or positive phrases), `Typos` (e.g. adding various typos), and `Emojis` (e.g. adding or removing positive or negative emoji). We highlight several signature transforms here and provide a more detailed listing in Appendix A.

Category	**Transformations**
Mixture	TextMix†, SentMix†, WordMix†
Generative	Concept2Sentence†, ConceptMix†
Swap	ChangeNumber, ChangeSynonym, ChangeAntonym, ChangeHyponym, ChangeHypernym, ChangeLocation, ChangeName, RandomSwap
Negation	AddNegation, RemoveNegation
Punctuation	ExpandContractions, ContractContractions
Text Insert	RandomInsertion, AddPositiveLink†, AddNegativeLink†, ImportLinkText†, InsertPositivePhrase, InsertNegativePhrase
Typos	RandomCharDel, RandomCharInsert, RandomCharSubst, RandomCharSwap, RandomSwapQwerty, WordDeletion, HomoglyphSwap
Emojis	Emojify†, AddEmoji†, AddPositiveEmoji†, AddNegativeEmoji†, AddNeutralEmoji†, Demojify†, RemoveEmoji†, RemovePositiveEmoji†, RemoveNegativeEmoji†, RemoveNeutralEmoji†

Table 1: Transformations currently available in `Sybil`. New transforms that we defined are marked with †.

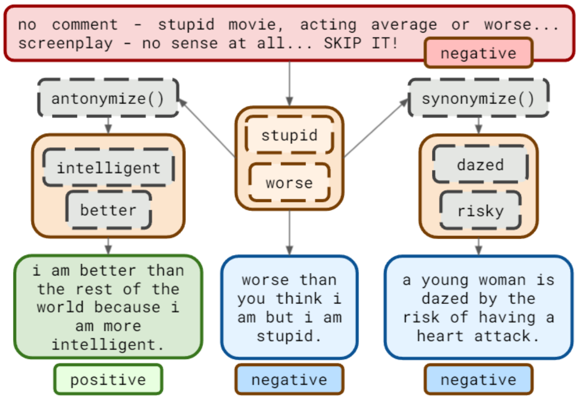

Figure 1: C2S intakes a text and its label (red) to extract keywords, [’stupid, worse’]. These words are used to generate a new INV sentence shown in red. Alternatively, antonym (left) and synonym (right) substitution can produce new concepts that further boost diversity.

Concept2Sentence (C2S). C2s is a two step process: (1) extract a short list of key concepts from a document and (2) generate a new sentence that retains critical semantic content of the original while varying its surface form, style, and even subject matter. To accomplish this, we leveraged integrated gradients (Sundararajan et al., 2017; Pierse, 2021) to produce saliency attributions that identify the most relevant tokens for a given class label. We then generate a well-composed sentence from the extracted concepts using a pre-trained BART (Lewis et al., 2019) model fine-tuned on the CommonGen dataset (Lin et al., 2019).

Prior to generation, it is possible to apply other transformations to the extracted concepts to encourage diversity or knowably alter the label. For example, on the left hand side of Figure 1 an antonym substitution produces a SIB effect by changing the extracted concepts from [’stupid’, ’worse’] to [’intelligent’, ’better’]. The new sentence exhibits a change in subject and style, but is correctly transmuted to have positive sentiment. C2S is thus an extremely promising transformation for diversifying text along both INV and SIB directions.

TextMix, SentMix, and WordMix. Mixture mutations, like mixup (Zhang et al., 2017) and cutmix (Yun et al., 2019) from the image domain, take a batch of inputs and blend them together to form new inputs with an interpolated loss and they have shown robustness to adversarial attacks. `TextMix` translates this idea to the text domain by merging two inputs and interpolating a *soft label* according to the proportion of tokens belonging to the constituent classes. While `TextMix` does a straightforward concatenation, `SentMix` shuffles the sentences and thus encourages long-range comprehension. `WordMix` concatenates and shuffles all words, encouraging keyword-to-topic understanding when sentence structure is compromised.

4 Experiments

4.1 Transformation Pipelines & Datasets

To compare the potential of INV, SIB, and both (INVSIB) in aggregate, we construct a *transformation pipeline* (TP) (Cubuk et al., 2019; Xie et al., 2019), where we uniformly sample n transformations of the selected kind to generate new $\{X_i, y_i\}$ pairs. We also create TPs that apply a single transform, $T_{\texttt{SINGLE}}$, to highlight the efficacy of `C2S`, `TextMix`, `SentMix`, `WordMix` and their adaptive versions, prefixed with α. In total, we evaluate 11 TPs per dataset, shown in Table 2.

Due to space limitations, we report the top performing TP of each kind using an asterisk (*). INV* represents the best from T_{INV} and T_{C2S}, while SIB* represents the best from T_{SIB} and the mixture mutations. For **RQ1**, we also compare against TMix (Chen et al., 2020a), EDA (Wei and Zou, 2019), and AEDA (Karimi et al., 2021). TMix is a recent *hidden*-space mixture mutation for text, as opposed to `Sybil`'s direct mixture mutation on the input space with greater transparency and examinability. EDA and AEDA are examples of recent INV transformations. Full results are available in the appendices.

Shorthand	Description
T_{ORIG}	0 transformations as baseline
T_{INV}	sample 2 INVs
T_{SIB}	sample 2 SIBs
T_{INVSIB}	sample 1 INV and 1 SIB
T_{SINGLE}	apply one from C2S, TextMix, SentMix, WordMix, αTextMix, αSentMix, αWordMix

Table 2: TP descriptions. TPs with an α-prefix use targeted, adaptive training (Section 2.2).

We study six benchmarks for two kinds of NLP tasks: topic classification and sentiment analysis. Table 3 summarizes their relevant details. To simulate different levels of resource availability, we create three data subsets with by varying number of examples per class — 10, 200, and 2500. These subsets were expanded 30× via augmentation for each TP. In total, we generated 144 new datasets (144 = 6 benchmarks * 3 levels of data availability * 8 TPs which persist data. αSIB is runtime only.)

4.2 Model Setting

We used a `bert-base-uncased` model (Devlin et al., 2018) with average pooling of encoder output, followed by a dropout layer (Srivastava et al., 2014) with probability 0.1, and a single linear layer with hidden size 768 and GELU (Hendrycks and Gimpel, 2016) activation. Maximum sentence length was set to 250. We use a batch size 16, an Adam optimizer (Kingma and Ba, 2014) with a linear warmup, a 0.1 weight decay, and compute accuracy every $2,000$ steps. All models were trained for 30 epochs on eight Nvidia RTX A6000 GPUs, with early stopping. In total, we constructed 198 different models.

For all TPs that produce a soft-label, we use a multi-class cross-entropy loss and computed performance via a weighted top-k accuracy,

$$\sum_{j}^{k} \lambda_l \cdot \mathbb{1}(y_l = \hat{y}_j), \tag{5}$$

where λ_j is the degree of class membership, $\mathbb{1}(\cdot)$ is the indicator function, and y_j and $\hat{y}_j$ are the indices of the j-th largest predicted score for the ground truth label and predicted label, respectively.

4.3 RQ1. Generalization Performance

For RQ1, we explore how model accuracy on the original test set is influenced by training data augmented with INV and SIB transformations. Table 4 shows the results on six benchmarks with three levels of data availability.

We observe the most significant performance gains when training 10 examples per class —accuracy is improved by 4.7% on average across all datasets and by a maximum of up to 15% for IMDB. Figure 2 shows that as the number of labeled training data increases, a dominant trend emerged —T_{SIB} always generalized better to unseen test data. In fact, the only kind of transformation to always outperform both T_{ORG} and TMix is SIB*. Figure 3 shows the performance delta between INV* and SIB* against the T_{ORG} baseline at 200 examples per class. For every dataset, either αSentMix or αTextMix is the best performing TP, while INV* actually leads to performance decreases for DBPedia, Yahoo! Answers, and IMDB.

One key reason that aided SIB in attaining strong performance is the use of adaptive training. On average, crafting new examples that target the

Dataset	Source	Task	Subject	Classes	Test	Avg Len
AG News	(Zhang et al., 2015)	Topic	News Articles	4	1,900	38
DBpedia	(Zhang et al., 2015)	Topic	Wikipedia Articles	14	5,000	46
Yahoo! Answers	(Zhang et al., 2015)	Topic	QA Posts	10	6,000	92
Amazon Polarity	(Zhang et al., 2015)	Sentiment	Product Reviews	2	200,000	74
Yelp Polarity	(Zhang et al., 2015)	Sentiment	Business Reviews	2	10,000	133
IMDB	(Maas et al., 2011)	Sentiment	Movies Reviews	2	12,500	234

Table 3: Dataset details. Test represents the number of examples per class in the test set.

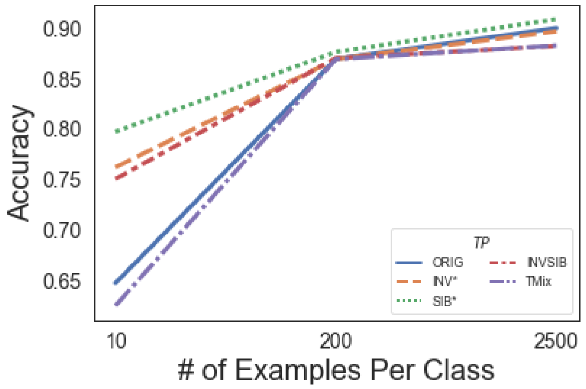

Figure 2: SIB* outperforms INV* most, when data availability is low, indicating the necessity of SIB to complement INV.

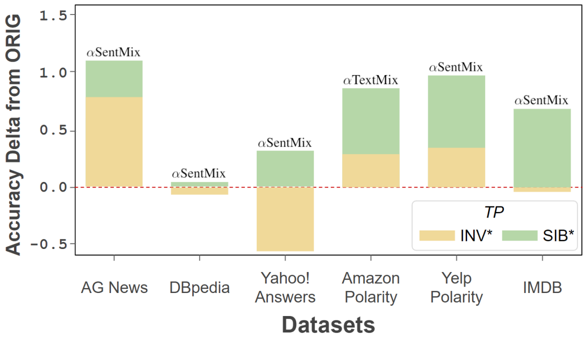

Figure 3: The best performing TP for each dataset trained on 200 examples per class. αSentMix or αTextMix leads to the highest performance gains. SIB* consistently outperforms INV*.

model's primary confusions during training added approximately 1% to accuracy relative to mixing classes uniformly at random. This shows another unique benefit of sibylvariance that is not transferable to its INV counterparts.

While our full scale experiments show a clear trend that SIB generally outperforms INV, we primarily evaluated TPs combining multiple transforms instead of assessing the efficacy of each in isolation. Initially, this was a logistical decision due to computational limitations. To investigate each transformation's effect individually, we conducted a small scale experiment training 756 models ((39 transformations + 3 αSIB) $\times$ 6 datasets $\times$ 3 runs) on 10 examples per class with a 3$\times$ augmentation multiplier. Based on this experiment, we then computed each transform's performance by averaging the accuracy change relative to a T_{ORIG} baseline across all datasets. Table 5 shows the top ten best performing transforms, six of which employ SIB techniques. These results expand support for the overall conclusion that sibylvariance represents an especially effective class of transformations for improving generalization performance.

Generalization Performance.
Models trained upon SIB-augmented data attained the highest test set accuracy in 89% (16 out of 18) of experimental configurations, with the adaptive mixture mutations being the most consistently effective.

4.4 RQ2. Defect Detection

For RQ2, we assess how generating new tests with INV and SIB can expose defective model behavior. A single test is simply an $\{X_i, y_i\}$ pair and a test suite is a set of such tests. Defective behavior is misclassification, which is measured via a test suite's accuracy. For each dataset D, we select a high-performing BERT model trained only on the original dataset without any augmentation. Then for each of eight TPs (excluding αSIB relevant to training only), we create 100 test suites, each containing 100 randomly sampled tests. This yields a total of 480,000 tests. We then report an average accuracy for each D and TP pair.

Figure 4 shows how defect detection is enabled by INV and SIB. With the exception of Yahoo! Answers, the models scored nearly perfect accuracy on T_{ORIG}; however, when the same models are tested using data generated with INV and SIB, they struggle to generalize. Test data synthesized with SIB can reveal most defects in these models, indicating the value of *sibylvariance* in constructing test oracles for ML models in the absence of

expensive human labeling and judgements.

Tests which lie outside the expected input distribution are not likely to be fair nor actionable. Since SIB transforms generally perturb data more aggressively than INV ones, they likewise possess more potential for creating unreasonable, out-of-domain tests of model quality. However, the positive results in **RQ1** may justify the use of SIB transformations as reasonable for testing. Had the newly transformed data truly belonged to a different distribution, model performance on the in-domain test set should have decreased as a result of dataset shift (Quiñonero-Candela et al., 2009; Hu et al., 2022). In fact, we observed the opposite as model performance was consistently improved. This suggests that SIB transforms yield data that is tenably in-domain and therefore may complement INV transforms in exposing defective model behavior.

We theorize that the effectiveness of SIB-generated tests comes from the expanded objectives it permits. For example, T_{TextMix} assess whether the model can recognize which classes are present and to what degree. T_{SentMix} does the same but further scrutinizes long-range comprehension by broadly distributing related topic sentences. Datasets with lengthy inputs are particularly vulnerable to transformations of this kind. Lastly, T_{WordMix} forces the model to forgo reliance on text structure and evaluates keyword comprehension amidst noisy contexts. In contrast, most INV transformations involve minor changes — e.g. expand contractions — and test the aspect of language already well modeled from extensive pre-training. The INV C2S transform is an exception that drastically alters input and thus reveals more defects than other T_{INV} pipelines.

Defect Detection. Models tested with SIB-transformed data exhibited the greatest number of defects in 83% (5 out of 6) of experimental configurations.

4.5 RQ3. Adversarial Robustness

For RQ3, we assess whether models trained on INV or SIB are more resilient to adversarial attacks than models trained on an original data. An adversarial text input is typically obtained via semantic preserving (i.e. *invariant*) perturbations to legitimate examples in order to deteriorate the model performance. The changes are typically generated by ascending the gradient of the loss surface with respect to the original example and improving robustness to adversarial attacks is a necessary precondition for real-world NLP deployment.

We select three attack algorithms based on their popularity and effectiveness: (1) TextFooler (Jin et al., 2019), (2) DeepWordBug (Gao et al., 2018), and (3) TextBugger (Li et al., 2018), all as implemented in TextAttack (Morris et al., 2020). We focus on models trained with 10 examples per class because the largest changes in generalization performance are more likely to exhibit the clearest trend for adversarial robustness. For each of 11 models and 3 attacks, we randomly sample 100 inputs from the original data and perturb them to create a total of 3,300 adversarial examples.

Table 6 shows that, of all the cases where adversarial robustness is improved over $T_{\texttt{ORIG}}$, 92% of them involve SIB. On average, SIB*-trained models improve robustness by 4%, while INV*-trained models sustain a 1% decrease. Topic classification is made more robust via training with augmented data. Consistently, $T_{\alpha\texttt{-SentMix}}$ produces the most resilient models. For sentiment analysis, improved generalization performance enabled by SIB does not necessarily lead to improved robustness to existing adversarial attacks. The underlying sentiment models trained with augmented data improves generalization over $T_{\texttt{ORIG}}$ by an average of 5%. However, counter-intuitively, the models are not more robust to the three attacks than $T_{\texttt{ORIG}}$ and that Pearson correlation is -0.28 between accuracy and adversarial robustness. This finding motivates future work to investigate why there is a negative correlation and how to design SIB such that accuracy improvement also translates to corresponding adversarial robustness.

Adversarial Robustness. Of all the experimental configurations where adversarial robustness was improved over the no-transform baseline, 92% (11 out of 12) of them involved models trained on SIB-augmented data.

5 Discussion

How does sibylvariance help? The primary purpose of data transformations in ML is to *diversify* datasets in the neighborhood of existing points, a principle formalized as Vicinal Risk Minimization (VRM) (Chapelle et al., 2001). Synthetic examples can be drawn from a vicinal distribution to find similar but different points that enlarge the original data distribution. For instance, within image classification, it is common to define the vicinity of an image as the set of its random crops, axal reflections, and other label-preserving INV transforms. While VRM can expose ML models to more diverse input space and consequently reduce generalization errors, the neighborhoods created by INV are relatively restricted. This is due to the label-preserving constraint limiting the degree of perturbation freedom on the original data.

Figure 5: UMAP visualizations of BERT `[CLS]` tokens for SST-2. Blue, red, and green represent “Negative,” “Positive,” and “Mixed”, respectively.

SIB effectively expands the vicinity relation via transmutations and mixture mutations. Newly created data can claim full or mixed membership in target classes. To support our intuition, we vi-

sualize the effects of various transformations on SST-2 (Socher et al., 2013). Figure 5 presents the UMAP-reduced (McInnes et al., 2020) `[CLS]` tokens produced by a BERT transformer for sentiment classification. Figure 5a shows that the classes are initially well separated and high performance can be obtained by selecting any separating surface between the two clusters. However, a more reasonable choice for the best boundary is one that exhibits the largest margin between classes — the very intuition behind Support Vector Machines (Cortes and Vapnik, 1995). Figure 5d suggests that a model trained on mixture mutations is likely to arrive at a boundary with the lowest loss. For example, in 5d, the augmented examples in green provide additional loss feedback from uncovered portions of the input space to encourage a decision boundary that maximizes the margin between class clusters. A similar expectation may hold for SIB in Figure 5c. However, the effects of INV transforms shown in Figure 5b do not appear to support such margin maximization.

Threats to Validity. External threats to validity include the generalization of our results to model architectures dissimilar to BERT (i.e. `bert-base-uncased`). It is possible that larger autoencoder models like RoBERTa (Liu et al., 2019) and auto-regressive models like XLNet (Yang et al., 2019) may respond differently to SIB transformations. Secondly, while the framework of sibylvariance is applicable to all data types, we have only provided empirical results supporting their efficacy for text classification models. We leave the exploration of SIB applications to image, time series, and other domains to future work.

Internal threats include how we derived mixed labels for generated text. We assumed that the critical semantics can be approximated via the ratio of words contributed by source text. This assumption may not account for other linguistic interaction and thus could lead to suboptimal labels. However, SIB did significantly improve upon the INV and the ORIG baselines in the **RQ1** generalization study, suggesting that the constructed soft labels still reflected useful semantics. This indirectly supports the validity of SIB-transformed data for testing in **RQ2**, although we acknowledge that additional caution is required for using any aggressively modified, synthetic data as a substitute for real data for the purpose of exposing defective model behavior.

6 Related Work

In this section, we broadly cover data transformations within and outside of the text domain because our proposed framework for sibylvariance is applicable to all classification contexts.

Data Augmentation. Effective data augmentation is a key factor enabling superior model performance on a wide range of tasks (Krizhevsky et al., 2012; Jiang et al., 2018; Xie et al., 2019). In many cases, practitioners leverage domain knowledge to reinforce critical invariances in the underlying data. In computer vision, for example, translation invariance is the idea that no matter where the objects of interest reside within an image, the model will still classify them correctly. Image translations and random crops encourage this more generalized conceptualization within the model (Simard et al., 1998) and all other transforms have a similar goal: reinforce a particular invariance that helps the learner perform well on future unseen data.

Numerous techniques have been proposed to assist with this learning objective and thereby improve generalization. Random erasing (Zhong et al., 2017; Devries and Taylor, 2017) and noise injection (Wen et al., 2020; Xie et al., 2019) support invariance to occlusions and promote robust features. Interpolating (Bowyer et al., 2011) and extrapolating (DeVries and Taylor, 2017) nearest neighbors in the input / feature space reinforces a linear relationship between the newly created data and the supervision signal while reducing class imbalance. However, nearly all of these approaches, and many others (Shorten and Khoshgoftaar, 2019;

Feng et al., 2021), are label-preserving and therefore limited in their capacity to induce deeper learning of invariant concepts.

Sibylvariant transforms enjoy several desirable aspects of INV transformations while mitigating their drawbacks. Similar to feature space functions (DeVries and Taylor, 2017), mixture mutations do not require significant domain knowledge. Like approaches that reduce dataset imbalance (Bowyer et al., 2011), SIB transforms can increase class representation through mixed membership or targeted transmutations that inherit diverse characteristics of the source inputs. In all cases, relaxing the label-preserving constraint enables SIB functions to both complement and enhance the learning of critical invariances by further expanding the support of the dataset in new directions.

Adversarial Attacks & Robustness. Adversarial attacks are a special class of INV transformations that simultaneously minimize perturbations to the input while maximizing the perception of change to a learner. This task is more difficult within the NLP domain due to the discrete nature of text, but several works (Alzantot et al., 2018; Zhang et al., 2020) have proven successful at inducing model errors. Real-world use of NLP requires resilience to such attacks and our work complements robust training (Parvez et al., 2018) and robust certification (Ye et al., 2020; Pruksachatkun et al., 2021) to produce more reliable models.

Emerging Sibylvariant Transforms. Specific transformations designed to alter the expected class of an input have existed prior to this work (Zhang et al., 2017; Yun et al., 2019; Guo, 2020; Zhu et al., 2017), albeit primarily in the image domain and also in a more isolated, ad hoc fashion. Among our primary contributions is to propose a unifying name, framework, and taxonomy for this family of sibylvariant functions. Furthermore, most prior works introduce a single transformation and evaluate its efficacy on training alone. In contrast, we proposed several novel transformations, a new adaptive training routine, and evaluated the broader impacts of 41 INV and SIB transforms on training, defect detection, and robustness simultaneously.

Recently published examples of SIB mixture mutations for text (Guo et al., 2019; Chen et al., 2020a) differ from ours in several important ways. Prior work operates exclusively within the *hidden* space inside specific models, which limits transferability between different algorithm types. All of our transformations operate in the *input* space, which is both more general and more challenging because we have to contend with rules of grammar and style. However, this also provides greater transparency. Furthermore, because our overall approach samples from 41 different transformations, we are able to exercise a broader range of model behaviors. For example, `SentMix` is designed to encourage long-range understanding, while other transforms evoke their own specific objectives. Any individual transformation is inherently more limited, e.g. TMix can only encourage the model to behave linearly for borderline cases.

7 Conclusion

Inspired by metamorphic testing, we proposed the notion of *sibylvariance* to jointly transform both input and output class (X_i, y_i) pairs in a knowable way. To explore the potential of sibylvariance, we define 18 new text transformations and adapt 23 existing transformations into an open source tool called `Sybil`. In particular, we define several types of mixture mutations and design a novel concept-based text transformation technique utilizing salience attribution and neural sentence generation. Across six benchmarks from two different NLP classification tasks, we systematically assess the effectiveness of INV and SIB for generalization performance, defect detection, and adversarial robustness. Our extensive evaluation shows that many SIB transforms, and especially the *adaptive* mixture mutations, are extremely effective. SIB achieves the highest training accuracy in 89% of the experimental configurations. When used for testing, SIB test suites reveal the greatest number of model defects in 5 out of 6 benchmarks. Finally, models trained on SIB-augmented data improve adversarial robustness $11\times$ more often than those trained on INV-augmented data.

Abstract

Domain Adaptation (DA) of Neural Machine Translation (NMT) model often relies on a pretrained general NMT model which is adapted to the new domain on a sample of in-domain parallel data. Without parallel data, there is no way to estimate the potential benefit of DA, nor the amount of parallel samples it would require. It is however a desirable functionality that could help MT practitioners to make an informed decision before investing resources in dataset creation. We propose a Domain adaptation Learning Curve prediction (DaLC) model that predicts prospective DA performance based on in-domain *monolingual* samples in the source language. Our model relies on the NMT encoder representations combined with various instance and corpus-level features. We demonstrate that instance-level is better able to distinguish between different domains compared to corpus-level frameworks proposed in previous studies (Xia et al., 2020; Kolachina et al., 2012). Finally, we perform indepth analyses of the results highlighting the limitations of our approach, and provide directions for future research.

1 Introduction

The classical Domain Adaptation scenario (Freitag and Al-Onaizan, 2016; Luong and Manning, 2015) usually relies on an existing NMT model trained on large datasets originated from various sources. This *general* model is adapted to the new domain, with a small sample of *in-domain parallel* data, through finetuning or other DA methods. Without any parallel in-domain data, we cannot estimate the quality of *general* NMT model on the domain of interest, nor can we anticipate what will be the benefits of the DA and how much parallel in-domain data is required.

In this work, we address the problem that translation service providers may regularly face when receiving a request for a new domain translation. In such case, a new domain is often defined by its source language samples, and the translation provider needs to invest into in-domain parallel dataset creation in order to be able to perform evaluation and Domain Adaptation of its *general* model. Current state of the art research in NMT Domain Adaptation rarely provides any insights on the amount of data required to perform Domain Adaptation depending on input domain characteristics. This is however a desirable feature that would allow to (i) estimate the data creation cost (time and money-wise) for the client requesting an adaptation to completely new domain; (ii) make an informed decision on how to distribute fixed data creation budget when there is a need to handle multiple DA simultaneously (as we demonstrate further sharing this budget equally across all domains may not be optimal). The goal of this work is to gain better insights on Domain Adaptation dynamics, and provide practical guidelines for such a real-life scenario.

Several studies address the problem of learning curve estimation models (Xia et al., 2020; Ye et al., 2021; Kolachina et al., 2012) of MT or NLP models without actually training those. This is done by training a prediction model which takes corpus-level representation X as an input and predicts the score y for this corpus as an output. In the case of MT learning curves prediction, X would correspond to the parallel data sample (used to train MT model), and y is the BLEU score achieved by an MT model trained on X. This means that each training point creation requires training a new MT model, which may become very costly if we want to create a training set of reasonable size. In this work, we propose a novel framework to perform the learning of the prediction model at *instance-level*. It can significantly decrease the cost of training samples creation, by leveraging instance-level representations.

There are multiple factors that would impact DA learning curve: the complexity of the new domain, characteristics of the in-domain samples, baseline performance on the new domain, DA algorithm and its hyperparameters. In this work, we concentrate on the factors related to domain complexity and in-domain sample characteristics. We are particularly interested to understand how much can we get from source only in-domain sample, which corresponds to the real-life scenario.

Aharoni and Goldberg (2020) points out that the notion of domain can be fuzzy. They suggest that pretrained language models (LMs) representation could contain rich information about different domains, and have demonstrated that there might be significant overlap between different domains at instance-level. In the context of NMT Domain Adaptation, NMT encoder representations are better suited to characterize different domains, and to evaluate the difficulty of those domains for the *general* NMT model (Del et al., 2021).

The main contributions of this work are:

(i) We formulate the problem of DA learning curves prediction as instance-level framework and demonstrate that instance-level representation favours fine-grained knowledge transfer across different domains thus significantly decreasing the cost of training samples creation;

(ii) We propose a prediction model that relies on NMT encoder representations combined with a number of other instance and corpus-level characteristics, computed from the monolingual (source) in-domain sample only;

(iii) We analyse how far we can go in DA performance prediction based on the source side information only, and outline some limitations of this constraint in Section 7.

2 Related work

The problem of Learning Curve prediction can be related to a number of different existing problems in Natural Language Processing (NLP) and Machine Learning. In this section, we briefly review few works that have tried to predict Learning Curves (also known as *Scaling Laws*) or domain shift for different NLP tasks. We also overview some works on Active Learning for NMT since those features can also be relevant to our task.

Learning Curve and domain shift prediction. There is a number of works that have attempted to predict model's performance without actually executing (and even training) the model in different contexts. Elsahar and Gallé (2019) predicts the classifier's performance drop under the domain shift problem; Elloumi et al. (2018) estimates the ASR performance for unseen broadcasts. Xia et al. (2020); Ye et al. (2021) study the problem of predicting a new NLP task performance based on the collection of previous observed tasks of different nature. Their proposed models are evaluated on MT among other tasks.

Closest to our work, Kolachina et al. (2012) predicts the learning curves for the Statistical Machine Translation(SMT) task. They formulate the task as a parametric function fitting problem, and infer the learning curve relying on set of features based on in-domain source and/or target sample (assuming no in-domain parallel sample is available). Most of the above-mentioned works rely on corpus-level score predictions and therefore require large amount of trained MT model instances to generate sufficient amount of training points for the predictor model.

There is very recent interest around modeling the *Scaling Laws* for a language model (Kaplan et al., 2020) or a NMT model (Gordon et al., 2021; Ghorbani et al., 2021). Similar to (Kolachina et al., 2012) these works try to derive a parametric function that would allow to make a connection between the model's training characteristics (amount of data, parameters or compute) and model's final performance. These models operate at corpus level and do not address the problem of Domain Adaptation (and the fact that different domains may follow different scaling laws functions).

To best of our knowledge, our work is the first attempt to specifically solve learning curves prediction in the context of NMT Domain Adaptation. We propose an instance-level framework relying on NMT encoder representations (which none of the previous work did) in combination with other features. Owing to this framework, our proposed framework requires a small amount of trained MT models with less than 10 models.

Active learning for NMT. Active Learning (AL) algorithms are built to select the most useful samples for improving the performance of a given model. Therefore, the criteria used by AL algorithms in NLP or MT tasks (Zhang et al., 2017; Zhao et al., 2020; Peris and Casacuberta, 2018;

Dou et al., 2020; Wang et al., 2020; Zhan et al., 2021) could also serve as discriminative features when it comes to predicting the future NMT performance. We reuse some of the scoring functions introduced by previous work as specified in Section 4.2. On the other hand, we believe that a successful Learning Curves prediction framework can help identify important features and/or samples for an AL framework.

3 Analysis of real Domain Adaptation Learning curves

In this section, we analyse several real learning curves for NMT Domain Adaptation to show how learning curves do behave across domains and to motivate our work. In order to perform this analysis, we first present the NMT baseline model (i.e., *general* model) we utilize, as well as datasets used for Domain Adaptation. We also discuss the NMT evaluation metrics that we can rely on when training the learning curve predictor model[1].

NMT model. We consider two different NMT systems: English-German and German-English systems trained on WMT20 dataset (Barrault et al., 2020). We provide technical details about architecture and datasets used to train those NMT systems in the Appendix A.

Domain Adaptation data. We rely on the dataset released by Aharoni and Goldberg (2020). The dataset consists of train/dev/test with deduplicated sentences. This dataset splits for 5 domains (Koran, IT, Medical, Law, Subtitles) from OPUS (Tiedemann, 2012) for German-English. For each domain, we create random samples $S_{n,d}$ of size n (with $n =$1K, 10K, 20K, 100K) at d domain. Those samples are then used to train instances of Domain Adapted models $M_{S_{n,d}}$ resulting in total 19 models[2]. We will further refer to the size of these different samples as *anchor points* (of the learning curve).

Domain Adaptation. For each *general* NMT model (*baseline*), we create a set of Domain Adapted models trained on different samples of in-domain data described previously (anchor points). Domain Adaptation is done via finetuning only with an in-domain dataset (Appendix A provides details).

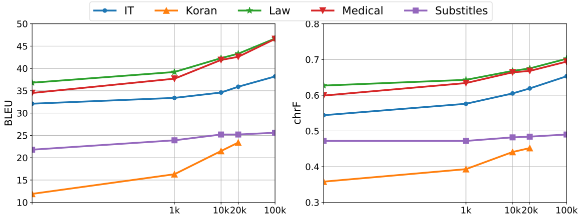

Figure 1: Domain Adaptation Learning Curves for English-German NMT model. Y-axis represents the performance of Domain adapted model (e.g., chrF or BLEU), X-axis: amount of in-domain samples used by Domain Adaptation (at log scale).

NMT evaluation. Our main goal is to obtain a corpus-level score that would allow us to assess the DA performance which is traditionally measured by BLEU score (Papineni et al., 2002). While BLEU score may exhibit reasonable correlation with human judgements at corpus-level, it is known to have poor correlation at instance-level. Recall that we are interested to exploit instance-level representations to favour knowledge transfer across domains, therefore we require a reliable instance-level metric to create gold annotations that the predictor model could learn from. We rely on *chrF* (Popović, 2015) score that, according to WMT 20 MT evaluation track (Mathur et al., 2020), provides reasonable correlation with human judgement for instance-level evaluations. For learning curves prediction we rely on *mean chrF* (average instance-level chrF across the whole test set) as a proxy for corpus-level score thus making connection with instance-level scores used for training of the predictor.

Analysis of Learning Curves. Figure 1 reports how BLEU and *mean chrF* scores progress with amount of in-domain samples used for Domain Adaptation (English-German). First, we note that *mean chrF* metric exhibits the same behaviour as BLEU when tracing the Learning Curve[3].

Second, we note the difference in a Domain Adaptation progress for each of domains. For instance, *Koran* learning curve is quite steep, while *Subtitles* domain improves very slightly and reaches a plateau performance at already 1K Do-

---

[1] In what follows we may refer to the *learning curve predictor model* as *predictor* to avoid the confusion with NMT model.

[2] We didn't train 100K-sampled DA model for *Koran* domain since it only has 20K parallel sentences in the training split

[3] Table 5 in Appendix A provides BLEU/chrF for German-English and confirms the above observation. All the evaluations are performed with SacreBLEU toolkit (Post, 2018).

main Adaptation anchor point. We also note that this behaviour isn't necessarily linked to the performance of the *baseline* model on those domains: *Law* and *Medical* domains achieve quite high scores when translated with the *baseline* NMT model (tables 5, 6 in the appendix), but they keep improving as in-domain data grows. *Subtitles* on the other hand has lower *baseline* BLEU and *mean chrF* scores and Domain Adaptation with growing in-domain data doesn't seem to help much. Such behaviour probably reveals the limitations of the dataset, and/or a Domain Adaptation method used for this domain that would merit further investigations. The problem that we want to address in our work is whether it is possible to forecast such behaviour in advance, and how far we can go in this task with source only in-domain data sample.

4 Approach

In this section, we first formalize the DA learning curve predictor. Then, we describe the representations and our model for the problem.

4.1 Problem setup

We are given a *baseline model* M_G (trained on general corpus G), input sentence x and a new domain d defined by its sample S_d. The *DA learning curve predictor* can be modeled as a scoring function g_θ which depends on the instance-level representation $\phi(x)$, and corpus-level representation $\xi(S_d^s)$[4].

Model M_{S_d} is an NMT model obtained by adapting M_G to the new domain(i.e., d on the in-domain sample of parallel sentences S_d). Learning of *DA learning curve predictor* can be done by regressing the actual scoring function $y = s(x, M_{S_d})$ that provides translation quality score for an input sentence (from the test domain) x translated with M_{S_d}. $s(x, M_{S_d})$ refers to *chrF* score as discussed in Section 3.

The learning objective is then formulated as

$$\min_{\theta} \sum_{d \in D} \sum_{x \in T_d} (s(x, M_{S_d}) - g_\theta(\phi(x), \xi(S_d^s)))^2$$

where D and T_d are a set of training domains[5] and training sentences of d domain[6], respectively.

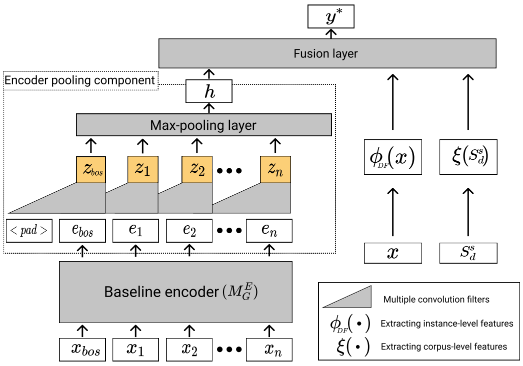

Figure 2: Overview of the learning curve predictor model, where x_i is the i-th token of x. M_G^E denotes the encoder of the baseline translation model(M_G)

4.2 Input representations

In this section, we describe different features we consider for input sentence x and for the source-side of in-domain sample S_d^s.

NMT encoder representations contain a wealth of information that can be very relevant to the *adaptability* of the model to the new domain. Therefore, we consider it as an important building block of our predictor model. In our implementation, we take the last encoder layer representation of each token, which are then aggregated through a pooling component in a single vector $\phi_{enc}(x)$ (*Encoder pooling component* at Figure 2).

Corpus-level features $\xi(S_d^s)$ allow us to characterize the in-domain sample S_d^s with respect to its size, diversity, and similarity to pretrained data G. In the simplest case we consider sample size (amount of instances) as a single corpus-level feature. In addition we add some of the features used by Xia et al. (2020); Kolachina et al. (2012) namely: (1) amount of tokens in S_d^s; (2) vocabulary overlap ratio between G and S_d^s; (3) the average sentence length (in characters, in tokens); (4) the number of unique tokens in S_d^s; and (5) type token ratio (Richards, 1987)[7].

Instance difficulty features (DF). The quality of the translation depends on how difficult input sentence is for the NMT system.

Difficulty features $\phi_{DF}(x)$ include model-based uncertainty functions from Zhao et al. (2020): (1)

---

[4] S_d^s denotes source side of in-domain sample S_d since we restrict ourselves to the case where we can only access source side of in-domain samples.

[5] We consider the scenario where the test domain is not known during the predictor learning phrase and disjoint form training domains.

[6] T_d does not contain the training sentence for adapted model.

[7] We apply log-scale to all feature values to reduce the variability in feature values.

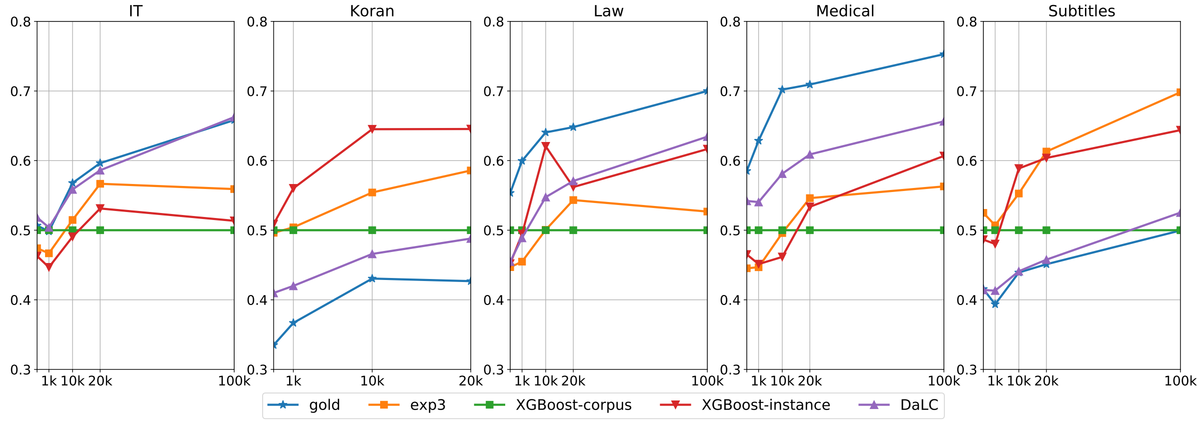

Figure 3: Learning curves provided by DaLC compared against *gold* predictions, baseline predictors (exp_3, XGboost-corpus, XGboost-instance) for German-English/FT.

least-confidence score, (2) margin score (3) average token entropy. Those features rely on the pretrained model M_G, and therefore could be seen as redundant with encoder representations. However, as we demonstrate in Section 6 they turn out to be helpful in some cases. Finally, we consider (4) the cross-lingual cosine similarity score between representation of the source sentence x and its translation $M_G(x)$. These representations are obtained from an external pretrained multilingual sentence embedding model, LaBSE (Feng et al., 2020).

4.3 Domain Adaptation Learning Curve (DaLC) predictor

DaLC predictor corresponds to the model depicted by Figure 2. It contains two main components: (1) *encoder pooling component* that processes NMT encoder representations (given as a sequence of vectors) and produces a single vector $\phi_{enc}(x)$. (2) *fusion layer* combining encoder representations $\phi_{enc}(x)$ with other pre-computed instance-level features $\phi_{DF}(x)$ and corpus-level features $\xi(S_d)$.

In our experiments, we use the multi-filter CNN architecture proposed by Kim (2014) that is widely used in text classification tasks as *encoder pooling component*. For*fusion component*, we simply stack K feed-forward layers followed by ReLU and Sigmoid activation functions at the final layer.

5 Experimental settings

5.1 Data and Evaluation

English-German. We rely on data described in Section 3. We use development split (2K sentences) for *predictor training*: it is randomly split into train (80%) and validation (20%) sets.

The predictor is evaluated on test split portion for each domain (2K sentences). The results reported for each domain are obtained with the predictor trained in Leave-one-out settings (e.g., predictor trained on *Law*, *IT*, *Koran*, *Medical* is evaluated on *Subtitles*). Such evaluation allows us to mimic real-life scenario where we need to predict performance for a completely new domain which is not known at training time.

The evaluation of the predictor is done by measuring error between the predicted score and the ground truth score (measured by *mean chrF*) across all the anchor points. Following Kolachina et al. (2012), we report Root Mean Square Error (RMSE) across all the available test anchor points. In addition, we report absolute error at each anchor point (when possible) to allow for finer-grained analysis of the results. Each experiment is repeated 5 times with different random seeds, and an average across all runs is reported.

English-Korean. We consider five specialized domains (*technology*, *finance*, *travel*, *sports* and *social science*) publicly available from AI-Hub [8]. The size of the validation and test sets are 10k and 5k, respectively. We randomly sample $S_{n,d}$ of 2K sentences following the settings of English-German experiment. Detailed information of baseline NMT models and DA models for English-Korean is described in Appendix A. We adopt the same evaluation scenario as in English-German (leave-one-out settings with RMSE evaluation)

5.2 Baseline predictor models

Traditionally predictor models are evaluated against a naive baseline predicting the *mean* over observations used for training. However, such baseline does not make much sense in the context of learning curve prediction since it is unable to extrapolate to new anchor points.

***exp3* baseline.** exp_3 is a 3-parameter function that is defined by $y = c - e^{(-ax+b)}$. Kolachina et al. (2012) has identified this function as a good candidate for SMT learning curve prediction fitting. In our experiment, we fit this function through least-squares algorithm to all the observations we dispose across all the domains and anchor points (19 points). This function can be seen as an extension of *mean* baseline allowing to extrapolate to unobserved anchor points.

XGboost-based baselines. Following Xia et al. (2020) we also use gradient boosting trees model (Friedman, 2000), implemented in XGboost (Chen and Guestrin, 2016). *XGboost-corpus* baseline corresponds to the XGboost model trained with the corpus-level features: this baseline is comparable with the one used by Xia et al. (2020). We also compare our model against *XGboost-instance* baseline which corresponds to the XGboost model trained with the full set of features (section 4.2) that DaLC predictor is trained with. NMT encoder representations are squeezed in a single vector via min-max pooling and fed to XGboost along with other instance-level features. Comparing *XGBoost-corpus* and *XGboost-instance* results allows us to decouple the impact of instance-level representations and impact of the predictor model learnt from these representations. Exact details of XGboost training are reported in Appendix B.

5.3 DaLC predictor

In our preliminary experiments, we observed that the capacity of *encoder pooling component* does not have much impact on the overall performance. We believe this is because NMT encoder outputs already provide rich contextualized representations of the input sequence. On the other hand, it is important to give enough capacity to the *Fusion layer* which should mix instance-level representations (including NMT encoder representation) with corpus-level features. In our experiments, *encoder pooling component* is a single layer multi-filter CNN (with 3 filters of size 2, 3, and 4). *Fusion layer* is composed of 4 feed-forward layers of hidden size 512, followed by ReLU activation, and final feed-forward layer followed by Sigmoid activation that brings the final prediction at 0-1 scale. We use Mean Squared Loss (MSE) for training. We

apply early stopping criteria with the patience of 10 epochs. We provide more training hyperparameters in the Appendix E.

6 Results

6.1 Prediction for observed anchor points

Table 1 reports the results across different domains for English-German and German-English. Table 2 reports the results for Korean-Enligsh. We compare corpus-level baselines (*exp3* and *XGboost-corpus*) against different instance-level predictors: (i) our *DaLC predictor* relying on the full set of instance- and corpus-level features described in the section 4.2; (ii) *XGboost-instance* (section 5.2) relying on same features as DaLC; (iii) Ablation of different groups of features from full model (DaLC/DF, DaLC/corpus or DaLC/NMT encoder)

For each domain, we report RMSE when comparing predicted *mean chrF* to the gold *mean chrF*[9] score averaged across all the anchor points (0, 1k, 10k, 20k and 100k).

Instance-level vs corpus-level. We note that instance-level models generally outperform corpus-level models for most of domains and language pairs. An exception is English-German direction, where *XGboost-corpus* leads to better prediction then *XGboost-instance* in *Koran* and *Subtitles* domain. According to additional visualisation of these result in Figure 3 and Figure 7 (in Appendix) we see that *XGboost-corpus* model actually fails to learn meaningful patterns as it predicts the same score (0.5) for all the domains across all the anchor points[10]. It leads to lower RMSE for *Koran* and *Subtitles* domains only because the gold *mean chrF* for those sets is very close to 0.5. Therefore, even if the instance-level leads to higher RMSE it provides more accurate predictions overall as shown by *Avg* column in Table 1.

We observe that while DaLC reaches lowest RMSE across all the domains for German-English and Korean-English, it is not necessarily true for English-German. We note however, that DaLC performance varies less across domains, and reaches overall best performance (reflected by *Avg* column) which means that it is less influenced by overall *mean* performance (as opposed to corpus-level models), and is able to better exploit instance-level representations that favour knowledge transfer across domains.

In addition in the Appendix C we report computation cost for instance-level and corpus corpus level models.

Impact of different features. We note that the impact of DF and corpus features varies across the domains. One clear trend is that NMT encoder features seem to be important for predictor quality. An interesting exception is the *Medical* domain, where the removal of NMT encoder representations seem to reach the best RMSE. Furthermore, Appendix J provides an in-depth ablation study for each feature used in the model.

Impact of DA algorithm. We examine the effectiveness of the proposed method on the different adaptation algorithm, comparing adapter layers (Bapna and Firat, 2019) to full finetuning. The Adapter layer is a small module inserted on top of each encoder and decoder block and updated only

---

[9] The gold mean chrF corresponds at anchor point K for domain d corresponds to the actual value of *mean chrF* obtained after adaptation of NMT model with K samples from domain d.

[10] We believe this might be due to the very small amount of corpus-level training samples.

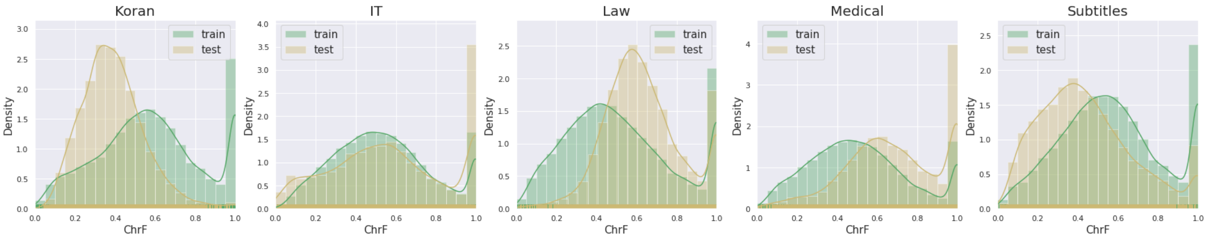

Figure 4: ChrF score distribution of training and test datasets across each experiment case in the German-English FT experiment. Each histogram shows the difference between the training and test ChrF score distributions in each leave one out setting. For instance, the ChrF score distribution of the Koran column obtains where training distribution denotes all training anchor points of IT, Law, Medical and Subtitles domain, and test distribution represent chrF score in all anchor points of the Koran domain.

with in-domain samples (while keeping the rest of the model frozen). The hidden dimension size of the adapter is 1024. Details of the adapted models is provided in Table 5.

Table 1 demonstrates the quality of predictions domain adapted model via Adapter layers in the De-En direction. Comparing to FT results on the De-En direction, we notice that the predictor quality behaves similarly for both DA methods. It indicates that DaLC can be extended to other DA methods.

Impact of other factors. We report additional experiments such as depending on the number of domains for training predictor and performance on a mixing of two different domains in Appendix H and Appendix D.

6.2 Interpolation and Extrapolation of DA performance

One of practical and possible scenarios is prediction of DA performance for the anchor points that were not observed in the training data. Table 3 shows the accuracy of our predictor for interpolation[11] ($3k$ and $40k$) and extrapolation[12] ($160k$) scenarios for *Subtitles* test domain in the De-En direction. We recall that the predictors have been trained on 0k, 10k, 20k and 100k anchor points for *IT*, *Medical*, *Law* and *Koran* domains.

We report the absolute error with respect to gold *mean chrF* (MAE) for these specific anchor points. We can see that DaLC achieves significantly lower error compared to other baselines. We note however that extrapolation error ($160k$) is higher compared to interpolation errors ($3k$ and $40k$).

model	3K	40k	160k
exp_3	0.1087	0.1640	0.1934
XGboost-instance	0.1546	0.0922	0.1125
DaLC	**0.0063**	**0.0080**	**0.0413**

Table 3: Results for interpolation and extrapolation of learnt models to new (unseen in training) anchor point: we report the absolute value of the difference between gold and predicted values (subtitles domain)

7 Analysis and Discussion

The results reported in previous section suggest that overall DaLC prediction error depends a lot on the nature of the test domain (as seen on Figures 3, 7 and Table 1). Thus, all the predictors tend to overestimate the *mean chrF* score on *Koran* domain, or underestimate the score on *Law* domain. In this section we try to analyse this phenomenon and explain such behaviour.

7.1 Train/test data distribution

Figure 4 provides visualization of training and test distribution for each domain. We can see that in the case of *Koran* and *Law* domains there is a highest shift between train and test distribution of chrF scores: *Koran* has more low-quality translations (low chrF value) compared to its training domains, while for *Law* it is the opposite. This discrepancy leads to underestimated scores for *Law* domain and overestimated scores for *Koran*. On the other hand, we can see the predictor has higher accuracy in other domains that have a similar distribution between training and test distributions. We observe the same patterns for the En-De direction (Figure 6), or when extending our framework to more training domains (Appendix H).

---

[11] Interpolation: prediction for the unseen anchor points that are within the range of observed anchors.

[12] Extrapolation: prediction for the anchor point that lies beyond observed anchors.

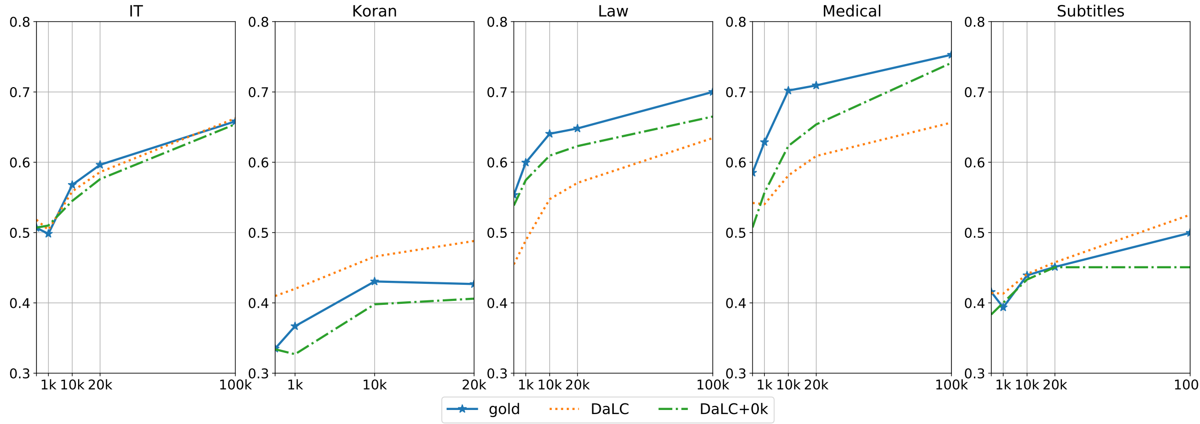

Figure 5: Comparison of learning curve prediction with DaLC and DaLC `+with 0k` on the De-En direction.

7.2 Adding 0 anchor point

The above finding regarding train/test discrepancy leading to a higher prediction error implies that even though our model is able to exploit instance-level representations to some extent (it achieves lower prediction error compared to corpus-level baseline), it is still heavily impacted by overall data distribution. One possible explanation for such behaviour would be the fact that source-level representations may not contain enough information for model to rely on to predict future translation quality. A simple example would be a source sentence that should be either translated in “formal” or “informal” manner depending on what the target domain is. When the model lacks information about target language distribution for the new domain its simply has no mean to learn faithful predictor.

In this experiment, we consider the scenario where we have access to a small sample of parallel data (2K sentences) for the test domain. When such sample is available the predictor training data can be enriched with 0-anchor point samples corresponding to the translations produced by our baseline model and their corresponding chrF scores.

Figure 5 and Figure 8 in Appendix demonstrate the results of this experiment (Table 13 reports RMSE scores for the reader interested in more in-depth analysis). We see that addition of 0k anchor point significantly improves the learning curves obtained by DaLC predictor. This confirms our hypothesis that relying on monolingual in-domain sample may limit the predictors’ performance for certain domains. Adding a small parallel sample to obtain 0k anchor point instances seems to be effective work around for this problem.

8 Conclusion

In this work, we formulate a problem of Domain Adaptation Learning Curves prediction for NMT as instance-level learning framework. We demonstrate that it is possible to learn reasonable learning curve prediction model with a very small amount of NMT model instances via instance-level learning rather than corpus-level learning that most previous works rely on. We propose a DaLC model relying on NMT encoder representations, combined with various instance and corpus-level features. We show that such model is able to achieve good results with small amount of pretrained model instances. We perform in-depth analysis of the results for the domains where the predictor was less successful and conclude that the capacity of the predictor relying on the source-side sample only can be limited for some domains. Further analysis of characteristics of such domains could lead to better Domain Adaptation strategies. Finally, we believe it will be interesting to deepen the connections between Active Learning framework and Learning Curves prediction frameworks which could mutually help one another.

A NMT model training and domain adaptation hyper parameters

A.1 Baseline

English-German Our baseline models rely on `transformer-base` architecture (Vaswani et al., 2017) trained on WMT-20 German-English dataset. For English-German direction we used inline casing (Berard et al., 2019) and tokenized text with BPE (Sennrich et al., 2016) using 24K vocabulary size encoding joint vocabulary shared between two languages. We also share embedding parameters between source and target. We use Fairseq toolkit (Ott et al., 2019) for training the baseline model with default training parameters for `transformer-base` architecture as proposed by Vaswani et al. (2017). Specifically, M_G consists of six layers, 512 units and eight heads. We utilize the same Adam warm-up optimizer as in the original paper. Note that the baseline model for Finetuning and Adapter experiments in the same language direction are identical regardless of Domain Adaptation methods.

Korean-English We follow the same experiment setting described in Appendix. E. We utilize `transformer-big` architecture (Vaswani et al., 2017) trained on the Ko-En direction. Training datasets of baseline model is constructed by using six categories datasets[13] in AI-Hub [14]. The total number of training dataset is 1.51M parallel sentences. We set the size of BPE as 32K.

A.2 Domain Adaptation

Hyper-parameters used for Domain Adaptation models are reported in the Table 4. We use early stopping criteria on the validation loss performance in order to avoid overfitting to the data. Note that at this stage we used greedy decoding to compute chrF scores. We verified that the actual learning curves with greedy decoding behaves similarly to the learning curves with beam search. We stick to greedy decoding because we believe that beam search brings additional complexity to the performance prediction. We leave the impact of decoding method on the performance prediction for future work.

Table 5 and Table 8 report the BLEU/mean chrF scores reached by each of our models on each language. We note that the model adapted via finetuning follows the same trend as the one adapted via adapter layers. Table 6 reports best achieved loss for each domain and each anchor point, as well as the number of epochs required to reach it. One needs to keep in mind that the size of a single epoch varies across anchor points (it is 10 times bigger for 10k anchor point than for 1k anchor point). Note that loss is directly comparable between different domains and different anchor points since it corresponds to Cross-entropy loss relying on the same vocabulary.

	En-De	De-En	Ko-En
Learning rate	0.001	0.001	0.001
batch size	4k	2k	2k

Table 4: Parameters used for Domain Adaptation of NMT system in each direction, where the batch size denotes the tokens per batch. En-De/FT and En-De/Adapter utilize the same learning rate and the batch size.

B Implementation details of XGboost

We run the XG-boost regressor using XGBoost library [15]. The learning rate of the XG-boost is set to 0.1. We follow the default regularization to alleviate the overfitting problem. The objective function of the XG-boost is RMSE. Regarding the model parameters, the number of trees and the maximum depth of trees are 100 and 10, respectively.

C Computation time and memory usage

We compare the computation time and memory usage of DaLC with other models on the learning curve prediction task in Table 7. Although, corpus-level frameworks(i.e., XGboost-corpus and exp3) require less computation cost and memory resources, the performances of these models with small number of anchor points are very far from the real value described in Table 1. The most computational heavy part of our model is the computation of anchor points used to train the predictor model. Anchor point implies training a Domain Adapted model with in-domain samples (200 300 sec in best case scenario of 1000 in-domain samples and up to 4h for larger in-domain samples). For this reason, instance-level frameworks are more practical in real-life scenarios as they achieve good performance with small amount of anchor points. Note,

Table 6: Domain Adaptation convergence statistics. We report the number of epochs when the Domain Adaptation reached the best validation loss, as well as the value of best validation loss. Note that each epoch corresponds to different amount of updates for different anchor point due to the difference in the in-domain samples used for DA. The loss however is comparable across different anchor points and different domains since it is always based on the same vocabulary.

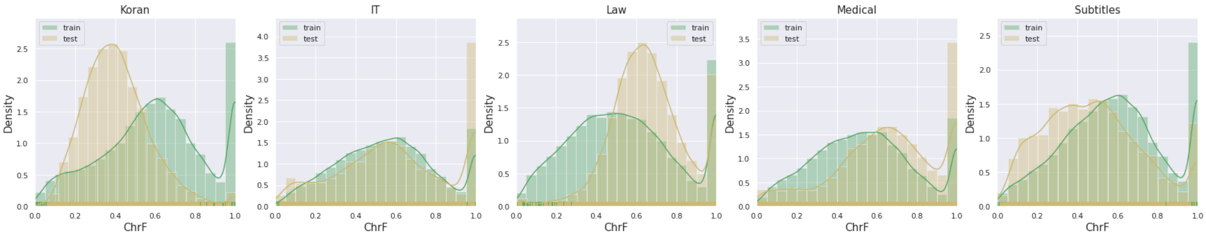

Figure 6: ChrF score distribution of training and test datasets across each experiment case in the English-German FT experiment. Each histogram shows the difference between the training and test ChrF score distributions in each least one out setting. For instance, the training distribution of Koran column obtains from all training anchor points of IT, Law, Medical and Subtitles domain. Test distribution of Koran column represents chrF score in all anchor points of the Koran domain.

Model	Train time(s/epoch)	Test time(s/anchor)	params
`exp3`	0.001	0.0002	3
XGboost-corpus	0.23	0.0013	100
XGboost-instance	1.44	0.0802	1.03M
DaLC	8.23	0.0914	3.9M

Table 7: Computation time and memory usage of each model, where the test time is the time to inference one anchor point.

that previous works Xia et al. (2020); Kolachina et al. (2012) relied on 50-90 of MT model instances to train reliable corpus-level predictor.

Considering the performance and total training time to obtain training anchor points, instance-level frameworks are feasible solutions to estimate the future performance without finetuning. In instance-level frameworks, DaLC is slightly slower than XGboost-instance but DaLC outperforms other approaches as shown in Table 1. Moreover, DaLC is a very light in terms of parameter size compared to transformer base (65M). Our model can accurately forecast the finetuning performance with only 4% of the total number parameters of `transformer base` without the need of computation resources for finetuning.

D Performance on the Mixed domain

We evaluate our model under a loosely defined domain, such as mixing of two domains. To simulate this scenario, we defines a mixed domain by aggregating Tech and TED domain. The samples $S_{n.d}$ of size n in the mixed domain uniformly sampled from each domain. The test set of a mixed domain also is constructed with all test sentences of both domains. We train DaLC with anchor points of Finance, Social, Sports and Travel (i.e., Except 'Tech' domain) and then evaluate the performance on the mixed domain. Table 10 summaizes the performance on each anchor point in the mixed domain experiment.

Table 9 demonstrates the RMSE errors across anchor points on the defined mixed domain and each domain. As previously, DaLC reaches lower (and more stable) prediction error compared to corpus-level models on averages. Thus, even the corpus-level can reach lower error in some cases (E.g., XGboost-corpus on TED) they still tend to be very close to predicting the mean score of the training data, and therefore their predictions are not stable across domains, while DaLC's predictions are more stable.

E Predictor implementation details

The overall architecture of the predictor is described in Figure 2. Our prediction is composed of two parts, the encoder pooling component and the fusion layer component. The encoder pooling component is based on the multi-filter CNN architecture proposed by Kim (2014) which is widely used in text classification tasks. It encodes the sentence to latent feature h_i, which contains context information to predict performance.

At first, the model obtains the encoder representation $e_i \in \mathcal{R}^d$ of the i-th token of the input $x = (x_1, x_2..., x_n)$ from the encoder of the baseline model(M^G), where d and n is the size of dimension and the length of x . The size of hidden dimension d is 512 in our implementation. Next, we apply the multiple convolution filters across the sequence in the same manner as the original paper, where the window sizes of convolution filters are 2,3 and 4. We then obtain the output $h_i \in \mathcal{R}^d$ from the max pooling operation along the sequence of convolution outputs. To fuse all features, we concatenate the features of encoder representations h_i, the pre-computed domain-difficulty features $\phi_{DL}(x)$ and the corpus-level features $\xi(S_d)$. The fusion layer forecasts the performance based on the concatenated features, where the fusion layer is constructed with a five layer feed-forward neural network with non-linear activation functions. We utilize a non-linear function as ReLU, but the last layer of the feed-forward neural network utilize the Sigmoid function to change the output from zero to one. Learning is done via MSE loss between the predicted score and the ground-truth score.

Training hyperparameters To optimize the model, we use the learning rate as 0.001 with Adam optimizer. Moreover, the learning rate gradually decreases based on an exponential decay scheduler. All experiments stop the training based on the early stopping with patience as 10. Note that the parameters of M^G encoder are fixed while training the predictor.

F Overview of predictor training dataset creation

- We start from the deduplicated train/dev/test splits.

- we sampled 1k, 10k, 20k or 100k samples from the train split

DaLC	0.105	0.112	0.099

Table 9: RMSE on the mixed domain experiments, where 'Mixed' column means RMSE error on performance estimation in the mixed domain test sentences. 'TED' and 'Tech' column represents the performance on only test sentences on the corresponding domain in the mixing domain.

	Mixed	TED	Tech
	Korean-English/FT		
Baseline	0.503	0.423	0.583
1K	0.562	0.427	0.697
10K	0.590	0.431	0.748
20K	0.596	0.429	0.763
100K	0.618	0.439	0.795

Table 10: ChrF scores on each test set with a mixed Domain Adaptation case, where the models trained with uniformly sampled TED and Tech training dataset. Note that a Domain Adaptation model on each anchor point(i.e.,row-wise) is the same adaptions model. 'Mixed' represents average chrF scores on test sentences of both TED and Tech domains.

- we finetuned English-German baseline NMT system on each of those samples
- We then were able to compute instance-level chrF for each domain, at each anchor point for dev and test splits.

G Additional results

Table 11 reports prediction errors (RMSE/MAE) across all available anchor points for all domains for **DaLC**. Additionally, we provide results of the learning curves depending on the different combination components of DaLC in Figure 9. Table 12 reports the deviation from the gold predictions for each anchor point, each domain. Figure 7 is the learning curve prediction result in the English-German direction. We also report Table 13 to demonstrate the detail RMSE errors with `+ with 0k` experiments described in Section 7.2

H Impact of the amount of domains

Elsahar and Gallé (2019) have shown one can obtain better precision at performance drop prediction due to domain shift when the amount of training domains increases. Inspired by this finding, we extend the set of our training domains with additional domains (English-German language pair only): *Bible*, *Tatoeba*, *Medline*, *TAUS*, *PatTR*, and *MuchMore*. We provide some details of these various datasets in the Appendix I.

For each of these datasets, we created a predictor training dataset following the same settings as previously (whole procedure is outlined in the Appendix F).

We train DaLC predictor keeping the same test domains as previously, but extend corresponding training domains with newly introduced domains. We consider following extensions of the training domains: (*Bible, Medline, PatTR*), (*TAUS, Tatoeba,*

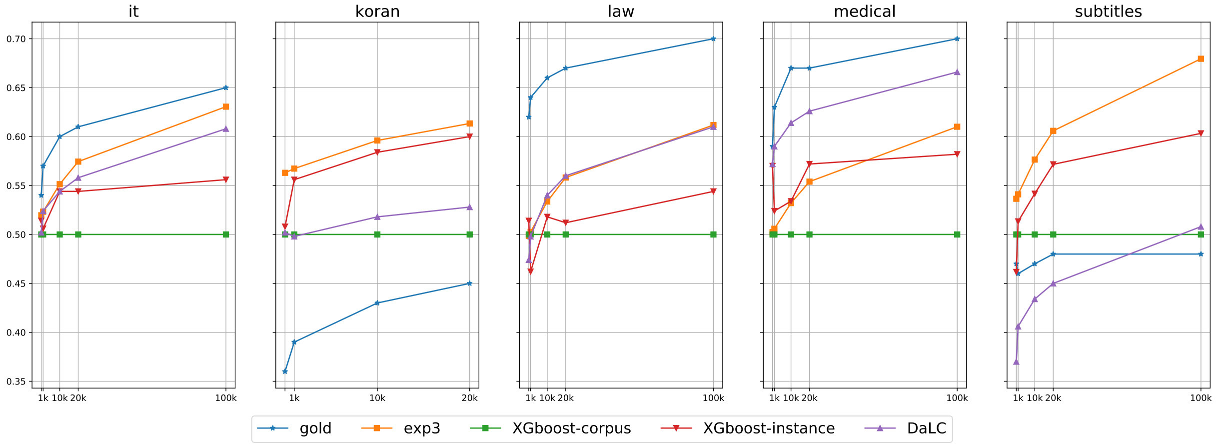

Figure 7: Learning curves provided by DaLC compared against *gold* predictions, baseline predictors (exp_3, XGboost-corpus, XGboost-instanc) for English-German.

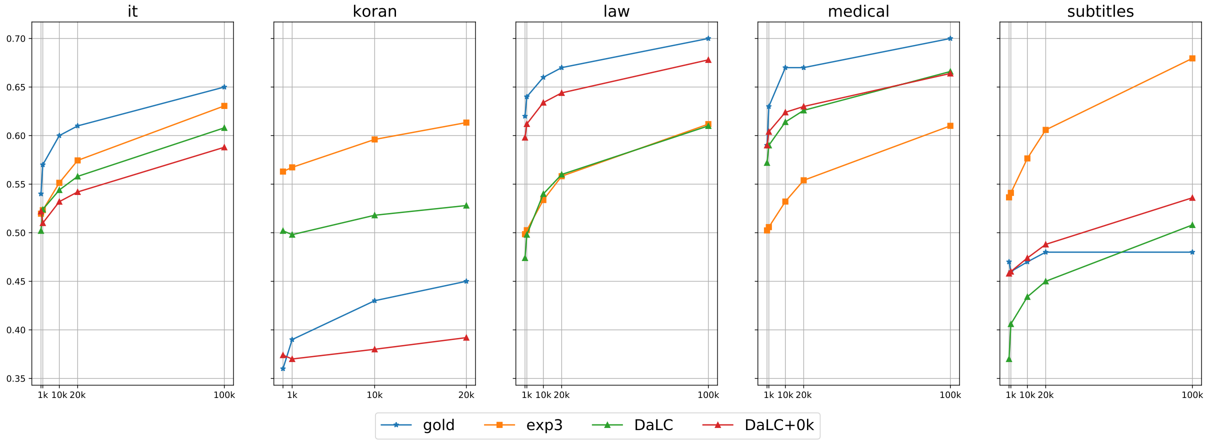

Figure 8: Comparison of learning curve prediction with DaLC and DaLC `+with 0k` on the English to German

MuchMore) or All (6 new domains). The goal of this split is to decouple the differences in performance that are due to the amount of training data from those due to the nature of new domains added. Table 15 reports the results. We can see that additional domains indeed improve the overall error. We note that error decreases *Law* domain, but error increases on *Koran* domain. When looking at the result we see that the addition of new domains simply leads to higher predictions scores overall (which is due to overall high chrF scores in the additional domains).

I Additional datasets

- Bible, Tatoeba from Opus Website[16]
- Medline: consists of abstracts from scientific publications, distributed as part of WMT-20 Biomedical translation challenge[17]
- TAUS[18]: TAUS Corona Crisis Corpora that consists of crawled documents related to Covid-19 crisis.
- PatTR[19]: patents related to medical domain
- MuchMore[20]: scientific medical abstracts obtained from the Springer Link web site.

J In-depth ablation study

Table 14 reports the results for in-depth ablation study on Subtitles domain. Table 14 shows the

Hey AI, Can You Solve Complex Tasks by Talking to Agents?

Tushar Khot **Kyle Richardson** **Daniel Khashabi** **Ashish Sabharwal**

Allen Institute for AI, Seattle, WA, U.S.A.
`{tushark,kyler,danielk,ashishs}@allenai.org`

Abstract

Training giant models from scratch for each complex task is resource- and data-inefficient. To help develop models that can leverage existing systems, we propose a new challenge: Learning to solve complex tasks by communicating with existing agents (or models) in natural language. We design a synthetic benchmark, COMMAQA, with three complex reasoning tasks (explicit, implicit, numeric) designed to be solved by communicating with existing QA agents. For instance, using text and table QA agents to answer questions such as "Who had the longest javelin throw from USA?". We show that black-box models struggle to learn this task from scratch (accuracy under 50%) even with access to each agent's knowledge and gold facts supervision. In contrast, models that learn to communicate with agents outperform black-box models, reaching scores of 100% when given gold decomposition supervision. However, we show that the challenge of learning to solve complex tasks by communicating with existing agents *without relying on any auxiliary supervision or data* still remains highly elusive. We release COMMAQA, along with a compositional generalization test split, to advance research in this direction.[1]

1 Introduction

A common research avenue pursued these days is to train monolithic language models with billions of parameters (Radford et al., 2019; Raffel et al., 2020; Brown et al., 2020) to solve every language understanding and reasoning challenge (Wang et al., 2018, 2019). In contrast, humans often tackle complex tasks by breaking them down into simpler sub-tasks, and solving these by interacting with other people or automated agents whose skill-sets we are familiar with. This approach allows us to learn to solve new complex tasks quickly and effectively, by building upon what's already known. Can AI systems learn to do the same?

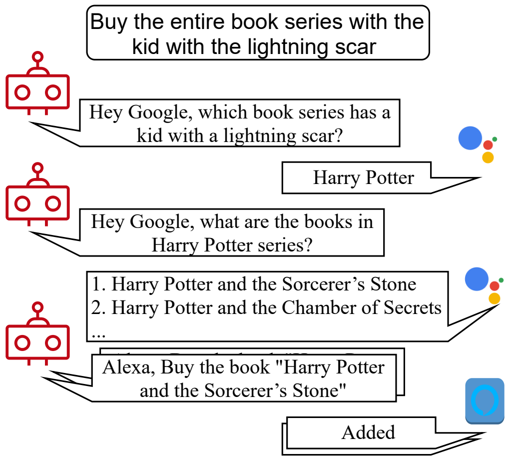

Figure 1: Motivating example for a setup where a system is expected to learn to accomplish goals by interacting with agents via a natural language interface.

To facilitate research in this direction, we propose a new reasoning challenge and a benchmark called COMMAQA where, in addition to the usual end-task supervision, one has access to a set of predefined AI agents with examples of their natural language inputs. Importantly, the target end-task is designed to be too difficult for current models to learn based only on end-task supervision. The goal is instead to build models that learn to solve the target task by decomposing it into sub-tasks solvable by these agents, and interacting with these agents in natural language to do so.

As a motivating example, consider the interaction depicted in Figure 1 where a system is asked to buy a book series with a certain property. The system breaks this goal down, using agent-1 (here Google Assistant) to identify the referenced book series as well as the list of books in that series, and then using agent-2 (here Amazon Alexa) to make the purchase. While both of these agents interact with the system in natural language, they have different and complementary skill sets,[2] rely on privately held knowledge sources, and have been

[2] but not necessarily mutually exclusive skills

Findings of the Association for Computational Linguistics: ACL 2022, pages 1808 - 1823
May 22-27, 2022

built at an enormous cost. At the same time, neither agent by itself can accomplish the original goal.

An alternative to building such a system that interacts with existing agents is to teach all requisite sub-tasks and skills to a large black-box system, say via multi-task learning (Khashabi et al., 2020; Gupta et al., 2021). This, however, not only wastes time and resources, but is often also infeasible. For example, agents such as Google Assistant and OpenAI GPT-3 use private knowledge resources and are computationally expensive to train even once. It would thus be nearly impossible to build a single system with the capabilities of both of these agents.

We note that agents need not be sophisticated AI assistants. An agent may simply be a previously developed question-answering (QA) model, a math module, a function of textual input, an image captioning system—anything the community already knows how to build. The goal is to *learn to leverage existing agents for more complex tasks.*

To enable the development of general systems for this task, we identify the minimal inputs that must be assumed for the task to be learnable—training data for the complex task, existing agents that together can solve the complex task, and examples of valid questions that can be asked of these agents (capturing the agents' capabilities). We build a new synthetic benchmark dataset called COMMAQA (Communicating with agents for QA), containing three complex multihop QA tasks (involving Explicit, Implicit, and Numeric reasoning) and four input QA agents that can solve these tasks.

COMMAQA is not yet another multi-hop reading comprehension dataset. It is designed to facilitate the development of a new family of techniques that teach systems to communicate with a wide variety of agents to solve different types of complex tasks.

We demonstrate that black-box models struggle on COMMAQA even when provided with auxiliary data, such as domain-relevant agent knowledge. On the other hand, a model that leverages the agents (Khot et al., 2021) can achieve very high accuracy but relies on auxiliary supervision (decomposition annotations). While it is possible to identify valid decompositions using just the end-task labels, the search space is extremely large and naïve approaches, as we show, help only with one of the datasets. COMMAQA thus serves as a new challenge for the NLP community.

Contributions: We (1) propose a new challenge of learning to solve complex tasks by communicating with agents; (2) develop a synthetic multi-hop QA dataset COMMAQA with three reasoning types; (3) provide auxiliary training data and a compositional generalization test set; (4) demonstrate the challenging nature of COMMAQA for black-box models; and (5) show the promise of compositional models that learn to communicate with agents.

2 Related Work

Multi-hop QA (Khashabi et al., 2018; Mihaylov et al., 2018; Khot et al., 2020; Geva et al., 2021) focuses on reasoning with multiple facts. Some multi-hop datasets (Yang et al., 2018; Dua et al., 2019) have been used to develop modular approaches such as TMNs (Khot et al., 2021), which are a step towards our goal—they try to solve complex questions by leveraging agents such as single-hop QA models. However, these approaches have had limited success because current datasets are insufficient for the development of such models, for two reasons. First, prevalent single-hop shortcuts (Min et al., 2019a; Trivedi et al., 2020) incentivize models trained on answer supervision alone to learn to exploit these shortcuts rather than learn to compositionally communicate with agents. E.g., they learn to answer a multi-hop question by just asking one single-hop question (Min et al., 2019b). Second, these datasets often contain sub-problems not solvable by existing models/agents, such as producing structured output (e.g., outputting a *list* of all touchdowns mentioned in the context).[3]

Semantic Parsing typically focuses on mapping language problems to executable symbolic representation based on a pre-defined grammar (Krishnamurthy et al., 2017; Chen et al., 2020). Similar ideas are also found in the area of program synthesis (Gulwani, 2011; Desai et al., 2016). These goals, like ours, seek to simplify complex problems into simpler executable forms, without relying on explicit intermediate annotation (Clarke et al., 2010; Berant et al., 2013). We, however, diverge from this line by seeking agent communication in free-form language, not bound to any pre-specified set of operations or domain specific languages.

Question Decomposition is used to solve multi-

---

[3] For instance, 65% of the errors of the ModularQA system (Khot et al., 2021) on HotpotQA were due to questions unanswerable by existing agents. Hence these datasets don't satisfy the basic task requirement of being solvable using existing agents. This makes the learning-to-communicate task ill-defined over these datasets and meaningful progress infeasible.

hop QA but the resulting models (Talmor and Berant, 2018; Min et al., 2019b; Perez et al., 2020; Khot et al., 2021) are often dataset-specific, rely on decomposition annotations, and limited to one or two QA agents. To address these limitations, our proposed challenge covers three dataset types and four agents. Additionally, models are expected to learn to decompose the task by interacting with the agents, rather than relying on human annotations.

Synthetic Reasoning Challenges have recently been proposed (Lake and Baroni, 2018; Sinha et al., 2019; Clark et al., 2020; Betz and Richardson, 2021) to help systematically identify the weaknesses of existing models and inspire modeling innovation (Liu et al., 2021). Our new tasks are unique and focus on simulating complex agent interaction to motivate the development of decomposition-based modeling approaches.

Text-Based Games, similar to our work, involve interacting in plain text in order to accomplish a goal (Yuan et al., 2019, 2020; Hausknecht et al., 2020; Ammanabrolu et al., 2021; Jansen, 2021). This is typically done in a physical environment, which acts as an “agent” in our setting. Unlike many works in this area, we focus on different classes of compositional questions (e.g, implicit, numerical) and formulate a challenge that makes minimal assumptions about having access to agents’ internal information or input language.

3 Challenge Task Definition

We formalize the new challenge task of *learning to talk with agents to solve complex tasks*. To ensure generality of solutions, we identify minimal inputs for the task to be well-defined and learnable.

First we must define $\{f_i\}_{i=1}^{m}$, the agents or models that solve simpler sub-tasks.[4] Minimally, we need to define the space of valid inputs $\mathcal{L}_i$ for each agent f_i, i.e., how can they be invoked. For a system to identify the appropriate agent for each subtask, we also need to define the capabilities of each agent. Since these agents are often defined for natural language tasks, the space of inputs captures the capabilities of these agents too. For instance, "Buy the book ‘Harry Potter and the Sorcerer’s Stone’" captures the Alexa agent’s capability of buying books. Instead of complex formal specifications of the agent’s capabilities, we use natural language inputs as a rich and convenient representation.

Next, we need a target task $\mathcal{T}$ that can be solved via a composition of the capabilities of various f_i.[5] Finally, to pose this as a machine learning problem, we need training data $\mathcal{D} = \{(x_k, y_k)\}_{k=1}^{N}$ for $\mathcal{T}$. Since collecting annotations for complex tasks can be difficult, $\mathcal{D}$ is expected to be relatively small. Models must therefore use the available agents, instead of learning the complex task from scratch.

Given these pre-requisites, we can define the challenge task as follows:

Challenge: Learn a model to solve a complex task $\mathcal{T}$, given only:
- Training dataset $\mathcal{D} = \{(x_k, y_k)\}_{k=1}^{N}$ for $\mathcal{T}$;
- Agents $\{f_1, \dots, f_m\}$ that can help solve $\mathcal{T}$;
- Examples from the space $\mathcal{L}_i$ of valid inputs for each agent f_i that captures its capabilities.

One example of this challenge is answering multi-hop questions given two agents: an open-domain TextQA agent f_1 and an open-domain TableQA agent f_2. Agent f_1 can use large textual corpora to answer questions such as "Who directed Kill Bill?". Agent f_2 can use tables (e.g., Filmography tables) to answer questions such as "List the movies directed by Quentin Tarantino". Finally, the training data $\mathcal{T}$ for the complex task would contain examples such as ("What movies has the director of Kill Bill appeared in?", ["Reservoir Dogs", ...,]).

4 Dataset: COMMAQA Benchmark

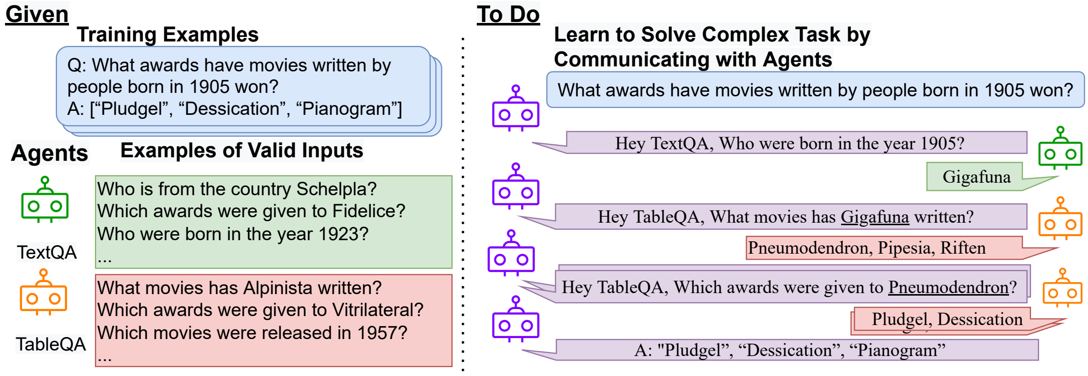
We next propose a new benchmark dataset COMMAQA that enables the development of models that can learn to communicate with existing agents. Specifically, we provide a collection of *three synthetic datasets* where each question is answerable by talking to simple QA agents. Note that we are not proposing a new class of questions but a new dataset for the proposed challenge task. A high-level overview of this dataset is shown in Fig. 2.

We choose QA as the underlying task and use QA agents for this challenge because the question-answer format can capture a broad range of tasks (Gardner et al., 2019) while also naturally surfacing the capability of each agent. For instance, the question "What are the key frames in v?" describes a capability of the invoked agent (namely, identifying key frames), in addition to the specific inputs. We next describe our framework for build-

---

[4] As mentioned earlier, we use *agents* to refer interchangeably to models, assistants, or functions that take free-text as input and produce free-text as output.

[5] Existing datasets lack this requirement, making it impossible to focus only on the agent communication aspect.



Q: What awards have movies written by people born in 1905 won?

ing COMMAQA, which we believe can be extended to other complex tasks, e.g., video summarization.

4.1 Agent Definition

To define the i-th agent, we build a knowledge base that captures its internal knowledge resource $\mathcal{K}_i$. We use natural language question templates to define the set of questions that this agent can answer over this internal knowledge. For example, given a KB with relations such as "directed(x, y)", the agent would answer questions based on the template: "Who directed the movie __?"

Knowledge Base, $\mathcal{K}_i$. To build the knowledge base, we define a KB schema as a set of binary relations between entity types, e.g., director(movie, person). We build a list of entity names that belong to each entity type. To avoid potential conflicts with the LM's pre-training knowledge, all entity names are generated non-existent words.[6]

Rather than building a static and very large KB, we sample *a possible world* independently for each question, by sub-sampling entities for each entity type and then randomly assigning the KB relations between these entities. This prevents memorization of facts across the train and test splits, which in the past has led to over-estimation of QA model performance (Lewis et al., 2021). This also encourages models to learn proper multi-hop reasoning using the agents, rather than memorizing answers.

Examples of Valid Inputs. To define the space of valid inputs for each agent f_i, we define a set of question templates that can be answered by it over $\mathcal{K}_{ik}$ (e.g., Who directed __?). We construct questions corresponding to a relation in both directions, e.g., "Who all directed __?" and "For which movies was __ a director?". To emulate diversity in natural language, we specify multiple phrasings for the same question. We use these templates to generate examples of valid inputs in $\mathcal{L}_i$ by grounding them with entities of the appropriate entity type (e.g., Who directed Kill Bill?).

To ensure generalization to a broad set of tasks, we do not limit the questions to only single span answers. Depending on the question, the agent can produce answers as a single string (span, boolean or a number), a list of strings (e.g., "Which movies did Spielberg direct?"), or a map (e.g., "What are the states and their capitals in USA?").

Implementation. To answer the question, agents convert questions into queries against their internal knowledge (based on the templates) which we implement as a symbolic function (written in Python), instead of a model. While a language model might be able to generalize to out-of-distribution variations in language, its behavior can be often unpredictable. By implementing the agents as pattern-based functions, we ensure that the resulting systems would stay within the language constraints of each agent and generalize to restricted language models. Additionally, this enables faster development of approaches without spending resources on running a large-scale LM for each agent.

4.2 Complex Task Definition

Given the space of valid input questions for each agent, we construct training examples for the complex task using templated theories. These theories consist of a complex question template and a composition rule expressed as a sequence of questions asked to appropriate agents. For example,

"What movies have the directors from $1 directed?"
#1 = [textqa] "Who is from the country $1?"
#2 = [tableqa] "Which movies has #1 directed?"

---

[6] https://www.thisworddoesnotexist.com

Operator	Pseudo-code	Example
select	return f_i(q(a))	#1=[23, 35] q="Which is largest value in #1?" f_i= mathqa → **35**
project	return [(x, f_i(q(x))) for x in a]	#1=[Jordan, Johnson] q="What were the lengths of throw by #1?" f_i= textqa → **[(Jordan, [23, 34]), (Johnson, [45, 56])]**
projectValues	return [(k, f_i(q(v))) for (k, v) in a]	#1=[(Jordan, [23, 34]), (Johnson, [45, 56])] q="Which is largest value in #1?" f_i= mathqa → **[(Jordan, 34), (Johnson, 56)]**
filter	return [x for x in a if f_i(q(x))]	#1=[23, 34, 56] q="Is #1 greater than 50?" f_i= mathqa → **[56]**
filterValues	return [(k, v) for (k, v) in a if f_i(q(v))]	#1=[(Jordan, 34), (Johnson, 56)] q="Is #1 greater than 50?" f_i= mathqa → **[(Johnson, 56)]**

Table 1: Compositional Operators used in this work to transform structured answers into queries answerable by an agent. The operator takes the agent f_i, a structured answer a (we use the answer index, e.g., #1, to refer to any answer), and a query with a placeholder as inputs and executes the pseudo-code shown here.

Composition Operators. While this simple theory would work for single span answers, these agents often return list or map answers. Even within this simple example, there can be multiple directors from a given country and this list cannot be directly fed to the tableqa model, i.e., "Which movies has [...] directed?". This problem gets even more challenging with complex structures. E.g., maintaining a map structure while operating on the values of the map (see 3rd row in Table 1).

To handle the different answer structures, we define a special set of compositional operators in Table 1. These operators take agent f_i, a structured answer a, and a query with a placeholder as inputs, and execute a set of queries (as defined by the pseudo-code in Table 1) against f_i. These operators are inspired by QDMR (Wolfson et al., 2020), but modified to be actually *executable*. E.g., the "project" operator in QDMR: "return directors of #1?" does not specify how to execute this query whereas our operation (project) [textqa] "Who are the directors of #1?" specifies how to use the TextQA model and #1 to generate a map.

We also define a set of agent-independent data structure transformations in Table 2, e.g., convert a map into a list of its keys. Since longer chains of reasoning are prone to more errors (Fried et al., 2015; Khashabi et al., 2019), we don't model these simple transformations as additional reasoning steps. Instead, we concatenate compositional operators with transformations to create about 20 new, combined operators such that transformations can be applied after an operation in a single step, e.g., project_Values operation performs the project operation followed by the Values transformation.

Given these operators, the final theory for the above example would look like:

"What movies have the directors from $1 directed?"
#1 = (select) [textqa] "Who is from the country $1?"
#2 = (project_values_flat_unique) [tableqa] "Which movies has #1 directed?"

Transf.	Procedure
FLAT	Flatten list of lists into a single list
UNIQUE	Return the unique items from a list
KEYS	Return the list of keys from a map
VALUES	Return the list of values from a map

Table 2: Simple transformations that modify the output data structure. These transformations can be chained together with an operation, e.g., PROJECT_VALUES.

Building Examples. Given a KB schema, question templates for each agent, and theories, we can now build examples for the complex task (Fig. 3). We first sample a possible world based on the KB schema. We assign each relation to one of the agents based on which agents are likely to answer such questions, i.e., only this agent would answer questions about this relation. This captures multimodality of knowledge, e.g., movie awards might be described in text or a table, but a person's birth date is likely described in text. When a relation can be captured by knowledge in multiple modalities, it is assigned to one of them per KB. This emulates the challenging setting where a model must interact with multiple agents to find the answer.[7] We use the templated theories to construct questions by grounding placeholders. We select m valid questions[8] for each KB such that each theory has the same number of examples across the dataset.

4.3 Auxiliary Information

In addition to the basic task definition, we also consider auxiliary information that may be available

---

[7] With real questions and agents, models may be able to avoid this by just memorizing the agents.

[8] has a non-empty answer and up to five answer spans

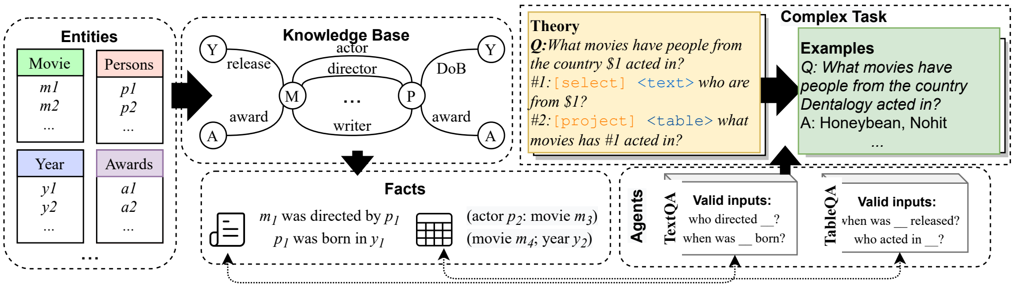

Figure 3: High-level schema of our dataset construction process. We use a list of entities and a KB schema to generate a list of facts. The QA agents operate over these facts to answer a set of pre-determined questions that form the examples of valid inputs from $\mathcal{L}_i$. We define multiple complex question templates and a corresponding *theory* that can be used to answer them. We then ground these question templates (i.e. sample $1) to create complex questions and use the agents to generate the answers.

in some cases. The main goal of this information is to (a) provide stepping stones for development of methods towards the final goal of learning to communicate with agents using answer supervision only, and (b) evaluate the abilities of current state-of-the-art assuming access to this additional information. We emphasize that such auxiliary information may not always be available (e.g., when using a proprietary agents such as Alexa).

We consider two kinds of such information—*auxiliary supervision* for the complex task's training examples $(x_k, y_k) \in \mathcal{D}$, and *auxiliary data* about the agents $\{f_i\}$ themselves (not tied to $\mathcal{D}$). This is summarized in Table 3.

Auxiliary Supervision for $(x_k, y_k) \in \mathcal{D}$:
- Gold Decomposition $\mathcal{D}_k$ for x_k
- Gold Knowledge $\mathcal{F}_k$ for x_k

Auxiliary Data for agents $\{f_i\}$:
- Training data $\mathcal{D}_{f_i} = \{(u_{ij}, v_{ij})\}_{j=1}^{M}$ for agent f_i, where $u_{ij} \in \mathcal{L}_i$ and $v_{ij} = f_i(u_{ij})$
- Complete knowledge resource $\mathcal{K}_i$ used by f_i, or a manageable subset $\mathcal{K}_{ik} \subset \mathcal{K}_i$ containing $\mathcal{F}_k$

Table 3: Auxiliary information as stepping stones towards the full COMMAQA task.

For auxiliary supervision, we consider having access to annotated decomposition $\mathcal{D}_k$ of a complex task training input x_k into valid inputs for various agents. We also consider annotated gold facts $\mathcal{F}_k$ that could be used to answer x_k.

For auxiliary data, we consider having access to the training data used to build the agents, or the underlying knowledge base $\mathcal{K}_i$ used by them (and possibly even a question-specific relevant subset $\mathcal{K}_{ik}$). For example, $\mathcal{K}_i$ would be equivalent to the entire text and table corpora used by TextQA and TableQA agents, and $\mathcal{K}_{ik}$ could be the texts and tables relevant to the question domain (e.g., movies). Such information can be used to train a stronger black-box model on the end-task, e.g., fine-tuning on the agent's training data first or using the gold facts to identify relevant context. These approaches that circumvent the agents are not the target of our dataset, but we nevertheless evaluate them to highlight their limits.

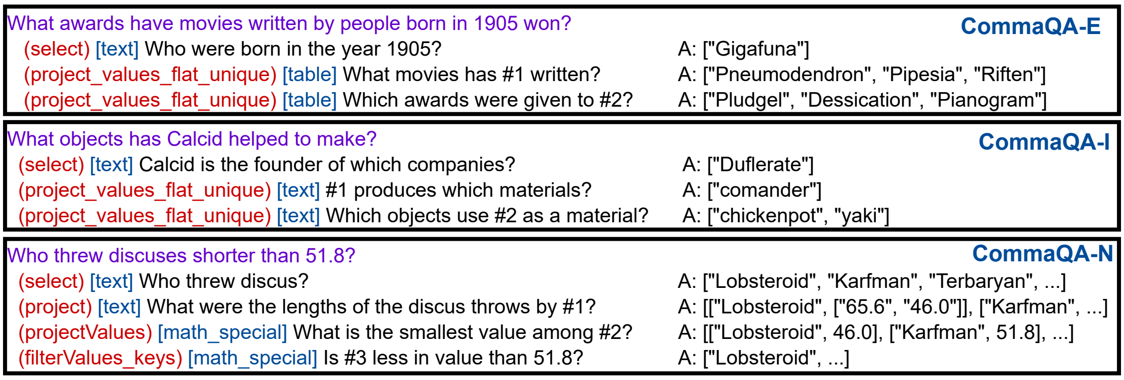
Building Auxiliary Information. We generate the gold decomposition $\mathcal{D}_k$ for each example x_k using the same language as the theories (see Fig. 4). We verbalize each relation to create the underlying knowledge resource $\mathcal{K}_{ik}$ used by the agent f_i (e.g., relation director(M, P) is converted into "M was a movie directed by P" or "movie: M ; director: P" depending on the agent assigned to this relation). While our KB and resulting facts are intentionally simple to show the limitations of black-box models, such verbalization may not always be possible with larger KBs and hence should not be relied upon. For each training example, we collect the facts used by each agent in the decomposition and treat these as gold facts $\mathcal{F}_k$.

4.4 COMMAQA Dataset

We use the above framework to build three datasets capturing three challenges in multi-hop reasoning.

COMMAQA-E: Explicit Decomposition. This dataset consists of multi-hop questions from the movie domain where the reasoning needed to answer the question is **E**xplicitly described in the question itself (Yang et al., 2018; Ho et al., 2020; Trivedi et al., 2021). For example, "What awards have the movies directed by Spielberg won?". We use a TextQA and TableQA agent where certain relations can either be expressed in text or table (more details in App. Fig. 6).

COMMAQA-I: Implicit Decomposition. This dataset consists of multi-hop questions where the



CommaQA-E

(projectValues) [math_special] What is the smallest value among #2?	A: [["Lobsteroid", 46.0], ["Karfman", 51.8], ...]
(filterValues_keys) [math_special] Is #3 less in value than 51.8?	A: ["Lobsteroid", ...]

Figure 4: Sample Decomposition Annotations for example questions in COMMAQA. We denote the composition operators using the format (operation) [agent] "question".

reasoning needed is Implicit (Khot et al., 2020; Geva et al., 2021), for example, "Did Aristotle use a laptop?". Inspired by such questions in StrategyQA (Geva et al., 2021), we create this dataset using three agents(TextQA, KBQA and MathQA) with just two question styles: (1) "What objects has __ likely used?" and (2) "What objects has __ helped make?". However each question has three possible strategies depending on the context (see App. Fig. 7 for more details). This is a deliberate choice as similar sounding questions can have very different strategies in a real world setting, e.g., "Did Steve Jobs help develop an Iphone?" vs. "Did Edison help develop the television?".

COMMAQA-N: Numeric Decomposition. This dataset consists of Numeric (also referred to as discrete) reasoning questions (Dua et al., 2019; Amini et al., 2019) requiring some mathematical operation, in addition to standard reasoning. For example, "Who threw javelins longer than 5 yards?". We create this dataset in the sports domain with TextQA, TableQA and MathQA agents (more details in App. Fig. 8).

Dataset Statistics. The final dataset[9] consists of the three QA sub-datasets described above, key statistics summarized in Table 4.

There are 10K total examples in each dataset with 80%/10%/10% train/dev/test split. To prevent models from guessing answer spans, we introduce more distractors by sampling a large number of facts for COMMAQA-E and COMMAQA-I. This results in a larger number of facts in the KB ($\sim$170) and larger length of the KB in these two datasets($\sim$2500 tokens). Since COMMAQA-N can have derived answers from numeric reasoning and has longer chains (avg #steps 4.7 vs. 2.7 in COMMAQA-E), we do not need a large number of distractor facts (80 facts/KB).

	COMMAQA		
	E	I	N
#questions	10K	10K	10K
#theories	6	6	6
#steps per theory	2.7	3.2	4.7
#entity types	7	13	5
#relations	11	16	4
#templates in $\mathcal{L}_i$	42	68	30
#entities per answer	3.21	3.29	1.36
#KB facts per KB	169.4	175.7	80
#T5tokens per KB	2252.9	2540.9	1513.4
#Gold facts per qn	7.5	6.9	15.4

Table 4: Statistics of COMMAQA. All per-question and per-KB statistics are averages.

Metrics. The answer y_k to each question x_k in COMMAQA is an unordered list of single-word entities.[10] By the design of the dataset, a model that performs the desired reasoning should be able to output y_k correctly, barring entity permutation. Hence, we use *exact match accuracy* as the metric.[11] (see appendix for a softer metric, F1 score)

5 Experiments

We evaluate various models on COMMAQA, including a baseline model (with no auxiliary information) for the task and state-of-the-art models that have access to auxiliary information.

5.1 Models

5.1.1 COMMAQA Baseline Model

We develop a baseline approach that directly targets the challenge task without relying on any auxiliary information. Specifically, we use the Text Modular Network (TMN) framework (Khot et al., 2021) that trains a `NextGen` model that communicates

---

[9] released under CC BY license

[10] Although not in the current dataset, entities in the unordered list y_k may be repeated, i.e., we have a multi-set.

[11] Our implementation uses "exact match" in the DROP multi-span evaluator, which accounts for entity reordering.

with the agents. This model is trained to produce the next question (including operation and agent) in a decomposition chain, given the questions and answers so far, which is then executed against the agent to produce the answer for the current step. Additionally this framework samples multiple questions at each step of the chain to search[12] for the most likely chain of reasoning.

We generate the training data for `NextGen` via distant supervision. Specifically, we perform a naïve brute-force search where we sample l questions at each step for up to o steps.[13] The operations are chosen randomly but we only consider the applicable operations (e.g., "select" for the first step). We use lexical overlap between the questions in the examples of valid inputs and the complex question to avoid wasteful random sampling.[14] We assume all chains that lead to the gold answer[15] represent valid decompositions, and use them to build the training dataset for TMNs. We refer to the model as TMN-S$_l$ (see App. B for details).

5.1.2 Auxiliary Supervision Models

We next present models that depend on auxiliary information and hence target a simpler variant of the task: (1) a model trained to communicate with agents using gold decomposition supervision, $\mathcal{D}$; (2) a black-box model trained to answer questions given all the agents' knowledge, $\mathcal{K}_i$; and (3) a two-stage model that first identifies the most-relevant context (using gold knowledge supervision $\mathcal{F}_i$) and uses this shorter context to answer the question.

Models with Decomposition Supervision: Given decomposition supervision, we can directly use this gold data to train the `NextGen` model. We refer to this model as TMN-S when we use this **s**earch and TMN-G when we **g**reedily select the most likely question at each step.

Models with Access to Agent Knowledge: Given access to the facts associated with each (train or test) question x_k, i.e., *each agent's domain-relevant knowledge* $\mathcal{K}_{ik}$, the facts can be concatenated to create a context and frame the challenge as a reading comprehension (RC) task.[16] We train two standard black-box models, T5-L (Raffel et al., 2020) and UnifiedQA-L (Khashabi et al., 2020),[17] to generate answers[18] given a question and context.

Model	Aux. Info	E	I	N	Avg.
TMN-S$_5$		0.0	0.0*	0.0	0.0
TMN-S$_{10}$		17.0	0.0*	0.0	5.7
Auxiliary Supervision Models					
T5-L	$\{\mathcal{K}_{ik}\}$	0.9	10.2	35.4	15.5
UQA-L	$\{\mathcal{K}_{ik}\}$	1.0	10.2	39.0	16.7
T5-L	$\mathcal{F}_k$, $\{\mathcal{K}_{ik}\}$	42.2	49.4	44.7	45.4
UQA-L	$\mathcal{F}_k$,$\{\mathcal{K}_{ik}\}$	40.1	49.7	43.4	44.4
T5-3B	$\mathcal{F}_k$, $\{\mathcal{K}_{ik}\}$	42.3	49.9	43.4	46.2
TMN-G	$\mathcal{D}_k$	75.4	36.0	100.0	70.5
TMN-S	$\mathcal{D}_k$	100.0	100.0	100.0	100.0

Table 5: Accuracy of models trained and tested separately on the 3 datasets. Last column reports average accuracy across the datasets (weighed equally). **TOP** highlighted rows: Target models for COMMAQA that try solve the task using no auxiliary supervision by communicating with agents. Naive search is able to generate some training data for COMMAQA-E but does not result in any valid decomposition (indicated by $*$) on COMMAQA-I. **BOTTOM** rows: Models that rely on auxiliary supervision. Black-box models struggle even when given the domain-relevant KB $\mathcal{K}_{ik}$. Using the additional fact supervision $\mathcal{F}_k$ helps these models, but their accuracy remains below 50%. TMN models with auxiliary decomposition supervision $\mathcal{D}_k$ can solve all tasks with search ("TMN-S") indicating that the task is solvable by communicating with agents.

Models with Fact Supervision: If, in addition to access to the underlying knowledge $\mathcal{K}_{ik}$, we also have the auxiliary supervision for the gold facts $\mathcal{F}_k$, we can use this annotation to train a model to first retrieve a small subset of relevant facts from $\mathcal{K}_{ik}$ (see App. D.1 for details). Since the context is shorter, we also train a T5-3B model[19] on this task.

5.2 Results

Table 5 reports the accuracy of these four classes of models on the COMMAQA dataset.

Baseline model has near-zero accuracy: The top two rows represent baseline models that use brute-force search to generate training data for TMNs. For COMMAQA-I, we don't find even a single chain leading to the gold answer, and hence no training data. With COMMAQA-E and COMMAQA-N, we do find valid decompositions

---

[12] Score is the sum log likelihood of the generated questions.

[13] o is set based on the length of the rules in each dataset, i.e., $o = 3$ for COMMAQA-E, $o = 4$ for I, $o = 7$ for N.

[14] We also found random generally performed worse.

[15] We use exact match since the correct decomposition with our error-free agents should lead to exactly the gold answer.

[16] We reiterate that it is often unreasonable to expect access to $\mathcal{K}_i$ and especially $\mathcal{K}_{ik}$. This model tries to solve COMMAQA without invoking agents, which deviates from the purpose of our benchmark dataset. Nevertheless, we conduct experiments in this setting for completeness.

[17] We use T5 models as they can handle longer contexts.

[18] We alphabetically sort answers for a deterministic order.

[19] T5-11B performed worse than or same as the 3B model.

for a subset of the questions (see statistics in Table 8 of Appendix), but not enough to train an effective `NextGen` model. Expanding the search to l=20 helps achieve ∼100% accuracy on COMMAQA-E (with ∼700K agent calls). However, we don't observe any gains on COMMAQA-I and COMMAQA-N with even 2M agent calls (see App. C).

Black-box models struggle even with access to agent knowledge : Due to the large number of distractors, black-box models —even with access to agent knowledge at both train and test time— struggle to learn the task across all three datasets with average accuracy below 20. The extremely low performance on COMMAQA-E is especially notable, given that the reasoning needed for each question is explicitly described. While these models are able to solve similar datasets (Yang et al., 2018), the low scores on our synthetic dataset with more distractors indicates that they are still unable to truly learn this kind of reasoning.

Fact annotations help but are insufficient: Models trained on shorter context (obtained by relying on gold fact training annotation) are able to take advantage of the reduced number of distractors, improving their score to about 45 pts across all datasets. However, even with the larger 3B model, there is no noticeable improvement, indicating 45 pts being roughly a ceiling for these models.

COMMAQA is solvable by talking to the agents: The TMN model, if given gold decomposition annotation for training, can solve this task (bottom two rows). This experiment is an oracle setting that shows that COMMAQA is noise-free, unambiguous, and solvable by a model that learns to talk to the agents (as designed). Note that greedily selecting the next question results in much lower performance on the two datasets (E and I) that have multiple decompositions for the same question.

5.3 Compositional Generalization

We also design compositional generalization test sets COMMAQA-E^{CG} and COMMAQA-N^{CG}. Specifically we create questions using novel composition of queries that have been seen during training but never together in this form. For instance, we create a new question "What awards have the directors of the __ winning movies received?", given that the model was trained on questions such as "What awards have the actors of the __ winning movies received?", "What movies have the directors from __ directed?", and "What movies have people from the country __ acted in?".

Model	Aux. Info	E^{CG}	N^{CG}
TMN-S_{10}		16.2	0.0
Auxiliary Supervision Models			
T5-L	$\mathcal{F}_k, \{\mathcal{K}_{ik}\}$	37.0	2.0
T5-3B	$\mathcal{F}_k, \{\mathcal{K}_{ik}\}$	39.2	23.8
TMN-S	$\mathcal{D}_k$	79.4	97.6

Table 6: Lower accuracy on compositional generalization test sets. TMN-S with decomposition supervision still outperforms other models.

As shown in Table 6, all models exhibit a drop in accuracy relative to their score in Table 5, but the compositional model trained on gold decomposition still outperforms black-box models. Our error analysis of TMN-S on COMMAQA-E identified this key issue: While TMN-S learns to generalize, it generates questions outside the space of valid agent inputs (e.g., "Who are the directors in the movie __?" vs. "Which movies has __ directed?").

6 Closing Remarks

We motivated a new challenge of solving complex tasks by communicating with existing AI agents. This challenge, we believe, will help develop more generalizable and efficient models. We introduced a new benchmark dataset COMMAQA with three multi-hop reasoning challenges, all solvable by composing four QA agents. State-of-the-art language models struggle to solve COMMAQA, even when provided with agents' internal knowledge. In contrast, a model that is able to learn to communicate with the agents, albeit using annotated decompositions, is able to solve this task. These results point to the need for and the potential of such approaches, but without reliance on auxiliary annotations, to solve complex tasks.

COMMAQA is only one instantiation of our overall framework. One can extend it in many ways, such as using LMs to enrich lexical diversity, emulating the behavior of imperfect real-world agents that even attempt to answer out-of-scope questions, diversifying to other reasoning types such as Boolean questions where using distant supervision is even harder (Dasigi et al., 2019), and extending the generalization dataset to include new examples of valid inputs as well as new agents.

A Multiple Answers in a Question

If a question refers to multiple answers, e.g. "Is #3 a part of #2?", the operator execution is unclear. To handle such cases, the operator must specify the answer to operate over as a parameter. E.g. (filter(#3)) [mathqa] "Is #3 a part of #2?" would filter the answers in #3 whereas (filter(#2)) [mathqa] "Is #3 a part of #2?" would filter the answers in #2.

B Search Approach Details

We describe in more detail the approach used to build the training data $\hat{\mathcal{D}}$ using the simple search technique. To generate the space of possible decompositions, for each question, we first select f operations from the list of valid operations in Table 7. We only consider these operations as these are the only operators needed for COMMAQA. Note that even with this restricted set of operators, models struggle on COMMAQA-I and COMMAQA-N. Additionally, we only consider the select operation for the first step. For all subsequent steps, we only consider replacements of __ with a previous answer index.

To select the questions, we first simplify the space of inputs by converting the questions into Fill-In-The-Blank (FITB) questions by removing the named entities. E.g "Who was born in 1991?" is changed to "Who was born in __?". This is also a necessary step as the operators need questions with placeholders to handle structured answers. At every step, we expand this pool of questions by replacing the blanks with entities in the complex question and any answer index from the previous steps (e.g. #1, #2 in the third step of a decomposition). To avoid wasteful sampling, we use lexical overlap between questions in this expanded question pool and the input question to identify the top g most relevant questions. The agent associated with each question is tracked throughout this process.

In the end, we consider the cross product between the f operations and g questions to produce $l = f \times g$ total questions at each steps. These l questions are then executed using the appropriate agent and only the successful questions (i.e. answered by the agent) are considered for the next step. This is the key reason why the search space is much smaller than l^o for o reasoning steps.

Table 8 presents the overall statistics of the search approach.

TMN-S (l=10)	17.0 / 17.1	0.0 / 0.0	0.0 / 0.0

Table 9: EM / F1 scores on the test set using the baseline approaches.

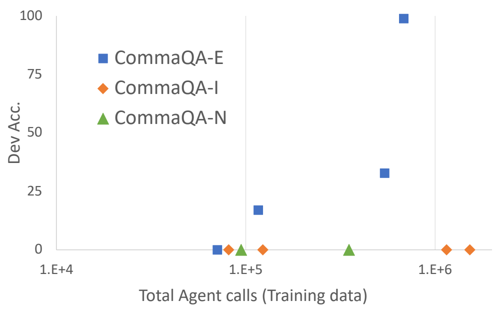

Figure 5: With an order of magnitude increase in search space, we can achieve close to 100% accuracy on CommaQA-E. However CommaQA-I and CommaQA-N need smarter search strategies to generate useful training supervision.

C Search Cost vs Accuracy

One could always exhaustively search for *all* possible decompositions to reproduce the gold decompositions for all the questions. But this would be computationally highly expensive as each call to the agent would often invoke a large-scale LM or a complex AI assistant. To characterize the computational cost of these approaches, we extend the search parameter to include l=15 and l=20 (capped at 5M agent calls) and compute the accuracy of the TMN-S model trained on the resulting dataset (shown in Fig. 5). We can achieve close to 100% accuracy on CommaQA-E where the search is sufficiently exhaustive(about 700K model calls) mainly due to the shorter rules and the lexical signal. CommaQA-I and CommaQA-N, on the other hand, even with an order of magnitude increase in the number of agent calls, we don't observe any increase in the model accuracy.

D Black-Box Models

We train the T5 models on each of the three datasets to generate the answer given the question and facts. We format the input sequence as `<concatenated facts> Q: <question> A:`. Since many of the answers can be multiple spans, we sort[20] and concatenate them into a single string with '+' as the separator. As noted in Table 4, the verbalized facts can result in a context over 2K tokens long. We trained T5-Large models on A100 80G GPUs and RTX8000s to train on such a long context. Transformers designed for longer documents (Beltagy et al., 2020; Zaheer et al., 2020) would be able to handle such contexts more efficiently but generally under-perform due to sparse attention. Hence we don't evaluate them here.

For all T5-based models, model tuning was standardly performed using a random hyper-parameter search in the style of Devlin et al. (2019) using the public huggingface implementation (Wolf et al., 2020); model selection was done based on the highest EM accuracy on the development sets. We specifically experimented with learning rates in the range of ($1e$-$3f$ to $5e$-$5f$) using both Adam and Adagrad optimizers and generally found the settings comparable to the original T5 pre-training parameters (Raffel et al., 2020) to be optimal (Adafactor, lr=0.001, 10 epochs, 0-1000 warmup steps, gradient accumulation was used extensively in place of batching to fit long sequences into GPU memory). The optimal T5-3B models and T5-L for full context on CommaQA-E were trained with lr=5e-5. All other models were trained with a lr of 1e-3. We will release the complete list of optimal hyper-parameters along with the code.

D.1 Models with Fact Supervision

To select the relevant facts, we train a RoBERTa-Large (Liu et al., 2019) model on the gold facts and select the top-scoring facts to produce a shorter context that fits in 512 tokens. The RoBERTa model was training using the AllenNLP library (Gardner et al., 2017) with the standard parameters used for RoBERTa – learning rate of 2e-5, triangular LR scheduler with 10% warmup steps, gradient clipping at 1.0, batch size of 16, 5 epochs of training with patience of 3 epochs. We didn't observe a noticeable difference in score with a random parameter search, so kept these parameters constant. The model was trained to score each fact independently on the train set and the best model was selected based on the accuracy on the dev set. The model was then evaluated on the facts from the train, dev and test set to produce the shorter context for all three sets. The facts were sorted based on the model's scores and the top-scoring facts were added to the context till the number of tokens did not exceed 512 tokens (white-space splitting).

E Text Modular Networks: Training

To train the NextGen model for TMNs, we use the same parameters as the prior work (Khot et al., 2021). We train a T5-Large model as the NextGen

Modality-specific Learning Rates for Effective Multimodal Additive Late-fusion

Abstract

In multimodal machine learning, additive late-fusion is a straightforward approach to combine the feature representations from different modalities, in which the final prediction can be formulated as the sum of unimodal predictions. While it has been found that certain late-fusion models can achieve competitive performance with lower computational costs compared to complex multimodal interactive models, how to effectively search for a good late-fusion model is still an open question. Moreover, for different modalities, the best unimodal models may work under significantly different learning rates due to the nature of the modality and the computational flow of the model; thus, selecting a global learning rate for late-fusion models can result in a vanishing gradient for some modalities. To help address these issues, we propose a Modality-Specific Learning Rate (MSLR) method to effectively build late-fusion multimodal models from fine-tuned unimodal models. We investigate three different strategies to assign learning rates to different modalities. Our experiments show that MSLR outperforms global learning rates on multiple tasks and settings, and enables the models to effectively learn each modality.

1 Introduction

Multimodal machine learning aims to jointly understand and process the inputs from different modalities (e.g., language, audio, vision). This usually requires a model to have the ability to incorporate the feature representations from each modality into a joint representation (the "multimodal fusion" problem). There are two types of commonly-used multimodal fusion methods: late-fusion and multimodal interaction. Late-fusion methods rely on the representation vectors computed from unimodal encoders, which are then combined into a joint representation using operations such as addition, multiplication (Kim et al., 2016), bi-linear pooling (Fukui et al., 2016; Yu et al., 2017b), and so on. Multimodal interactive methods apply complex operations such as cross-modal attention (Yu et al., 2017a), modulation (Yao et al., 2018), and multi-head self-attention such as multimodal transformers (Tan and Bansal, 2019; Tsai et al., 2019).

Despite the intuition that multimodal interaction leverages the inter-dependency across different modalities, (Hessel and Lee, 2020) proposed that there is a method to simulate the outputs of an additive late-fusion model that has the closest possible performance to an *arbitrary* interactive model (but not how to find the specific structure). According to the experimental results in (Hessel and Lee, 2020), the accuracy of the closest additive models is competitive with the corresponding interactive models in some selected tasks. This indicates that: (1) Currently, some interactive models are not strong enough to catch the complex real-world inter-dependencies between modalities. Studying the upper-bound of late-fusion methods can help evaluate the limitations of interactive models. (2) The application of late-fusion models is still open to in-depth research because they have the potential of reducing the computational costs while maintaining some effectiveness.

An additive late-fusion method with two modalities M, N and inputs m, n can be fomulated as follows:

$$f(m,n) = f_M(m) + f_N(n). \qquad (1)$$

We assume that such a well-performing $f(m,n)$ can be built up with the most effective unimodal structures for f_M and f_N, i.e., a transformer (Vaswani et al., 2017) for the textual modality and convolution neural networks (CNN) (Ren et al., 2015) for the visual modality. While training $f(m,n)$, the most common current practice is to select a global learning rate. However, the optimal unimodal learning rates of f_M and f_N can be significantly different. For example, with an Adam optimizer (Kingma and Ba, 2014), the best learn-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1824 - 1834
May 22-27, 2022

ing rate for the transformer is usually around 2e-5, while the best learning rate for Multi-Layer Perceptrons (MLP) can be up to 1e-3. While combining the two structures into a late-fusion model with a global learning rate, i.e., 3e-4, the transformer part turns out to be nearly frozen in the training procedure (see the "Conductance Analysis" subsections in the Experimental Results section).

To address this issue, we propose the Modality-Specific Learning Rate (MSLR) method, which uses different learning rates for different modalities while training an additive late-fusion model. We explore different model structures, tasks, and learning rate assignment strategies to analyse the impact of MSLR on the gradient effectiveness, predicative behaviors, and evaluation results.

Our contributions are as follows. Firstly, we propose MSLR as an effective strategy to train an additive late-fusion model for multimodal tasks; secondly, we analyse the predicative behavior and layer conductance to prove the necessity of using MSLR instead of global learning rates in some conditions; finally, experiments on three different tasks: MuSE Stress Detection (Jaiswal et al., 2019, 2020), MELD Sentiment Analysis (Poria et al., 2019), and MM-IMDb Movie Genre Classification (Ovalle et al., 2017) indicate that MSLR outperforms global learning rates with certain assignment strategies.

2 Related Work

2.1 Multimodal Classification

We focus on multimodal classification tasks which have broad applications in real life. In multimodal classification, the logits of each class predicted by each unimodal sub-part of the joint late-fusion model can be directly summed up and converted into an output distribution. Examples of commoly-studied multimodal classification tasks include sentiment analysis (Zadeh et al., 2016; Yao et al., 2020; Poria et al., 2019), emotion recognition (Busso et al., 2008; Jaiswal et al., 2020; Zadeh et al., 2018), and other real-world applications such as disaster classification (Tian et al., 2018) and movie genre classification (Ovalle et al., 2017).

The inputs of multimodal classification models are usually videos, which contain visual image frames, audio utterances and textual transcripts. These modalities are typically processed by different models based on the nature of each modality. For example, visual features are extracted by pre-trained Convolutional Neural Networks (CNNs) (Simonyan and Zisserman, 2014; Szegedy et al., 2017), spectral or temporal acoustic features are extracted using tools such as OpenSmile (Eyben et al., 2010) and Covarep (Degottex et al., 2014), textual features are usually achieved by pre-trained word embeddings (Peters et al., 2018) and Transformers (Devlin et al., 2019). An effective model should be able to incorporate these features with different numerical properties and natural distributions.

2.2 Multimodal Fusion

There are two mainstream methods to encode and combine multimodal features. The first approach is late-fusion, in which the features from different models are first encoded separately by unimodal encoders, and the single-vector representation is then combined into a joint representation and fed into the final classifier (Kim et al., 2016; Fukui et al., 2016; Yu et al., 2017b). The advantages of late-fusion is that the model is relatively light-weighted and interpretable, and the sub-parts processing each modality can be well-monitored. However, the low-level alignments across the modalities, such as the correspondence between a textual word and a visual object, can not be detected while computing the unimodal feature vectors. On the other hand, the multimodal interaction methods enable the encoders to interact with each other via cross-modal attention mechanisms (Yu et al., 2017a; Tan and Bansal, 2019; Tsai et al., 2019).

Although it is intuitive that the interaction methods can have better capability, Hessel and Lee (2020) showed that the prediction of any interactive model can be simulated by a corresponding late-fusion model, making it possible to reduce the computational costs without severely hurting the performances.

2.3 Modality Specific Learning

2.3.1 Modality-Specific Early Stopping.

A closely related work to ours is called Modality-Specific Early Stopping (MSES) (Fujimori et al., 2019). They stated the issue in multimodal learning as "overfitting in some modalities," and attributed it to "the convergence rate and generalization performance differ among modalities," which is similar to our claims and observations. However, they did not explore the cause of this overfitting, and proposed to solve the problem by applying early stopping for the modalities that have appeared to be converged regarding the validation performances. Their method does not actually assign different step-sizes for different modalities and still chooses a global learning rate instead. In contrast, we investigate the layer conductance of the model and observe that the overfitting in certain modalities is because the global learning rate is beyond the numerical range where the model structure for that modality can work regularly. While one modality receives a vanishing gradient, the unimodal performance no longer improves and appears to overfit. Thus, we directly modify the initial learning rates according to the knowledge on learning rates achieved from unimodal fine-tuning. Our method is able to delay the overfitting to some extent, instead of simply choosing the best saved parameters for the overfit modalities and stopping training.

2.3.2 Gradient Blending

Another related work is Gradient Blending (Wang et al., 2020), which also states the difficulty of joint training as overfitting. Unlike MSES (Fujimori et al., 2019), they directly modifies the gradient descent process by substituting the total loss with a weighted sum of multiple unimodal loss, and the weight is computed based on a "overfitting-to-generalization ratio" (OGRs) that describes the overfitting conditions for each modality. However, the computation of OGRs relies on training each unimodal model for the first several epochs, while the initial learning rate for each modality is still chosen globally and does not guarantee the training behavior of these initial steps. As a result, if a model does not receive gradient at all when the training starts (which is possible in some of our experiments), the initial OGRs can be ill-formed, limiting the usage of Gradient Blending.

Besides, the tasks and situations they deal with are different from ours: in most of their cases, the joint training underperforms unimodal training, but in our tasks, a joint training with global learning rate can already outperform the unimodal results, and our method can bring further improvement. Also, the performance of Gradient Blending on the textual modality is not explored, while our method works well with both textual-visual and textual-audio data, as shown in our experiments.

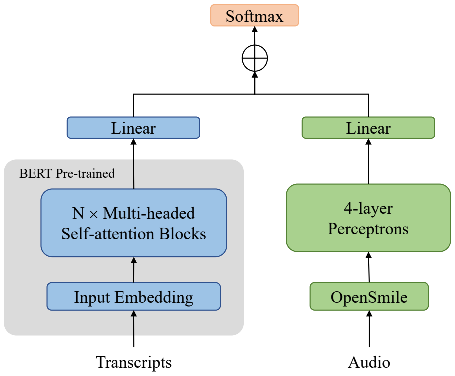

Figure 1: Late-fusion architecture for MuSE stress detection.

3 Modality-Specific Learning Rates

3.1 Learning Rates

The best learning rate for a model depends both on its structure and the optimization algorithm. The models structure further depends significantly on the modality of inputs, i.e., a transformer is effective for the textual modality, CNN for local image parts, and MLP is enough for a single hand-crafted feature vector. As a result, the best range for learning rates can be largely different across modalities.

For different optimizers, the default learning rate range also has large variation from less than 1e-3 (Adam-like) to 1.0 (Adadelta, (Zeiler, 2012)).

We propose to use modality specific learning rates, and include different *learning rate assigment strategies* to keep the models that work for each single modality still work in multimodal training, as described in the following three subsections. To focus on analysing the influence of modality, we use an AdamW optimizer (Loshchilov and Hutter, 2017) for all of our models. In this setting, the term "learning rate" stands for the step size α. Step size is a hyper-parameter independent of the cumulated first moment m_t and second moment v_t in each step of gradient descent. Please refer to (Kingma and Ba, 2014; Loshchilov and Hutter, 2017) for more details. In our strategies, we either choose a fixed α value for each modality or adjust α dynamically based on unimodal performance, which is still independent of the first and second moments.

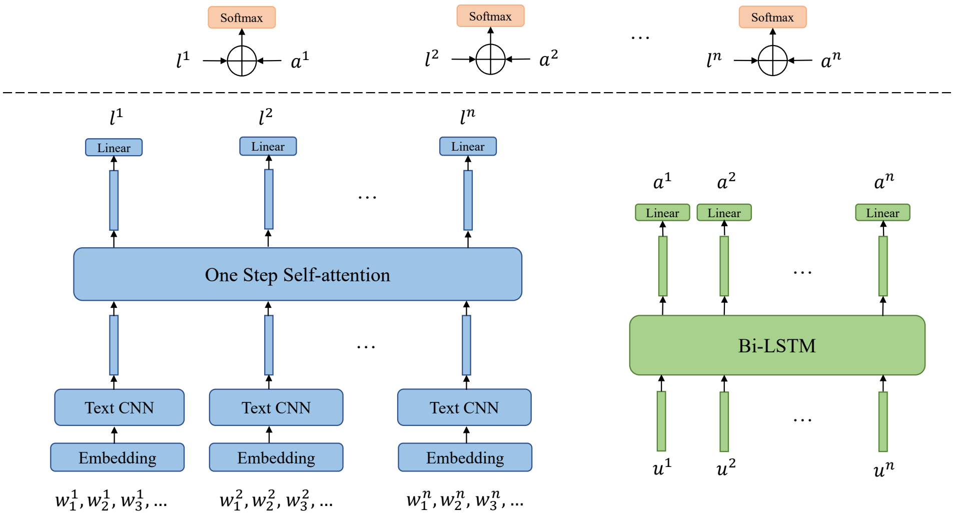

Figure 2: Late-fusion architecture for MELD sentiment analysis.

Table 1: Overlap and Confusion matrix for MSLR-Keep and Joint-global, compared to Audio-only.

Metrics	Overlap	1-1	0-0	1-0	0-1
Audio-only vs. Joint-global	0.86	0.46	0.39	0.09	0.05
Audio-only vs. Keep-ep20	0.81	0.47	0.34	0.09	0.11
Audio-only vs. Keep-ep100	**0.65**	**0.39**	**0.26**	**0.16**	**0.18**
Text-only vs. Joint-global	0.62	0.37	0.25	0.24	0.14
Text-only vs. Keep-ep20	0.70	0.44	0.25	0.17	0.13
Text-only vs. Keep-ep100	**0.73**	**0.46**	**0.27**	**0.15**	**0.11**
Text-only vs. Audio-only	0.62	0.40	0.23	0.22	0.16
Joint-global vs. Keep-ep20	0.84	0.47	0.38	0.11	0.04
Joint-global vs. Keep-ep100	0.62	0.37	0.25	0.24	0.14

3.2 The "Keep" Strategy

The most straight-forward MSLR strategy is keeping the best fine-tuned unimodal learning rate for different modalities while training the late-fusion model. This strategy is expected to ensure that each unimodal sub-part still has effective gradients.

3.3 The "Smooth" Strategy

The "Smooth" strategy compromises different learning rates by shifting the learning rate for different modalities to be closer to the average learning rate of all modalities, resulting in smaller margins. This is supposed to lead to more stable training and yields better results when all the modalities work in relatively close learning rate ranges.

3.4 The "Dynamic" Strategy

Motivated by the dynamic sampling strategies (Guo et al., 2018; Gottumukkala et al., 2020; Yao et al., 2021) in multi-task learning, we leverage the validation set to measure how fast the model is learning each of its unimodal sub-parts. We start from the "Keep" strategy in the first epoch, and update the step-size for modality N after each epoch based on the performance of the unimodal prediction $f_N(n)$ on the validation set. Specifically, for epoch t and modality N, we update the step-size by:

$$\alpha_{t,N} = \alpha_{0,N} * r^{val}_{t,N}, \tag{2}$$

where $r^{val}_{t,N}$ is the ratio of the unimodal performance on the validation set in epoch t to the average performance of the previous 5$\sim$10 epochs, which is usually slightly larger or smaller than 1.0. We name this as the "Dynamic" strategy. The motivation for this strategy is that if the unimodal performance of a modality is significantly improved in an epoch, the learning rate for this modality should be increased to make full use of the current gradient direction; otherwise, if there is no significant difference with respect to previous epochs, we should maintain the current learning rate to keep it in the effective range for this modality.

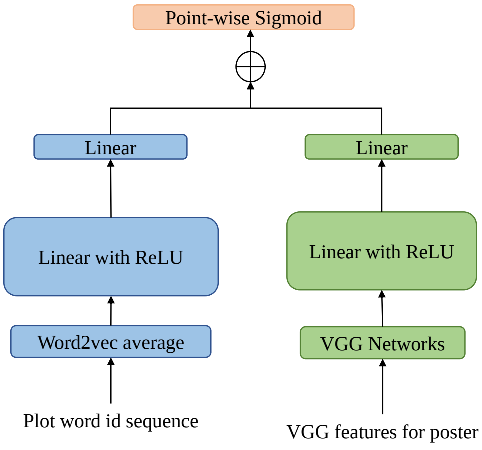

Figure 3: Late-fusion architecture for MM-IMDb Movie Genre Classification.

3.5 Computational Cost

A common concern of our methods might be the computational cost: all the MSLR strategies rely on searching for a best unimodal learning rate for each modality before the multimodal training starts. However, it is worth noticing that every model structure has its best learning rate range, which is sometimes unknown. Thus, it is necessary to do this search for newly-designed models and previously-unseen tasks. In other cases where the unimodal model structure and task is well-studied (i.e., BERT for textual classification), the best unimodal learning rate can also be directly determined based on one's experience.

In the worst case, existing methods train K times if there are K candidate learning rate values, while MSLR trains for additional K times for each modality involved, which grows only linearly with respect to the number of modalities. Besides, the unimodal models trained in these steps are not simply discarded: they can be used to make unimodal predictions while data from the other modalities are missing, which is often the case in real-world applications.

4 Tasks and Models

4.1 MuSE Stress Detection

Multimodal Stressed Emotion (MuSE) (Jaiswal et al., 2019, 2020) is a multimodal dataset for emotion recognition and stress detection, which is collected from student monologue sessions recorded before or after their final exams. The topic and content of each monologue is directed by random emotion-eliciting questions such as "tell me about an unhappy experience in your life." Monologue sentence clips are annotated with binary stress labels: "stressed" for monologues recorded right before final exams, and "non-stressed" for those after exams. For each sample, we make predictions using the audio utterance of a sentence in the monologue session, as well as its textual transcription. We use 1853, 200, and 273 samples for training, validation, and testing, respectively.

For the model structure, shown in Figure 1, we use a Transformer pre-trained with BERT (Devlin et al., 2019) as our textual encoder for the transcripts. For the audio inputs, we extract an 88-dimensional acoustic feature using OpenSmile (Eyben et al., 2010) with eGeMaps (Eyben et al., 2015) configuration for each sentence, and pass it through a 4-layer 256-dimensional MLP. The top-level 256-dimensional representations from both modalities are concatenated and projected into the output logits by a linear layer, which is equivalent to an additive late-fusion.

4.2 MELD Sentiment Analysis

The Multimodal Emotion Lines Dataset (MELD) (Poria et al., 2019) is an expansion of the Emotion Lines multi-party conversation dataset (Chen et al., 2018) and contains the audios and transcrips for the dialogues from the TV-series *Friends*, in which each sentence is annotated with emotion and sentiment labels. For the multimodal sentiment analysis task, there are three classes: positive, negative, and neutral, and two modalities: audio and textual. We use 1038, 114, and 280 dialogues for training, validation, and test, respectively.

For preprocessing, we follow (Poria et al., 2019) to apply feature selection on the 6373 dimensional acoustic features from OpenSmile, resulting in a 1422 dimensional dense audio representation for each sentence. We consider the dialogue as a sequence of sentences, regardless of the specific speaker. The maximum dialogue length is 33.

Our sentiment analysis model (Figure 2) contains a textual encoder and an audio encoder. The textual encoder has a word-level 2d Convolutional Neural Network (Zhang and Wallace, 2017) that outputs a 512-dimensional sentence embedding from the word embeddings. For the sentence embedding, we apply one step of masked self-

Table 2: Evaluation metrics for MuSE stress detection. “lr” stands for learning rate.

Model	Textual lr	Audio lr	Accuracy	Precision	Recall	F-score
Text-only	2e-5	-	0.69	0.77	0.74	0.75
Audio-only	-	5e-3	0.82	0.83	0.82	0.83
Joint-global	3e-4	3e-4	0.82	0.83	0.83	0.83
MSES (Fujimori et al., 2019)	3e-4	3e-4	0.80	0.79	**0.85**	0.82
MSLR: Keep	2e-5	5e-3	0.83	0.85	0.81	0.83
MSLR: Smooth	1e-4	1e-3	0.81	0.84	0.81	0.82
MSLR: Dynamic	-	-	**0.84**	**0.86**	0.83	**0.84**

Table 3: Evaluation metrics for MELD Sentiment Analysis.

F-score (%)	Textual lr	Audio lr	Neutral	Positive	Negative	Average
Text-only	1e-4	-	76.32	56.03	59.71	66.97
Audio-only	-	1e-3	64.40	12.94	42.38	47.10
Joint-global	5e-4	5e-4	76.58	53.97	57.32	65.92
MSES(Fujimori et al., 2019)	5e-4	5e-4	76.41	53.41	57.79	65.87
MSLR: Keep	1e-4	1e-3	75.61	55.40	59.31	66.37
MSLR: Smooth	2.5e-4	7.5e-4	76.44	**56.34**	**60.10**	**67.21**
MSLR: Dynamic	-	-	**77.14**	52.73	56.41	65.65

attention (Vaswani et al., 2017) on the sentence sequence in the same dialogue, resulting in a sequence of 512-dimensional textual hidden states. For the audio encoder, we use a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) which takes the audio features for each utterance as input, and outputs 300 dimensional hidden states. For each time step (sentence), the output of self-attention layer and audio LSTM are concatenated and projected by a 512-dimensional linear layer to predict its sentiment class (additive late-fusion).

4.3 MM-IMDb Movie Genre Classification

The Multimodal IMDb (MM-IMDb) (Ovalle et al., 2017) dataset is built with 25,959 IMDb movies with their plots and posters; each movie is labeled with more than one genre, making it a multi-label classification task. There are two modalities: plot (textual) and poster (visual). We use a training/validation/test split of 15552/2608/7799 movies, respectively.

As for preprocessing, following related work (Ovalle et al., 2017) and (Fujimori et al., 2019), we use the VGG Neural Network (Simonyan and Zisserman, 2014) pre-trained on ImageNet (Deng et al., 2009) which produces 4096-dimensional visual features for the posters, and 300-dimensional Word2Vec [1] embeddings for the textual plots.

We implement the same model structure as described by (Fujimori et al., 2019), which is a linear layer with 2048 hidden states and ReLU activation, followed by a 512-dimensional linear layer as the classifier, for both modalities (Figure 3). There are 23 output neurons corresponding to the 23 genre classes. Each neuron has a sigmoid activation instead of softmax for multi-label classification. The motivation of using a Multi-layer Perceptrons (MLP) structure on both modality is to test the efficiency of our MSLR strategies while different modalities have similar computational flows, as well as to have a comparison with the related MSES method (Fujimori et al., 2019).

5 Experimental Results

5.1 General Settings

For all our experiments with the “Dynamic” strategy, we compute the ratio r with respect to the previous 5 epochs. All the MSES methods used for comparison are based on our implementation. The best unimodal and global learning rates for each task, as well as all the other hyperparameters, are found by a linear search based on the metrics on the validation sets. All our experiments are implemented with Pytorch[2] and ran on 1 GeForce RTX

2080 super GPU and Intel i7 9700k processor.

5.2 MuSE Stress Detection

For the MuSE stress detection task and late-fusion structure with a Transformer + MLP structure, we use a batch size of 32. A learning rate of 2e-5 works the best for the textual modality, while 5e-3 works best for the audio modality. The late-fusion model works the best with a global learning rate of 3e-4. We name these models “Text-only”, “Audio-only”, and “Joint-global”, respectively.

5.2.1 Conductance Analysis

Layer Conductance (Sundararajan et al., 2017; Shrikumar et al., 2018) evaluates the importance of each neuron to the final prediction. It is worth noticing that the conductance value itself is not directly related to the training gradients with respect to this specific neuron. However, we compute the average Layer Conductance of all the neurons in the textual/visual/audio representations, and further averaged over all the samples in the dataset. The result stands for the importance of each single modality as a whole. If the Layer Conductance of a modality is close to 0, it is reasonable to claim that this modality is not effectively trained at all and has vanishing gradients in the training procedure.

We analyse the Layer Conductance for the outputs of the textual and acoustic encoder, separately, using the Captum (Kokhlikyan et al., 2020) package. The layer conductance result for MuSE Stress Detection is averaged among all the 256 neurons of the linear layer for each modality and shown in Table 5.

Table 5: Layer conductance for different models on the textual and audio modality for the MuSE Stress Detection task.

Modality	Textual	Audio
Text-only	0.002	-
Audio-only	-	0.25
Joint-global	1e-8	0.01
MSLR: Keep - epoch 20	0.005	0.014
MSLR: Keep - epoch 100	0.007	0.015

We observe in Table 5 that with a joint-global learning rate (3e-4), the textual Transformer works beyond its comfort zone (around 2e-5) and has vanished gradients (conductance close to 0). This indicates that the model’s multimodal performance is limited because it can not effectively learn the textual modality while using a global learning rate. In contrast, we observe that using the MSLR “Keep” strategy solves this issue.

5.2.2 Prediction Similarity

Another approach of exploring how different are the learned models with MSLR and global learning rates is to directly analyse the predictions on the test set. If the language encoder has vanished gradients, the multimodal predicative behavior should be close to the unimodal audio model. In Table 1, we show the overlap rate (the ratio of the two models making the same prediction for a sample) for different model pairs, as well as the full confusion matrix for the stressed (1) and non-stressed (0) labels. We choose the joint model at the 20-th epoch (Keep-ep20, when the training is on-going) and the 100-th epoch (Keep-ep100, when the training is converged) for comparison with the Audio-only and Text-only models. We highlight the joint model that is less similar to the audio model and more similar to the textual model, since going closer to the textual model indicates a valid gradient for the textual modality.

We observe that without MSLR, the joint-global model has 0.86 overlap with the Audio-only model and only 0.62 with the Text-only model. However, if MSLR is applied, as the training goes on (from epoch 20 to 100), MSLR gets away from the Audio-only model and becomes closer to the Text-only model, which is consistent with Table 5 showing that the textual part is receiving gradients. Besides, after 100 epochs, MSLR results in a very different model from all the joint and unimodal models.

5.2.3 Evaluation Metrics

The evaluation metrics we use for the MuSE Stress Detection task include the total accuracy and the precision, recall and F-score for the "stressed" label (Table 2). We observe that the "Keep" strategy achieves competitive scores with the best global learning rate model while the model's predicative behavior is very different as shown by the previous subsection. Additionally, the "Dynamic" strategy significantly outperforms both the global learning rate and the Multimodal Early Stopping (MSES) method ($p < 0.05$, t-test). We believe that starting from "Keep" enables the model to learn both modalities with valid gradients, and the "Dynamic" strategy helps adjust the learning rate according to the validation performance of the unimodal models, which brings further improvements.

5.3 MELD Sentiment Analysis

For the MELD Sentiment Analysis dataset, we use a batch size of 10; the best learning rate for Text-only, Audio-only and Joint-global is 1e-4, 1e-3 and 5e-4, respectively. For the "Smooth" strategy, we use a learning rate of 2.5e-4 for textual modality and 7.5e-4 for audio.

5.3.1 Conductance Analysis

We apply Layer Conductance analysis on the 512 neurons of the top linear layer for each modality, as we did in the MuSE Stress Detection. The results are in Table 6. In this case, since the gap between the suitable learning rate for the two modalities is smaller than the MuSE task, we observe non-zero layer conductance for both modalities for the global learning rate method. The MSLR method, on the other hand, still achieves higher value of conductance as the training goes on.

5.3.2 Evaluation Metrics

Following (Poria et al., 2019), the MELD Sentiment Analysis task is evaluated with the F-scores for each class and their weighted average (Table 3).

We observe that the "Smooth" strategy works slightly better than the "Keep" strategy in this case. This is potentially because the smaller learning rate gap makes 5e-4 an acceptable learning rate for both modalities with valid gradient flows. The "Keep" strategy maintains the large gap, which makes the training less stable compared to the "Smooth" strategy which can be considered as a reconcile with the global learning rate. The "Smooth" strategy also outperforms the "Dynamic" strategy since the latter starts from the same initial learning rates with a large gap as in the "Keep" strategy.

Table 6: Layer conductance for different models on the textual and audio modality for the MELD Sentiment Analysis task.

Modality	Textual	Audio
Text-only	0.011	-
Audio-only	-	0.024
Joint-global	0.011	0.006
MSLR: Keep - epoch 20	0.034	0.027
MSLR: Keep - epoch 100	0.041	0.033

5.4 MM-IMDb Movie Genre Classification

For the MM-IMDB dataset, we use a batch size of 128. We name the unimodal model using only the plot the "Text-only" model, and the model using only the poster the "Visual-only" model. The best fine-tuned learning rates for Text-only, Visual-only and Joint-global models are 1e-2, 1e-4, and 1e-3, respectively. It is worth noticing that although we have similar MLP structures for both modalities, the best learning rates can still have a 100-time gap between the two modalities. This is perhaps because of the numerical properties of the features from different modalities, as well as the pre-processing methods. For the "Smooth" strategy, we use a learning rate of 3e-3 for the textual modality and 3e-4 for the visual modality.

5.4.1 Conductance Analysis

We apply the same Layer Conductance analysis as the other two datasets on the 512 hidden units of the top-level linear layer for each modality. The results are in Table 7.

We observe that the textual representation has relatively low average conductance compared to the visual one when the model converges with a global learning rate. The MSLR strategy helps alleviate this issue and makes the training more efficient.

Based on the gradient analysis on all the three tasks, we conclude that choosing an initial learning rate according to unimodal results is a simple and effective approach to help with the vanishing gradient problem in certain cases.

Table 7: Layer conductance for different models on the textual and audio modality for the IMDb Movie Genre classification task.

Modality	Textual	Audio
Text-only	0.010	-
Visual-only	-	0.007
Joint-global	0.002	0.019
MSLR: Keep - epoch 20	0.006	0.007
MSLR: Keep - epoch 100	0.011	0.031

5.4.2 Evaluation Metrics

Following (Ovalle et al., 2017), the performance of genre classification is evaluated by F-scores computed by four different averaging algorithms: micro, macro, weighted, and samples. The results are shown in Table 4. We reach the same conclusion as in the MuSE Stress Detection task: when the best learning rates are extremely different, the "Keep" and "Dynamic" strategies work better than "Smooth" and all the other baselines.

6 Lessons Learned

In this work, we proposed modality-specific learning rates (MSLR) for training multimodal late-fusion models built up with unimodal encoders. To summarize, we have the following findings:

Firstly, we showed that learning multimodal late-fusion models can be difficult if the best learning rate for each modality is significantly different. A global learning rate may not work for all the modalities according to our Layer Conductance analysis for the representations from different modalities.

Secondly, we tried solving this problem using MSLR. According to both the conductance analysis and the predicative performance with the "Keep" Strategy, we conclude that it helps prevent the vanishing gradient, and when the training converges, it results in a model that is different compard to the global learning rates.

Thirdly, we evaluated three different MSLR strategies on three different multimodal tasks with various model structures. We observed that MSLR generally achieves competitive or better scores on most of the commonly-used evaluation metrics as compared to baselines using a global learning rate or related modality-specific learning methods.

Specifically, the experimental results on the MELD Sentiment Analysis task indicated that when different modalities have close ranges of best learning rates, the model with a global learning rate is a strong baseline, while MSLR achieves competitive performance with the "Smooth" strategy performing the best. Otherwise, in the MuSE and MM-IMDb tasks where the learning rate gaps are large, the "Keep" and "Dynamic" strategies outperform the global learning rate model because they ensure a valid gradient on all the modalities.

A potential disadvantage of MSLR is the unstable training process, which can be the topic of future work. We also hope that our work inspires more research on new learning strategies for multimodal interactive models and generative tasks.

Abstract

Aspect-based sentiment analysis (ABSA) is a fine-grained sentiment analysis task that aims to align aspects and corresponding sentiments for aspect-specific sentiment polarity inference. It is challenging because a sentence may contain multiple aspects or complicated (*e.g.,* conditional, coordinating, or adversative) relations. Recently, exploiting dependency syntax information with graph neural networks has been the most popular trend. Despite its success, methods that heavily rely on the dependency tree pose challenges in accurately modeling the alignment of the aspects and their words indicative of sentiment, since the dependency tree may provide noisy signals of unrelated associations (*e.g.,* the "*conj*" relation between "*great*" and "*dreadful*" in Figure 2). In this paper, to alleviate this problem, we propose a **Bi**-**Syn**tax aware **G**raph **At**tention Network (**BiSyn-GAT+**). Specifically, **BiSyn-GAT+** fully exploits the syntax information (*e.g.,* phrase segmentation and hierarchical structure) of the constituent tree of a sentence to model the sentiment-aware context of every single aspect (called ***intra***-context) and the sentiment relations across aspects (called ***inter***-context) for learning. Experiments on four benchmark datasets demonstrate that BiSyn-GAT+ outperforms the state-of-the-art methods consistently.

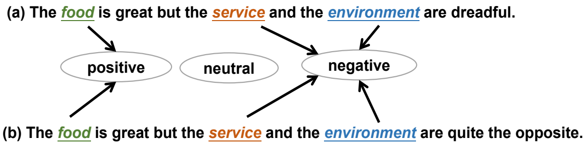

Figure 1: Examples of ABSA task. Each underlined aspect is classified to corresponding sentiment polarity.

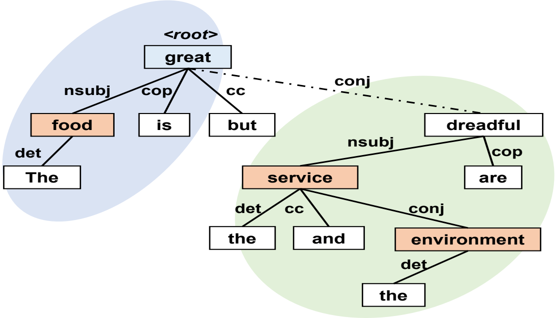

Figure 2: Dependency tree of "The food is great but the service and the environment are dreadful". Two separate ellipses encircle its two clauses. The "conj" edge between "great" and "dreadful" is a noise.

1 Introduction

Aspect-based sentiment analysis (ABSA) aims to identify the sentiment polarity towards a given aspect in the sentence. Many previous works (Yang et al., 2018; Li et al., 2019) mainly focus on extracting sequence features via Recurrent Neural Networks (RNNs) or Convolution Neural Networks (CNNs) with attention mechanisms, which often assume that words closer to the target aspect are more likely to be related to its sentiment. However, the assumption might not be valid as exemplified in Figure 1 (a), "service" is obviously closer to "great" rather than "dreadful", and these methods may assign the irrelevant opinion word "great" to "service" mistakenly.

To mitigate this problem, there already exists several efforts (Wang et al., 2020a; Chen et al., 2020) dedicated to research on how to effectively leverage non-sequential information (*e.g.,* syntactic information like dependency tree) via Graph Neural Networks (GNNs). Generally, a dependency tree (*i.e.,* Dep.Tree), linking the aspect terms to the syntactically related words, stays valid in the long-distance dependency problem. However, the inherent nature of Dep.Tree structure may introduce noise like the unrelated relations across clauses, such as "conj" relation between "great" and "dreadful" in Figure 2, which discourages capturing the sentiment-aware context of each aspect, *i.e., intra*-context. Figure 3: Constituent tree of the sentence “The food is great but the service and the environment are dreadful”. Context words are in rectangles and parsed phrase types are in rounded rectangles.

over, the Dep.Tree structure only reveals relations between words and, thereby, in most cases, is incapable of modeling complicated (*e.g.,* conditional, coordinating, or adversative) relations of sentences, therefore failing to capture sentiment relations between aspects, *i.e., inter*-context.

Hence, in this paper, we consider fully exploiting the syntax information of the constituent tree to tackle the problem. Typically, a constituent tree (*i.e.,* Con.Tree) often contains precise and discriminative phrase segmentation and hierarchical composition structure, which are helpful for correctly aligning the aspects and their corresponding words indicative of sentiment. The former can naturally divide a complicated sentence into multiple clauses, and the latter can discriminate different relations among aspects to infer the sentiment relations of different aspects. We illustrate this with an example in Figure 3: (1) Clause “The food is great” and the clause “the service and environment are dreadful” are segmented by the phrase segmentation term “but”; (2) In Layer-1, the term “and” indicates the coordinating relation of “service” and “environment”, while the term “but” in Layer-3 reflects the adversative relation towards “food” and “service” (or “environment”).

Thus, to better align aspect terms and corresponding sentiments, we propose a new framework, **Bi**-**Syn**tax aware **G**raph **At**tention Network (**BiSyn-GAT+**), to effectively leverage the syntax information of constituent tree by modeling *intra*-context and *inter*-context information. In particular, BiSyn-GAT+ employs: 1) a syntax graph embedding to encode the *intra*-context of each aspect based on the fusion syntax information within the same clause in a bottom-up way, which combines the phrase-level syntax information of its constituent tree and the clause-level syntax information of its dependency tree. 2) an aspect-context graph consisting of phrase segmentation terms and all aspects to model the *inter*-context of each aspect. Specifically, it aggregates the sentiment information of other aspects according to the influence between the current aspect and its neighbor aspects, which is calculated based on aspect representations learned from bi-directional relations over the aspect context graph, respectively.

Our main contributions are as follows:

(1) To the best of our knowledge, this is the first work to exploit syntax information of constituent tree (*e.g.,* phrase segmentation and hierarchical structure) with GNNs for ABSA. Moreover, it shows superiority in the alignments between aspects and corresponding words indicative of sentiment.

(2) We propose a framework, **Bi**-**Syn**tax aware **G**raph **At**tention Network (**BiSyn-GAT+**), to fully leverage syntax information of constituent tree (or, and dependency tree) by modeling the sentiment-aware context of each single aspect and the sentiment relations across aspects.

(3) Extensive experiments on four datasets show that our proposed model achieves state-of-the-art performances.

2 Related Work

Sentiment analysis is an important task in the field of natural language processing (Zhang et al., 2018; Yang et al., 2020) and can be applied in downstream tasks, like emotional chatbot (Wei et al., 2019; Li et al., 2020a; Lan et al., 2020; Wei et al., 2021), recommendation system (Zhao et al., 2022; Wang et al., 2020b), QA system (Wei et al., 2011; Qiu et al., 2021). Here we focus on a fine-grained sentiment analysis task — ABSA. Recently, deep learning methods have been widely adopted for ABSA task. These works can be divided into two main categories: methods without syntax information (*i.e.,* Syntax-free methods) and methods with syntax information (*i.e.,* Syntax-based methods).

Syntax-free methods: Neural networks with attention mechanisms (Wang et al., 2016; Chen et al., 2017; Song et al., 2019) have been widely used. Chen et al. (2017) adopts a multiple-attention mechanism to capture sentiment features. Song et al. (2019) uses an attentional encoder network (AEN) to excavate rich semantic information from word embeddings.

Syntax-based methods: Recently, utilizing dependency information with GNNs has become an effective way for ABSA. Zhang et al. (2019) uses graph convolutional networks (GCN) to learn node representations from Dep.Tree. Tang et al. (2020) proposes a dependency graph enhanced dual-transformer network (DGEDT) by jointly considering representations from Transformers and corresponding dependency graph. Wang et al. (2020a) constructs aspect-oriented dependency trees and proposes R-GAT, extending the graph attention network to encode graphs with labeled edges. Li et al. (2021) proposes a dual graph convolutional networks (DualGCN) model, simultaneously considering syntax structures and semantic correlations. All above works use syntax information of Dep.Tree, which may introduce noise, as we said before. Thus, we exploit syntax information of Con.Tree with GNNs. Precisely, we follow the Con.Tree to aggregate information from words within the same phrases in a bottom-up way and capture *intra*-context information.

Moreover, some works resort to modeling aspect-aspect relations. Some (Hazarika et al., 2018; Majumder et al., 2018) adopt aspect representations to model relations by RNNs or memory networks, without utilizing context information. And some (Fan et al., 2018; Hu et al., 2019) propose alignment loss or orthogonal attention regulation to constrain aspect-level interactions, which fail when aspects have no explicit opinion expressions or multiple aspects share same opinion words. Recently, there are some works utilizing GNNs to model aspect relations. Liang et al. (2020) constructs an inter-aspect graph based on relative dependencies between aspects. Zhao et al. (2020) constructs a sentiment graph, where each node represents an aspect, and each edge represents the sentiment dependency relation. However, these works fail to explicitly use phrase segmentation information, such as conjunction words. Thus, we propose an aspect-context graph consisting of all aspects and phrase segmentation terms to model *inter*-context information.

GNNs with constituent tree: To our knowledge, we are the first work to utilize the constituent tree for ABSA task. But in aspect-category sentiment analysis task, which predicts sentiment polarity towards a given predefined category in the text, Li et al. (2020b) proposes a Sentence Constituent-Aware Network (SCAN) that generates representations of the nodes in Con.Tree. Unlike SCAN, we view parsed phrases as different spans of the input text instead of individual nodes. So we don't introduce any inner nodes of Con.Tree (*e.g.,* "NP","VP" of Figure 3) into the representation space, decreasing the computational overhead.

3 Methodology

3.1 Overview

Problem Statement. Let $\mathbf{s} = \{w_i\}_n$ and $\mathbf{A} = \{a_j\}_m$ be a sentence and a predefined aspect set, where n and m are the number of words in $\mathbf{s}$ and the number of aspects in $\mathbf{A}$, respectively. For each $\mathbf{s}$, $\mathbf{A_s} = \{a_i | a_i \in \mathbf{A}, a_i \in \mathbf{s}\}$ denotes the aspects contained in $\mathbf{s}$. We treat each multiple-word aspect as a single word for simplicity, so a_i also means the i-th word of $\mathbf{s}$. The goal of ABSA is to predict the sentiment polarity $y_i \in \{\text{positive, negative, neural}\}$ for each aspect $a_i \in \mathbf{A_s}$.

Architecture. As shown in Figure 4, our proposed architecture takes the sentence and all aspects that appear in the text as the input, and outputs the sentiment predictions of the aspects. It contains three components: 1) the ***intra*-context module** encodes the input $\{w_i\}$ to obtain aspect-specific representations of the target aspects, which contains two encoders: a context encoder that outputs contextual word representations and a syntax encoder that utilizes syntax information of the parsed constituent tree (or, and dependency tree). 2) the ***inter*-context module** includes a relation encoder applied to the constructed aspect-context graph to output relation-enhanced representations. The aspect-context graph composes all aspects of the given sentence and phrase segmentation terms obtained from a designed rule-based map function applied to the constituent tree. 3) the **sentiment classifier** takes output representations of the above two modules to make predictions.

3.2 *Intra*-Context Module

In this part, we utilize a context encoder and a syntax encoder to model the sentiment-aware context of every single aspect and generate aspect-specific representation for each aspect. Note that for multi-aspect sentences, we use this module multiple times, as each time deals with one aspect.

3.2.1 Context Encoder

We use BERT (Devlin et al., 2019) to generate contextual word representations. Given target aspect a_t, we follow **BERT-SPC** (Song et al., 2019) to construct a BERT-based sequence:

$$BERT\_seq_t = [\text{CLS}] + \{w_i\} + [\text{SEP}] + a_t + [\text{SEP}]\,, \quad (1)$$

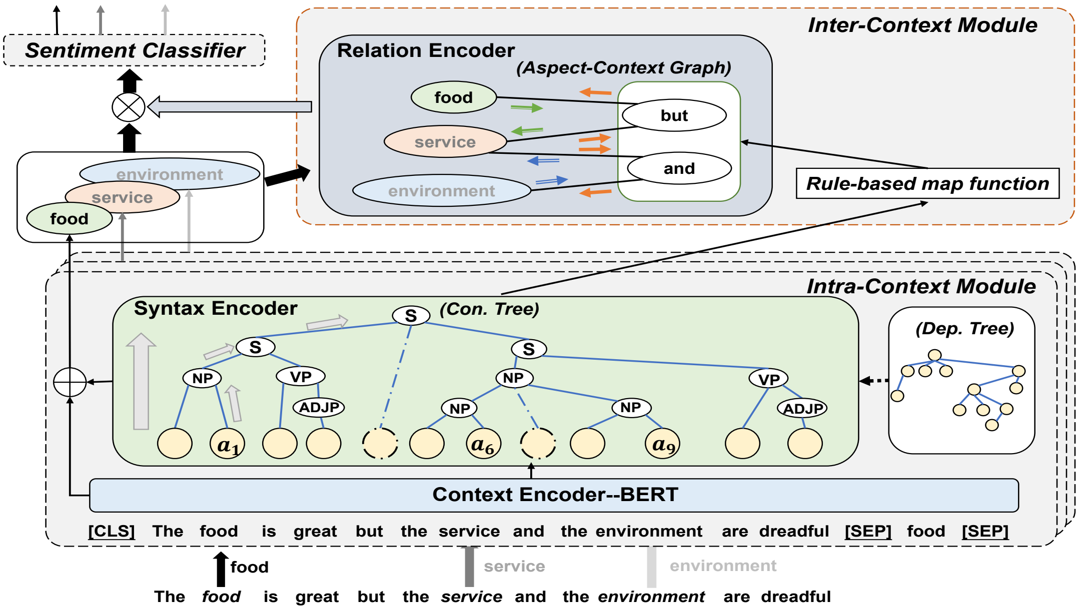

Figure 4: Overall architecture. It takes the sentence and all aspects as input and outputs sentiment predictions for all aspects. It has three components: 1) the ***intra*-context module** contains two encoders: a context encoder that outputs contextual word representations and a syntax encoder that utilizes syntax information of the parsed constituent tree (or, and dependency tree). Output representations from two encoders are fused to generate aspect-specific representations; 2) the ***inter*-context module** includes a relation encoder applied to the constructed aspect-context graph to obtain relation-enhanced representations. The aspect-context graph includes all aspects and phrase segmentation terms obtained from a designed rule-based map function applied to the constituent tree. 3) the **sentiment classifier** takes the outputs from two modules to make predictions.

Then, the output representation is obtained by,

$$h^t = \left\{h_0^t, h_1^t, \ldots, h_{n'}^t, \ldots, h_{n'+2+m'_t}^t\right\} \tag{2}$$

where n' and m' are lengths of input text and target aspect a_t after BERT tokenizer separately, h_0^t is "BERT pooling" vector representing the BERT sequence, h_i^t is the contextual representation of each token. Note that w_i may be split into multiple sub-words by BERT tokenizer. So we calculate the contextual representation of w_i as follows,

$$\hat{\mathbf{h}}_i^t = \frac{1}{|BertT(w_i)|} \sum_{k \in BertT(w_i)} h_k^t, \tag{3}$$

where $BertT(w_i)$ returns an index set of w_i's sub-words in BERT sequence, and $|\ |$ returns its length.

3.2.2 Syntax Encoder

The above representations only consider semantic information, so we propose a syntax encoder to utilize rich syntax information. Our syntax encoder is stacked by several designed Hierarchical Graph ATtention (HGAT) blocks, and each block consists of multiple graph attention (*i.e.,* GAT) layers that encode syntax information hierarchically under the guidance of the constituent tree (or, and the dependency tree). The key point is the construction of corresponding graphs.

Graph construction. As Figure 4 shows, we follow the syntax structure of Con.Tree in a bottom-up way. Each layer l of Con.Tree consists of several phrases $\{ph_u^l\}$ that compose the input text, and each phrase represents an individual semantic unit. *e.g.,* $\{ph^3\}$ in Figure 3 is {The food is great, but, the service and the environment are dreadful}. We construct corresponding graphs based on those phrases. *i.e.,* For layer l that consists of phrases $\{ph_u^l\}$, we construct the adjacent matrix $\mathbf{CA}$ that shows word connections:

$$\mathbf{CA}_{i,j}^l = \begin{cases} 1 & \text{if } w_i, w_j \text{ in same phrase of } \left\{ph_u^l\right\} \\ 0 & \text{otherwise} \end{cases}, \tag{4}$$

which is exemplified as *Con.Graphs* in Figure 5.

HGAT block. A HGAT block aims to encode syntax information into word representations hierarchically. As Figure 5 shows, a HGAT block is stacked by several GAT layers that utilize a masked self-attention mechanism to aggregate information from neighbors and a fully connected feed forward network to map representations to the same semantic space. Attention mechanism can handle the diversity of neighbors with higher weights assigned to more related words. It can be formulated as follows,

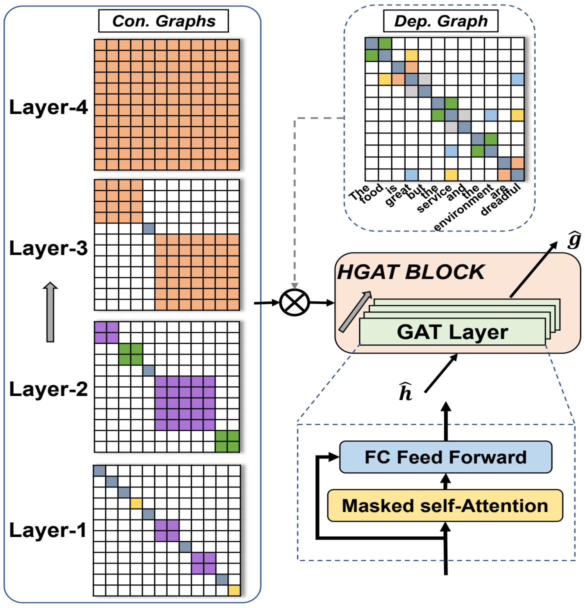

Figure 5: HGAT Block. It is stacked by several GAT layers, and each GAT layer is applied to the graph obtained from one layer of the constituent tree (or, and the dependency tree).

$$\hat{\mathbf{g}}_i^{t,l} = FC(\mathbf{g}_i^{t,l} + \hat{\mathbf{g}}_i^{t,l-1}), \tag{5}$$

$$\mathbf{g}_i^{t,l} = \|_{z=1}^{Z} \sigma \left(\sum_{j \in \mathcal{N}^{t,l}(i)} \alpha_{ij}^{lz} \mathbf{W}_g^{lz} \hat{\mathbf{g}}_j^{t,l-1} \right), \tag{6}$$

$$\alpha_{ij}^{lz} = \frac{\exp\left(f\left(\hat{\mathbf{g}}_i^{t,l-1}, \hat{\mathbf{g}}_j^{t,l-1}\right)\right)}{\sum_{j' \in \mathcal{N}^l(i)} \exp\left(f\left(\hat{\mathbf{g}}_i^{t,l-1}, \hat{\mathbf{g}}_{j'}^{t,l-1}\right)\right)}, \tag{7}$$

where $\mathcal{N}^l(i)$ is the set of neighbors of w_i in layer l, $\hat{\mathbf{g}}_i^{t,l}$ is the final representation of w_i in layer l, FC is fully connected feed forward network. $\mathbf{g}_i^{t,l}$ is the representation of w_i after masked self-attention mechanism. $||$ denotes vector concatenation. Z is the number of attention heads, σ is activation function. W_g^{lz} is trainable parameter of the zth head of layer l. f is a score function that measures the correlation of two words. Stacked HGAT block takes the output of previous one as the input, and the input of the first HGAT block is $\hat{\mathbf{h}}^t$. The output of syntax encoder is defined as $\hat{\mathbf{g}}^t$ for simplicity.

With dependency information. We also explore the fusion of two syntax information. Following previous works, we consider the Dep.Tree as an undirected graph and construct adjacent matrix **DA**, which is formulated as follows,

$$\mathbf{DA}_{i,j} = \begin{cases} 1 & \text{if } w_i, w_j \text{ link directly in Dep.Tree} \\ 0 & \text{otherwise} \end{cases} \tag{8}$$

We consider three operations: **position-wise dot**, **position-wise add**, and **conditional position-wise add**. Each corresponding adjacent matrix **FA** is shown as follows,

A. position-wise dot. For each layer of Con.Tree, this operation only considers neighbors of the Dep.Tree that are also in the same phrase.

$$\mathbf{FA} = \mathbf{CA} \cdot \mathbf{DA} \tag{9}$$

B. position-wise add. For each layer of Con.Tree, this operation considers words in the same phrases and neighbors of the Dep.Tree. Some edges of Dep.Tree can shorten paths between aspect words and relevant opinion words, *e.g.*, "food" and "great" in Figure 3.

$$\mathbf{FA} = \mathbf{CA} + \mathbf{DA} \tag{10}$$

C. conditional position-wise add. This operation considers phrase-level syntax information of Con.Tree and clause-level syntax information of Dep.Tree. Specifically, it first deletes all dependency edges that are across clauses (*e.g.*, the edge between "great" and "dreadful" in Figure 2) and then conducts **position-wise add** operation with the remaining dependency edges.

$$\mathbf{FA} = \mathbf{CA} \oplus \mathbf{DA} \tag{11}$$

Thus, the output of the *intra*-context module contains both contextual information and syntax information, which is formulated as follows,

$$\mathbf{v}_t^{as} = \left[\hat{\mathbf{h}}_t^t + \hat{\mathbf{g}}_t^t; h_0^t\right] \tag{12}$$

3.3 *Inter*-Context Module

The *intra*-context module ignores the mutual influence of aspects. Thus, in *inter*-context module, we construct an aspect-context graph to model the relations across aspects. This module only works for multi-aspect sentences, with aspect-specific representations of all aspects from *intra*-context module as input and outputs relation-enhanced representation of each aspect.

Phrase segmentation. Aspect relations can be revealed by some phrase segmentation terms, like conjunction words. Thus, we design a rule-based map function PS that returns phrase segmentation terms of two aspects: Given two aspects, it first finds their lowest common ancestor (LCA) in the Con.Tree, which contains information of two aspects and has the least irrelevant context. We call branches from LCA that between sub-trees which two aspects are separately in as "inner branches". PS returns all text words in the inner branches if they exist; else, it returns words between two aspects of the input text. It is formulated as follows,

$$PS(a_i, a_j) = \begin{cases} \{w_k\}, & \text{if } |Br(a_i, a_j)| = 0 \\ Br(a_i, a_j), & otherwise \end{cases}, \tag{13}$$

where $i < k < j$ and $Br(a_i, a_j)$ returns text words in the inner branches of a_i and a_j. *e.g.*, in Figure 3, given aspects food and service, the LCA node is S of Layer-4 that has three branches, with food in the first and service in the third. So "but" in the second branch (inner branch) is the phrase segmentation term that reflects sentiment relation of two aspects.

Aspect-context graph construction. We notice that the influence range of one aspect should be continuous, and the mutual influence of aspects attenuates with distance. Considering all aspect pairs introduces noise caused by long distance and increases computational overhead. So we only model relations across neighbor aspects. After extracting phrase segmentation terms of neighbor aspects by PS function, we construct an aspect-context graph by linking aspects with corresponding phrase segmentation terms to help infer relations. To distinguish the bi-directional relations over the aspect-context graph, we build two corresponding adjacent matrices. The first handles influence from aspects in odd-index among all aspects of the sentence, to neighbor even-index aspects, the second handles the opposite. An example is shown in Figure 6. Then, taking $\{v_t^{as}, t \in \mathbf{A_s}\}$ and corresponding phrase segmentation terms representations encoded by BERT as the input, the above HGAT blocks are applied as the relation encoder to obtain relation-enhanced representation v_t^{aa} for each aspect a_t.

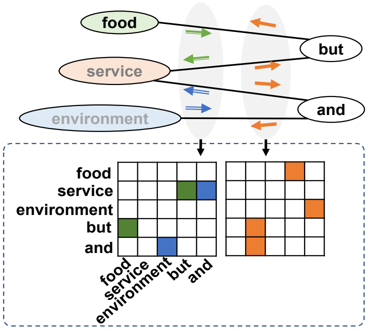

Figure 6: Example of an aspect-context graph and corresponding two adjacent matrices for distinguishing the bi-directional relations.

Dataset		Sentence-Level			Aspect-Level		
		Multi-Asp.	Single-Asp.	All	Pos.	Neg.	Neu.

	Test	0	677	677	172	169	336

Table 1: Statistics of datasets. Multi-Asp., Single-Asp. indicate the number of sentences with multiple or single aspect; Pos., Neg., and Neu. show the number of aspects towards positive, negative and neutral label.

3.4 Training

The outputs of the ***intra*-context module** and ***inter*-context module** are combined to form the final representations, which are later fed to a fully connected layer (*i.e.,* sentiment classifier) with a softmax activation function, generating the probabilities over the three sentiment polarities:

$$\mathbf{o_t} = \mathbf{v}_t^{as} + \mathbf{v}_t^{aa}, \tag{14}$$

$$\mathbf{p}(\mathbf{t}) = softmax(\mathbf{W_p o_t} + \mathbf{b_p}), \tag{15}$$

where $\mathbf{W_p}$, $\mathbf{b_p}$ are parameters of the classifier[1].

The loss is defined as the cross-entropy loss between golden polarity labels and predicted polarity distributions of all (sentence, aspect) pairs:

$$L(\theta)^{Sentiment} = -\sum_{s} \sum_{a_t \in A_s} loss(\mathbf{p}(\mathbf{t}), y(t)), \tag{16}$$

where a_t is the aspect and also the t-th word in s, $loss$ is the standard cross-entropy loss, θ represents model parameters.

4 Experiment

4.1 Datasets and Setup

We evaluate our models on four English dataset: Laptop, Restaurant datasets from SemEval2014 (Task 4) (Pontiki et al., 2014), MAMS (Jiang et al., 2019), and Twitter (Dong et al., 2014). Laptop and Restaurant contain both multi-aspect and single-aspect sentences. Each sentence in MAMS contains at least two aspects with different sentiments.

---

[1] In Eq14, $\mathbf{v}_t^{aa}$ is set to zero in single-aspect sentence.

Table 3: Ablation study. Notations "con." and "dep." represent syntax information from constituent tree and dependency tree, respectively. $\times, +, \oplus$ represent the position-wise dot, position-wise add, conditional position-wise add operations, respectively, when fusing two syntax information. "AA" represents modeling aspect-aspect relations. The best performances are in **bold**, and second-best are <u>underlined</u>.

Twitter contains only one-aspect sentences. Dataset statistics are shown in Table 1.

We adopt SuPar[2] as parser. Specifically, we use CRF constituency parser (Zhang et al., 2020) to get the constituent tree; and following previous works (Wang et al., 2020a; Bai et al., 2020), we use deep Biaffine Parser (Dozat and Manning, 2017) to get the dependency tree. Our context encoder is BERT-base-uncased [3] model. Adam optimizer is adopted with a learning rate 2×10^{-5} and a L_2 regulation 10^{-5} for model training. Number of GAT layers of one HGAT block is 3, and number of HGAT blocks is in range [1,3] on different datasets. "Accuracy" and "Macro-Averaged F1" are evaluation metrics. More details are in Appendix A.

4.2 Baselines

We compare our model with the following models:

1) Syntax-free baselines: **BERT-SPC** (Song et al., 2019), **AEN-BERT** (Song et al., 2019);

2) Syntax-based baselines: **R-GAT** (Wang et al., 2020a), **RGAT+** (Bai et al., 2020), **DGEDT** (Tang et al., 2020), **DualGCN** (Li et al., 2021);

3) Baselines that model aspect-aspect relations: **SDGCN-BERT** (Zhao et al., 2020), **InterGCN** (Liang et al., 2020);

Model		Dataset			
		Restaurant		MAMS	
		Acc.(%)	F1.(%)	Acc.(%)	F1.(%)
	BiSyn-GAT	87.49	81.63	84.90	84.43
aspect-context graph	w/ Bi-relation	**87.94**	**82.43**	**85.85**	**85.49**
	w/o Bi-relation	87.85	82.27	85.10	84.69
aspect graph	adjacent	87.49	81.69	85.10	84.61
	Bi-adjacent	87.40	81.53	85.18	84.74
	global	87.49	81.70	85.32	84.88

Table 4: Performance comparison of aspect-context graph variants on Restaurant and MAMS dataset. The best performances are in **bold**.

Ours are also syntax-based, including:

a) **BiSyn-GAT+**: our full model, which contains the *intra*-context module that combines two syntax information by **conditional position-wise add** operation, *inter*-context module, and sentiment classifier to make predictions;

b) **BiSyn-GAT**: full model without *inter*-context module;

Baselines and our models are all BERT-based.

4.3 Main Results

Table 2 shows results of the baselines and our models. For fairness of comparison, we present the reported results of those baselines. Observations are: 1) Our proposed models outperform most baselines, and our full model ***BiSyn-GAT+*** achieves state-

	SuPar	87.49	81.63	84.90	84.43
BiSyn-GAT+	Stanford Parser	87.84	82.39	85.78	85.40
	SuPar	87.94	82.43	85.85	85.49

Table 5: Experiments results with different parsers. w/o dep. is one variant of BiSyn-GAT, only using constituent information.

of-the-art performances in all datasets, especially 1.27 and 1.75 F1 improvements on Restaurant and MAMS. 2) Models with syntax information outperform those without, which means syntax structure is helpful. 3) Our models show superiority to those that only use dependency information, which implies that constituent tree can provide profitable information. 4) ***BiSyn-GAT+*** shows consistent improvement compared to ***BiSyn-GAT***, which means modeling aspect-aspect relations can improve performance, especially when more multi-aspect sentences are available, *e.g.,* 0.8 and 1.06 F1 improvements on Restaurant and MAMS.

4.4 Ablation Study

We also conduct an ablation study to verify the effectiveness of our proposed method. The results are shown in Table 3. We set the context encoder of our model as the base model, *i.e., BERT+*. The observations are that: 1) *BERT+* achieves the lowest performance, which shows syntax information is helpful in ABSA task. 2) In category *w/o AA*, **w/o con.** is inferior to **w/o dep.**, which means syntax information of Con.Tree is useful. Moreover, the comparison between **w/o con.** and **con.×dep.** verifies that some dependency edges that cross the phrases indeed bring noise, as the former considers all dependency edges and the latter ignores those across phrases obtained from Con.Tree for each layer. 3) Fusing two syntax information in the proper ways can boost performance. In category *w/o AA*, **con.+dep.** and **con.⊕dep.** both outperform **w/o dep.** and **w/o con.** in all datasets. However, **con.×dep.** is inferior to **w/o dep.**. One possible reason is that the position-wise dot operation ignores most connections within phrases, causing the graphs to be more sparse. It also verifies that words within the same phrases of Con.Tree are essential for aligning aspects and corresponding opinions. 4) Modeling aspect-aspect relations is beneficial from the comparison between *w/ AA* and *w/o AA*, especially in Restaurant and MAMS that contain more multi-aspect sentences.

5 Effects of Aspect-context graph

We also investigate the effects of our bi-relational modeling of the proposed aspect-context graph. Firstly, we use **BiSyn-GAT** as base model to see whether the approach modeling aspects relations improves the performance; Secondly, based on our proposed aspect-context graph, we consider two variants: (a) **w/ Bi-relation**, a directed one that distinguishes the influence one aspect imposes on other aspects and is received from other aspects, *i.e.,* our full model BiSyn-GAT+; (b) **w/o Bi-relation**, an undirected one that ignores the direction of the influence; Thirdly, inspired by Zhao et al. (2020), we define the aspect graph as the graph with all aspects as its nodes, *i.e.,* our aspect-context graph without any segmentation terms. Based on the aspect graph, we propose three variants: (c) **adjacent aspect graph**, an undirected one where neighbor aspects are connected; (d) **bi-adjacent aspect graph**, a directed one where neighbor aspects are connected; (e) **global aspect graph**, an undirected one where all aspects are connected; The above five variants are illustrated in Figure 7. Experimental

Sentences	Aspects	BiSyn-GAT	BiSyn-GAT+
it doesn't look like much on the **outside**$_{neg}$, but the minute you walk inside, it's a whole other **atmosphere**$_{pos}$.	outside atmosphere	neu ✗ pos ✓	neg ✓ pos ✓
while the **service**$_{neg}$ and **setting**$_{neg}$ were average , the **food**$_{pos}$ was excellent.	service setting food	neg ✓ neu ✗ pos ✓	neg ✓ neg ✓ pos ✓
food was average, the **appetizers**$_{pos}$ were better than the **main courses**$_{neu}$.	appetizers main courses	pos ✓ pos ✗	pos ✓ neu ✓
i have no complaints about the **wait**$_{pos}$ or the **service**$_{pos}$ but the **pizza**$_{neg}$ was bit at all something to write home about.	wait service pizza	neu ✗ neg ✗ neg ✓	pos ✓ pos ✓ neg ✓

Table 6: Predictions from *BiSyn-GAT* and *BiSyn-GAT+*. The notations pos, neg, and neu in the table represent positive, negative, and neutral. For each sentence, the aspects are displayed in bold, with golden sentiment polarities as the subscripts. The phrase segmentation words are shown underline between the corresponding two aspects. False predictions are marked with ✗while true predictions are marked with ✓.

results are shown in Table 4 and we can observe that: 1) w/ Bi-relation (*i.e.,* BiSyn-GAT+) outperforms w/o Bi-relation consistently, which indicates distinguishing the bi-relational influences is beneficial; 2) Overall, aspect-context graph shows superiority compared with aspect graph, which means the phrase segmentation terms can help model aspects relations; 3) Unlike in aspect-context graph, bi-adjacent aspect graph does not guarantee performance improvement compared with adjacent aspect graph, which reflects the importance of phrase segmentation terms when modeling aspect-aspect relations; 4) Overall, global aspect graph performs better than adjacent aspect graph, which is correlated with the results in Zhao et al. (2020); 5) In Restaurant dataset, adjacent aspect graph and global aspect graph show comparable performance. One possible reason is that the number of samples that contain at least three aspects is very limited, as shown in Table 8 of Appendix. And adjacent aspect graph equals global aspect graph when faced with two aspects.

5.1 Effects of Parsing

We conduct experiments to study the influence of paring accuracy on model performance. Two parsers are selected: (a) Stanford Parser (Manning et al., 2014), a well-known toolkit; it has transition-based dependency parser (Chen and Manning, 2014) and shift-reduce constituency parser (Zhu et al., 2013); (b) SuPar, which RGAT+ (Bai et al., 2020) and our proposed models adopt; it has deep biaffine dependency parser (Dozat and Manning, 2017) and neural CRF constituency parser (Zhang et al., 2020). Generally, SuPar has better parsing performances than Stanford Parser. We use BERT+ as the base model and compare the performance of model **w/o dep**, **Bisyn-GAT**, **BiSyn-GAT+** when using different parsers. The results are shown in Table 5. Observations are that: 1) With Stanford Parser, our models can also achieve good performance. 2) Models with SuPar perform better than models with Stanford Parser, which is correlated with the parsing accuracy of two parsers.

5.2 Case Study

As shown in Figure 6, we present four examples to help better understand our proposed model, especially *inter*-context module when faced with complex sentences. The first is a comparative sentence with two clauses connected by the conjunction "but". Both models make correct predictions for **atmosphere**. However, *BiSyn-GAT* predicts wrong over **outside** while *BiSyn-GAT+* still makes a correct prediction, which show the *inter*-context module correctly captures the reversed sentiment relation between **outside** and **atmosphere** by phrase segmentation terms ", but". The rest examples all show that *inter*-context module can use relations across aspects to help correct the predictions.

6 Conclusion

In this paper, we propose the BiSyn-GAT+ framework to model the sentiment-aware context of each aspect and sentiment relations across aspects for learning by fully exploiting the syntax information of the constituent tree. It includes two well-designed modules: 1) *intra*-context module that fuses related semantic and syntax information hierarchically; 2) *inter*-context module that models relations across aspects with the constructed aspect-context graph. To the best of our knowledge, it is the first work to exploit the constituent tree with GNNs for the ABSA task. Moreover, our proposed model achieves state-of-the-art performances on four benchmark datasets.

A Dataset and Implementation Detail

A.1 Statistics of constituent tree depth

Table 7 shows more detailed statistics about four benchmark datasets at the aspect level. We define the "constituent tree depth" as the number of nodes in the path from the aspect term node to the root node in the Con.Tree. It means we treat the layer that the aspect term is in as the bottom layer for constituent graph construction and drop layers below it. The aspect term has no other neighbors in those layers and thus fails to update its representation through the graph encoder. According to the constituent tree depth statistics, we set the number of GAT layers of one HGAT block in the syntax encoder to 3, the most common depth.

A.2 Multi-aspect Distribution of datasets

Table 8 shows the multi-aspect distribution of the Restaurant, Laptop, and MAMS datasets. This can explain the improvement of BiSyn-GAT+ compared to BiSyn-GAT on different datasets: MAMS > Restaurant > Laptop. MAMS contains the most multi-aspect sentences that our proposed *Inter-context* module can fully utilize.

A.3 Training Detail

The numbers of parameters of BiSyn-GAT and BiSyn-GAT+ are 112M and 233M. Each epoch takes about 60s or 70s in RTX 2080 Ti. We test the model that performs best on validation data, and for datasets without official validation data, we follow the dataset settings of previous work (Bai et al., 2020). We use the grid search to find the best parameters for our model and report the maximum results. The number of HGAT blocks within our relation encoder is in range [1,3] on different datasets and the number of its inner GAT layers is set to 2; the dropout rate is 0.1 for the input and output and is in the range [0.2, 0.7] between layers; In each HGAT block of our syntax encoder, for samples with fewer constituent tree layers, we only adopt the same number of GAT layers to encode; for samples with more constituent tree layers, we prune them to three layers.

B Discussion about phrase segmentation term

We firstly provide more cases about the phrase segmentation terms in this section. For each case, the aspects are displayed in **bold** and phrase segmentation words are underlined between the corresponding two aspects:

1) However, we went for **lunch** and were the only ones eatting there and yet the **service** seemed eager for use to be done and to get out.

2) We were so excited since I was reading great review of this **place**, however we were disappointed with the **taste** of the **food**.

3) Then the **manager** gave us **lemon juice** instead of **ceasar dressing** for a ceasar salad which ruined the salad.

4) The only drawback was slow **service**, but the **food** and **ambiance** are so nice that your **wait** is a) pleasant and b) worth it.

5) Compared to the **soup** of average taste, the **rice** is better in this restaurant.

The top 4 cases show that our approach can capture words, such as "and", "but", "yet", "however", "instead of" to help infer aspects relations.

However, we also notice there is a limitation of our method: it can only find the phrase segmentation terms within the two aspects, failing to capture some important words indicative of relations that appear in other locations. *e.g.,* in case 5), our approach capture "," instead of "compared to", while only the latter can show the reversed sentiment of two aspects. We leave this problem as the future work, considering that our current approach is simple and can also achieve good performance.

C Limitations and future work

This section discusses some improvements that can be made in future work. 1) Our full model adopts two BERT encoders, one in *Intra*-context module for encoding input text and aspects and one in *Inter*-context module for encoding the phrase segmentation terms. The pros are that our *Inter*-context can easily generalize to other ABSA models, taking their output aspect representations and generating the relation enhanced representations. However, this causes the parameters of BiSyn-GAT+ up to 233M. We will consider other encoding strategies instead of simply using another BERT; 2) We notice that the label information from Con.Tree can also provide valuable information, *e.g.,* NP node and VP node, which together form the S node, may contain the aspect term and corresponding opinion words separately, as shown in Figure 3. It is worth trying to utilize more information from Con.Tree, and we will continue to explore it in future work.

IndicBART: A Pre-trained Model for Indic Natural Language Generation

Abstract

In this paper, we study pre-trained sequence-to-sequence models for a group of related languages, with a focus on Indic languages. We present IndicBART, a multilingual, sequence-to-sequence pre-trained model focusing on 11 Indic languages and English. IndicBART utilizes the orthographic similarity between Indic scripts to improve transfer learning between similar Indic languages. We evaluate IndicBART on two NLG tasks: Neural Machine Translation (NMT) and extreme summarization. Our experiments on NMT and extreme summarization show that a model specific to related languages like IndicBART is competitive with large pre-trained models like mBART50 despite being significantly smaller. It also performs well on very low-resource translation scenarios where languages are not included in pre-training or fine-tuning. Script sharing, multilingual training, and better utilization of limited model capacity contribute to the good performance of the compact IndicBART model.

1 Introduction

Recently, there has been significant progress in deep learning based natural language generation (NLG) for machine translation, abstractive summarization, data-to-text generation, etc. due to the adoption of attention-based sequence-to-sequence (S2S) models (conditional language models) (Wu et al., 2016; Paulus et al., 2018; Puduppully et al., 2019). Pre-trained S2S models have been shown to be useful to improve performance on various NLG tasks (Rothe et al., 2020; Kale and Rastogi, 2020; Lewis et al., 2020). Specifically, multilingual pre-trained S2S models jointly trained on monolingual corpora from multiple languages such as mBART25 (Liu et al., 2020), mBART50 (Tang et al., 2020a) and mT5 (Xue et al., 2021) have seen increased adoption and low-resource languages have benefitted from cross-lingual transfer. However, these massively multilingual massive (M3) models have major limitations. They serve only a few of the world's languages (<100 languages), the pre-training corpora are dominated by high-resource languages, the vocabulary representation for low-resource languages is inadequate, and the models are large, making them expensive and slow to train, fine-tune and decode.

An alternative approach is to build pre-trained S2S models for a group of related languages. Previous work has shown the benefits of pre-trained language models as well as NMT models that cater to a set of related languages (Kakwani et al., 2020; Tan et al., 2019; Khanuja et al., 2021; Reid et al., 2021). Owing to their public availability, these models have seen heavy adoption[1]. However, such a study on multilingual pre-trained S2S models for Indic languages is missing in the literature. In this work, we address this gap in the literature by studying multilingual pre-trained S2S models for Indic languages.

The result of this study is *IndicBART*, a multilingual pre-trained sequence to sequence model specifically trained for Indic languages, which are spoken by more than a billion users[2]. It **supports English and 11 Indian languages** including 7 Indo-Aryan (Assamese, Bengali, Gujarati, Hindi, Marathi, Oriya, Punjabi) and 4 Dravidian (Kannada, Malayalam, Tamil, Telugu) languages. Of these, mBART25, mBART50 and mT5 support only 2, 7 and 9 languages respectively. There are linguistic similarities between the two language families on account of contact relatedness resulting from geographical colocation. Within, the two language families there are genetic relations between languages due to them being derived from

common ancestor languages[3][4]. Due to this, the Indian subcontinent is considered to be a *linguistic area* or *sprachbund* (Emeneau, 1956). There is evidence that such contact-relatedness can result in positive cross-lingual transfer for NLP applications like NMT (Goyal et al., 2020a). Hence, we train a single model for all Indic languages. It is a **compact model with just 244M parameters**, which is much smaller than the M3 models such as mBART50 and mT5(-base) which contain 611M and 580M parameters respectively. We also propose a variant of IndicBART, i.e. **IndicALBART**, that is highly compact with just **97M parameters**.

We compare IndicBART with M3 models on two downstream generation tasks: machine translation and extreme summarization (Narayan et al., 2018). The results indicate that IndicBART is competitive or better by up to 2 BLEU/ROUGE compared to M3 models like mBART50. IndicBART also performs well in the following zero-shot scenarios: (a) on languages not included in pre-training, and (b) languages for which there is no fine-tuning data.

The following aspects of the IndicBART model contribute to its strong performance and increased language coverage within the Indic group vis-à-vis M3 models, while being highly compact:

1. It is trained on a smaller set of related languages, which reduces model capacity requirements. Moreover, available model capacity is effectively utilized, since transfer learning works when languages share linguistic features and data represents shared topical themes.

2. It is trained on the largest publicly available Indic language corpora, IndicCorp (Kakwani et al., 2020), which includes large, high-quality news crawls for Indian languages as well as English content from Indian websites - thus being representative of Indian English and topics.

3. We utilize the orthographic similarity between Indic scripts (Kunchukuttan et al., 2018) to map all the Indic language data to a single script, effectively reducing the number of scripts from 9 to 1 (each script having approximately 50 characters). This increases the shared subwords in the vocabulary, and we observe that single script models enable better cross-lingual transfer while fine-tuning. Since subwords embeddings consume a significant fraction of the parameter space, single script models also better utilize available vocabulary budget[5].

4. Extremely compressed pre-trained S2S models (IndicALBART) suitable for deployment can be trained by sharing parameters across layers of the transformer layers. For related languages, we show compressed pre-trained models are competitive with full models on downstream tasks when fine-tuned on distilled data.

The IndicBART model and its variants, along with details on how to fine-tune them, can be accessed at `https://github.com/AI4Bharat/indic-bart/`. We also release the models on the HuggingFace model hub at `https://huggingface.co/ai4bharat/IndicBART` and `https://huggingface.co/ai4bharat/IndicBARTSS`. Models are available under an MIT license to spur further innovation in NLG for Indic languages and study of pre-trained S2S models for related languages.

2 Related Work

Pre-trained models. Pre-trained models learned using self-supervised objectives and large monolingual corpora have contributed to rapid advances in NLU (Devlin et al., 2019) and NLG (Lewis et al., 2020). Following initial work on English pre-trained models, multilingual pre-trained models have been proposed for NLU (Devlin et al., 2019; Conneau et al., 2020) as well as NLG (Liu et al., 2020; Tang et al., 2020a; Xue et al., 2021) supporting around 100 languages. These pre-trained M3 models have proven to be very useful in improving NLG performance in low-resource settings, especially for applications other than translation.

Language group-specific models. The proposed IndicBART model is also a multilingual pre-trained S2S model, similar in architecture and training to mBART. However, in contrast to mBART and mT5, the proposed IndicBART caters specifically to Indic languages. While language-group specific NLU language models like IndicBERT (Kakwani et al., 2020) and MuRIL (Khanuja et al., 2021) and NMT models (Tan et al., 2019) have been proposed, ours is one of the first efforts to create a pre-trained S2S model for a specific language group (and the first for Indic languages). AfroMT (Reid et al., 2021) is a concurrent effort focussed on African languages and low monolingual corpora scenarios

---

[3] `https://en.wikipedia.org/wiki/Proto-Indo-Aryan_language`

[4] `https://en.wikipedia.org/wiki/Proto-Dravidian_language`

[5] Where mBART-25 and mBART-50 have vocabularies of 250K subwords to accommodate 25 to 50 languages, IndicBART has a vocabulary of 64K subwords which is 4 times smaller.

belonging to various language families. However, AfroMT heavily relies on synthetic data, which may not reflect the true data distribution across languages. Furthermore, AfroMT effort is focussed only on MT, whereas we investigate IndicBART on an additional NLG task - abstractive summarization. Interestingly, the publicly available group-specific language models (IndicBERT and MuRIL) both cater to Indic languages, pointing to perceived need for Indic language specific models.

Language relatedness. Language-group specific models are motivated from previous work that emphasizes the role of language relatedness in cross-lingual transfer for NMT (Nguyen and Chiang, 2017; Dabre et al., 2017; Aharoni et al., 2019; Kudugunta et al., 2019; Dabre et al., 2020) and NLU (Kakwani et al., 2020; Khemchandani et al., 2021; Dhamecha et al., 2021). We use a single script for representing Indic data since orthographic similarity between Indic languages has been utilized to represent data in a common script and improve cross-lingual transfer for machine transliteration (Kunchukuttan et al., 2018), machine translation (Dabre et al., 2018; Goyal et al., 2020b; Ramesh et al., 2021) and NLU (Khemchandani et al., 2021; Dhamecha et al., 2021).

Parameter Sharing and Distillation. Parameter sharing across layers has shown promise for NMT (Dabre and Fujita, 2019) and pre-trained LMs (Lan et al., 2020) in building compressed models while maintaining end-task performance. The IndicALBART model proposed in this work is the first model to explore parameter-sharing across layers for pre-trained S2S models. For NMT models trained from scratch, sequence-to-sequence distillation (Kim and Rush, 2016) has been shown as an effective way to transfer knowledge to smaller models, while training large models on distilled data (a form of self-training) has been shown to improve translation quality (Dabre and Fujita, 2020). Our results indicate that these results hold when fine-tuning on pre-trained S2S models as well.

3 IndicBART

The **IndicBART** model is conceptually based on the mBART25/50 model family, which are Transformer models (Vaswani et al., 2017) trained on monolingual corpora with masked span reconstruction objective. We refer the readers to the mBART literature (Lewis et al., 2020; Liu et al., 2020) for architectural details and highlight specific details and differences from the mBART25/50 setup.

3.1 Design Considerations for IndicBART

Considerations that drove our model choices are:

Compactness: The model should be compact given our focus on a smaller set of related languages, as well as to accelerate training and fine-tuning. Such a model will be usable by a larger base of users with limited computational resources.

Content Relevance: In addition to Indian languages, we include English since transfer-learning from English is a natural use case, and English is widely used in the Indian subcontinent. We also use English content from the Indian subcontinent to reflect relevant content.

Leveraging Relatedness: We utilize orthographic similarity between Indian languages, most of which use abugida scripts derived from the Brahmi script. The logical character set has high overlaps, though each script has its own code-point range in the Unicode standard (Kunchukuttan et al., 2018). We map all the data to Devanagari, enabling better transfer learning[6] with a more compact vocabulary compared to mBART.

3.2 Model and Training Details

IndicBART uses (N=) 6 encoder and decoder layers with hidden and filter sizes of 1024 and 4096, respectively, and 16 attention heads (244M parameters). Similar to mBART, we mask (p=)35% of the words in each sentence by randomly sampling a span length according to a Poisson distribution ($\lambda = 3.5$). We use dropouts of 0.1, label smoothing of 0.1, Adam optimizer with a maximum learning rate of 0.001, weight decay of 0.00001, linear learning rate warm-up and decay with 16,000 warm-up steps, batch sizes of 4096 tokens. We train for 750,000 iterations on 48 NVIDIA V-100 GPUs, corresponding to roughly 2 epochs, taking around 5 days[7]. In comparison, mBART25/50 models need much longer time (2+ weeks) on 256 GPUs.

To explore more compressed pre-trained models, we train **IndicALBART**, a variant of IndicBART with cross-layer parameter sharing, i.e., sharing parameters across layers. For ablation studies on the impact of single script representation, we also

---

[6] There is a substantial amount of shared vocabulary between Indian languages written in different scripts. Mapping scripts to Devanagari enables direct sharing of vocabulary, leading to improved transfer learning.

[7] Longer training was limited by the availability of many GPUs simultaneously.

train a variant of IndicBART with a 64K vocabulary using the original scripts, which we call separate script IndicBART (SSIndicBART).

The models have been trained with the YANMTT toolkit[8] (Dabre and Sumita, 2021) which is based on the mBART implementation of the HuggingFace Transformers library (Wolf et al., 2020).

3.3 Training Data and Pre-processing

We train the IndicBART model on the IndicCorp (IC) dataset (Kakwani et al., 2020) which contains 11 Indic languages and English. The Indic languages are: Assamese (as), Bengali (bn), Gujarati (gu), Hindi (hi), Kannada (kn), Malayalam (ml), Marathi (mr), Oriya (or), Punjabi (pa), Tamil (ta) and Telugu (te). The corpora statistics are mentioned in Table 7 of the appendix. We train the model on a total of approx. 450 million sentences and 9 billion tokens, where corpora sizes are balanced with temperature (T=5) based sampling (Arivazhagan et al., 2019). All the Indic language data is represented in a single script, i.e., the Devanagari script using the IndicNLP library[9] (Kunchukuttan, 2020). We use a vocabulary of 64K subwords learned using SentencePiece (Kudo, 2018; Kudo and Richardson, 2018) on randomly sampled 1M raw sentences from the IndicCorp for each language, for a total of 12M sentences. The model is trained at the sentence-level, unlike the mBART50 model, which is trained on contiguous text chunks potentially spanning multiple sentences.

4 Experiments: NMT

Machine Translation is a standard, popular, cross-lingual generation task for which various pre-trained models are evaluated. We compare IndicBART and its variants with mBART50, which should be the most directly comparable model. We study their performance in: (a) low-resource, (b) multilingual and (c) zero-shot training settings.

4.1 Models Compared

We study IndicBART via the following models:
Models trained from scratch: We train bilingual (Bi) as well as multilingual many-to-one (M2O) and one-to-many (O2M) transformer models.
Fine-tuned models: We fine-tune mBART50 (MB50), IndicBART (IB) and its variants namely IndicALBART (IALB) and separate script IndicBART (SSIB). The type of fine-tuning is indicated by +type, which can be Bi, O2M or M2O. If needed, the corpus is indicated by +corpus.
Distilled models: We use the multilingually fine-tuned IndicBART model and translate the training data source sentences, which yields distillation data (Kim and Rush, 2016). We use this data to train M2O and O2M models from scratch, as well as by fine-tuning on mBART50, IndicBART and IndicALBART. This was motivated by Dabre and Fujita (2020) who show that the distillation data generated using models employing transfer learning significantly improves the performance of compact models for low-resource languages.

4.2 Datasets and Preprocessing

The statistics of training corpora are in Table 7 in the appendix.
Training: For a low-resource setting (LR), we use the PMI subset (Haddow and Kirefu, 2020) of the WAT 2021 MultiIndicMT[10] (Nakazawa et al., 2021) training set for finetuning. This represents an extremely low-resource parallel corpus setting where we expect IndicBART to be the most helpful. We experiment with extending the PMI data (approximately 326K pairs) with the CVIT-PIB (henceforth PIB: 930K pairs) data (Siripragrada et al., 2020) which is similar in domain to the former. We also use the high-resource, general domain Samanantar corpus (Ramesh et al., 2021) (46.2M pairs) to compare with the generalization capabilities of pre-trained models which are fine-tuned with small corpora (PMI, PIB).
Testing: We use the WAT 2021 MultiIndicMT test-set and the FLORES101 devtest (Goyal et al., 2021) for evaluation of our models. Both these test sets are n-way parallel (2,390 and 1,012 sentences respectively). The WAT 2021 test set shares the same domain as the training set. The FLORES devtest comes from a different, general domain. We rely on the FLORES dataset to evaluate performance of models trained on the PMI/PIB domain on a more general domain.
Validation: We use the WAT2021 development set of 1,000 sentences.
Preprocessing: For IndicBART and IndicALBART, we use the Indic NLP library to convert the Indic side of the parallel data to the Devanagari script. For mBART50, only Kannada, Punjabi

---

[8] https://github.com/prajdabre/yanmtt

[9] https://github.com/anoopkunchukuttan/indic_nlp_library

[10] http://lotus.kuee.kyoto-u.ac.jp/WAT/indic-multilingual

and Oriya scripts are converted to Devanagari as mBART50 does not support these languages. Results for these are italicized. For separate script IndicBART we do not do script conversion.

With this setup, we study the benefits of pretraining in low-resource settings (fine-tuned on PMI and PIB) and compare it with high-resource settings (trained on Samanantar) on in-domain (WAT2021) and general (FLORES) test sets. Unless explicitly mentioned, our models are assumed to be trained/fine-tuned/distilled with the PMI training data.

4.3 Model Training Settings

We use a single GPU for bilingual and 8 GPUs for multilingual models, all of which are Transformers. Multilingual models are trained using the approach in Johnson et al. (2017) where corpora for various language pairs are first balanced according to their size, then concatenated after appending target language indicator tokens, and finally fed to the NMT model for training. Wherever possible and applicable, we tuned hyperparameters such as hidden sizes, dropout, label smoothing, warm-up, tokens per batch, per GPU, learning rate and weight decay. The ADAM optimizer was used. We train our models till convergence on the development set BLEU scores (Papineni et al., 2002). We decode train/tests sets using beam search with a beam of size 4 and a length penalty of 0.8. We report the BLEU scores on the decoded results computed using sacreBLEU[11] (Post, 2018). For additional details, refer to section B in the appendix.

4.4 Comparison of Pre-trained Models

We first describe the main results of using IndicBART and its variants for machine translation and compare it with other relevant models. Table 1 shows results for models trained on the PMI corpus and evaluated on the WAT21 test set.

Language specific models are compact and competitive: Considering bilingual models, IndicBART outperforms models trained from scratch and gives competitive results when compared to mBART50. For Indic to English translation, mBART50 tends to be better, but this is not surprising because it is trained on far larger amounts of English data in addition to being almost 3 times larger than IndicBART. For English to Indic translation, both models tend to give similar scores. In the case of multilingual models, IndicBART is, once again, vastly better than its counterpart trained from scratch and when compared to mBART50 the gap which existed in case of bilingual settings disappears and sometimes reverses in favor of IndicBART. In both cases, IndicBART outperforms mBART50 for Kannada, Punjabi and Oriya which the latter is not trained for. This shows that having a compact language group specific model can be competitive with if not better than a general purpose model trained on a larger number of languages while only having one-third the number of parameters as the latter.

Extreme compression has its downside: Comparing the performance of IndicBART and mBART50 against IndicALBART in multilingual settings, it seems that a 60% and 84% reduction of parameters, respectively, has a negative impact on the translation quality, which results in drops of up to 3 BLEU. However, this may be considered as a reasonable tradeoff given the high levels of compression achieved. Especially given that IndicALBART is 84% smaller than mBART50, means that large capacity GPUs (which not everyone has easy access to) may not be needed. Furthermore, the drops in quality can be addressed via distillation.

Distillation successfully transfers performance from large to smaller models: We see that fine-tuning the pre-trained IndicALBART on distilled data from IndicBART can match the performance of the IndicBART model. Fine-tuning pre-trained IndicALBART performs better than training a randomly initialized model on the same distilled data in the XX-En direction. On the other hand, both the approaches are competitive in the En-XX direction.

Self-training on distilled data is beneficial: When IndicBART and MB50 are fine-tuned on distillation data generated from a previously fine-tuned model, we see significant improvements in the XX-En direction, and modest improvements in the En-XX directions. These observations are mostly in line with Dabre and Fujita (2020).

In summary, compact language group specific pre-trained models are competitive with large universal language models. This can result in reasonable gains in fine-tuning multilingual models (3.3-3.5 hours for IndicBART variants vs 4.7-5 hours for mBART50) and significantly reduce the memory footprint (97-244M vs 611M) for deployment.

---

Table 2: Ablation studies on the impact of multilingualism and script unification on downstream performance of IndicBART. Scores are on the WAT 2021 test set.

4.5 Ablation Studies

We now perform ablation experiments to study the (a.) impact of script unification on translation, (b.) impact of corpora sizes and domains on translation, (c.) translation quality for languages unseen during fine-tuning, and (d.) translation quality on languages unseen during pre-training. Although we train models on all languages, we only report on a subset due to lack of space. Please see Sections C, D in the appendix for more detailed results.

4.5.1 Impact Of Script Unification

Table 2 contains the ablation tests, giving the results for the impact of script unification with multilingual fine-tuning. Comparing scores of models fine-tuned on unified script IndicBART (IB+M2O/O2M) against separate script IndicBART (SSIB+M2O/O2M) it is clear that overall, the for-

Model	bn	hi	ml	or	ta
	Test Set: WAT 2021

Samanantar	**30.7**	**36.0**	**30.4**	**28.6**	**27.7**
IB+Samanantar	30.1	35.3	29.1	28.5	26.6

Table 3: Ablation study of the impact of using different fine-tuning corpora sizes (PMI+PIB) and their comparison against a model trained from scratch as well as fine-tuned on a general domain corpus (Samanantar). We evaluate Indic to English translation on the WAT 2021 as well as the FLORES test sets.

Setting	M2O		O2M	
	kn-en	pa-en	en-kn	en-pa
IB+Full	32.4	35.7	18.5	26.4
IB+Zero	27.5	31.5	6.1	10.4
SSIB+Zero	24.0	28.2	3.9	7.4

Table 4: Evaluation of Kannada and Punjabi to/from English translation, which aren't seen when fine-tuning.

mer is better than the latter which could indicate that script unification enables languages to better benefit from each other. The case of Kannada, Punjabi and Oriya, further, illustrates the utility of script unification. The results for these languages are italicized in the rows labelled MB50+Bi and MB50+O2M/M2O in Table 1. mBART50 was not pre-trained on these languages, so we converted the training data in these languages in the Devanagari script[12]. With this trick, we still managed to get large performance improvements over the baselines trained from scratch, and these improvements are often close to those exhibited by using IndicBART. This shows that we may not need to pre-train on all languages. However, explicitly training on the languages of interest should lead to better translation quality (Tang et al., 2020b).

4.5.2 Impact Of Corpora Size and Domain

Table 3 shows the impact of corpora sizes as well as training data domain on some Indic to English pairs (complete results in Appendix D). All models are multilingual (M2O), have the same size and are trained on unified script data. In order to clearly assess the impact of domains, we evaluate on the WAT 2021 as well as the FLORES test sets. Regardless of the test sets or testing domains, comparing rows IB+PMI and IB+PMI+PIB, it is clear that increasing the amount of fine-tuning data has a positive impact on the final translation quality. However, PMI+PIB data is in-domain for the WAT 2021 test set but out-of-domain for the FLORES test set, and the performance on the latter test set still improves.Furthermore, comparing rows IB+PMI+PIB and Samanantar, we can see widely different results depending on the test set. For the WAT 2021 test set, fine-tuning on the PMI+PIB dataset is comparable to training on Samanantar from scratch, indicating that for domain specific models, having a small in-domain fine-tuning data is sufficient. On the other hand, on the more general domain FLORES test sets training on the more diverse Samanantar data is clearly better. Finally, the scores in the row IB+Samanantar show that pre-training has minimal impact when the parallel corpora are large, an observation in line with Liu et al. (2020).

4.5.3 Unseen Languages During Fine-Tuning

We evaluate Kannada and Punjabi to/from English translation where the IndicBART model, with and without script unification, is fine-tuned on the multilingual PMI data where the training data for these languages is missing (denoted by "Zero"). We compare against a setting where the training data is used (denoted by "Full"). Table 4 shows what happens when languages are seen during pre-training but not during fine-tuning. There are two critical observations: First, despite not having seen any training data for the given language pairs, we still obtain a reasonable translation for translation into English. However, the quality of translation from English is poor due to the decoder not having seen those specific Indic languages during fine-tuning. Incorporating a monolingual de-noising objective for unseen target languages during fine-tuning could alleviate this problem. Second, script unification has a large impact on the final performance, often improving performance by up to 3.5 BLEU over a separate script model.

4.5.4 Unseen Languages During Pre-Training

We study Nepalese (ne) and Sinhala (si) to English translation using the parallel training data from Guzmán et al. (2019) (also used in Liu et al. (2020))

---

[12] None of the pre-training languages use the same script as kn, pa, or.

Model	**ne-en**	**si-en**
Bi (Scratch)	5.2	4.3
IB+Bi	**10.5**	**8.5**
(Liu et al., 2020)	14.5	13.7

Table 5: Evaluation of Nepali and Sinhala to English translation where IndicBART hasn't seen Nepali and Sinhala during pre-training.

for bilingual fine-tuning, and evaluate on the FLORES devtest set[13]. Note that for Sinhala we have to resort to script mapping into Devanagari. Table 5 shows what happens when we perform fine-tuning for languages that IndicBART is not trained on. The baselines, trained using the unified script IndicBART vocabulary, will seem weaker than what is reported in previous work, but it should be noted that the vocabulary was not actually trained for Nepali and Sinhala. Regardless, fine-tuning leads to substantial improvements in translation quality, which indicates the utility of IndicBART even for unseen languages. Comparing against Liu et al. (2020) who use the same fine-tuning data as us but their mBART model is pre-trained on both languages, we can see that our models are not too far behind.

5 Experiments: Extreme Summarization

We compare the performance of fine-tuning IndicBART, its variants and mBART50 on the challenging *extreme summarization* task (Narayan et al., 2018) for Indic languages. The small datasets, enable a good study of the utility of pre-training.

5.1 Models Trained

We fine-tune and compare the mBART50 (MB), IndicBART (IB), IndicALBART (IALB) and the separate script IndicBART model (SSIB) models. Punjabi is not present in mBART50 and has its script mapped to Devanagari before fine-tuning (italicized results).

5.2 Datasets and Preprocessing

We used the multilingual XL-Sum dataset (Hasan et al., 2021) for our experiments. The Indic languages we focus on for evaluating our IndicBART models are: Bengali, Gujarati, Hindi, Marathi, Punjabi, Tamil and Telugu. We use the updated splits of Hasan et al. (2021), the statistics of which are given in their GitHub page[14]. Since the splits are not n-way parallel, we do not conduct multilingual fine-tuning due to potential content overlaps between splits across languages. Like we did in NMT, we map all scripts to Devanagari as applicable for fine-tuning (only Punjabi for mBART50, all languages for IndicBART and IndicALBART and none for separate script IndicBART). Statistics are given in Table 10 in the appendix.

Lang	**MB50**	**IB**	**SSIB**	**IALB**
bn	**21.87**	21.46	20.52	19.86
gu	**18.28**	18.20	16.38	16.81
hi	**31.71**	30.94	30.33	30.04
mr	18.33	**19.00**	18.66	18.44
pa	*22.14*	24.82	**25.08**	23.29
ta	19.50	**20.40**	20.23	17.41
te	13.34	**14.38**	13.34	13.55

Table 6: Rouge-L scores for summarization on XL-Sum.

5.3 Model Training Settings

Similar to NMT, we use YANMTT for fine-tuning. We use maximum document-summary lengths of 512-64 tokens, which loosely follows previous work (Lewis et al., 2020). Most of the optimal hyperparameters were the same as for NMT. We train our models till convergence on the development set Rouge-L F1 scores (RL) (Lin, 2004). For decoding test sets, we use beam size of 5, length penalty of 1.2 and a decoding n-gram repetition limit of 4[15]. We report RL scores on the decoded results computed using multilingual Rouge scoring toolkit[16]. Refer to section F in the appendix for details.

5.4 Results

Table 6 contains the results for the summarization experiments. IndicBART (IB) and mBART50 are competitive with each other where the former performs slightly better for Marathi, Punjabi, Tamil and Telugu. Once again, separate script IndicBART (SSIB) fared poorer than IndicBART except for Punjabi, indicating the importance of script unification. Similar to NMT, fine-tuning IndicALBART gives poorer results, often lagging 1-3 RL points

[14] `https://github.com/csebuetnlp/xl-sum/`

[15] This means that 4-grams won't be repeated in the output.

[16] `https://github.com/csebuetnlp/xl-sum/tree/master/multilingual_rouge_scoring`

behind IndicBART which we consider to be a reasonable tradeoff given the reduced parameter sizes. We expect that distillation may help improve performance, like it does for NMT. Overall, the major conclusions are in line with the those observed for the low-resource NMT task.

6 Conclusion and Future Work

We presented IndicBART, a multilingual, pre-trained sequence-to-sequence model to support development of NLG applications for Indian languages. IndicBART supports 11 Indian languages and English, and utilizes the orthographic similarity of Indic scripts to enable better cross-lingual transfer. IndicBART presents a case-study for language group-specific pre-trained S2S models. Our experiments on fine-tuning IndicBART for NMT and summarization showed that the model is competitive with large models such as mBART50. We further compressed IndicBART while maintaining downstream task performance via parameter sharing (IndicALBART) combined with multilingual distillation. We showed that script unification has a strong positive impact on translation and summarization. We also showed that IndicBART, thanks to its script independent nature, can be readily used for enabling translation for languages such as Sinhala and Nepali which IndicBART has not been explicitly pre-trained for. Furthermore, we showed that fine-tuning IndicBART on one set of languages enables translation for another unseen set of languages, which shows that pre-trained models enable translation without parallel corpora.

In the future, we plan to support more Indic languages in IndicBART; starting with all the 22[17] languages listed in the 8^{th} schedule of the Indian constitution. Increased language coverage and models with lower compute demands can democratize access to NLP technologies. We also plan to focus on training models on longer text chunks (documents) and larger text corpora, incorporating advances in multilingual pre-training, cross-lingual transfer and cross-lingual tasks for Indian languages.

Table 7: Statistics of monolingual and parallel corpora (#sentences) for pre-training IndicBART and fine-tuning it, respectively.

A Corpora statistics

Table 7 gives the statistics for the monolingual corpora, Indiccorp (IC), and parallel corpora, PMI, PIB and Samanantar (Sam) used in this paper. Indiccorp is used for pre-training IndicBART and the parallel corpora are used for fine-tuning or for training models from scratch. PMI and PIB have similar domains. PMI is used to simulate a realistic low-resource domain specific setting, and PIB is used to simulate a middle-resource domain specific setting. Samanantar is used to simulate a high resource general domain setting.

B NMT Model Training Settings

We use a single GPU for bilingual and 8 GPUs for multilingual models, all of which are Transformers. Multilingual models are trained using the approach in Johnson et al. (2017). Due to the large number of models we train, we did not perform exhaustive hyperparameter tuning. We mainly focused on tuning the learning rates, batch sizes and warm-ups. We found that high dropouts were surprisingly ineffective, especially for multilingual settings, regardless of training from scratch or fine-tuning. Nevertheless, for fine-tuning IndicBART and its variants, we determined the following optimal hyperparameters: dropouts of 0.1, label smoothing of 0.1, warm-up of 16,000 steps, 2048 tokens per batch per GPU, learning rate of 0.001 and weight decay of 0.00001 with the ADAM optimizer for training. For mBART50, we used warm-up of 2,500 steps, 512 tokens per batch per GPU, and a learning rate of 0.00003.[18] For bilingual and multilingual models trained from scratch on the small PMI and PIB data, we use smaller models with hidden and filter sizes of 512 and 2048, respectively, while keeping all other hyperparameters the same as for IndicBART which we found to be highly effective. As Samanantar data is much larger, we keep its size the same as IndicBART. Except for separate script IndicBART and mBART50, all models use the same vocabulary as IndicBART for consistency.

We train our models till convergence on the development set BLEU scores (Papineni et al., 2002) which are computed via greedy decoding every 1,000 batches. For multilingual models, we use the global development set BLEU score, an average of BLEU scores for each language pair. During decoding the test sets, we use beam search with a beam of size 4 and a length penalty of 0.8. We report the BLEU scores on the decoded results computed using sacreBLEU[19] (Post, 2018).

C NMT Results: Impact of Script Unification

Table 8 contains the results of ablation studies on the impact of script unification in bilingual and multilingual settings. Regardless of bilingual or multilingual fine-tuning, it is clear that script unification tends to give better results on average as compared to using separate scripts to represent all languages.

D NMT Results: Effect of Corpora Size and Domain

Table 9 contains the results showing the impact of varying corpora sizes and domain on translation quality. In the main paper, we could not show results for all languages and directions, due to lack of space. There are three key points to note: (a.) fine-tuning using small in-domain corpora (PMI) gives competitive results compared to using a large general domain corpus. (b.) Additional corpora from a related domain (PMI) leads to substantial improvements in translation quality for in- as well as out-of-domain performance, indicating that fine-tuning a pre-trained model on a corpus belonging to a different domain (PMI/PIB) is a viable option in case

---

[18] A small learning rate is needed since we can train on very small batches given the large model size.

Table 9: Ablation study of the impact of using different sizes of fine-tuning corpora (PMI and its combination with PIB) and their comparison against a model trained from scratch as well as fine-tuned on a general domain corpus (Samanantar). We evaluate on the WAT 2021 as well as the FLORES test sets.

training corpus for the target domain (FLORES) is unavailable. Furthermore, going from low-resource to middle resource settings does not diminish the contribution of pre-trained models. (c.) General domain corpora inevitably lead to the best performance, but since training large models on large general domain corpora is more time-consuming, fine-tuning is a more attractive option since pre-training needs to be done only once.

E Corpora statistics for summarization experiments

Table 10 contains statistics of the Indic section of the XL-sum dataset, which we use for summa-

te	10,421	1,302	1,302

Table 10: Statistics of the Indic portion of the multilingual XL-Sum dataset (Hasan et al., 2021) that we used for training our summarization models.

rization experiments. We preprocess languages by mapping their scripts to Devanagari as applicable (all languages for IndicBART and IndicALBART; none for separate script IndicBART; only Punjabi for mBART50).

F Summarization Model Training Settings

Similar to NMT, we use YANMTT for fine-tuning. We use maximum document-summary lengths of 512-64 tokens, which loosely follows previous work (Lewis et al., 2020). Unlike NMT, we do not train models from scratch, as they would not work given the small data sizes and difficulty of summarization. For IndicBART and its variants, we determined the following optimal hyperparameters: batch sizes of 4,096 tokens, dropouts of 0.1, label smoothing of 0.1, learning rate warmup steps of 4,000, learning rate of 0.001 and weight decay of 0.00001 with the ADAM optimizer. For mBART50 we use sentence level batching with 2 document-summary pairs per batch and learning rate of 0.00001 which we found to be optimal. We train our models till convergence on the development set Rouge scores (Rouge-L F1) (Lin, 2004) for all languages, which are computed via greedy decoding every 1,000 batches. Similar to NMT, we save the best performing checkpoints for each language. During decoding the test sets, we use beam search with a beam of size 5, length penalty of 1.2 and a decoding n-gram repetition limit of 4-grams[20]. We report Rouge scores on the decoded results computed using multilingual Rouge scoring toolkit[21].

---

[20] This means that 4-grams won't be repeated in the output.

Sentence-T5 (ST5): Scalable Sentence Encoders from Pre-trained Text-to-Text Models

**Jianmo Ni, Gustavo Hernández Ábrego, Noah Constant, Ji Ma,
Keith B. Hall, Daniel Cer, Yinfei Yang**
Google Research
Mountain View, CA

Abstract

We provide the first exploration of sentence embeddings from text-to-text transformers (T5) including the effects of scaling up sentence encoders to 11B parameters. Sentence embeddings are broadly useful for language processing tasks. While T5 achieves impressive performance on language tasks, it is unclear how to produce sentence embeddings from encoder-decoder models. We investigate three methods to construct Sentence-T5 (ST5) models: two utilize only the T5 encoder and one using the full T5 encoder-decoder. We establish a new sentence representation transfer benchmark, SentGLUE, which extends the SentEval toolkit to nine tasks from the GLUE benchmark (Wang et al., 2018). Our encoder-only models outperform the previous best models on both SentEval and SentGLUE transfer tasks, including semantic textual similarity (STS). Scaling up ST5 from millions to billions of parameters shown to consistently improve performance. Finally, our encoder-decoder method achieves a new state-of-the-art on STS when using sentence embeddings.[1]

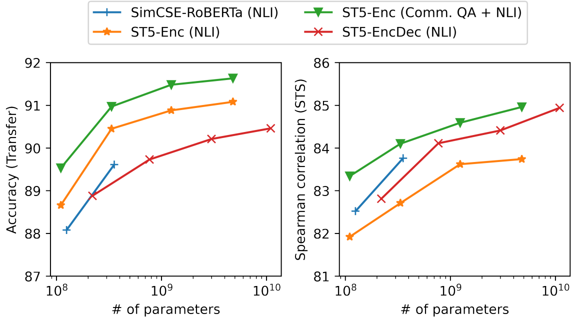

Figure 1: Scaling up our ST5 model size improves performance on SentEval (left) and STS (right).

	Transfer	STS
ST5-EncDec (11B params)	90.46	84.94
ST5-Enc (11B params)	**91.63**	**84.96**
SimCSE-RoBERTa (large) (Gao et al., 2021)[2]	90.23	83.76
SBERT (large) (Reimers and Gurevych, 2019)	87.69	76.55
USE (Cer et al., 2018)	85.10	71.22
InferSent (Conneau et al., 2017)	85.59	65.01

Table 1: ST5 versus notable sentence embedding models on SentEval tasks. The reported numbers are the average of transfer tasks (classification accuracy) and STS tasks (spearman correlation).

1 Introduction

Sentence embeddings providing compact meaning representations that are broadly useful for a variety of language processing tasks include classification, question-answering, semantic retrieval, bitext mining, and semantic similarity tasks. We explore sentence embeddings from a new family of pre-trained models: Text-to-Text Transfer Transformer (T5) (Raffel et al., 2020). Unlike encoder-only models, which use a transformer encoder to predict random masked tokens, T5 uses an encoder-decoder architecture and a generative span corruption pre-training task. T5 models can be scaled up to hundreds of billions of parameters (Fedus et al., 2021) and have achieved state-of-the-art performance on a broad range of NLP tasks including Generalized Language Understanding Evaluation (GLUE) (Wang et al., 2018) and SuperGLUE (Wang et al., 2019). However, it is difficult to efficiently apply T5 to some tasks such as retrieval or clustering. To score retrieval candidates, T5 would need to perform full inference with cross-attention on each query-candidate pair. In contrast, sentence embeddings allow for efficient retrieval and clustering (Gillick et al., 2018; Reimers and Gurevych, 2019; Yang et al., 2020).

As shown in Figure 2, we explore three ways of turning a pre-trained T5 encoder-decoder model into a sentence embedding model: (i) using the

---

[1] Our models are released at `https://tfhub.dev/google/collections/sentence-t5/1`.

[2] SimCSE-RoBERTa achieves its best performance on transfer tasks by adding an additional masked language model loss during training, which is not used by ST5 or other models.

Figure 2: Architecture diagrams for T5 and three ST5 variants to extract sentence representations from T5.

first token representation of the encoder; (ii) averaging all token representations from the encoder; (iii) using the first token representation from the decoder. We evaluate the quality of the resulting sentence embeddings on sentence transfer tasks using the SentEval (Conneau and Kiela, 2018) toolkit and on our extension of SentEval to GLUE benchmark tasks (SentGLUE) in addition to semantic textual similarity (STS) (Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017). We contrast raw representations from pre-trained T5 models with those learned through fine-tuning T5 on natural language inference (NLI) using dual encoders and contrastive learning (Conneau et al., 2017; Cer et al., 2018; Gao et al., 2021). We introduce a multi-stage contrastive learning recipe involving fine-tuning first on semi-structured web-mined corpora and then on NLI. Finally, we investigate scaling our T5 sentence embedding model up to 11B parameters. Illustrated in Figure 1, performance on transfer tasks and semantic textual similarity (STS) both improve with increased model capacity.

To our knowledge, we are the first to study using large-scale pre-trained text-to-text models for sentence representation learning and to scale sentence embedding models up to 11 billion parameters. We summarize our contributions as follows: (i) even without fine-tuning, encoder-only ST5 models perform well on sentence transfer tasks, outperforming state-of-the-art fine-tuned models such as SimCSE BERT and SimCSE RoBERTa (Gao et al., 2021); (ii) encoder-decoder sentence embedding models achieve strong performance on STS, establishing a new state-of-the-art on sentence embedding based STS; (iii) contrastive learning is effective for fine-tuning sentence encoders from T5-style pre-trained models, particularly using our proposed two-stage contrastive learning approach; (iv) training ST5 longer and with more data using a contrastive loss leads to consistent improvement on both sentence transfer and STS tasks; (v) creating a new sentence representation transfer benchmark, SentGLUE, which extends the SentEval sentence evaluation toolkit (Conneau and Kiela, 2018) to nine tasks from the GLUE benchmark (Wang et al., 2018). We contribute baselines on SentGLUE using influential sentence embedding models from prior work and contrast the performance with our proposed ST5 embedding models.

2 Related work

Sentence embedding models have been trained using a variety of methods including: supervised natural language inference pairs (NLI) (Conneau et al., 2017; Reimers and Gurevych, 2019, 2020; Gao et al., 2021); conversational input-response and question-answer pairs (Cer et al., 2018; Yang et al., 2020); translation pairs (Yang et al., 2020; Feng et al., 2020); paraphrasing pairs (Wieting et al., 2016) and adjacent sentence pairs (Kiros et al., 2015; Logeswaran and Lee, 2018). Gao et al. (2021) achieved the previous state-of-the-art on STS with BERT and RoBERTa models by combining contrastive learning that constructs positive and negative sentence pairs using NLI data.

In parallel, Text-to-Text transfer transformers (T5) (Raffel et al., 2020), as shown in Figure 2a, are gaining popularity due to their competitive performance, effective scaling to larger model sizes, and ease of use in solving tasks as simple text-to-text mapping problems. However, extracting high quality text embeddings from T5 has not been previously explored. Moreover, while recent work has shown that scaling up models improves sentence embedding performance (Gao et al., 2021), the largest model sizes investigated only include

355 million parameters rather than the 11 billion parameters available in the largest T5 model.

3 Sentence-T5 (ST5)

We explore producing sentence embeddings from T5 models, ranging in size from 220 million to 11 billion parameters, both as raw sentence embeddings extracted from pretrained T5 models and using fine-tuning to refine the representations.

3.1 Model Architecture

As shown in Figures 2b to 2d, we explore three strategies to extract T5 sentence representations:

- **Encoder-only first** (ST5-Enc first): the encoder output of the first token.
- **Encoder-only mean** (ST5-Enc mean): the average encoder output across all input tokens.
- **Encoder-Decoder first** (ST5-EncDec first): the first decoder output when the input text is fed into the encoder and the standard "start" symbol is fed as the only decoder input.

The first two are pooling strategies widely used in encoder-only pre-trained models such as BERT. Unlike BERT models, T5 models do not have a 'CLS' token at the beginning of each sentence. For T5 encoder-decoder models, we assume the decoder is aware of the semantics of the entire input sentence when generating its first token prediction; and if so, the first decoder output embeddings (i.e. input to the softmax layer) might naturally capture the sentence semantics.

For sentence encoder training, we adopt a *dual encoder* architecture (Gillick et al., 2018; Cer et al., 2018; Reimers and Gurevych, 2019). As shown in Figure 3, this architecture consists of two shared-weight transformer modules that encode the inputs. The transformer module can be either an encoder-only or encoder-decoder architecture. In our experiments, we initialize the transformer modules from a pre-trained T5 model. After each module computes a fixed-length representation for its input sentence, a projection layer and L2 normalization are applied to the resulting embeddings. The projection layer transforms the output to a configurable fixed dimension sentence embedding. The embeddings from paired encoding towers can be scored for similarity tasks using a dot-product[3] or provided to additional layers layers for classification tasks (e.g., NLI).

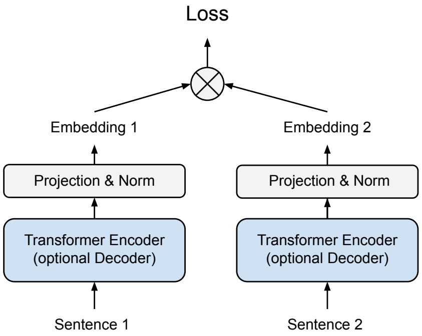

Figure 3: Architecture of the dual encoder model.

3.2 Contrastive Learning

Applying contrastive learning to sentence embeddings improves the uniformity of the embedding space, leading to better performance on downstream tasks such as STS (Gao et al., 2021). We apply contrastive learning to fine-tune the T5 sentence representations.[4]

3.2.1 Contrastive Loss

Using a contrastive loss to train a sentence encoder requires paired examples $\mathcal{D} = \{(v_i, v_i^+)\}$ as a training set, where v_i is an input sentence and v_i^+ is a related sentence (e.g., that is semantically nearby). During training, v_i^+ is considered as a positive example for v_i and all other examples in a batch are considered as negatives. The model should learn to pull the positive pairs closer together while pushing away the in-batch negatives. We operationalize our contrastive loss using an in-batch sampled softmax (Henderson et al., 2017):

$$\mathcal{L} = \frac{e^{\mathrm{sim}(v_i, v_i^+)/\tau}}{\sum_{j \in \mathcal{B}} e^{\mathrm{sim}(v_i, v_j^+)/\tau}}, \quad (1)$$

The similarity scoring function is *sim*. $\mathcal{B}$ is a mini-batch of examples and τ is the softmax temperature. When additional negatives v_j^- are provided for the input example v, the loss can be computed as:

$$\mathcal{L} = \frac{e^{\mathrm{sim}(v_i, v_i^+)/\tau}}{\sum_{j \in \mathcal{B}} e^{\mathrm{sim}(v_i, v_j^+)/\tau} + e^{\mathrm{sim}(v_i, v_j^-)/\tau}}. \quad (2)$$

---

[3] Since L2 normalization is applied to the output of each tower, the dot-product between the embeddings will produce their cosine similarity.

[4] In preliminary experiments, we also explored fine-tuning with the classification loss used in InferSent (Conneau et al., 2017) and Sentence-BERT (Reimers and Gurevych, 2019). However, as previously reported in (Gao et al., 2021), our results confirmed that fine-tuning for classification on an NLI dataset is inferior to contrastive learning.

3.3 Two-stage Training

We explore two-stage training to refine T5 sentence embeddings: (i) first training on web mined conversational input-response and question-answering pairs; (ii) then, contrastive training on NLI pairs.

4 Experimental Setup

4.1 Training Corpus

For our fine-tuned sentence embeddings, we follow prior work showing good sentence embeddings can be obtained from supervised training on NLI (Conneau et al., 2017; Reimers and Gurevych, 2019, 2020; Gao et al., 2021) in combination with training to match conversational input-response and question-answer (CQA) pairs (Cer et al., 2018; Yang et al., 2020). We make use of two-stage training using two datasets: one is comprised of 2 Billion conversational input-response and QA (CQA) pairs drawn from web forums such as Reddit and StackExchange; the other consists of NLI pairs from the Stanford Natural Language Inference (SNLI) (Bowman et al., 2015) and Multi-Genre Natural Language Inference (MNLI) (Williams et al., 2017) datasets. For the first stage, we fine-tune using the CQA pairs under a dot-product retrieval loss with batch negatives (Cer et al., 2018; Yang et al., 2018, 2020). For the second stage, we use NLI pairs with a contrastive loss (Gao et al., 2021), where the positives are the 'entailment' pairs while the negatives are the 'contradict' pairs.[5]

4.2 Evaluation

We evaluate using SentEval, which includes 7 transfer and 7 STS tasks (Conneau and Kiela, 2018) and using our extension of SentEval to the GLUEBenchmark tasks (SentGLUE). For the transfer tasks, sentence embeddings are evaluated by how well they perform as features for a linear classification model. For STS, embeddings are evaluated by how well their cosine similarities correlate with human annotated similiarity scores.[6]

4.3 Configurations

Our models are implemented using JAX[7] and trained on Cloud TPU-v3. We initialize the dual encoder modules from public T5 checkpoints. [8] During training, we use Adafactor (Shazeer and Stern, 2018) as the optimizer and set the learning rate to 0.001. Linear decay is applied after 10% of the total number of training steps, reducing the learning rate to 0 by the end of training. To fine-tune on NLI we use a batch size of 512, while for the Community QA (CQA) dataset the batch size is 2048. We use a softmax temperature τ of 0.01.

5 Experimental Goals

Our experiments aim to answer the following:

- Q1: What is the best way to extract sentence representations from T5?
- Q2: How well do raw T5 sentence embeddings perform on downstream tasks?
- Q3: How much do contrastive sentence embedding tasks (e.g., NLI, QA) improve T5 sentence embeddings.
- Q4: Can we benefit from scaling up T5 model capacity for better sentence representations?

With these goals, we study transfer and STS performance of T5 sentence embeddings using a variety of model and training configurations, comparing ST5 to state-of-the-art methods including SBERT/SRoBERTa (Reimers and Gurevych, 2019) and SimCSE (Gao et al., 2021).

6 Results

Table 2 and 3 provide performance on transfer and STS tasks, respectively. We compare ST5 models with two types of baselines: (ii) a model that extracts sentence embeddings from a pre-trained BERT model, listed in rows 1–2 of each table; (ii) the current state-of-the-art sentence embedding models fine-tuned from BERT or RoBERTa, listed in rows 6–8 of each table.

6.1 Raw T5 Sentence Embeddings

We evaluate T5 sentence embeddings without fine-tuning using the extraction strategies from section 3.1: (i) Encoder-only first token, (ii) Encoder-only mean, and (iii) Encoder-decoder start token.

Transfer tasks Results for ST5 models using raw embeddings on transfer tasks are shown in rows 3–5 of Table 2. Unlike BERT, T5's first token is not reserved as a special placeholder (i.e., CLS)

---

[5] Using only the entailment and contradict pairs results in 275K contrastive NLI pairs being available for training.

[6] Following SimCSE (Gao et al., 2021), we report Spearman's correlation for the 'all' setting for all STS tasks which aggregates the data across different subsets.

and there are no specific pre-training tasks using the first token's embeddings. It is unlikely that without additional fine-tuning the first token's representation would capture the semantics of the whole sentence. Indeed, our experiments show the first token's representation from encoder or decoder are much worse on all SentEval tasks compared to the mean pooling of the encoder-only model.

Mean pooled T5 encoder embeddings greatly outperform mean pooled BERT embeddings. Moreover, even without fine-tuning, *mean pooled T5 encoder embeddings outperform the prior best model, SimCSE-RoBERTa (Gao et al., 2021), on transfer learning even though SimCSE-RoBERTa benefited from contrastive fine-tuning on NLI.*

The strong performance of ST5 may be due to the fact that T5 is trained on more data than BERT or RoBERTa. Additionally, the original T5 models also include downstream tasks (e.g., GLUE, SuperGLUE) during pre-training, and this multi-task setting may improve transfer performance. However, we note that there are only two SentEval tasks (SST and MRPC) included in GLUE while the other five tasks are not. As shown in Table 2, we observe significant improvements on the five tasks that are not included.

STS tasks As shown in rows 3–5 of Table 3 and similar to prior work involving BERT and RoBERTA (Ethayarajh, 2019; Gao et al., 2021), mean pooling of T5 embeddings performs poorly on STS, achieving an average correlation of 55.97. While slightly better than BERT using mean pooling, this is still worse than sentence embedding models that have been fine-tuned on supervised tasks such as Sentence-BERT and SimCSE.

6.2 Fine-Tuning T5 Sentence Embeddings

We next evaluate ST5 models that are fine-tuned on CQA and NLI tasks using our contrastive loss.

Fine-tuning on NLI Given that mean pooling performs much better than the first token output representation from encoder only T5, we opt to discard the first token T5 model for our fine-tuning experiments. The last three rows of Table 2 show that the transfer performance of ST5 models is very consistent across different embedding extracting strategies after fine-tuning. The best fine-tuned model is 0.57 better than the best raw T5 sentence embeddings. In Table 3, we see that fine-tuning on NLI data significantly improves the STS task performance of ST5.

Fine-tuning on CQA + NLI To investigate the impact of additional training data on contrastive learning, we experiment with the ST5 models first trained on CQA and then fine-tuned on NLI. As shown in Tables 2 and 3, fine-tuning on an additional dataset brings a large performance boost for both transfer and STS tasks. This suggests that we may be able to improve sentence embedding quality further through the mining of additional semi-structured data for continued contrastive learning.

To exclude the effect of mixing in downstream tasks, we also trained a ST5 variant based on the T5 1.1 model which was only pre-trained on the C4 dataset (Raffel et al., 2020). As shown on the last row of Table 2 and Table 3, it achieves comparable performance to the original T5 model, outperforming on most tasks but under-performing on STS.

6.3 Encoder-only vs. Encoder-decoder

In this section, we compare the performance of two architectures: encoder-only and encoder-decoder.

Better generalizability for T5's encoder In Table 2, we saw that the encoder-only Base model performs on-par with the encoder-decoder model on transfer tasks. When we scale the ST5 model up from Base to Large, 3B and 11B, the encoder-only models' performance on transfer tasks consistently outperforms the encoder-decoder models as shown in Table 5. This shows that building ST5 on top of the T5's encoder gives strong transfer performance.

Recently, Chung et al. (2021) have shown that larger output embeddings (i.e. larger embedding size) effectively prevent the encoder from over-specializing to the pre-training task, thus making the encoder's representations more general and more transferable. We hypothesize that the decoder in the encoder-decoder architecture can improve the generalizability of the encoder's representation in a similar fashion, as the decoder focuses on optimizing for specific tasks.

Effectiveness of the decoder In the last two rows of Table 3, we observe that the encoder-decoder architecture outperforms encoder-only models for all STS tasks. As we scale up the ST5 model, we also observe improvement on STS tasks. As shown in Table 5, the ST5 encoder-decoder Large model outperforms the state-of-the-art model SimCSE-RoBERTa Large, improving the Spearman's correlation score from 83.76 to 84.11.

Model \ # of params	Base	Large	3B	11B
ST5-Enc	110M	335M	1.24B	4.8B
ST5-EncDec	220M	770M	3B	11B

Table 4: Number of parameters for different models.

One explanation is that the additional parameters from the decoder are helpful for improving performance on textual similarity tasks. Another possibility is that the decoder architecture itself helps to improve the sentence embedding quality. As shown in Figure 2d, the decoder can be considered as an additional attention pooling layer on top of the encoder outputs.

7 Scaling up T5

We leverage the existing checkpoints from large T5 models to study the effect of scaling sentence encoders. The parameters of the T5 models are listed in Table 4. Note however that ST5-EncDec doesn't fully leverage the model parameters; the decoder's learned self-attention is effectively ignored as only the start token is fed into the decoder.

7.1 Effect on Directly Using T5 Embeddings

As shown in Table 5, the performance on the transfer tasks of directly using T5 embeddings consistently improves as T5 scales up. This corroborates that large pre-trained models can improve transfer performance of sentence embeddings.

On the other hand, increasing the model capacity alone is not enough to achieve good performance. Even the embeddings from the T5 11B model still do worse on STS tasks than the fine-tuned models. We believe that the pre-training corruption task of T5 does not require models to avoid anisotropy.[9] This highlights the importance of choosing fine-tuning tasks for sentence embedding models that are aligned to the goal of similarity and/or retrieval performance.

---

[9] Having sentence embeddings smoothly and uniformly distributed within the learned embedding space, which however can be be achieved by using a contrastive loss or regularization.

Table 5: Comparison of model performance on the SentEval benchmark when scaling up model size. ♣ results are from (Gao et al., 2021). The first set of results are for transfer tasks, while the second set are for the similarity task.

7.2 Scaling Up Improves Fine-tuning

As shown in Table 5, we find that scaling up model capacity leads to consistently better performance on all downstream tasks. For the ST5 11B model, the encoder-only model achieves an average score of 91.08 for transfer tasks which is better than 90.45 from the ST5 Large model; while the encoder-decoder model pushes the STS score to 84.94 and also outperforms the ST5 Large model. For STS tasks, we observe that the gain from increasing model size from 3B to 11B is smaller than that from Large to 3B. This might be due to the fact that the embedding sizes are fixed for all models in our experiments. One potential exploration is to increase the sentence embedding size for larger models to fully leverage the model capacity.

7.2.1 Alignment and Uniformity

We further investigate the quality of the sentence embeddings by measuring aggregate distance metrics in the learned geometric space. In particular, we compute the alignment loss and uniformity loss as defined in Wang and Isola (2020):

$$\mathcal{L}_{\text{align}} = - \mathop{\mathbb{E}}_{v,v^{+}\sim p_{pos}} \|f(v) - f(v^{+})\| \qquad (3)$$

$$\mathcal{L}_{\text{uniform}} = \log \mathop{\mathbb{E}}_{v,w \overset{\text{i.i.d}}{\sim} p_{\text{data}}} e^{-2\|f(v)-f(w)\|}, \qquad (4)$$

Above, p_{pos} is all positive data and p_{data} is the data distribution. $\mathcal{L}_{\text{align}}$ denotes the expected distance between embeddings of the positive pairs, while $\mathcal{L}_{\text{uniform}}$ indicates how uniformly the embeddings are distributed.

For both losses, lower numbers indicate better performance. Gao et al. (2021) has shown that models with lower numbers for these two aggregate metrics tend to have better performance on downstream tasks. As shown in Figure 4, when models scale up, both the encoder and encoder-decoder models decrease the uniformity loss by a large marge meanwhile only slightly increasing the alignment loss. This indicates that scaling up might help the sentence embeddings to spread out more uniformly in the space while keeping semantically similar pairs clustered together. We leave the further exploration of the connection between

model capacity and the geometry characteristics of resulting sentence embeddings to future work.

8 SentGLUE Evaluation

In this section, we introduce a new sentence representation transfer benchmark – SentGLUE – which extends the sentence evaluation toolkit, SentEval, to nine tasks from the GLUE benchmark including: CoLA, SST-2, MRPC, STS-B, QQP, MNLI-m, MNLI-mm, QNLI, RTE [10]. The GLUE benchmark has been widely adopted for assessing language understanding models. GLUE tasks are either single sentence or sentence pair classification (e.g. NLI) or similarity (STS) tasks. The best models on the GLUE leaderboard are fine-tuned cross-attention models like BERT or T5. Such models change all the parameters in the underlying model during fine-tuning and for pairwise tasks they allow for early fusion of input features from both sentences being compared. For SentGLUE, we introduce the constraint that each input needs to be independently encoded into a fixed embedding space representation that can then be feed to additional layers in order to make a prediction. We believe this best adapts the spirit of the original SentEval benchmark for sentence embeddings to the GLUE tasks.

From Table 6, ST5-Enc Base outperforms both SBERT-RoBERTa Base and SimCSE-RoBERTa Base on all SentGLUE tasks except CoLA and MNLI. [11] With the model's increased capacity, ST5 Enc 11B's sentence embeddings achieve the best overall performance. Notably, as model size is scaled up, aggregate performance using sentence embeddings approaches that of T5 base. This is remarkable given that T5 base makes use of full cross-attention between sentence pairs and adjusts all of the parameters in the model during fine-tuning.

9 Conclusion

We obtaining sentence embeddings from T5, investigating three architectures and two-stage contrastive learning for fine-tuning our representations. We compare the difference between encoder-only and encoder-decoder methods and analyze their performance on downstream tasks. Through extensive experiments on STS, SentEval and GLUE tasks, we show that encoder-only models have strong transfer performance while encoder-decoder models perform better on STS tasks. We demonstrate the effectiveness of scaling up T5 models, greatly improving sentence embedding quality. These findings suggest that future improvements in the scale and quality of pre-trained T5 models may provide further sentence embeddings improvements.

---

[10] We found the WNLI task from the GLUE benchmark is too challenge for existing sentence embedding models, thus we exclude it in the current version.

[11] SimCSE and ST5 only use the 'entailment' and 'contradict' pairs from MNLI datasets; while for SBERT, it also uses the 'neutral' pairs. This might explain why SBERT outperforms the others on MNLI.

Acknowledgments

We thank the anonymous reviewers for their helpful comments. We thank Zora Tung, Daniel Andor, Adam Roberts, Hyung Won Chung, Anselm Levskaya and Livio Baldini Soares for help with the JAX implementation, and Alexis Conneau and Chris Tar for feedback and suggestions.

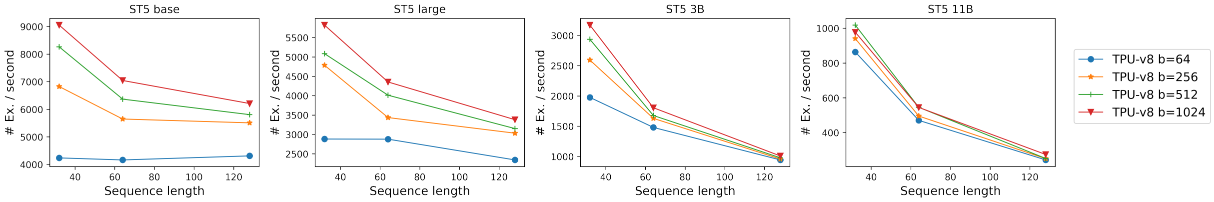
A Model Inference

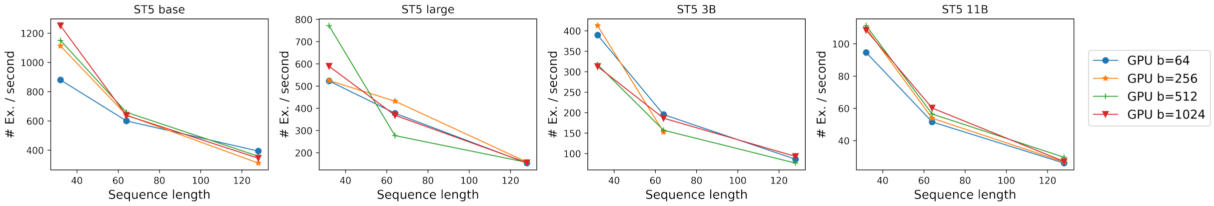
We run ST5 encoder-only on different platforms to investigate the computational cost of inference. Figure 5 summarizes the inference speed for different model sizes, sequence length, batch size and platforms. ST5 achieves the fastest inference speed on Cloud TPU-v3. As we increase the batch size, the inference speed can be further improved. For the 11B model, we are able to achieve a speed of 274 examples per second for sequence length 128 and batch size 1024. This shows the feasibility of deploying such large models on TPU hardware.

We also report the speed on Nvidia Tesla V100 GPU and CPU. The ST5 11B model is able to run on 4 V100 GPUs with sequence length 128 and batch size 1024, achieving an inference speed of 27 examples per second. For CPU, with batch size 512, ST5 11B achieves 0.5 examples per second.

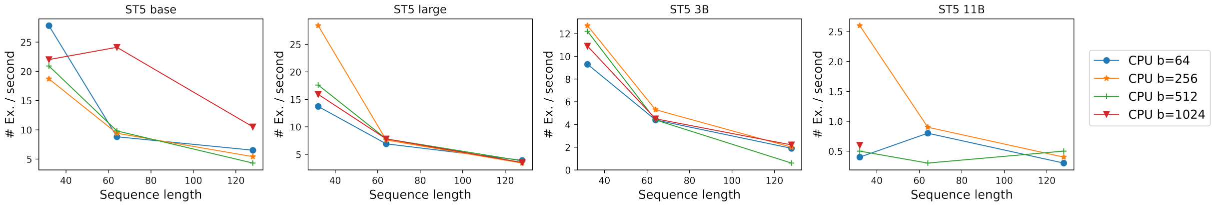
Although the speed on GPU and CPU are considerably slower than on TPU, the sentence embedding models are much faster than cross-attention based models whose computation time increases quadratically with the number of examples (e.g., clustering 1,000 sentences requires inference over 1 million sentence pairs).



(a) TPU inference speed vs. sequence length.



(b) GPU inference speed vs. sequence length.



(c) CPU inference speed vs. sequence length.

Abstract

Relation extraction (RE) is an important natural language processing task that predicts the relation between two given entities, where a good understanding of the contextual information is essential to achieve an outstanding model performance. Among different types of contextual information, the auto-generated syntactic information (namely, word dependencies) has shown its effectiveness for the task. However, most existing studies require modifications to the existing baseline architectures (e.g., adding new components, such as GCN, on the top of an encoder) to leverage the syntactic information. To offer an alternative solution, we propose to leverage syntactic information to improve RE by training a syntax-induced encoder on auto-parsed data through dependency masking. Specifically, the syntax-induced encoder is trained by recovering the masked dependency connections and types in first, second, and third orders, which significantly differs from existing studies that train language models or word embeddings by predicting the context words along the dependency paths. Experimental results on two English benchmark datasets, namely, ACE2005EN and SemEval 2010 Task 8 datasets, demonstrate the effectiveness of our approach for RE, where our approach outperforms strong baselines and achieve state-of-the-art results on both datasets.[1]

1 Introduction

Relation extraction (RE) provides deep analyses of the input text by extracting the relation between two given entities in the input. Therefore, it is an important task in natural language processing (NLP) and is widely used in many downstream NLP applications such as summarization (Wang and Cardie, 2012), question answering systems (Xu et al., 2016) and text mining (Distiawan et al., 2019). To correctly extract the relation between two entities, it normally requires a good modeling and analysis of the input text. Recent models such as LSTM, Transformers (Vaswani et al., 2017), and pre-trained language models (e.g., BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019)) have significantly improved the performance of RE models with an important reason of their encoding power on contextual information. However, such models still reach a bottleneck because it is hard for them to capture structural information of the running text (which is essential for RE) by modeling the text as a linear sequence of words. To deal with this situation, extra knowledge and features (e.g., syntactic knowledge) are used in many studies, while of all choices, the dependency parses have been widely used and demonstrated to be effective (Xu et al., 2015; Zhang et al., 2018; Guo et al., 2019; Mandya et al., 2020; Sun et al., 2020; Yu et al., 2020b; Tian et al., 2021), for the reason that the dependency trees are able to provide long-distance word-word relations which are important structural complement to existing models for RE.

To leverage dependency information, most existing approaches in NLP either treat it as extra input features (Prokopidis and Papageorgiou, 2014; Kiperwasser and Goldberg, 2015; Yu and Bohnet, 2017), which requires heavy feature engineering, or use complicated architectures (Xu et al., 2015; Roth and Lapata, 2016; Marcheggiani and Titov, 2017; Zhang et al., 2018; Li et al., 2018; Guo et al., 2019; Nie et al., 2020; Li et al., 2020a,b; Chen et al., 2020) to encode it, which suffers from the difficulty of designing an effective model. In addition, these approaches normally require dependency trees as extra input when processing sentences, and thus potentially suffer from noises from the dependency trees because of errors from automatic parsing. Therefore, an alternative is needed to leverage dependency information, especially auto-generated

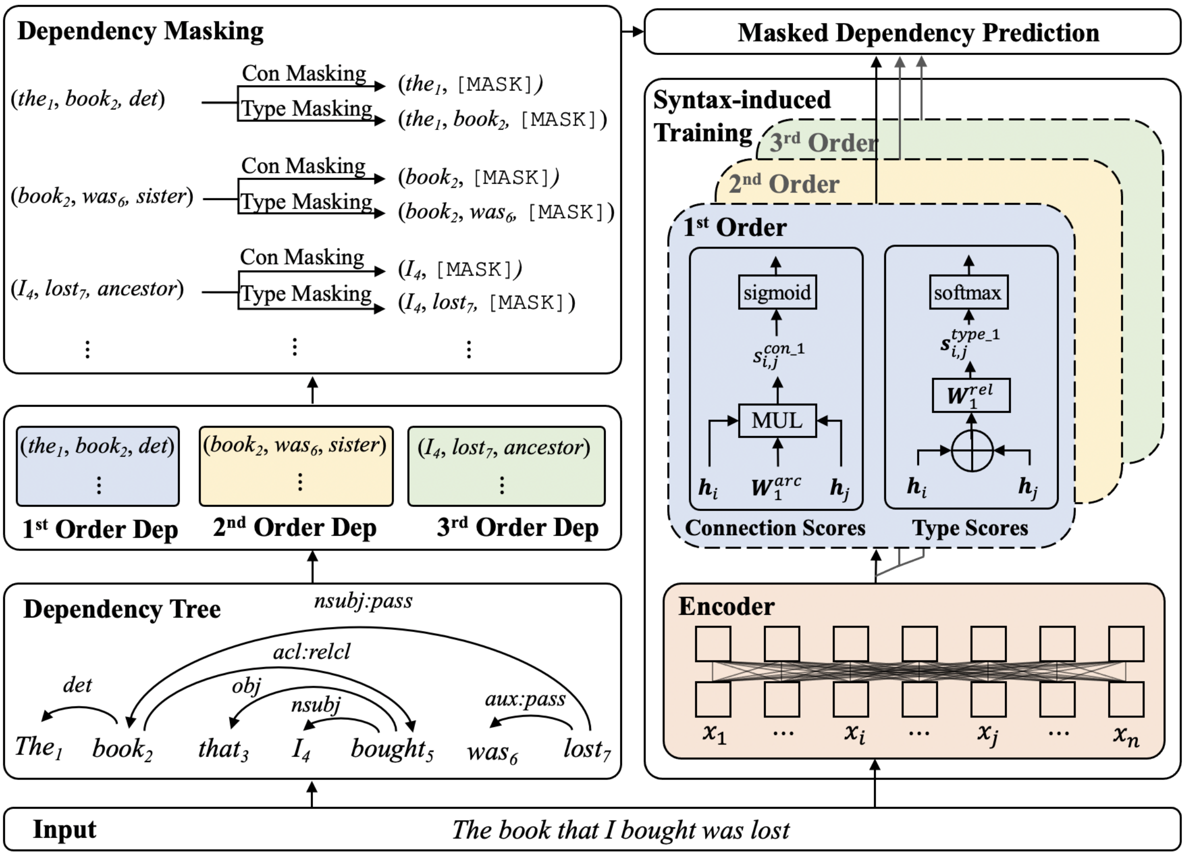

Figure 1: An overview of our approach to train a syntax-induced encoder (highlighted in the red box). The left part shows the process to extract and mask dependencies (connection and type masking, respectively) in first, second, and third orders, where the word subscript denotes its sentential index. The right part illustrates the process to compute the scores of dependency connections and types in different orders to recover the ones that being masked.

ones, for NLU tasks, so as to overcome the aforementioned issues.

In this paper, we propose to enhance RE through learning a good encoder equipped with dependency information, where the learning is carried out by a dependency-guided process. In detail, a dependency masking approach is designed to introduce such information, where we firstly apply an off-the-shelf dependency parser to large raw data and extract the dependency connections and types from the auto-parsed dependency trees, and then mask these connections and types so as to pre-train a syntax-induced encoder by recovering (predicting) them, which significantly differs from that of training word embeddings (Levy and Goldberg, 2014; Komninos and Manandhar, 2016) by predicting the context words along the dependency relations. In doing so, the dependency information weakly supervises the encoder and the pre-training on dependency masking ensures a selective learning process on those frequent and important dependency relations, which is more flexible than taking dependency parses (with noises) as fixed knowledge. In addition, by noting that higher order dependency information is beneficial in many cases (Coppola and Steedman, 2013; Kamigaito et al., 2018; Li et al., 2020b), we further enhance our approach by pre-training with masking second and third order word dependencies rather than just doing it on the first order. Once pre-trained, the resulted encoder is applied with ordinary fine-tune procedure for RE. Experimental results on two English benchmark datasets, namely, English ACE2005EN[2] and SemEval 2010 Task 8 (Hendrickx et al., 2010), for RE demonstrate the effectiveness of our approach, which outperforms strong baselines and achieves state-of-the-art results on both of the datasets.

2 The Approach

To learn a text encoder with important structural information for RE, we propose to pre-train it with masking and recovering word-word dependency connections and types that are auto-analyzed from

---

[2] `https://catalog.ldc.upenn.edu/LDC2006T06`

existing parsers. The resulted syntax-induced encoder is thus weakly supervised by such information and provided with necessary syntax integration. In doing so, the dependency information is introduced during pre-training the encoder, thus no extra input is required in applying it to real applications, avoiding particular design of models to leverage such information during inference. Figure 1 illustrates the architecture of our approach to learn from an input sentence $\mathcal{X} = x_1 x_2 \cdots x_i \cdots x_j \cdots x_n$ with n words and its dependency tree $\mathcal{T}_X$, so that the masking and recovering can be formalized by

$$Y^*_{\mathrm{M}} = \mathcal{DM}(\mathcal{DE}(\mathcal{T}_X)) \qquad (1)$$

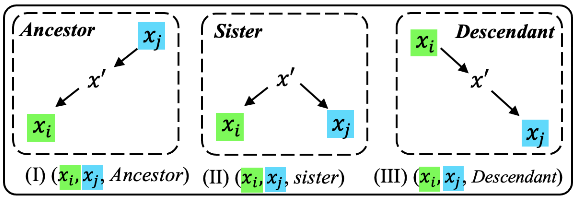
and

$$\widehat{Y}_{\mathrm{M}} = f(\mathcal{EN}(\mathcal{X})) \qquad (2)$$

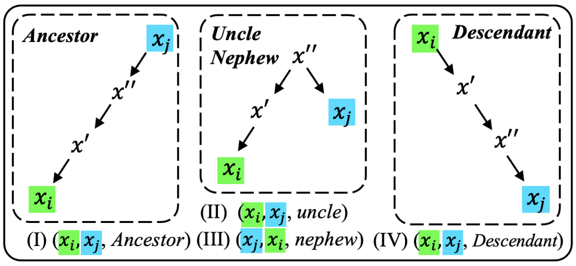
respectively, where Y^*_{M} is the set of all masked dependency connections and types obtained by dependency extraction ($\mathcal{DE}$) and dependency masking ($\mathcal{DM}$), and f the process (with pre-training on it) to recover (predict) Y^*_{M} to $\widehat{Y}_{\mathrm{M}}$, with the base encoder $\mathcal{EN}$ trained accordingly during the process. In the following text, we firstly illustrate dependency extraction, then the process to integrate syntax information into the encoder with dependency masking, and finally the steps to apply the resulted syntax-induced encoder to RE.

2.1 Dependency Extraction

To extract dependency information form the input text, we firstly apply an off-the-shelf dependency parser to the input and obtain its dependency tree $\mathcal{T}_X$. Then, we extract first, second, and third order[3] dependency information from $\mathcal{T}_X$ and represent them in the form of tuple, i.e., $(x_i, x_j, type)$, where there is a connection between x_i and x_j and the dependency type (which is directional) of x_j towards x_j is $type$. Specifically, for the first order dependencies, we directly use the dependency connections and types in $\mathcal{T}_X$, where we construct a directed connection between x_i and x_j (denoted by (x_i, x_j)) if x_j is the head of x_i and the dependency type between them is the syntactic role (e.g., nominal subject) of x_i with respect to x_j. For the second order dependencies, we construct a second order dependency connection between x_i and x_j if there is a word x' that connects to both x_i and x_j by two connections (x_i, x') and (x', x_j) in $\mathcal{T}_X$. In the second order case, we define three types for their connections namely, *ancestor*, *sister*, and *descendant*, according to the position of x_i and x_j in the dependency tree $\mathcal{T}_X$, which are illustrated in (I), (II), and (III) in Figure 2 (a), respectively.[4] Similarly, for third order dependencies, we extend the types to four ones, namely, *ancestor*, *uncle*, *nephew*, and *descendant*, which are illustrated in (I)-(IV) in Figure 2 (b).



(a) Second-order Dependencies



(b) Third-order Dependencies

Figure 2: An illustration of the three second-order (a) and four third-order (b) dependency types between x_j and x_i, based on their positions in the parse tree.

2.2 Dependency Masking and Prediction

Previous studies leveraging dependency information by pre-training mainly focused on predicting the context words associated through dependency connections. Compared with these approaches, ours focuses on a different direction to leverage auto-parsed dependency information through learning word-word associations (i.e., dependency connections) and their dependency types. In doing so, we propose a weakly supervised learning task, namely, dependency masking (DM) with masked dependency prediction (MDP), to enhance text encoder pre-training, where they are paired processes that DM masks all connections and dependency types associated with each x_i (the masked connections and relations are denoted by $(x_i,$ `[MASK]`$)$ and $(x_i, x_j,$ `[MASK]`$)$ in Figure 1, respectively) and MDP aims to recover them during training.

---

[3] Most previous studies (Coppola and Steedman, 2013; Ji et al., 2019; Li et al., 2020b) use second or third order dependencies and some (Kamigaito et al., 2018) try higher orders yet show comparable performance.

[4] One can directly combine the dependency types of the connections (x_i, x') and (x', x_j) to represent such type for this scenario, but there will be huge numbers of combinations of syntactic roles, potentially leading to overfitting.

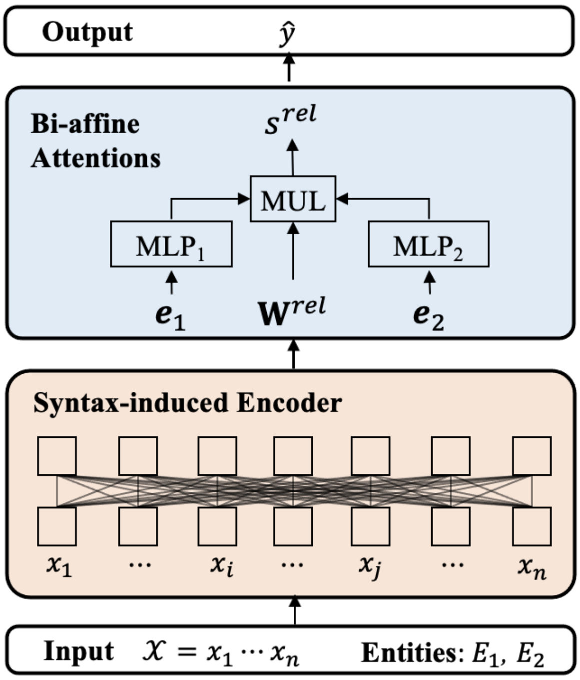


Figure 3: The architecture of our model for RE with the syntax-induced encoder (highlighted in red color) pre-trained on auto-parsed data through DMP.

Specifically, to recover the masked dependency connections and types, we firstly pass the input $\mathcal{X}$ into the base encoder (shown in the red box in Figure 1) that can be initialized in different ways (e.g., by a pre-trained language model) and obtain the hidden vector $\mathbf{h}_i$ of the word x_i. Then, we use three modules with the same architecture to recover masked dependency connections and types from first, second, and third order dependencies. Taking the first order dependencies as examples, we compute the connection score $s^{con\_1}_{i,j}$ and type scores $\mathbf{s}^{type\_1}_{i,j}$ for each pair of x_i and x_j by

$$s^{con\_1}_{i,j} = \mathbf{h}_j^\top \cdot \mathbf{W}^{con}_1 \cdot \mathbf{h}_i \tag{3}$$

$$\mathbf{s}^{type\_1}_{i,j} = \mathbf{W}^{type}_1 \cdot (\mathbf{h}_i \oplus \mathbf{h}_j) \tag{4}$$

where $\oplus$ denotes vector concatenation; $\mathbf{W}^{con}_1$ and $\mathbf{W}^{type}_1$ are trainable matrices. Herein, $s^{con\_1}_{i,j}$ is a scalar and $\mathbf{s}^{type\_1}_{i,j}$ is a vector with the values representing the scores for all possible types between x_i and x_j. Similarly, we use the same procedure to obtain the connection scores $s^{con\_2}_{i,j}$, $s^{con\_3}_{i,j}$ and the type score vectors $\mathbf{s}^{type\_2}_{i,j}$, $\mathbf{s}^{type\_3}_{i,j}$ for second and third order dependencies, respectively. Based on the connection and type scores of the first, second, and third order dependencies, our model recovers the masked connection by treating it as a binary classification using `sigmoid` function and predicts the masked type by applying `softmax` to the type score vectors. As a result, dependency information in different orders is implicitly introduced into the base encoder by the gradients back-propagated from the MDP process.

2.3 RE with Syntax-induced Encoder

Once the encoder is trained, we extract the obtianed syntax-induced encoder and fine-tune it on RE tasks, where the goal of our RE model is to predict the relation $\widehat{y} \in \mathcal{R}$ ($\mathcal{R}$ is the set for all relation types) between two given entities E_1 and E_2 in the input $\mathcal{X}$, which is formally expressed by

$$\widehat{y} = \arg\max_{rel \in \mathcal{R}} \; s\left(rel | \left(\mathcal{X}, E_1, E_2\right)\right) \tag{5}$$

where $s(\cdot)$ computes the score s^{rel} for a particular relation type $rel \in \mathcal{R}$ with the given input $\mathcal{X}$ and entities (i.e., E_1 and E_2). In doing so, we firstly fed $\mathcal{X}$ into the pre-trained syntax-induced encoder and obtain the hidden vectors $\mathbf{h}_i$ for each x_i. Next, we apply the max pooling operation to the hidden vectors of the words in each entity and obtain the vector representations, namely, $\mathbf{e}_1$ and $\mathbf{e}_1$, of E_1 and E_2. Then, we apply bi-affine attentions (Vaswani et al., 2017) to $\mathbf{e}_1$ and $\mathbf{e}_2$ to compute the score s^{rel} for the particular relationship rel. Specifically, bi-affine attentions pass $\mathbf{e}_1$ and $\mathbf{e}_2$ into two different multi-layer perceptrons (MLP), namely, MLP$_1$ and MLP$_2$, and use a trainable relationship matrix $\mathbf{W}^{rel}$ to compute s^{rel} via

$$\mathbf{e}'_1 = \text{MLP}_1(\mathbf{e}_1) \tag{6}$$

$$\mathbf{e}'_2 = \text{MLP}_2(\mathbf{e}_2) \tag{7}$$

$$s^{rel} = (\mathbf{e}'_1 \oplus [1])^\top \cdot \mathbf{W}^{rel} \cdot (\mathbf{e}'_2 \oplus [1]) \tag{8}$$

where [1] is a one-dimensional unit vector which is the bias term for $\mathbf{e}'_1$ and $\mathbf{e}'_2$. Afterwards, we compute the scores s^{rel} for all types of relations and predict the one with the highest score.

3 Experimental Settings

3.1 Datasets

We use the newest English Wikipedia dump (Wiki) as the raw data to train the syntax-induced encoder through masked dependency prediction (MDP). We filter out sentences whose lengths are fewer than 10 words and obtain the resulting corpus with 92M sentences and 2,380M tokens. In obtaining dependency relations, we use Berkeley Neural Parser[5]

---

[5] We obtain their models from `https://github.com/nikitakit/self-attentive-parser`.

Datasets		Sent. #	Token #	Instance #
ACE05	Train	7K	145K	5K
	Dev	2K	36K	1K
	Test	2K	31K	1K
SemEval	Train	8K	141K	8K
	Test	3K	48K	3K

Table 1: The statistics of the two English benchmark datasets used in our experiments for relation extraction, where the number of sentence, tokens, and instances (i.e., entity pairs) are reported.

(Kitaev and Klein, 2018) trained on English Penn Treebank (PTB)[6] (Marcus et al., 1993) to automatically parse the Wiki data into constituency trees and then convert them into dependency trees by Stanford Dependency converter[7] (Manning et al., 2014). For relation extraction, we use English ACE2005EN (ACE05)[8] and SemEval 2010 Task 8 (SemEval)[9] (Hendrickx et al., 2010) with the standard train/dev/test splits[10] and follow previous studies (Christopoulou et al., 2018; Ye et al., 2019; Zhang et al., 2017; Soares et al., 2019) to process them. The statistics, namely, the number of sentences and tokens, as well as the number of instances (i.e., entity pairs), of both datasets are reported in Table 1.

3.2 Implementation Details

Since a good text representation plays an important role in achieving outstanding performance in many NLP tasks (Song and Shi, 2018; Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019; Lewis et al., 2020; Song et al., 2021; Sun et al., 2021), in the experiments, we use pre-trained language models, i.e., BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019) that have demonstrate their effectiveness in many NLP tasks (Yan et al., 2020; Tian et al., 2020; Ke et al., 2021; Shi et al., 2020; Du et al., 2020; Qin et al., 2021a) as the base encoder for syntax inducing (pre-training) with dependency masking. For both BERT and XLNet, we try their base and large version following the default hyper-parameter settings, where their base version uses 12 layers of self-attentions with 768 dimensional hidden vectors and the large version uses 24 layers of self-attentions with 1024 dimensional hidden vectors for their large version.[11]

Pre-training Step	**700K**, 1,400K, 2,100K, 2,800K
Learning Rate	**1e-5**, 5e-5
Warmup Rate	**0.08**, 0.1, 0.2
Batch Size	**16**, 32

Table 2: The hyper-parameters tested in tuning our models for relation extraction. The best ones used in our final experiments are highlighted in boldface.

For syntax inducing, we train the model on the auto-parsed English Wiki for 700K steps[12] with the batch size set to 32. It is worth noting that, since English Wiki is used as a part of the data to train BERT and XLNet, it could be considered that we do not use additional data in experiments. For the process of fine-tuning the final RE model, we use the obtained syntax-induced encoder with randomly initialized bi-affine attentions. For other hyper-parameters, Table 2 reports the ones tested in training our models for training the relation extraction models. We test all combinations of them for each model and use the one achieving the highest results (i.e., F1 scores) on the development set. For evaluation, we follow previous studies to use the micro-F1 scores for ACE05 and use the official evaluation script[13] for SemEval.

4 Results and Analyses

4.1 Overall Results

Table 3 reports the results of our approach on the test set of ACE05 and SemEval with different encoders trained on first, second, and third order of dependencies (e.g., "+ DM (2nd)" denotes our approach with induced first and second order dependencies), as well as their corresponding baselines with only using the initial encoders (e.g., BERT and XLNet). We also run baselines with the standard graph convolutional networks (GCN) and the standard graph attentive networks (GAT) (Veličković et al., 2017) to leverage the auto-parsed dependency trees obtained in the same process as we obtain the auto-parsed Wiki (i.e., parsing and converting).

+ DM (3rd)	74.51	89.76

(b) XLNet-based Models

Table 3: Experimental results of different models using base and large version of BERT and XLNet on the test set of ACE05 and SemEval. "+ GCN" and "+ GAT" refer to the models with the standard graph convolutional network and standard graph attentive networks, respectively. "+ DM" denotes our approaches with based encoder trained through dependency masking (DM) on word dependencies of different orders ("2nd" means both first and second order dependencies are masked and learnt, the same for "3rd").

There are several observations. First, our approach works well with different pre-trained language models (i.e., base and large BERT and XLNet), where the models with syntax-induced encoder outperform the vanilla BERT and XLNet baselines on both datasets, even though the baseline models have already achieved desirable performance. Second, compared with baseline models with standard GCN and GAT to leverage auto-parsed dependencies, our approach with different orders of dependency information consistently outperforms those baselines, which further confirms the effectiveness of our approach to leverage auto-parsed dependency information. Third, among models that leveraging dependency information in different orders, the ones with second order dependencies (i.e., "+ DM (2nd)") achieve the best performance in most cases. This observation confirms that RE models can benefit from high-order word dependencies since they provide association information among words with longer syntactic relations so as leading to better structure-aware understanding towards a sentence. However, it is still worth noting that, incorporating further higher order word dependencies (e.g., third order) may introduce noise or task-irrelevant information to the encoder since they are provided with auto-generated parses, which results in inferior performance comparing to using the second order dependencies.

4.2 Comparison with Previous Studies

We further compare our best performing model with previous studies on the test set of ACE05 and SemEval and report the results in Table 4. It is observed that, our approach outperforms all previous studies with different settings and encoders and achieves state-of-the-art scores on both datasets, which further confirms the effectiveness of our approach. Particularly, compared with previous studies (Zhang et al., 2018; Guo et al., 2019; Mandya et al., 2020; Sun et al., 2020; Yu et al., 2020b) that leverage the auto-parsed dependency tree of the input sentence through a particular module (e.g., Guo et al. (2019) proposed an graph-based approach with attentions to leverage dependency connections), where such dependency trees are required as extra input in inference, our approach uses an encoder to learn the dependency information through DMP and then fine-tune the obtained syntax-induced encoder on RE task. Such design in our approach allows our final RE model to be used without requiring the dependency tree of the sentence as the extra input in inference, which allows our model to run faster than previous approaches.

4.3 The Effect of Encoder Initialization

To explore the effect of encoder initialization with our approach, we run experiments by training our encoder starting from Transformer that uses the same architecture as BERT-base (i.e., 12 layers of

Table 4: The comparison of F1 scores between previous studies and our best model with BERT-large on the test sets of ACE05 and SemEval. Previous studies that leverage syntactic information (e.g., the dependency tree of the input sentence) are marked by "†".

multi-head attentions with 768 dimensional hidden vectors) with random initialization (without using parameters from pre-trained language models or word embeddings). Table 5 reports the results of our approach when using different orders of dependency information, as well as the baseline results from the Transformer. As demonstrated, our approach significantly improves the baseline Transformer on both datasets, where around 30% absolute boost is observed on both ACE05 and SemEval datasets. This observation further confirms not only the effectiveness of our approach in improving base encoder with leveraging dependency information, but also its robustness of being applied to a randomly initialized base encoder.

4.4 The Effect of Training Steps

To analyze the performance change of the learned syntax-induced encoder on RE along with the increasing of training steps, we investigate the learned encoder (randomly initialized by a vanilla Transformer or pre-trained BERT-base model) with second order dependencies obtained from different training steps by fine-tuning it on ACE05 and SemEval. The test results (i.e., F1 scores) of our approach based on the vanilla Transformer and the BERT-base model with respect to the training steps (in 100 thousands) are illustrated in Figure 4 (a) and (b), respectively, and the performance of BERT-base baseline on different datasets is illustrated in dashed lines in different colors[14] in Figure 4 (b). In addition, we also evaluate the performance of the learned encoders (i.e., vanilla Transformer and the BERT-base model) trained by MDP on the test set of PTB for dependency parsing to illustrate how intensive of dependency information is introduced during the pre-training process[15], where the labeled attachment score (LAS) curves are presented in Figure 4 (c) for reference.

Models	ACE05	SemEval
Transformer	31.85	54.62
+ DM (1st)	**66.79**	79.37
+ DM (2nd)	66.67	**80.02**
+ DM (3rd)	64.54	79.95

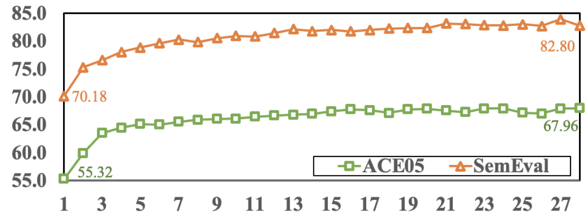
Table 5: Comparisons of RE results from vanilla Transformer and our approach that being applied to a randomly initialized Transformer (without pre-trained language models or word embeddings).

It is shown that, when the Transformer is used, consistent improvements are observed with more training steps for both datasets. When a pre-trained language model (i.e., BERT-base) is used, it is observed that RE benefits much at the beginning of the pre-training (where the noisy auto-parsed dependency information is not intensively learning) and reach the peak (i.e., 74.11% for ACE05 and 89.02% for SemEval) when the training step reaches around 1,000K (where the syntax-induced encoder does not hurt by the noise in the dependencies). This phenomenon confirms the observations in previous studies (Xu et al., 2015; Zhang et al., 2018; Yu et al., 2020b; Sachan et al., 2021) that intensively leverage dependency information may introduce noise and confusion to relation classification, so that effective dependency pruning and introduce is of great importance. It also shows the effectiveness of our approach to address the noise by controlling the intensity of dependency information learning during pre-training.

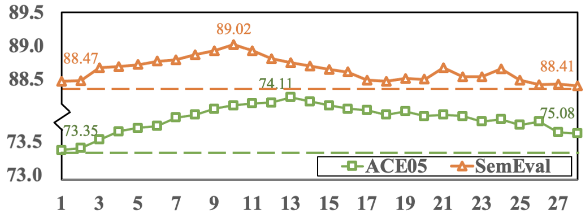
---

[14] The performance on ACE05 and SemEval are illustrated in green and orange colors, respectively.

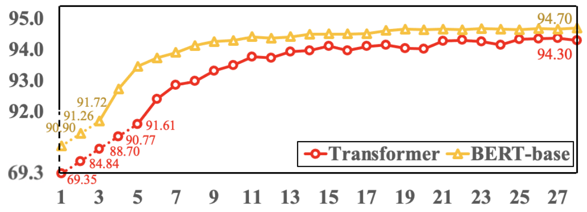
[15] Herein, the higher the performance of learned encoders on dependency parsing, the more intensive the dependency information is introduced in pre-training.



(a) Transformer



(b) BERT-base



(c) Masked Dependency Prediction

Figure 4: Curves of fine-tuning different base encoders (Transformer (a) and BERT-base (b)) on ACE05 and SemEval with respect to the number of training steps (in 100K). For reference, (c) shows the dependency parsing performance (LAS) of the learned encoders (Transformer and BERT-base) on the test set of English Penn Treebank (PTB) against its pre-training steps, where higher scores suggest that more intensive introduction of dependency information.

4.5 The Effect of Learned Representations

In previous results and analysis, we already show that the syntax-induced encoder outperforms baselines on RE with implicit integration of dependency information. Therefore, it is interesting to analyze the encoded word representations by qualitatively investigating their relations, which is similar to what has been done for word embeddings. In doing so, we collect word representations from the last layer of the trained syntax-induced encoder (XLNet-large). Then, for each word, we average its representation vectors under different contexts and use the resulting vector as its final representations. Figure 5 visualizes (by t-SNE) the representations of some example words, where the distance between two words indicates their similarity (closer distances indicate more relevant relations). It is observed that words with relevant syntactic properties (e.g., similar form or part-of-speech role) and semantic meanings are grouped into the same cluster (words in different clusters are represented in different colors). For example, all plural nouns of job names, e.g., "*teachers*", "*journalists*", "*publisher*", "*librarians*", "*shipowners*", and "*supporters*", are in the same cluster (represented in red color), while they are far away from irrelevant words, e.g., "*praying*". This finding is inspiring since such representations are automatically generated so that the MDP process shows its validity in learning syntax-aware word representations and ensuring that their relevance in syntax and semantics are appropriately modeled, which allows our model to achieve promising performance.

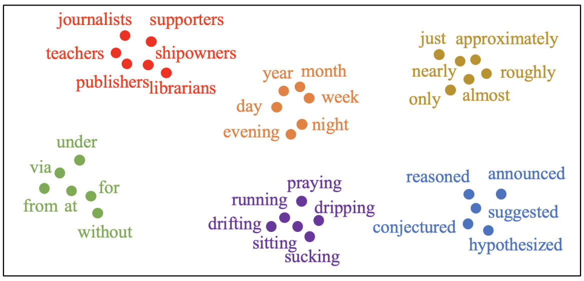


Figure 5: Visualizations of the learned representations through the syntax-induced encoder for some example words. The distance between any two words illustrates their similarity in terms of syntax and semantics. Words are presented in clusters and those in the same cluster are represented in the identical color.

5 Related Work

Relation extraction is an important task in NLP and it requires deep understanding of the input text to achieve model performance. Therefore, in addition to leveraging advanced text encoders (e.g., biLSTM, Transformer (Vaswani et al., 2017), BERT (Devlin et al., 2019)) to capture contextual information, structural information, namely, the dependency information, of the running text has been widely used as an effective resource to improve RE (Xu et al., 2015; Zhang et al., 2018; Guo et al., 2019; Yu et al., 2020b; Chen et al., 2021). In most recent studies in NLP, the dependency information is leveraged either as extra input features (Prokopidis and Papageorgiou, 2014; Kiperwasser and Goldberg, 2015; Yu and Bohnet, 2017) or modeled by complicated graph-based architectures, such as convolutions neural networks (Marcheggiani and Titov, 2017; Zhang et al., 2018) and tree LSTMs (Peng et al., 2017; Li et al., 2018). Previous studies also tried to use attention mechanism to weight different dependency features (Guo et al., 2019; Yu et al., 2020b; Qin et al., 2021b) and LSTM to encode linearized dependency path (Xu et al., 2015; Roth and Lapata, 2016). In addition to modeling dependency information, there is another track to leverage it by pre-training dependency-based word embeddings through predicting the context words in auto-parsed dependency trees (Levy and Goldberg, 2014; Komninos and Manandhar, 2016) or designing an auxiliary module to learn the dependency information by treating the dependencies as additional input during pre-training (Xu et al., 2021). This research follows the pre-training paradigm and offers an alternative way to do so.

Specifically, compared with existing studies, our approach leverages the dependency information by inducing it to the pre-training process through masked dependency prediction, whose object is to predict the masked dependencies rather than directly using it as extra fixed input along with the input sentence through an additional module. Also, since the dependency information is learnt by the syntax-induced encoder and the encoder is further fine-tuned on the training data in the same way as general RE model, our approach neither requires any additional input features nor needs complicated architectures to encode them, which allows our model to be efficient in inference.

6 Conclusion

In this paper, we propose to use dependency masking and recovering to improve the text encoder and thus enhance RE that requires deep understanding of the running text, where the encoder is trained on large scaled auto-parsed data. Specifically, we try such masking on first, second, and third order word dependencies from the auto-parsed data, and train a base encoder that is able to recover all the masked dependencies. In doing so, the resulted syntax-induced encoder is integrated with dependency information in a dynamic and flexible manner and it can be directly applied to different downstream tasks requiring no extra input or particular design to accommodate dependency information. Experimental results and analyses on two English benchmark datasets (i.e., ACE05 and SemEval) for RE show the effectiveness of our approach, where our approach outperforms strong baselines and achieve state-of-the-art on both datasets.

Striking a Balance: Alleviating Inconsistency in Pre-trained Models for Symmetric Classification Tasks

Ashutosh Kumar

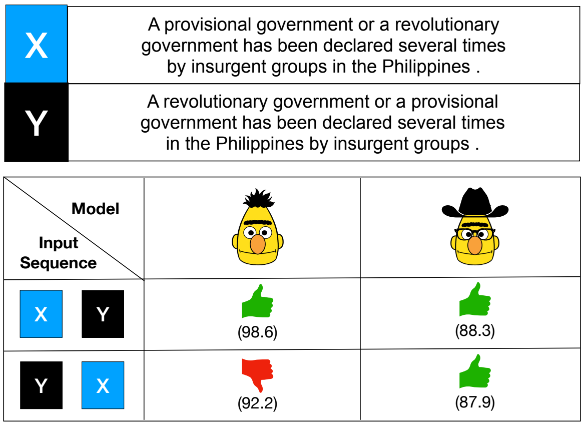
`ajoshi@seek.com.au`

Abstract

While fine-tuning pre-trained models for downstream classification is the conventional paradigm in NLP, often task-specific nuances may not get captured in the resultant models. Specifically, for tasks that take two inputs and require the output to be invariant of the order of the inputs, inconsistency is often observed in the predicted labels or confidence scores. We highlight this model shortcoming and apply a consistency loss function to alleviate inconsistency in symmetric classification. Our results show an improved consistency in predictions for three paraphrase detection datasets without a significant drop in the accuracy scores. We examine the classification performance of six datasets (both symmetric and non-symmetric) to showcase the strengths and limitations of our approach.

1 Introduction

Symmetric classification tasks involve two inputs and require that the model output should be independent of the order in which the two input texts are given. In other words, *the output of the classifier should be the same and the confidence score must not be significantly different*, if the inputs X and Y are instead supplied as Y and X. Paraphrase detection, multi-lingual semantic similarity are examples of symmetric classification tasks. Although attention-based (Bahdanau et al., 2015; Vaswani et al., 2017) pre-trained language models have led to significant performance gains in multiple text classification tasks, they demonstrate a peculiar erratic behaviour on symmetric classification: inconsistency. An example[1] of *inconsistency* for paraphrase detection is shown in Figure 1. Additional examples can be found in the Appendix (Table 4). To alleviate such an inconsistency for symmetric classification tasks, we propose a simple additional *drop-in* fine-tuning objective, based on either the Kullback-Leibler (KL) or Jensen-Shannon (JS) divergence (or any f-divergence (Rubenstein et al., 2019)), to the cross-entropy loss for symmetric tasks. We refer to this as the *consistency loss*.



X: A provisional government or a revolutionary government has been declared several times by insurgent groups in the Philippines .

Y: A revolutionary government or a provisional government has been declared several times in the Philippines by insurgent groups .

Figure 1: Impact of reordering an example input pair (X and Y) on standard fine-tuned BERT and BERT-with-consistency-loss. The pair are true paraphrases. 👍 and 👎 denote that the model predicted them to be paraphrases and not-paraphrases, respectively. Confidence scores are reported in brackets. Details in Section 1.

The main contributions of this paper are:
(a) Highlight inconsistency issues in symmetric classification tasks,
(b) Describe a consistency loss function to alleviate inconsistency, and
(c) Demonstrate the applicability and limitations of the loss function via qualitative and quantitative analyses on tasks from the GLUE benchmark.

Additionally, to drive future research, we have made the data and code public[2].

Note: The problem of inconsistency can be attributed in part to the positional embedding. However, it has been shown that eliminating positional

---

[1] Note that, while this particular example is based on our fine-tuned model, it will change depending on the trained model. The overall argument is valid, nonetheless.

embedding results in a poor performance of the model (Wang and Chen, 2020; Wang et al., 2021).

2 Related Work

Pre-trained Classification Models like BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2020) are typically fine-tuned for classification tasks using a low capacity neural network classifier connected to the pre-trained model on its first token (typically `[CLS]` token). We demonstrate the inconsistency in the case of symmetric classification tasks for pairs of inputs, depending on the order of inputs. To the best of our knowledge, this is the first work that incorporates task-specific nuances to ensure consistency in symmetric classification.

Consistency Loss has been used in style transfer tasks to minimize the distance between round-trip generation of candidates for image-to-image translation (Zhu et al., 2017) or text style transfer (Huang et al., 2020). In a similar vein, we apply consistency loss (formulated as either the Kullback-Leibler or the Jensen-Shannon divergence loss) to alleviate the inconsistency problem in symmetric tasks.

Embedding-based Semantic Similarity Scores based on BERT-based models like SBERT (Reimers and Gurevych, 2019; Thakur et al., 2021) can map surface form realizations to embeddings. Their performance is worse than directly using BERT-style cross-encoder models for tasks such as semantic similarity (Thakur et al., 2021). However, the primary aim of such embedding-based scorers is orthogonal and, at best, complementary to the goal of our work since we want to ensure high-performing, consistent classifiers. Similarly, an alternative for symmetric classification is to separately obtain predictions for (X, Y) and (Y, X), and then average the confidence scores during test time. But, this is a weakly grounded, heuristic-driven approach. In general, *averaging does not rectify the mistakes made by the model, only masks it.*

3 Method

3.1 Problem Description

Category	**Datasets**	**Train**	**Val.**	**Test**
Pairwise Symmetric	**QQP**	327462	40430	36384
	PAWS	49401	8000	8000
	MRPC	3302	408	366
Single Sentence	**SST2**	60615	6872	6734
Pairwise Non-symmetric	**QNLI**	99506	5463	5237
	RTE	2241	277	249

Table 1: Datasets Statistics. Please refer to Section 4.

A. Given a pair of input sentences (X, Y), label $l_{(X,Y)}$, and a pre-trained BERT-based model $\mathcal{M}_{\text{PRE}}$, the goal is to output a *reliable model* $\mathcal{M}_{\text{REL}}$ to predict an output label for a new input pair (X_{test}, Y_{test}) such that the *inconsistency* between its different ordering is minimized. While we only experiment with semantic similarity (or paraphrasing), the description holds true for other symmetric relations too (such as predicting if two sentences have the same polarity).

B. Given a model fine-tuned on the task above $\mathcal{M}_{\text{REL}}$, can it help in providing a better initialization for transfer learning an empirically superior model $\mathcal{M}'$ on other downstream tasks?

3.2 Setup

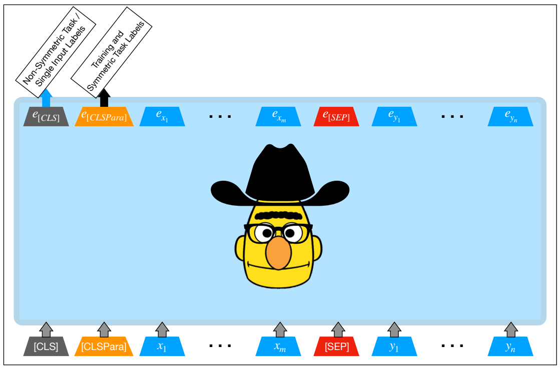

Figure 2: BERT-with-consistency-loss. We use an additional classification token: `[CLSPara]` for our input, upon which the consistency objective is applied. Please refer Section 3.2 for details.

For problem **A** (Section 3.1), the input is a concatenation of tokenized strings $X = x_1, \ldots, x_m$ and $Y = y_1, \ldots, y_n$ separated using a special token (`[SEP]` in the case of BERT). The concatenated inputs with the special token are passed through multiple self-attention layers (Vaswani et al., 2017). In the traditional approach, the representation of the first token (`<s>` or `[CLS]`) is passed through a fully connected classifier layer (the same final representation is used irrespective of the arity of the task inputs). In our approach, we use the `[CLSPara]` representation for symmetric classification tasks whereas we use the standard first token (`<s>` or `[CLS]`) representation for single input and non-symmetric classification tasks (Section 4). Since we first fine-tune the model on `[CLSPara]` representation, our approach allows for pair-wise knowledge to be transferred to other downstream classification tasks (problem **B** (Section 3.1)).

We call this method BERT-with-consistency-loss and is shown in Figure 2. Contrasting this with a traditional BERT-based approach, we see that, in the traditional BERT-based approach approach, the input is pre-pended with another special symbol (`[CLS]` in case of BERT and `<s>` in case of RoBERTa). In BERT-with-consistency-loss, we concatenate an extra symbol with the special symbol. We call the extra symbol `[CLSPara]`. This extra token is specifically used for symmetric classification tasks to ensure consistency of prediction. The standard objective used for fine-tuning BERT-based models is the cross-entropy loss, which maximizes the probability of predicting the correct output class for a given input, given as:

$$\mathcal{L}_{ce}(y, \hat{y}) = -\sum_{i} y_i \log \hat{y}_i, \tag{1}$$

where y is the one-hot representation of the target class, $\hat{y}$ is the softmax output of the model, and i is the associated co-ordinate. As described earlier, this objective may produce an inconsistent prediction based on the order of the two inputs. To overcome this weakness, we propose an additional consistency loss formulated in terms of either the KL or the JS Divergence. We pass the inputs X and Y through the same model twice, once as a pair (X, Y) (called $L2R$) and then as the pair (Y, X) (called $R2L$). Having obtained the outputs from the model for $L2R$ and $R2L$, the final objective function for 🤠 is as follows:

$$\begin{aligned}\mathcal{L} &= \mathcal{L}_{ce}(y, \hat{y}_{L2R}) + \mathcal{L}_{ce}(y, \hat{y}_{R2L}) \\ &\quad + \lambda * \mathcal{D}(p_{L2R}||p_{R2L}),\end{aligned} \tag{2}$$

where λ is the weight assigned to the consistency loss, p_{L2R} and p_{R2L} are the associated confidence/softmax vectors assigned by the model for $L2R$ and $R2L$ sentence pairs, and $\mathcal{D}$ is one of the following:

1. $KL(p||q) = \sum_{x \in X} p(x) \log \frac{p(x)}{q(x)}$
2. $JS(p||q) = \frac{1}{2}KL(p||m) + \frac{1}{2}KL(q||m)$,

Here p, q are probability distributions and $m = \frac{1}{2}(p + q)$. Minimizing divergences between two distributions brings them closer to each other.

4 Experimental Setup

4.1 Datasets

We experiment with 5 standard datasets from the GLUE benchmark (Wang et al., 2019) as well as the PAWS dataset (Zhang et al., 2019)[3]. We categorize them under the following headings:

A. For Symmetric Tasks: **(i) QQP:** Quora Question Pairs (Iyer et al., 2017) data set contains pairs of questions marked with either 1 (paraphrases) or 0 (not paraphrases).

(ii) PAWS: Paraphrase Adv. from Word Scrambling (Zhang et al., 2019), contains human labeled sentence pairs annotated in line with QQP. The uniqueness about this dataset is the creation procedure which involves back-translation and word swapping. **(iii) MRPC:** Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) comprises human annotated sentence pairs collected from newswire articles.

B. For Single Input Task: **(i) SST2:** Stanford Sentiment Treebank (Socher et al., 2013). This is a collection of human-annotated movie reviews. We work with the standard two class setting where the annotations have opposite polarities (1 for positive sentiment and 0 otherwise).

C. For Non-symmetric tasks: **(i) QNLI:** Natural Language Inference dataset constructed from SQuAD (Rajpurkar et al., 2016) related to a two-class classification problem to determine if the premise entails a hypothesis or not.

(ii) RTE: Recognizing Textual Entailment (Dagan et al., 2005; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009) Corpus is a combination of multiple RTE datasets containing one of two labels (1 for entailment and 0 for non-entailment).

4.2 Evaluation

We analyse the results of the traditional objective as well as our approach on BERT-BASE and ROBERTA-BASE across four different seeds under the following categories:

1. **Prediction Consistency:** This evaluation is done only for the symmetric task. Score $= \frac{\mathbb{1}_{(l_{L2R}=l_{R2L})}}{(\#\text{ of } L2R\text{ Samples})} * 100$, where l_{L2R}, l_{R2L} denote labels for $L2R$ and $R2L$, respectively. Note that this is not related to the ground truth labels.

2. **Confidence Consistency:** We perform these evaluations specifically for symmetric task.

---

[3] Since the test split of these datasets is not available in the GLUE benchmark(Wang et al., 2019), we use splits as given in Table 1. The validation dataset is kept as original and the new train and test sets are created by randomly splitting initial train data into train and test sets.

	(A) $L2R$ and $R2L$ Prediction Consistency Mean ± stddev (Section 4.2: Evaluation [1])			**(B) $L2R$ and $R2L$ Confidence Consistency** Pearson Correlation [MSE * 1000] (Section 4.2: Evaluation [2])		
Models	**QQP**	**PAWS**	**MRPC**	**QQP**	**PAWS**	**MRPC**
BERT-BASE	96.6 ± 0.15	96.0 ± 0.54	91.1 ± 1.41	98.2 [5.89]	96.5 [14.2]	92.7 [17.0]
BERT-BASE W/ KL	**99.3 ± 0.02**	**98.1 ± 0.12**	**97.7 ± 0.82**	99.9 [0.12]	99.6 [0.5]	99.5 [0.3]
BERT-BASE W/ JS	**98.9 ± 0.05**	**98.1 ± 0.22**	**96.9 ± 0.93**	99.8 [0.48]	99.3 [1.9]	99.0 [1.1]

ROBERTA-BASE W/ JS	90.0 / 86.6	92.3 / 91.6	79.2 / 84.9	95.1 ± 0.12	86.8 ± 1.51	61.4 ± 1.06

Table 2: **Parts (A) & (B)**: $L2R$ and $R2L$ Prediction and Confidence Consistency. **Part (C) Classification Metrics**. (*-BASE) indicate 🙂, (*- $W/$ *) indicate 🤠. Higher Accuracy, Higher Pearson Correlation and lower MSE are better. Numbers in **bold** are statistically significant. Underlined numbers are better on average than baselines. Please refer to Section 5.1 for a discussion.

This is to analyze how aligned are the confidence (softmax output associated with label 1) predicted by the model for $L2R$ and $R2L$ setting. The metrics used are the pearson correlation (scaled by 100) and the mean squared error (MSE - scaled by 1000) between the two confidence scores of the test data.

3. **Standard Classification Metrics:** These are task-specific metrics (accuracy/F1) used in the standard GLUE tasks (Wang et al., 2019)

4.3 Implementation Details

To fine-tune the model for symmetric classification tasks, we club together three paraphrase detection datasets: (a) QQP, (b) PAWS, and (c) MRPC. To make sure that all the models see the same data, we augment the dataset with its reverse samples during training. The model is then trained by passing the `[CLSPara]` (Section 3.2) representation through a low-capacity classifier, and optimized using Equation 1 for baseline models and Equation 2 for the consistency inducing models (Ours). We then use these models to conduct two sets of evaluations. We first evaluate the paraphrase detection results on QQP, PAWS, and MRPC individually. We then take the fine-tuned model obtained above and additionally fine-tune (`[CLS]` or `<s>` token) on the single input task (SST-2) and non-symmetric tasks (QNLI, RTE).

We use the hugging-face library (Wolf et al., 2020) for tokenizing the input, and the pytorch-lightning framework (Falcon et al., 2019) for loading the pre-trained models and fine-tuning them. We optimize the objective using the AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of 2e-5 (obtained through hyperparameter tuning {2e-4, 2e-5, 4e-5, 2e-6}). Since the input contains an additional token `[CLSPara]`, we extend the tokenizer vocabulary for each of the models. Each model was fine-tuned on a single Nvidia 1080Ti GPU (12 GB) for a maximum of 3 epochs (≈ 6hrs/experiment). In case of BERT (Devlin et al., 2019), we use the `bert-base-cased` model while for RoBERTa (Liu et al., 2020), we use the `RoBERTa-base` model. For training stability, we perform lambda-annealing i.e., increase the λ parameter from 0.0 to 100.0 as the training progresses. This ensures that the model has developed the capability to classify the sentence pairs with some degree of correctness before making it adhere to the appropriate symmetric confidence scores. We also experimented with fixed λ, but the resultant models were slow to converge (≈ 15 epochs).

5 Results

Our experiments address three questions:

Q1. What are the shortcomings of the current objective function for symmetric classification tasks? (Section 1, Section 5.2)

Q2. Does adding the consistency loss alleviate the inconsistency problem? (Section 5.1)

Q3. Can consistency-based fine-tuning improve other downstream tasks? (Section 5.1)

5.1 Quantitative Analysis

Table 2 presents our results. **Parts (A) & (B)** compare $L2R$ and $R2L$ models in terms of prediction consistency and confidence consistency. Models trained with the consistency loss (indicated by $W/*$) assign more similar predictions (indicated by higher scores in (A)) and confidence scores (indicated by higher correlation in (B)) as compared to the base model (indicated by $-BASE$), for both the base models (BERT-BASE/RoBERTa-BASE) and all symmetric test data sets (QQP, PAWS, MRPC). Moreover, the MSE (indicated within square brackets in part (B)) with consistency training is an order-of-magnitude smaller than without it. The improvements in part (A) are statistically significant at significance level (α) of 0.01 according to McNemar's statistical test (Dror et al., 2018).

Part (C) shows the results on **downstream fine-tuning.** Our models (indicated by $W/*$) do not compromise significantly (statistically evaluated) on the classification metrics for QQP, PAWS, and MRPC (F1/accuracy). The consistency loss does not change the accuracy scores of single sentence input tasks (SST-2), but affects the non-symmetric tasks (QNLI, RTE) negatively. This seems natural since the final objective of both the tasks is quite different and, in many cases, uncorrelated or negatively correlated. Incorporating consistency loss before fine-tuning on non-symmetric tasks (such as entailment) should, therefore, be avoided.

Limitations: Our goal is to increase the reliability (measured in terms of confidence scores) of the model and not specifically target classification performance metrics like accuracy and F1. Cases where they increase, can only partially be attributed to a stricter consistency constraint.

5.2 Qualitative Analysis

We sample 30 instances that were assigned opposite labels for $L2R$ and $R2L$ by the BERT-BASE models (majority voting) for QQP, MRPC and PAWS. An evaluator with NLP expertise analysed these examples and grouped them into recall error types. We then check the predictions for the same set of instances from BERT + JS (recall). Counts for these error types (defined in Section 7.1) are shown in Table 3. Out of those 30 examples for QQP, MRPC and PAWS, 26, 26 and 23 respectively get corrected by 🤠. In general, the numbers reduce for all error types.

Error type	🙂	🤠
QQP		
Different expected answer	4	0
Different answer type + Additional details	8	1
Different answer type + Additional details + Pronoun change	1	0
Additional details and/or pronoun change	17	3
MRPC		
Additional details missing	13	2
Reordering of phrases	3	0
Named entities and pronouns	6	1
Focus of sentences is different	6	0
Synonyms	2	1
PAWS		
Phrases are changed	10	4
Nouns/adjectives are changed	12	1
Nouns/adjectives and phrases are changed	4	0
Named entities are changed	3	1
Names entities and nouns/adjectives are changed	1	1

Table 3: Recall errors in QQP, MRPC & PAWS: BERT (🙂) and BERT with JS (🤠). Please refer to Section 5.2.

6 Conclusion

In this paper, we proposed an additional objective: consistency loss between $L2R$ and $R2L$ predictions so as to alleviate the problem of input order-sensitive inconsistency in the case of symmetric classification tasks. For three symmetric classification tasks, our proposed solution, BERT-with-consistency-loss, results in an improved consistency in terms of Pearson's correlation and MSE. As expected, consistency loss results in a drop in the performance of non-symmetric classification tasks such as QNLI and RTE. Surprisingly, using KL divergence results in marginally higher *consistency* than the JS counterpart. We leave this analysis for future work. Our qualitative analysis shows that all error types, including change in phrases or addition/deletion of details are reduced when the consistency loss is incorporated.

While consistency loss ensures that the predicted labels are the same even if the order of inputs is swapped, it can be adapted in the future to ensure expected outputs for anti-symmetric classification tasks (where $\mathbb{P}(L2R) = 1 - \mathbb{P}(R2L)$) like next and previous sentence prediction, where reordering the inputs must result in an opposite predicted label. In addition, the proposed method can be applied to evaluate paraphrase generation models (Kumar et al., 2019, 2020) as well. In order to validate that paraphrasing models are indeed generating semantically similar outputs, BERT-with-consistency-loss can be used to either evaluate and filter out incorrect generations or be used as an objective to train learned metrics like BLEURT (Sellam et al., 2020).

Ethical Considerations

The primary aim of this work is to highlight the inconsistency in labels and confidence scores of generated by standard pre-trained models for symmetric classification tasks. To mitigate the aforementioned inconsistency, we propose a loss function that incorporates divergence between outputs when the input order is swapped. We do not anticipate any additional ethical issues being introduced by our loss function as compared to the original standard pre-trained models, specifically BERT and RoBERTa. All the datasets used in our experiments are subset of the datasets from previously published papers, and to the best of our knowledge, do not have any attached privacy or ethical issues. That being said, further efforts should be made to study the inherent biases encoded in the pre-trained language models and the datasets.

7.1 Recall Error Types in Qualitative Analysis

The qualitative analysis compares types of errors with and without consistency loss. The recall error types can be described as follows:

A. QQP:

1. **Different expected answer**: This error is said to occur in the case of QQP when the two input questions have a different expected answer. An example of such a pair is: '*Is consciousness possible without self-awareness?*' and '*Is self-awareness possible without consciousness?*'. The two questions are essentially complements of each other.

2. **Different answer type + Additional details**: This error is said to occur when one of the inputs is structured in a way that the answer would solicit additional details. For example, the input pair '*How do I structure a big PHP project?*' and '*How do I build a perfect PHP project?*' are similar - but nuances between 'structuring' and 'building' a project may result in different answers.

3. **Additional details and/or pronoun change**: The input pair '*What are the best ways to get thick and wavy hair?*' and '*How can I get thick, wavy hair (as a guy)?*' is similar - although the latter uses the first-person proverb.

Dataset	Example pair	True label	$L2R$ Label	$R2L$ Label
MRPC	**(1)** *Shares in Wal-Mart closed at \$ 58.28 , up 16 cents , in Tuesday trading on the New York Stock Exchange.* **(2)** *Wal-Mart shares rose 16 cents to close at \$ 58.28 on the New York Stock Exchange.*	1	0	1
	(1) *Darren Dopp , a Spitzer spokesman , declined to comment late Thursday.* **(2)** *John Heine , a spokesman for the commission in Washington , declined to comment on Mr. Spitzer 's criticism.*	0	0	1
QQP	**(1)** *How do I retrieve my deleted history from Google chrome?* **(2)** *Can history be retrieved after deleting Google chrome?*	1	0	1
	(1) *Is consciousness possible without self-awareness?* **(2)** *Is self-awareness possible without consciousness?*	0	1	0
PAWS	**(1)** *This iteration is larger and has a smaller storage capacity than its previous versions.* **(2)** *This iteration is smaller and has a greater storage capacity than its previous versions*	0	0	1
	(1) *To get there , take Marine Drive west from the Lions Gate Bridge past Horseshoe Bay to Lighthouse Park and then continue on to 7100 Block Marine Drive.* **(2)** *To get there , take the Marine Drive from the Lions Gate Bridge to the west , past the Horseshoe Bay , Lighthouse Park and continue on to the 7100 Marine Drive block.*	1	1	0

Table 4: Sample pairs which are classified differently by the fine-tuned model based on their input order in the standard classification setting in each of the paraphrase dataset. Please refer Section 1, Section 3.2 for details.

B. MRPC:

1. **Additional details missing**: One of the inputs contains information (*i.e.*, details) that are not present in the other input. For example, '*The caretaker, identified by church officials as Jorge Manzon, was believed to be among the nine missing - some of them children*' contains the number of missing persons that are not present in '*The caretaker, identified by church officials as Jorge Monzon, was believed to be among the missing, who are presumed dead*'.

2. **Reordering of phrases**: The two inputs contain the same information although the information may be represented using different phrasal structures. For example, '*Shares in Wal-Mart closed at \$ 58.28 , up 16 cents , in Tuesday trading on the New York Stock Exchange.*' conveys the same information as '*Wal-Mart shares rose 16 cents to close at \$ 58.28 on the New York Stock Exchange .*' The former uses passive voice while the latter uses 'shares' as the main verb.

3. **Named entities and pronouns**: One input replaces entities with pronouns, as in the case of '*The bonds traded to below 60 percent of face value earlier this year*' and '*They traded down early this year to 60 percent of face value on fears Aquila may default .*'

4. **Focus of sentences is different**: While information in one input is subsumed by the other, the latter might focus on a broader context. For example, '*A power cut in New York in 1977 left 9 million people without electricity for up to 25 hours*' is implied in the sentence '*The outage resurrected memories of other massive power blackouts , including one in 1977 that left about 9 million people without electricity for 25 hours .*' However, the latter describes a resurrection of memories of the event in 1977.

5. **Synonyms**: One or more words in an input may be replaced by its synonyms in the other input. For example, '*In 2001 , the number of death row inmates nationally fell for the first time in a generation*' can be converted to '*In 2001 , the number of people on death row dropped for the first time in a decade.*' by replacing the word 'fell' with 'dropped'.

C. PAWS

1. **Nouns/adjectives are changed**: In the case of these errors, adjectives are replaced. An example pair is '*This iteration is larger and has a smaller storage capacity than its previous versions*' and '*This iteration is smaller

and has a greater storage capacity than its previous versions .'

2. **Named entities are changed**: This refers to pairs where named entities (locations/people) are different. An example is the pair '*When Mexico was within Los Angeles , Botello was chief of staff for Mexican General Ramirez y Sesma . His two brothers also married daughters of the general*' and '*When Los Angeles was within Mexico , Botello was Chief of Staff of the Mexican General Ramirez y Sesma , his two brothers also married the general 's daughters .*'

Diversifying Content Generation for Commonsense Reasoning with Mixture of Knowledge Graph Experts

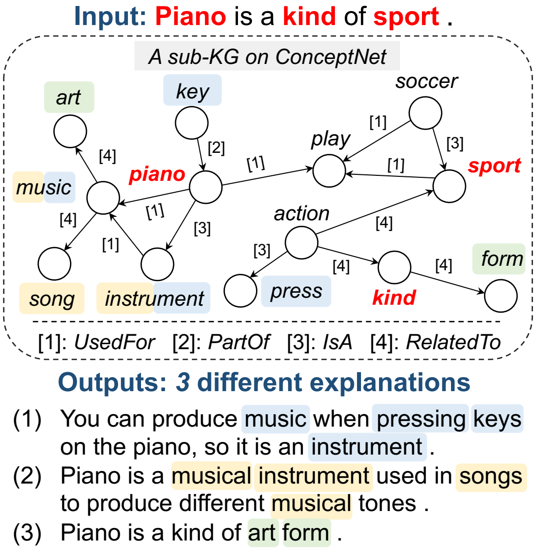
Abstract

Generative commonsense reasoning (GCR) in natural language is to reason about the commonsense while generating coherent text. Recent years have seen a surge of interest in improving the generation quality of commonsense reasoning tasks. Nevertheless, these approaches have seldom investigated diversity in the GCR tasks, which aims to generate alternative explanations for a real-world situation or predict all possible outcomes. Diversifying GCR is challenging as it expects to generate multiple outputs that are not only semantically different but also grounded in commonsense knowledge. In this paper, we propose MoKGE, a novel method that diversifies the generative reasoning by a mixture of expert (MoE) strategy on commonsense knowledge graphs (KG). A set of knowledge experts seek diverse reasoning on KG to encourage various generation outputs. Empirical experiments demonstrated that MoKGE can significantly improve the diversity while achieving on par performance on accuracy on two GCR benchmarks, based on both automatic and human evaluations.

1 Introduction

An important desideratum of natural language generation (NLG) is to produce outputs that are not only correct but also diverse (Tevet and Berant, 2021). The term "diversity" in NLG is defined as the ability of a generative model to create a set of possible outputs that are each valid given the input and vary as widely as possible in terms of *content, language style, and word variability* (Gupta et al., 2018). This research problem is also referred as *one-to-many generation* (Shen et al., 2019; Cho et al., 2019; Yu et al., 2021; Shen et al., 2022).

Diversity in NLG has been extensively studied for various tasks in the past few years, such as machine translation (Shen et al., 2019) and paraphrase generation (Gupta et al., 2018). In these tasks, output spaces are constrained by input context, i.e., the contents of multiple outputs should be similar, and globally, under the same topic. However, many NLG tasks, e.g., generative commonsense reasoning, pose unique challenges for generating multiple reasonable outputs that are *semantically different*.



Input: **Piano** is a **kind** of **sport** .

Outputs: *3* different explanations

(1) You can produce music when pressing keys on the piano, so it is an instrument .
(2) Piano is a musical instrument used in songs to produce different musical tones .
(3) Piano is a kind of art form .

Figure 1: An example of diverse commonsense explanation generation. It aims at generating multiple reasonable explanations given a counterfactual statement. Relevant concepts on the commonsense KG (in shade) can help to perform diverse knowledge reasoning.

Figure 1 shows an example in the commonsense explanation generation (ComVE) task. The dataset has collected explanations to counterfactual statements for sense-making from three annotators (Wang et al., 2020). From the annotations, we observed that different annotators gave explanations to the unreasonable statement from different perspectives to make them diverse in terms of content, e.g., wrong effect and inappropriate usage.

In order to create diversity, existing methods attempted to produce *uncertainty* by introducing random noise into a latent variable (Gupta et al., 2018) or sampling next token widely from the vo-

Findings of the Association for Computational Linguistics: ACL 2022, pages 1896 - 1906
May 22-27, 2022

Table 1: Under human evaluation, the performance of existing diversity promoting methods is still far from that of humans. Our method MoKGE can exceed the human performance on the ComVE task.

	ComVE	α-NLG
Avg. # human references	3.00	4.20
Avg. # meanings ($\Uparrow$)		
Human references	2.60	**3.79**
Nucleus sampling	2.15	3.35
MoKGE (our method)	**2.63**	3.72

cabulary (Holtzman et al., 2020). However, these methods were not able to explicitly control varying semantics units and produce outputs of diverse content. Meanwhile, the input text alone contains too limited knowledge to support diverse reasoning and produce multiple reasonable outputs (Yu et al., 2022c). As an example, Table 1 shows the human evaluation results on two GCR tasks. While human annotators were able to produce 2.60 different yet reasonable explanations on the ComVE dataset, one SoTA diversity-promoting method (i.e., nucleus sampling (Holtzman et al., 2020)) could produce only 2.15 reasonable explanations.

To improve the diversity in outputs for GCR tasks, we investigated the ComVE task and found that 75% of the concepts (nouns and verbs) in human annotations were among 2-hop neighbors of the concepts contained in the input sequence on the commonsense KG ConceptNet[1]. Therefore, to produce diverse GCR, our idea is enabling NLG models to reason from different perspectives of knowledge on commonsense KG and use them to generate diverse outputs like the human annotators.

Thus, we present a novel **M**ixture **o**f **K**nowledge **G**raph **E**xpert (MoKGE) method for diverse generative commonsense reasoning on KG. MoKGE contains two major components: (i) a knowledge graph (KG) enhanced generative reasoning module to reasonably associate relevant concepts into the generation process, and (ii) a mixture of expert (MoE) module to produce diverse reasonable outputs. Specifically, the generative reasoning module performs compositional operations on KG to obtain structure-aware representations of concepts and relations. Then, each expert uses these representations to seek different yet relevant sets of concepts and sends them into a standard Transformer model to generate the corresponding output. To encourage different experts to specialize in different reasoning abilities, we employ the stochastic hard-EM algorithm by assigning full responsibility of the largest joint probability to each expert.

We conducted experiments on two GCR benchmarks, i.e., commonsense explanation generation and abductive commonsense reasoning. Empirical experiments demonstrated that our proposed MoKGE can outperform existing diversity-promoting generation methods in diversity, while achieving on par performance in quality.

To the best of our knowledge, this is the first work to boost diversity in NLG by diversifying knowledge reasoning on commonsense KG.

2 Related Work

2.1 Diversity Promoting Text Generation

Generating multiple valid outputs given a source sequence has a wide range of applications, such as machine translation (Shen et al., 2019), paraphrase generation (Gupta et al., 2018), question generation (Cho et al., 2019), dialogue system (Dou et al., 2021), and story generation (Yu et al., 2021). For example, in machine translation, there are often many plausible and semantically equivalent translations due to information asymmetry between different languages (Lachaux et al., 2020).

Methods of improving diversity in NLG have been explored from various perspectives. Sampling-based decoding is one of the most effective solutions to improve diversity. For example, nucleus sampling (Holtzman et al., 2020) samples next tokens from the dynamic nucleus of tokens containing the vast majority of the probability mass, instead of decoding text by maximizing the likelihood. Another line of work focused on introducing random noise (Gupta et al., 2018) or changing latent variables (Lachaux et al., 2020) to produce uncertainty. In addition, Shen et al. (2019) adopted a mixture of experts to diversify machine translation, where a minimum-loss predictor is assigned to each source input. Shi et al. (2018) employed an inverse reinforcement learning approach for unconditional diverse text generation.

However, no existing work considered performing diverse knowledge reasoning to generate multiple reasonable outputs of different contents.

2.2 Knowledge Graph for Text Generation

Incorporating external knowledge is essential for many NLG tasks to augment the limited textual

---

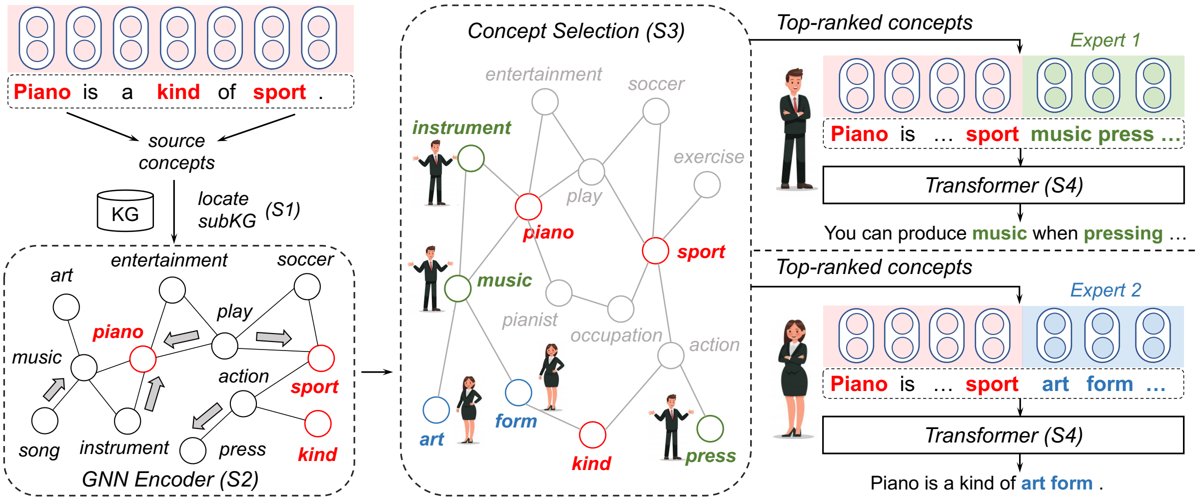

Figure 2: The overall architecture of MoKGE. The MoKGE consists of four steps: (S1) the model constructs a sequence-associated subgraph from the commonsense KG; (S2) a relational-GCN iteratively updates the representation of a concept node by aggregating information from its neighboring nodes and edges; (S3) each knowledge expert selects different salient concepts that should be considered during generation; (S4) the model generates the outputs by integrating the token embeddings of the input sequence and the top-ranked entities.

information (Yu et al., 2022c; Dong et al., 2021; Yu et al., 2022b). Some recent work explored using graph neural networks (GNN) to reason over multi-hop relational knowledge graph (KG) paths (Zhou et al., 2018; Jiang et al., 2019; Zhang et al., 2020a; Wu et al., 2020; Yu et al., 2022a; Zeng et al., 2021). For example, Zhou et al. (2018) enriched the context representations of the input sequence with neighbouring concepts on ConceptNet using graph attention. Ji et al. (2020) performed dynamic multi-hop reasoning on multi-relational paths extracted from the external commonsense KG. Recently, some work attempted to integrate external commonsense knowledge into generative pretrained language models (Guan et al., 2020; Bhagavatula et al., 2020; Liu et al., 2021). For example, Guan et al. (2020) conducted post-training on sythetic data constructed from commonsense KG by translating triplets into natural language texts using templates. Yu et al. (2022c) wrote a comprehensive survey for more detailed comparisons of different knowledge graph enhanced NLG methods.

3 Proposed Method

Problem formulation. In this paper, we focus on diversifying the outputs of generative commonsense reasoning (GCR) tasks, e.g. commonsense explanation generation and abductive commonsense reasoning. These tasks require *one-to-many* generation, i.e., creating a set of reasonable outputs that vary as widely as possible in terms of contents, language style and word variability. Formally, given a source input x, our goal is to model a conditional distribution for the target outputs $p(y|x)$ that assigns high values to $\{p(y_1|x), \cdots, p(y_K|x)\}$ for K mappings, i.e., $\{x \rightarrow y_1, \cdots, x \rightarrow y_K\}$. Meanwhile, the outputs $\{y_1, \cdots, y_K\}$ are expected to be diverse with each other in terms of *contents*.

Existing diversity-promoting methods only varied the language styles and failed to perform different knowledge reasoning to generate diverse contents (Cho et al., 2019; Shen et al., 2019; Holtzman et al., 2020). Here, incorporating commonsense KG is essential for the generative reasoning (GR) tasks because the KG cannot only augment the limited information in the input text, but also provide a rich searching space for knowledge reasoning. Therefore, we propose to employ commonsense KG to play the central role of performing diverse knowledge reasoning, then use different sets of selected concepts to produce diverse outputs.

Model Outline. Our model has two major components: (i) a knowledge graph (KG) enhanced generative reasoning module to reasonably associate relevant concepts and background into the generation process, and (ii) a mixture of expert (MoE) module to diversify the generation process and produce multiple reasonable outputs.

3.1 KG-enhanced Generative Reasoning

The KG-enhanced generative reasoning module is illustrated in Figure 2. It consists of four steps.

First, a sequence-associated subgraph is retrieved from the KG given the input sequence (§3.1.1). Then, a multi-relational graph encoder iteratively updates the representation of each node by aggregating information from its neighboring nodes and edges (§3.1.2). Next, the model selects salient concepts that should be considered during generation (§3.1.3). Finally, the model generates outputs by integrating the token embeddings of both the input sequence and the top-ranked concepts (§3.1.4).

3.1.1 Sequence-aware subgraph construction

To facilitate the reasoning process, we resort to an external commonsense knowledge graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$, where $\mathcal{V}$ denotes the concept set and $\mathcal{E}$ denotes the edges with relations. Since direct reasoning on the entire graph is intractable, we extract a sequence-associated subgraph $\mathcal{G}_x = \{\mathcal{V}_x, \mathcal{E}_x\}$, where $\mathcal{V}_x$ consists of the concepts extracted from the input sequence (denoted as C_x) and their inter-connected concepts within two hops, i.e., $\mathcal{V}_x = \{C_x \cup \mathcal{N}(C_x) \cup \mathcal{N}(\mathcal{N}(C_x))\}$. For example, in Figure 2, $C_x = \{\text{piano}, \text{sport}, \text{kind}\}$ and $\mathcal{V}_x = \{\text{piano}, \text{sport}, \text{kind}, \text{art}, \text{music}, \text{press}, ...\}$. Next, the generation task is to maximize the conditional probability $p(y|x, \mathcal{G}_x)$.

3.1.2 Multi-relational graph encoding

To model the relational information in the commonsen KG, we employ the relational graph convolutional network (R-GCN) (Schlichtkrull et al., 2018) which generalizes GCN with relation specific weight matrices. We follow Vashishth et al. (2020) and Ji et al. (2020) to use a non-parametric compositional operation $\phi(\cdot)$ to combine the concept node embedding and the relation embedding. Specifically, given the input subgraph $\mathcal{G}_x = \{\mathcal{V}_x, \mathcal{E}_x\}$ and an R-GCN with L layers, we update the embedding of each node $v \in \mathcal{V}_x$ at the $(l+1)$-th layer by aggregating information from the embeddings of its neighbours in $\mathcal{N}(v)$ at the l-th layer:

$$\mathbf{o}_v^l = \frac{1}{|\mathcal{N}(v)|} \sum_{(u,v,r)\in\mathcal{E}} \mathbf{W}_N^l \phi(\mathbf{h}_u^l, \mathbf{h}_r^l), \quad (1)$$

$$\mathbf{h}_v^{l+1} = \text{ReLU}(\mathbf{o}_v^l + \mathbf{W}_S^l \mathbf{h}_v^l), \quad (2)$$

where $\mathbf{h}_v$ and $\mathbf{h}_r$ are node embedding and relation embedding. We define the compositional operation as $\phi(\mathbf{h}_u, \mathbf{h}_r) = \mathbf{h}_u - \mathbf{h}_r$ inspired by the TransE (Bordes et al., 2013). The relation embedding is also updated via another linear transformation:

$$\mathbf{h}_r^{l+1} = \mathbf{W}_R^l \mathbf{h}_r^l. \quad (3)$$

Finally, we obtain concept embedding $\mathbf{h}_v^L$ that encodes the sequence-associated subgraph context.

3.1.3 Concept selection on knowledge graph

Not all concepts in $\mathcal{G}$ appear in the outputs. Thus, we design a concept selection module to choose salient concepts that should be considered during generation. For each concept $v \in \mathcal{V}_x$, we calculate its probability of being selected by taking a multi-layer perception (MLP) on the top of graph encoder: $p_v = Pr[v \text{ is selected}|x] = \text{MLP}(\mathbf{h}_v^L)$.

To supervise the concept selection process, we use the overlapping concepts between concepts appearing in the output sequence C_y and concepts in input sequence associated subgraph $\mathcal{G}_x$, i.e., $\mathcal{V}_x \cap C_y$, as a simple proxy for the ground-truth supervision. So, the concept selection loss (here only for one expert, see MoE loss in Eq.(8)) is:

$$\mathcal{L}_{\text{concept}} = -\Big(\sum_{v\in\mathcal{V}_x\cap C_y} v \log p_v + \sum_{v\in\mathcal{V}_x - C_y} (1-v)\log(1-p_v) \Big). \quad (4)$$

Finally, the top-N ranked concepts on the subgraph G_x (denoted as $v_1, ..., v_N$) are selected as the additional input to the generation process.

3.1.4 Concept-aware sequence generation

We utilize a standard Transformer (Vaswani et al., 2017) as our generation model. It takes the concatenation of the sequence x and all the selected concepts $v_1, ..., v_N$ as input and auto-regressively generates the outputs y. We adopt the cross-entropy loss, which can be written as:

$$\begin{aligned}\mathcal{L}_{\text{generation}} &= -\log p(y|x, v_1, \cdots, v_N) \quad (5)\\ &= -\sum_{t=1}^{|y|} \log p(y_t|x, v_1, \cdots, v_N, y_{<t}).\end{aligned}$$

Note that since the selected concepts do not have a rigorous order, we only apply positional encodings (used in Transformer) to the input sequence x.

3.1.5 Overall objective

We jointly optimizes the following loss:

$$\mathcal{L} = \mathcal{L}_{\text{generation}} + \lambda \cdot \mathcal{L}_{\text{concept}}. \quad (6)$$

where λ is a hyperparameter to control the importance of different tasks[2].

---

[2] We performed a hyperparameter search and found when λ was around 0.3, the model performed the best. Therefore, we set $\lambda = 0.3$ in the following experiments.

3.2 MoE-Promoted Diverse Generation

To empower the generation model to produce multiple reasonable outputs, we employ a mixture of expert (MoE) module to model uncertainty and generate diverse outputs. While the MoE models have primarily been explored as a means of increasing model capacity, they are also being used to boost diverse generation process (Shen et al., 2019; Cho et al., 2019). Formally, the MoE module introduces a multinomial latent variable $z \in \{1, \cdots, K\}$, and decomposes the marginal likelihood as follows:

$$p(y|x, \mathcal{G}_x) = \sum_{z=1}^{K} p(z|x, \mathcal{G}_x) p(y|z, x, \mathcal{G}_x). \quad (7)$$

Training. We minimize the loss function (in Eq.(6)) using the MoE decomposition,

$$\begin{aligned} &\nabla \log p(y|x, \mathcal{G}_x) \quad (8) \\ &= \sum_{z=1}^{K} p(z|x, y, \mathcal{G}_x) \cdot \nabla \log p(y, z|x, \mathcal{G}_x), \end{aligned}$$

and train the model with the EM algorithm (Dempster et al., 1977). Ideally, we would like different experts to specialize in different reasoning abilities so that they can generate diverse outputs. The specialization of experts means that given the input, only one element in $\{p(y, z|x, \mathcal{G}_x)\}_{z=1}^{K}$ should dominate in value (Shen et al., 2019). To encourage this, we employ a hard mixture model to maximize $\max_z p(y, z|x, \mathcal{G}_x)$ by assigning full responsibility to the expert with the largest joint probability. Training proceeds via hard-EM can be written as:

- E-step: estimate the responsibilities of each expert $r_z \leftarrow \mathbb{1}[z = \arg\max_z p(y, z|x, \mathcal{G}_x)]$ using the current parameters θ;
- M-step: update the parameters with gradients of the chosen expert ($r_z = \mathbb{1}$) from E-step.

Expert parameterization. Independently parameterizing each expert may exacerbate overfitting since the number of parameters increases linearly with the number of experts (Shen et al., 2019). We follow the parameter sharing schema in Cho et al. (2019); Shen et al. (2019) to avoid this issue. This only requires a negligible increase in parameters over the baseline model that does not uses MoE. In our experiments, we compared adding a unique expert embedding to each input token with adding an expert prefix token before the input text sequence, where they achieved very similar performance.

Producing K outputs during inference. In order to generate K different outputs on test set, we follow Shen et al. (2019) to enumerate all latent variables z and then greedily decoding each token by $\hat{y}_t = \arg\max p(y|\hat{y}_{1:t-1}, z, x)$. In other words, we ask each expert to seek different sets of concepts on the knowledge graph, and use the selected concepts to generate K different outputs. Notably, this decoding procedure is efficient and easily parallelizable. Furthermore, to make fair comparisons with sampling-based methods, we use greedy decoding without any sampling strategy.

4 Experiments

4.1 Tasks and Datasets

Commonsense explanation generation. It aims to generate an explanation given a counterfactual statement for sense-making (Wang et al., 2019). We use the benchmark dataset ComVE from SemEval-2020 Task 4 (Wang et al., 2020). The dataset contains 10,000 / 997 / 1,000 examples for training / development / test sets, respectively. The average input/output length is 7.7 / 9.0 words. All examples in the dataset have 3 references.

Abductive commonsense reasoning. It is also referred as α-NLG. It is the task of generating a valid hypothesis about the likely explanations to partially observable past and future. We use the $\mathcal{ART}$ benchmark dataset (Bhagavatula et al., 2020) that consists of 50,481 / 1,779 / 3,560 examples for training / development / test sets. The average input/output length is 17.4 / 10.8 words. Each example in the $\mathcal{ART}$ dataset has 1 to 5 references.

4.2 Baseline Methods

We note that as we targeted at the *one-to-many* generation problem, we excluded those baseline methods mentioned in the related work that cannot produce multiple outputs, e.g., Zhang et al. (2020a); Ji et al. (2020); Liu et al. (2021). Different from aforementioned methods, our MoKGE can seek diverse reasoning on KG to encourage various generation outputs *without any additional conditions*.

To the best of our knowledge, we are the first work to explore diverse knowledge reasoning on commonsense KG to generate multiple diverse output sequences. Therefore, we only compared our MoKGE with existing diversity-promoting baselines without using knowledge graph.

VAE-based method. The variational auto-encoder (VAE) (Kingma and Welling, 2014) is a deep generative latent variable model. VAE-based methods produce diverse outputs by sampling different latent variables from an approximate posterior distribution. CVAE-SVG (SVG is short for sentence variant generation) (Gupta et al., 2018) is a conditional VAE model that can produce multiple outputs based an original sentence as input.

MoE-based method. Mixture models provide an alternative approach to generate diverse outputs by sampling different mixture components. We compare against two mixture of experts (MoE) implementations by Shen et al. (2019) and Cho et al. (2019). We refer them as MoE-prompt (Shen et al., 2019) and MoE-embed (Cho et al., 2019).

Sampling-based method. Sampling methods create diverse outputs by sampling next token widely from the vocabulary. We compare against two sampling algorithms for decoding, including truncated sampling (Fan et al., 2018) and nucleus sampling (Holtzman et al., 2020). Truncated sampling (Fan et al., 2018) randomly samples words from top-k probability candidates of the predicted distribution at each decoding step. Nucleus sampling (Holtzman et al., 2020) avoids text degeneration by truncating the unreliable tails and sampling from the dynamic nucleus of tokens containing the vast majority of the probability mass.

4.3 Implementation Details

All baseline methods were built on the Transformer architecture with 6-layer encoder and decoder, and initialized with pre-trained parameters from BART-base (Lewis et al., 2020), which is one of the state-of-the-art pre-trained Transformer models for natural language generation (Gehrmann et al., 2021). In our MoKGE, the Transformer parameters were also initialized by BART-base, in order to make fair comparison with all baseline methods. The R-GCN parameters were random initialized.

For model training, we used Adam with batch size of 60, learning rate of 3e-5, L2 weight decay of 0.01, learning rate warm up over the first 10,000 steps, and linear decay of learning rate. Our models were trained by one Tesla V100 GPU card with 32GB memory, and implemented on PyTorch with the Huggingface's Transformer (Wolf et al., 2020). All Transformer-based methods were trained with 30 epochs, taken about 4-5 hours on the ComVE dataset and 7-9 hours on the α-NLG dataset.

In addition to our MoKGE implementation, we also provide the baseline implementation code on GitHub `https://github.com/DM2-ND/MoKGE`.

4.4 Automatic Evaluation

We evaluated the performance of different generation models from two aspects: *quality* (or say *accuracy*) and *diversity*. *Quality* tests the appropriateness of the generated response with respect to the context, and *diversity* tests the lexical and semantic diversity of the appropriate sequences generated by the model. These evaluation metrics have been widely used in existing work (Ott et al., 2018; Vijayakumar et al., 2018; Zhu et al., 2018; Cho et al., 2019; Yu et al., 2021).

Quality metrics (⇑). The quality is measured by standard N-gram based metrics, including the BLEU score (Papineni et al., 2002) and the ROUGE score (Lin, 2004). This measures the highest accuracy comparing the best hypothesis among the top-K with the target (Vijayakumar et al., 2018). Concretely, we generate hypotheses $\{\hat{Y}^{(1)}, \cdots \hat{Y}^{(K)}\}$ from each source X and keep the hypothesis $\hat{Y}^{\text{best}}$ that achieves the best sentence-level metric with the target Y. Then we calculate a corpus-level metric with the greedily-selected hypotheses $\{Y^{(i),\text{best}}\}_{i=1}^{N}$ and references $\{Y^{(i)}\}_{i=1}^{N}$.

The diversity of evaluated by three aspects: concept, pairwise and corpus diversity.

Concept diversity. The number of unique concepts (short as Uni.C) measures how many unique concepts on the commonsense KG are covered in the generated outputs. A higher value indicates the higher concept diversity. Besides, we also measure the pairwise concept diversity by using Jaccard similarity. It is defined as the size of the intersection divided by the size of the union of two sets. Lower value indicates the higher concept diversity.

Pairwise diversity (⇓). Referred as "self-" (e.g., self-BLEU) (Zhu et al., 2018), it measures the within-distribution similarity. This metric computes the average of sentence-level metrics between all pairwise combinations of hypotheses $\{Y^{(1)}, \cdots, Y^{(K)}\}$ generated from each source sequence X. Lower pairwise metric indicates high diversity between generated hypotheses.

Corpus diversity (⇑). Distinct-k (Li et al., 2016) measures the total number of unique k-grams normalized by the total number of generated k-gram tokens to avoid favoring long sentences. Entropy-k (Zhang et al., 2018) reflects how evenly the empirical k-gram distribution is for a given sentence when word frequency is considered.

Table 2: Diversity and quality evaluation on the **ComVE** (upper part) and α-**NLG** (lower part) datasets. Each model is required to generate three outputs. All experiments are run three times with different random seeds, and the average results on the test set is calculated as the final performance, with standard deviations as subscripts.

Methods	Model Variant	Concept diversity		Pairwise diversity		Corpus diversity		Quality	
		#Uni.C(⇑)	Jaccard (⇓)	SB-3 (⇓)	SB-4 (⇓)	D-2(⇑)	E-4(⇑)	B-4 (⇑)	R-L (⇑)

4.4.1 Experimental results

Comparison with baseline methods. We evaluated our proposed MoKGE and baseline methods based on both *quality* and *diversity*. As shown in Table 2, MoE-based methods achieved the best performance among all baseline methods. MoKGE can further boost diversity by at least 1.57% and 1.83% on Self-BLEU-3 and Self-BLEU-4, compared with the vanilla MoE methods. At the same time, MoKGE achieved on par performance with other baseline methods based on the quality evaluation. Specifically, on the ComVE dataset, MoKGE achieved the best performance on BLEU-4 and ROUGE-L, and on the α-NLG dataset, the performance gap between MoKGE and the best baseline method was always *less than 0.5%* on BLEU-4.

Ablation study. We conducted an ablation study to analyze the two major components in the MoKGE. The experimental results are shown in Table 3. First, we note that when not using MoE (line –w/o MoE), we used the most basic decoding strategy – beam search – to generate multiple outputs. We observed that the outputs generated by beam search differed only on punctuation and minor morphological variations, and typically only the last few words were different from others. Besides, integrating commonsense knowledge graph into the MoE-based generation model brought both quality and

Table 3: Ablation studies. When not suing MoE (line –w/o MoE), we set beam as three to generate three outputs.

diversity improvement on the ComVE, but might sacrifice a little quality (less than 0.5% on BLEU-4) on the α-NLG dataset. Overall, our MoKGE benefited from KG and MoE modules, and achieved great performance on both diversity and quality.

4.5 Human Evaluation

Automatic diversity evaluation (e.g., Self-BLEU, Distinct-k) cannot reflect the *content-level diversity*. Therefore, we conducted extensive human evaluations to assess both the quality and diversity of outputs generated from different models.

The human evaluation was divided into two parts: *independent scoring* and *pairwise comparisons*. All evaluations were conducted on Amazon Mechanical Turk (AMT), and each evaluation form was answered by at least three AMT workers.

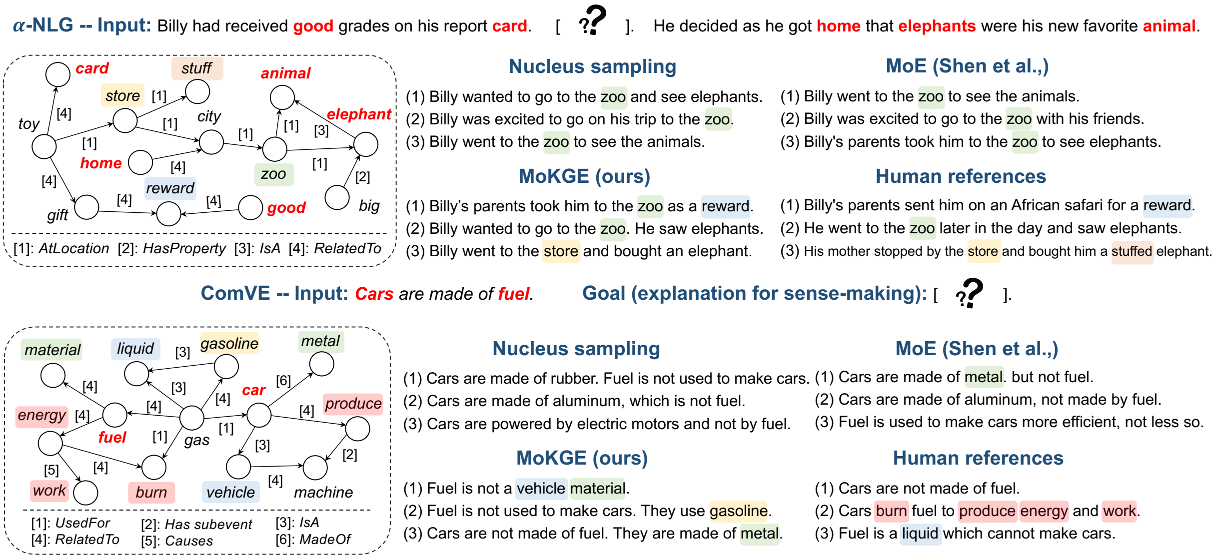
Independent scoring. In this part, human annotators were asked to evaluate the generated outputs from a single model. We first presented top-3 generated outputs from a certain model to human annotators. The annotators would first evaluate the *diversity* by answering "How many different meanings do three outputs express?" Then we presented human-written outputs to the annotators. The annotator would evaluate the quality by comparing machine generated outputs and human-written outputs, and answering "How many machine generated outputs are correct?" The diversity and quality scores are normalized to the range from 0 to 3. Besides, the annotators need to give a fluency and grammar score from 1 to 4 for each generated output.

Pairwise comparisons. In this part, the annotators were given two sets of top-3 generated explanations from two different methods each time and instructed to pick the more diverse set. The choices are "win," "lose," or "tie."

As shown in Table 4-5, our MoKGE can significantly outperform the state-of-the-art sampling-based methods in *diversity* evaluation (p-value < 0.05 under paired t-test), even slightly better than human performance on the ComVE task. At the same time, we can observe MoKGE is able to obtain on par performance with other methods based on *quality* evaluation. The p-value is not smaller than 0.05 (i.e., not significant difference) under paired t-test between MoKGE and baseline methods based on the quality evaluation.

4.6 Case Study

Figure 3 demonstrates human-written explanations and generated explanations from different diversity-promoting methods, including nucleus sampling, mixture of experts (MoE) and our MoKGE. Overall, we observed that the nucleus sampling and MoE methods typically expressed very similar



α-NLG -- Input: Billy had received good grades on his report card. [?]. He decided as he got home that elephants were his new favorite animal.

Nucleus sampling

(1) Billy wanted to go to the zoo and see elephants.
(2) Billy was excited to go on his trip to the zoo.
(3) Billy went to the zoo to see the animals.

MoE (Shen et al.,)

(1) Billy went to the zoo to see the animals.
(2) Billy was excited to go to the zoo with his friends.
(3) Billy's parents took him to the zoo to see elephants.

MoKGE (ours)

(1) Billy's parents took him to the zoo as a reward.
(2) Billy wanted to go to the zoo. He saw elephants.
(3) Billy went to the store and bought an elephant.

Human references

(1) Billy's parents sent him on an African safari for a reward.
(2) He went to the zoo later in the day and saw elephants.
(3) His mother stopped by the store and bought him a stuffed elephant.

ComVE -- Input: *Cars are made of fuel.* **Goal (explanation for sense-making):** [?].

Nucleus sampling

(1) Cars are made of rubber. Fuel is not used to make cars.
(2) Cars are made of aluminum, which is not fuel.
(3) Cars are powered by electric motors and not by fuel.

MoE (Shen et al.,)

(1) Cars are made of metal. but not fuel.
(2) Cars are made of aluminum, not made by fuel.
(3) Fuel is used to make cars more efficient, not less so.

MoKGE (ours)

(1) Fuel is not a vehicle material.
(2) Fuel is not used to make cars. They use gasoline.
(3) Cars are not made of fuel. They are made of metal.

Human references

(1) Cars are not made of fuel.
(2) Cars burn fuel to produce energy and work.
(3) Fuel is a liquid which cannot make cars.

Figure 3: Case studies. MoKGE can produce diverse knowledge reasoning on commonsense KG, select different relevant concepts (in shades of different colors), then generate diverse outputs. The outputs diversity of MoKGE is significantly better than that of beam search and nucleus sampling, and close to human performance.

meanings, e.g., "go to the zoo and see elephants" and "took him to the zoo and see elephants" in the α-NLG case. On the contrary, MoKGE can generate semantically richer and more diverse contents than the other two methods by incorporating more commonsense concepts on the knowledge graph.

5 Future Directions

Improving content diversity in NLG. Most of the existing diversity-promoting work has focused on improving syntactic and lexical diversity, such as different language style in machine translation (Shen et al., 2019) and word variability in paraphrase generation (Gupta et al., 2018). Nevertheless, methods for improving content diversity in NLG systems have been rarely studied in the existing literature. We believe that generating diverse content is one of the most promising aspects of machine intelligence, which can be applied to a wide range of real-world applications, not only limited to commonsense reasoning.

Besides, leveraging knowledge graph is not the only way to promote content diversity as it is a highly knowledge-intensive task. Many existing knowledge-enhanced methods (Yu et al., 2022c) can be used to acquire different external knowledge for producing diverse outputs, e.g., taking different retrieved documents as conditions for generator.

Designing neural diversity metrics. In spite of growing interest in NLG models that produce diverse outputs, there is currently no principled neural method for evaluating the diversity of an NLG system. As described in Tevet and Berant (2021), existing automatic diversity metrics (e.g. Self-BLEU) perform worse than humans on the task of estimating content diversity, indicating a low correlation between metrics and human judgments.

Therefore, neural-based diversity metrics are highly demanded. Intuitively, the metrics should include computational comparisons of multiple references and hypotheses by projecting them into the same semantic space, unlike metrics for evaluating the generation quality, e.g., BERTScore (Zhang et al., 2020b) and BLEURT (Sellam et al., 2020), which only measures the correlation between a pair of reference and hypothesis.

6 Conclusions

In this paper, we proposed a novel method that diversified the generative reasoning by a mixture of expert strategy on commonsense knowledge graph. To the best of our knowledge, this is the first work to boost diversity in NLG by diversifying knowledge reasoning on commonsense knowledge graph. Experiments on two generative commonsense reasoning benchmarks demonstrated that MoKGE outperformed state-of-the-art methods on diversity, while achieving on par performance on quality.

Abstract

Pre-trained language models (PLMs) aim to learn universal language representations by conducting self-supervised training tasks on large-scale corpus. Since PLMs capture word semantics in different contexts, the quality of word representations highly depends on word frequency, which usually follows a heavy-tailed distribution in the pre-training corpus. Thus, the embeddings of rare words on the tail are usually poorly optimized. In this work, we focus on enhancing language model pre-training by leveraging definitions of the rare words in dictionary. To incorporate a rare word definition as a part of input, we fetch it from the dictionary and append it to the end of the input text sequence. In addition to training with the masked language modeling objective, we propose two novel self-supervised pre-training tasks on word-level and sentence-level alignment between the input text and rare word definition to enhance language representations. We evaluate the proposed model named Dict-BERT on the GLUE benchmark and eight specialized domain datasets. Extensive experiments show that Dict-BERT significantly improves the understanding of rare words and boosts model performance on various NLP downstream tasks.

1 Introduction

Recently pre-trained language models (PLMs) such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) have revolutionized the field of natural language processing (NLP), yielding remarkable performance on various downstream tasks (Qiu et al., 2020). However, these PLMs suffer from lacking knowledge when completing real-world tasks. To address this issue, some methods have incorporated the knowledge to enrich language representations, ranging from linguistic (Wang et al., 2021a), commonsense (Guan et al., 2020; Liu et al., 2020), factual (Wang et al., 2021b), to domain knowledge (Liu et al., 2020; Yu et al., 2022b).

Nevertheless, rare words (Schick and Schütze, 2020) and unseen words (Cui et al., 2021) are still blind spots of pre-trained language models when they are fine-tuned on downstream tasks. For instance, in a dialogue system, users often talk to chatbots about recent hot topics, e.g., “Covid-19”, which may not appear in the pre-training corpus (Cui et al., 2021). Since PLMs capture word semantics in different contexts to address the issue of polysemous and the context-dependent nature of words, consequently they usually perform poorly when a user mentions such novel words (Wu et al., 2021; Ruzzetti et al., 2021). As indicated by Wu et al. (2021), the quality of word representations highly depends on the word frequency in the pre-training corpus, which typically follows a heavy-tail distribution. Thus, a large proportion of words appear very few times and the embeddings of these rare words are poorly optimized (Gong et al., 2018; Schick and Schütze, 2020). Such embeddings usually carry inadequate semantic meaning, which complicate the understanding of input text, and even hurt the pre-training of the entire model.

In this work, we focus on enhancing language model pre-training by leveraging rare word definitions in English dictionaries (e.g., Wiktionary). Definitions in dictionaries are intended to describe the meaning of a word to a human reader. We append the definitions of rare words to the end of the input text and encode the whole sequence with Transformer encoder. The pre-training tasks are mainly based on the alignment between input text and the appended word definitions, some of which are randomly sampled polluted words and don’t explain the input. We propose two types of pre-training objectives: 1) a word-level contrastive objective aims to maximize the mutual information between Transformer representations of a rare word

Findings of the Association for Computational Linguistics: ACL 2022, pages 1907 - 1918
May 22-27, 2022

appeared in the input text and its dictionary definition. 2) a sentence-level discriminative objective aims at learning to differentiate between correct and polluted word definitions. During downstream fine-tuning, in order to avoid the appended rare word definitions diverting the sentence from its original meaning, we employ a knowledge attention mechanism that makes word definitions only visible to the corresponding words in the input text sequence. We name our method Dict-BERT. Notably, Dict-BERT is general and model-agnostic, in the sense that any pre-trained language model (e.g., BERT, RoBERTa) suffices and can be used.

Overall, our main contributions in this work can be summarized as follows:

1. We are the first work to enhance language model pre-training with rare word definitions from dictionaries (e.g., Wiktionary).
2. We propose two novel pre-training tasks on word-level and sentence-level alignment between input text sequence and rare word definitions to enhance language modeling with dictionary.
3. We evaluate Dict-BERT on the GLUE (Wang et al., 2019) benchmark, in which our model pre-trained from scratch can improve accuracy by +1.15% on average over the vanilla BERT.
4. We follow the domain adaptive pre-training (DAPT) setting (Gururangan et al., 2020), where language models are continuously pre-trained with in-domain data. We evaluate Dict-BERT on eight specialized domain datasets. Our method can improve F1 score by +0.5%/+0.7% on average over the BERT-DAPT/RoBERTa-DAPT settings.

2 Related Work

Rare word representation in language models. The quality of word representations highly depends on word frequency creating a heavy-tail distribution (Wu et al., 2021). Recent works have shown rare words that are not frequently covered in the corpus can hinder the understanding of specific yet important sentences (Noraset et al., 2017; Bosc and Vincent, 2018; Schick and Schütze, 2020; Ruzzetti et al., 2021). Due to the poor quality of rare word representations, the pre-training model built on top of it suffers from noisy input semantic signals which lead to inefficient training. Gao et al. (2019) provided a theoretical understanding of the rare word problem, which illustrates that the problem lies in the sparse stochastic optimization of neural networks. Schick and Schütze (2020) adapted attentive mimicking to explicitly learn rare word embeddings to language models. Wu et al. (2021) proposed to maintain a note dictionary and saves a rare word's contextual information as notes. When the same rare word occurs again during language model pre-training, the note information saved beforehand can be employed to enhance the semantics of the current sentence. Different from aforementioned works that keep a fixed vocabulary of rare words during pre-training and fine-tuning, our method can dynamically adjust the vocabulary of rare words, obtain and represent their definitions in a dictionary in a plug-and-play manner.

Language model pre-training and knowledge-enhanced methods Recent years have seen substantial pre-trained language models (PLMs) such as BERT (Devlin et al., 2019) and T5 (Raffel et al., 2020) have achieved remarkable performance in various NLP downstream tasks. However, these PLMs suffer from lacking domain-specific knowledge when completing many real-world tasks (Yu et al., 2022c). For example, BERT cannot give full play to its value when dealing with electronic medical record analysis tasks in the medical field (Liu et al., 2020). A lot of efforts have been made on investigating how to integrate knowledge into PLMs (Yu et al., 2022b; Liu et al., 2021; Xiong et al., 2020; Guan et al., 2020; Zhou et al., 2021; Yu et al., 2022a,d). Overall, these approaches can be grouped into two categories: The first one is to explicitly inject knowledge representation into PLMs, where the representations are pre-computed from external sources (Zhang et al., 2019; Liu et al., 2021). However, it has been argued that the embedding vectors of input words and knowledge are obtained in separate ways, making their vector-space inconsistent (Liu et al., 2020). The second one is to implicitly model knowledge information into PLMs by performing knowledge-related tasks, such as concept order recovering (Zhou et al., 2021), entity category prediction (Yu et al., 2022b). However, none of existing work has explored using dictionary to enhance language model pre-training.

3 Proposed Method

In this section, we introduce the details of our model Dict-BERT. We first describe the notations and how to incorporate rare word definitions as a part of input. Then we detail the two novel self-supervised pre-training objectives. Finally, we introduce the knowledge attention during fine-tuning.

3.1 Notation and Problem Definition

Given the input text sequence $X = [\text{CLS}, x_1, x_2, \cdots, x_L, \text{SEP}]$ with L tokens, a language model f_{LM} produces the contextual word representation $f_{LM}(X) = [h_{\text{CLS}}, h_1, h_2, \cdots, h_L, h_{\text{SEP}}]$. For a specific downstream task, a header function f_H further uses $f_{LM}(X)$ and generates the prediction as $f_H(h_{\text{CLS}})$ for sequence classification tasks.

The goal of our work is to learn better contextual word representation $f_{LM}(x)$ by leveraging definitions of the rare words in dictionaries (e.g., Wiktionary). Suppose $S = [s_1, \cdots, s_K]$ and $C = [c^{(1)}, \cdots, c^{(K)}]$ are the sets of rare words in the input text sequence X and their definitions in the dictionary. When a rare word s_i appears in the input text sequence, we fetch its definition from the dictionary as $c^{(i)} = [c_1^{(i)}, \cdots, c_{N_i}^{(i)}]$ with N_i tokens, and append it to the end of the input text sequence. If a word has multiple definitions, we use the definition of their first etymology (i.e., the most commonly used meaning). Therefore, an input sequence X with appended definitions of K rare words can be written as: $[\text{X}; \text{C}] = [\text{CLS}, x_1, x_2, ..., x_L, \text{SEP}^{(1)}, c_1^{(1)}, c_2^{(1)}, ..., c_{N_1}^{(1)}; ...; \text{SEP}^{(K)}, c_1^{(K)}, c_2^{(K)}, ..., c_{N_K}^{(K)}, \text{SEP}]$, and the corresponding contextual representation generated from the language model f_{LM} as: $f_{LM}(\text{X}, \text{C}) = [h_{\text{CLS}}, h_1, h_2, \cdots, h_L, h_{\text{SEP}}^{(1)}, h_1^{(1)}, \cdots, h_{N_1}^{(1)}; \cdots\cdots; h_{\text{SEP}}^{(K)}, h_1^{(K)}, \cdots, h_{N_K}^{(K)}, h_{\text{SEP}}]$. For a specific downstream task, a header function f_H still uses $f_{LM}(\text{X}, \text{C})$ to generate the prediction as $f_H(h_{\text{CLS}})$ for sequence classification tasks.

3.2 Choosing the Rare Words

There are different ways to choose the rare word set S in a pre-training corpus. One way is to use a pre-defined absolute frequency value as the threshold. Wu et al. (2021) used 500 as the threshold to divide frequent words and rare words, and maintained a fixed vocabulary of rare words during pre-training and fine-tuning. However, rare words can vary greatly in different corpora. For example, rare words in the medical domain are very different from those in general domain (Lee et al., 2020). Besides, keeping a large threshold for a small downstream datasets makes the vocabulary of rare words too large. For example, only 51 words in the RTE dataset have a frequency of more than 500.

Therefore, we propose to choose specialized rare words for each pre-training corpus and downstream tasks. Specifically, we ranked all word frequency from smallest to largest, and add them to the list one by one until the word frequency of the added word reaches 10% of the total word frequency. Compared with Wu et al. (2021) which maintained a fixed vocabulary, our method can dynamically adjust the vocabulary of rare words, obtain and represent their definitions in dictionary in a plug-and-play manner. To fetch the definition of rare words, we leveraged the largest online dictionary, i.e., Wiktionary, and collected a dump of Wiktionary which includes definitions of 999,614 concepts.

We noted that when choosing the rare words, we used a word tokenizer (i.e., NLTK) instead of using any subword tokenizer (e.g., WordPiece). This is mainly because quite a few rare subwords, either generated by BPE or in WordPiece, do not have specific understandable semantic meanings to humans, such as “123@@”, “elids”, “al”, “ch”, “di”. For such subwords, their contexts can be very diverse due to their vague semantic meanings. As most rare words have their own concrete semantics, the subword meanings cannot act as effective auxiliary semantics to enhance the current input.

3.3 Dict-BERT: Language Model Pre-training with Dictionary

Dict-BERT is based on the BERT architecture, which can be initialized either randomly or from a pre-trained checkpoint with the same structure. It is worth noting that we slightly modified the type embedding, in which the type embedding of the input text is set as 0, and the type embedding of the dictionary definitions is set as 1. In addition, we used the absolute positional embedding.

We represent each input text sequence and dictionary definitions pair as a tuple (X, C). The semantics of a word in the input text depends on the current context, while the semantics of a word in the dictionary is standardized by linguistic experts. In order to better align the representations between them, we propose two novel pre-training tasks on word-level and sentence-level alignment between input text sequence and rare word definitions to enhance pre-trained language models with dictionary.

3.3.1 Word-level Mutual Information Maximization

Recently, there has been a revival of approaches inspired by the InfoMax principle (Oord et al., 2018; Tschannen et al., 2020): maximizing the mutual

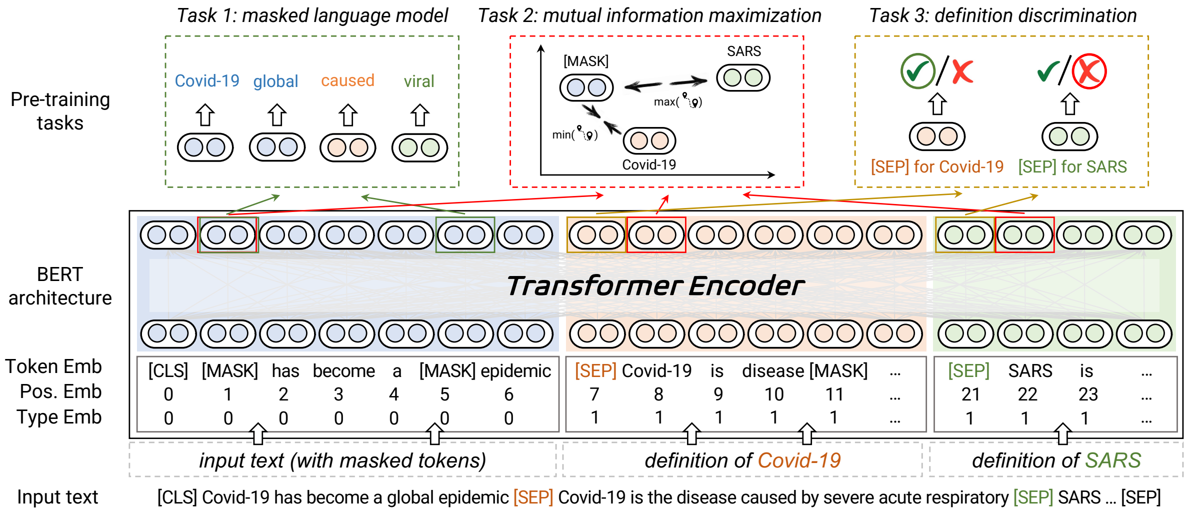

Figure 1: The overall architecture of Dict-BERT. The definitions of rare words are appended to the end of input text. In additional to training with masked language modeling, Dict-BERT performs two novel self-supervised learning tasks: word-level mutual information maximization (§3.3.1) and sentence-level definition discrimination (§3.3.2).

information (MI) between the input and its representation. MI measures the amount of information obtained about a random variable by observing another random variable. As the input text sequence and rare word definitions are obtained from different sources, in order to better align their semantic representations, we proposed to maximize the MI between a rare word x_i in the input sequence and its well-defined meaning in the dictionary $c^{(i)}$, with joint density $p(x_i, c^{(i)})$ and marginal densities $p(x_i)$ and $p(c^{(i)})$, is defined as the Kullback–Leibler (KL) divergence between the joint and the product of the marginals,

$$I(x_i; c^{(i)}) = D_{KL}\big(p(x_i, c^{(i)}) || p(x_i)p(c^{(i)})\big) \quad (1)$$

The intuition of maximizing mutual information between a rare word appeared in the input text sequence and its definitions in the dictionary is to encode the underlying shared information and align the semantic representation between the contextual meaning and well-defined meaning of a word. Nevertheless, estimating MI in high-dimensional spaces is a notoriously difficult task, and in practice one often maximizes a tractable lower bound on this quantity (Poole et al., 2019). Intuitively, if a classifier can accurately distinguish between samples drawn from the joint $p(x_i, c^{(i)})$ and those drawn from the product of marginals $p(x_i)p(c^{(i)})$, then x_i and $c^{(i)}$ have a high mutual information.

In order to approximate the mutual information, we adopted InfoNCE (Oord et al., 2018), which is one of the most commonly used estimators in the representation learning literature, defined as

$$I(x_i; c^{(i)}) \geq \mathbb{E}\Big[\sum_{i=1}^{K} \log \frac{e^{f_{\mathrm{MI}}(h_i, h^{(i)})}}{\sum_{j=1}^{K} \mathbb{1}_{[j \neq i]} e^{f_{\mathrm{MI}}(h_i, h^{(j)})}}\Big]$$
$$\triangleq I_{NCE}(x_i; c^{(i)}), \quad (2)$$

where the expectation is over K independent samples $\{(h_i, h^{(i)})\}_{i=1}^{K}$ from the joint distribution $p(x_i, c^{(i)})$ (Poole et al., 2019). Intuitively, the critic function $f_{\mathrm{MI}}(\cdot)$ measures the similarity (e.g., inner product) between two word representations. The model should assign high values to the positive pair $(h_i, h^{(i)})$, and low values to all negative pairs. We compute InfoNCE using Monte Carlo estimation by averaging over multiple batches of samples (Chen et al., 2020). By maximizing the mutual information between the encoded representations, we extract the underlying latent variables that the rare words in the input text sequence and their dictionary definitions have in common.

3.3.2 Sentence-level Definition Discrimination

Instead of locally aligning the semantic representation, learning to differentiate between correct and polluted word definitions helps the language model capture global information of input text and dictionary definitions. We denote the set of definitions of rare words in the input text as C. We then create a set of "polluted" word that are randomly sampled from the entire vocabulary together with its definition. The number of sampled "polluted" words is equal to the number of rare words appeared in the

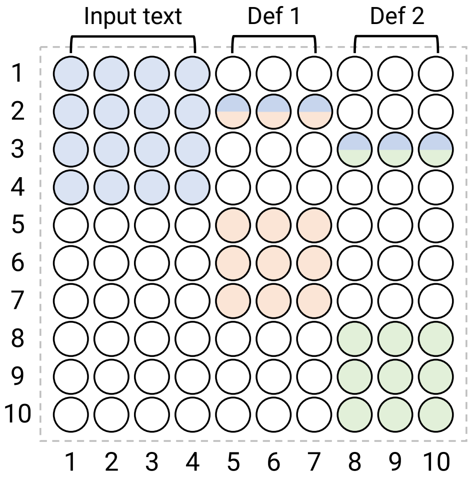

Figure 2: An illustration of knowledge-visible attention matrix. "Def 1" is the dictionary definition of the second word in the input text, and "Def 2" is the definition of the third word in the input text. Colored circle means token i can attend information from token j, while white circle means no attention from token i to token j.

input text sequence.

$$\mathcal{L}_{\text{DD}} = -\mathbb{E}\sum_{i=1}^{K} \log p(y|f_{\text{MLP}}(h_{\text{SEP}}^{(i)}). \tag{3}$$

3.3.3 Overall objective.

Now we present the overall training objective of Dict-BERT. To avoid catastrophic forgetting (McCloskey and Cohen, 1989) of general language understanding ability, we train the masked language modeling together with word-level mutual information maximization (MIM) and definition discrimination (DD) tasks. We denote $\mathcal{L}_{\text{MIM}}$ as the loss function of the MIM task which is the opposite of expectation in Equation 2. Hence, the overall learning objective is formulated as:

$$\mathcal{L} = \mathcal{L}_{\text{MLM}} + \lambda_1 \mathcal{L}_{\text{MIM}} + \lambda_2 \mathcal{L}_{\text{DD}} \tag{4}$$

where λ_1, λ_2 are introduced as hyperparameters to control the importance of each task.

3.4 Dict-BERT: Fine-tuning with Knowledge-visible Attention

Most existing work uses the final hidden state of the first token (i.e., the [CLS] token) as the sequence representation (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019). For a sequence classification task, a multi-layer perception network function f_H takes the output of f_{LM} as input and generates the prediction as $f_H(h_{\text{CLS}})$. Notably, when fine-tuning a language model on downstream tasks, there could be many rare/unseen words in the dataset. So, in the fine-tuning stage, when encountering a rare word in the input text, we append its definition to the end of input text, just like what we did in pre-training.

However, the appended dictionary definitions may change the meaning of the original sentence since the [CLS] token attend information from both input text and dictionary description. As pointed in Liu et al. (2020) and Xu et al. (2021), too much knowledge incorporation may divert the sentence from its original meaning by introducing a lot of noise. This is more likely to happen if there are multiple rare words in the input text. To address this issue, we adopt the visibility matrix (Liu et al., 2020) to limit the impact of definitions on the original text. In BERT, an attention mask matrix is added with the self-attention weights before softmax. If token j is not supposed to be visible to token i, we add a -∞ value in the attention matrix (i, j).

As shown in Figure 2, we modify the attention mask matrix such that a token i can attend to another token j only if: (1) both tokens belong to the input text sequence, or (2) both tokens belong to the definition of the same rare word, or (3) i is a rare word in the input text sequence and j is from its definition in the dictionary.

4 Experiments

4.1 Tasks and Datasets

To show the wide adaptability of our Dict-BERT, we conducted experiments on 16 NLP benchmark datasets. We use BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) as the backbone pretrained language methods. First, we followed Liu et al. (2019) and Wu et al. (2021) to use 8 natural language understanding tasks in GLUE, including CoLA, RTE, MRPC, STS, SST, QNLI, QQP, and MNLI. Second, we followed Gururangan et al. (2020) to use 8 specialized domain tasks, including Chemprot, RCT-20k, ACL-ARC, SciERC, HyperPartisan, AGNews, Helpfulness, IMDB.

4.2 Rare Word Collection

Here, we briefly introduce the statistic of rare words in BERT pre-training corpus: English Wikipedia and BookCorpus. By concatenating these two datasets, we obtained a corpus with roughly 16GB in size. The total number of unique words in the pre-training corpus is 504,812, of which 112,750 (22.33%) words are defined as frequent words. In other words, the sum of the occurrences of

Table 1: Performance of different models on GLUE tasks. Each configuration is run five times with different random seeds, and the average of these five results on the validation set is reported in the table. *We note that* our code is implemented on Huggingface Transformer (Wolf et al., 2020). The performance of our implemented BERT is consistent with the official performance, but it is slightly lower than the performance reported by Wu et al. (2021). We reported the relative improvement (Δ) of BERT-TNF and Dict-BERT compared with the original BERT.

these 112,750 words in the corpus accounts for 90% of the occurrences of all words in the corpus. We look up definitions of the remaining 392,062 (77.67%) words in the Wiktionary, of which 252,581 (64.42%) can be found. The average length of definition is $11.51_{\pm 6.84}$ words.

4.3 Pre-training Corpus and Tasks

Experiments on the GLUE benchmark. The language model is first pre-trained on the general domain corpus, and then fine-tuned on the training set of different GLUE tasks. Following BERT (Devlin et al., 2019), we used the English Wikipedia and BookCorpus as the pre-training corpus. We removed the next sentence prediction (NSP) as suggested in RoBERTa (Liu et al., 2019), and kept masked language modeling (MLM) as the objective for pre-training a vanilla BERT.

Experiments on specialized domain datasets. The language model is not only pre-trained on the general domain corpus, but also pre-trained on domain specific corpus before fine-tuned on domain specific tasks. We initialized our model with the checkpoint from pre-trained BERT/RoBERTa and continue to pre-train on domain-specific corpus (Gururangan et al., 2020). The four domains we focus on are biomedical science (BIOMED), computer science (S2ORC-CS), news text (REALNEWS), and e-commerce reviews (AMAZON).

4.4 Baseline Methods

Vanilla BERT/RoBERTa. We use the off-the-shelf BERT-base (Devlin et al., 2019) and RoBERTa-base (Liu et al., 2019) model and perform supervised fine-tuning for each downstream tasks.

BERT-DAPT/RoBERTa-DAPT. It continues pre-training BERT/RoBERTa on a large unlabeled domain-specific corpus (e.g., BioMed, RealNews) by MLM objective (Gururangan et al., 2020).

BERT-TNF. It takes notes for rare words on the fly during pre-training to help the model understand them when they occur next time. Specifically, it maintains a note dictionary and saves a rare word's contextual information in it as notes when the rare word occurs in a sentence (Wu et al., 2021).

4.5 Implementation Details

We introduce our pre-training and fine-tuning details and hyperparameter choices in Appendix A.2 to A.4. We also listed several detail discussions about using Wiktioanry in Appendix A.6.

4.6 Ablation Settings

Dict-BERT-F means that we load the vanilla BERT checkpoint and fine-tune on the downstream tasks by using knowledge attention for dictionary.

Dict-BERT-P means that we only leverage dictionary in the pre-training stage and fine-tune Dict-BERT on downstream tasks without dictionary.

Dict-BERT-PF indicates that we use dictionary in both pre-training and fine-tuning stages.

Furthermore, Dict-BERT w/o MIM removes the word-level mutual information maximization task and Dict-BERT w/o DD removes the sentence-level definition discriminative task during pre-training.

4.7 Experimental Results

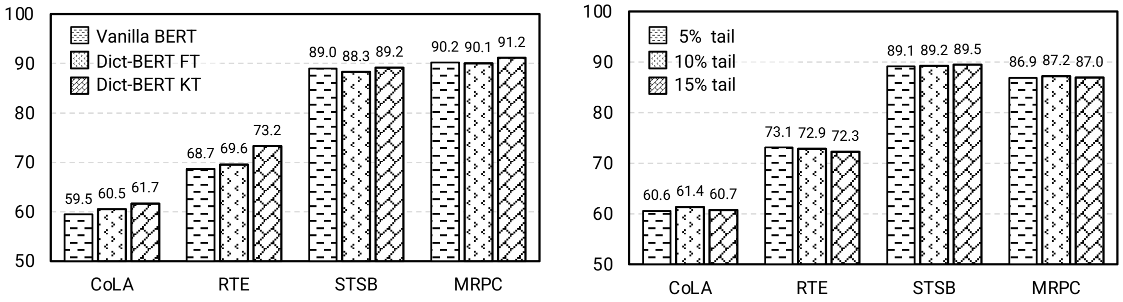
Dict-BERT-F v.s. BERT. As shown in Table 1, comparing the vanilla BERT with Dict-BERT-F, we observed that only using dictionary during fine-tuning could even hurt the model performance on the GLUE benchmark, especially on those small datasets (e.g., RTE, MRPC). This indicated the existing pre-trained language models cannot better understand the input sequence by using word definitions when not pre-trained with dictionary. They might be even misled by the noisy explanations in the dictionary. Thus, it is important to incorporate dictionary into language model pre-training so the dictionary definitions can be better utilized.

Dict-BERT-PF v.s. BERT. As shown in Table 1, Dict-BERT-PF outperformed the vanilla BERT on the GLUE benchmark by improving +1.15% accuracy on average. This indicated leveraging word definitions in dictionary can improve language model pre-training and boost performance on various NLP downstream tasks. On RTE, Dict-BERT-P obtained the biggest performance improvement compared with the vanilla BERT. On another small-data sub-tasks CoLA, Dict-BERT-PF also outperformed the baseline with considerable margins. This indicated when Dict-BERT was fine-tuned on a small downstream dataset, the improvement was particularly significant. Besides, as shown in Table 2, Dict-BERT-DAPT outperformed BERT-DAPT on the specialized domain datasets by improving +0.68% F1 on average. The same observation was obtained from the RoBERTa setting.

Dict-BERT-PF v.s. Dict-BERT-P. As shown in Table 1, we compared model performance between using dictionary in fine-tuning (i.e., Dict-BERT-PF) and not using dictionary in fine-tuning (i.e., Dict-BERT-P). First, after pre-training the language model with dictionary, even without using dictionary in fine-tuning, the performance has been greatly improved. This indicated pre-training language model with dictionary generally improved the language representation and provided better initiation before fine-tuning the language model on the downstream tasks. Besides, we also observed the performance of Dict-BERT-PF performed slightly better than Dict-BERT-P. We hypothesized the reason behind can be the distribution discrepancy of the pre-training and fine-tuning data.

Ablation study. As shown in Table 1 and Table 2, we conducted ablation study on both GLUE benchmark and specialized domain datasets. First, both MIM and DD helped learn knowledge from dictionary and improve language model pre-training. Specifically, DD demonstrated larger average improvement than MIM. The average improvements on GLUE benchmark brought by DD and MIM are +0.63% and +0.52%. Second, combining MIM and DD together achieved the highest performance on the GLUE benchmark, in which the average gain enlarges to +1.15%. For specialized domain datasets, we had the same observations as above.

Knowledge attention v.s. Full attention. As we mentioned in the Section 3.4, too much knowledge incorporation may divert the sentence from its original meaning by introducing some noise. This is



(a) Full attn. (FT) v.s. Knowledge attn. (KT) (b) Rare word ratios (5% v.s. 10% v.s. 15%)

Figure 3: Model performance on CoLA, RTE, STSB and MRPC when (a) using two different attention mechanisms and (b) selecting different rare word ratios on the downstream task datasets during fine-tuning.

more likely to happen if there are multiple rare words appeared in the input text. Therefore, we compared the model performance between using knowledge attention and full attention. As shown in Figure 3(a), we observed that using knowledge attention can consistently perform better than using full attention mechanism during the fine-tuning stage on CoLA, RTE, STSB and MRPC datasets. Besides, Dict-BERT with full attention even underperformed than the vanilla BERT without using any dictionary definition, which indicates the appended description in the dictionary may change the meaning of the original sentence. For example, STSB compares similarity between two sentence. Using full attention includes semantic meanings of definitions into the sentence representation, which might reduce the sentence similarity score and hurt the model performance.

Learning with different rare word ratios. As we mentioned in Section 3.2, we select rare words for each downstream tasks by truncating the tail distribution of the word frequency. In order to verify the impact of using different tail proportions of rare words on the downstream tasks, we selected three different ratios (i.e., 5%, 10%, and 15%) and experimented on CoLA, RTE, STSB and MRPC datasets. As shown in Figure 3(b), on the CoLA and STSB datasets, the model achieves the best performance when using 10% words at the tail as rare words. On the MRPC data, there is no significant difference of model performance in using different proportions of rare words. However, the performance on RTE data demonstrates a trend, that is, the more rare words selected, the worse the performance of the model. This is consistent with the conclusion of whether the dictionary is used in fine-tuning in Table 1, i.e., the performance of not using dictionary is better than using dictionary on the RTE dataset. Thus, the selection of rare words with different tails has no obvious correlation with the performance of the model on downstream tasks.

Table 3: Performance of different models on WNLaMPro test set, subdivided by word frequency.

Methods	RARE (0, 10)			FREQUENT (100, +∞)		
	MRR	P@3	p@10	MRR	P@3	p@10
BERT (base)	0.117	0.053	0.036	0.356	0.179	0.116
Dict-BERT	**0.145**	**0.068**	**0.041**	**0.359**	**0.181**	**0.117**
⊢ w/o MIM	0.144	0.067	**0.041**	0.357	0.180	0.115
⊢ w/o DD	0.141	0.065	0.040	0.355	0.179	0.116

Unsupervised language model probing. In order to assess the ability of language models to understand words as a function of their frequency, we used WordNet Language Model Probing (WNLaMPro) dataset (Schick and Schütze, 2020) to test how well a language model understands a given word: we can ask it for properties of that word using natural language. For example, a language model that understands the concept of "guilt", should be able to correctly complete the sentence "Guilt is the opposite of ___" with the word "innocence". WNLaMPro contains four different kinds of relations: antonym, hypernym, cohyponym+, and corruption. Based on the word frequency in English Wikipedia, WNLaMPro defines three subsets based on keyword counts: RARE $(0, 10)$, MEDIUM $(10, 100)$, and FREQUENT $(100, +\infty)$. As shown in Table 3, Dict-BERT can greatly improve the word representation compared with the vanilla BERT without using a dictionary during pre-training. Based on the word frequency, we observe Dict-BERT can significantly help learn rare word representations. Compared to the vanilla BERT, Dict-BERT improves MRR and P@3 by relatively +23.93% and +28.30%, respectively. In addition, Dict-BERT is also able to learn better frequent word representations. Although we did not directly take frequent word definitions as part of the input, Dict-BERT spends less memory on rare words, because it is easier to predict rare words than the vanilla BERT, so the saved memory power could be used to memorize the facts involving popular words and interactions between popular words.

5 Conclusions

In this work, we leveraged rare word definitions in English dictionary to improve language model pre-training. When encountering a rare word in the input text during pre-training, we fetched its definition from Wiktionary and appended it to the end of the input text. In order to make better interactions between the input text and rare word definitions, we proposed two novel self-supervised training tasks to help language model learn better representations for rare words. Experimental on the GLUE benchmark and eight specialized domain datasets demonstrated that our method significantly improved the understanding of rare words and boosted model performance on various downstream tasks.

A Appendix

A.1 Preliminary: BERT Pre-training

We use the BERT (Devlin et al., 2019) model as an example to introduce the basics of the model architecture and training objective of PLMs. BERT is developed on a multi-layer bidirectional Transformer (Vaswani et al., 2017) encoder. The Transformer encoder is a stack of multiple identical layers, where each layer has two sub-layers: a self-attention sub-layer and a position-wise feed-forward sub-layer. The self-attention sub-layer produces outputs by calculating the scaled dot products of queries and keys as the coefficients of the values,

$$\text{Attention}(Q, K, V) = \text{Softmax}(\frac{QK^T}{\sqrt{d}})V. \quad (5)$$

Q(Query), K(Key), V(Value) are the hidden representations produced by the previous self-attention layer and d is the dimension of the hiddens. Transformer also extends the aforementioned self-attention layer to a multi-head self-attention layer version in order to jointly attend to information from different representation subspaces.

BERT uses the Transformer model as its backbone neural network architecture and trains the model parameters with the masked language modeling (MLM) objective on large text corpora. In the masked language modeling task, a random sample of the words in the input text sequence is selected. The selected positions will be either replaced by special token [MASK], replaced by randomly picked tokens or remain the same. The objective of masked language modeling is to predict words at the masked positions correctly given the masked sentences. RoBERTa (robustly optimized BERT approach) is a retraining of BERT with improved training methodologies, 1000% more data (i.e., 160 GB) and computation power (i.e., 1024 V100 GPUs). To improve the training procedure, RoBERTa introduces dynamic masking so that the masked token changes during the training epochs. Larger batch-training sizes were also found to be more useful in the training procedure.

A.2 BERT Pre-training Details

We conducted experiments on pre-training BERT-base with 110M parameters (Devlin et al., 2019). BERT-base consists of 12 Transformer layers. For each layer, the hidden size is set to 768 and the number of attention head is set to 12. All models (including BERT-base and Dict-BERT-base) are pre-trained for 300k steps with batch size 2,000 and maximum sequence length 512. We use Adam (Kingma and Ba, 2015) as the optimizer, and set its hyperparameter ϵ to $1e$-6 and (β_1, β_2) to $(0.9, 0.98)$. The peak learning rate is set to $7e$-4 with a 10k-step warm-up stage. We set the dropout probability to 0.1 and weight decay to 0.01. All configurations are reported in Table 4.

A.3 Domain Adaptive Pre-training Details

We conducted experiments on domain adaptive pre-training (DAPT) of BERT-base and RoBERTa-base. RoBERTa (Liu et al., 2019) is a retraining of BERT with improved training methodologies, 1000% more data (i.e., 160 GB) and computation power (i.e., 1024 V100 GPUs). To improve the training procedure, RoBERTa removes the next sentence prediction task from BERT's pre-training and introduces dynamic masking so that the masked token changes during the training epochs. To train the models, we followed (Gururangan et al., 2020) and domain adaptive pre-training for 12.5k steps with batch size 2,000. All other configurations are reported in Table 4.

A.4 Fine-tuning Details

Following previous work, we search the learning rates during the fine-tuning for each downstream task. The details are listed in Table 5. Each configuration is run five times with different random seeds, and the average of these five results on the validation set is calculated as the final performance of one configuration. We report the best number over all configurations for each task.

A.5 Evaluation Metrics

For GLUE, we followed RoBERTa (Liu et al., 2019) and reported Matthews correlation for CoLA, Pearson correlation for STS-B, and Accuracy for other tasks. For specialized tasks, we followed (Gururangan et al., 2020) and reported Micro-F1 for Chemprot and RCT-20k, and Macro-F1 for other tasks. For WNLaMPro, we followed (Schick and Schütze, 2020) and reported MRR and P@K.

A.6 Usage of Wiktionary

Polysemy in Wiktionary. There are plenty of English words having multiple meanings (aka. polysemy). If multiple meanings of a word are appended to the input text sequence simultaneously,

Table 4: Hyperparameters for model pre-training and domain-adaptive pre-training (DAPT).

Hyperparameter	Assignments	
Pre-training setting	BERT pre-training	Domain adaptive pre-training
number of steps	300K	12.5K
batch size	2,000	2,000
maximum learning rate	7e-4	1e-4
learning rate optimizer	Adam	Adam
Adam epsilon	1e-6	1e-6
Adam beta weights	0.9, 0.98	0.9, 0.98
Weight decay	0.01	0.01
Warmup proportion	0.06	0.06
learning rate decay	linear	linear

Table 5: Hyperparameters for model fine-tuning on GLUE and specialized domain benchmarks.

Hyperparameter	Assignments	
Fine-tuning setting	GLUE benchmark	Specialized domain
number of epochs	5 or 10	10
batch size	24 or 168	168
learning rate	2e-5	2e-5 or 3e-5
learning rate optimizer	Adam	Adam
Adam epsilon	1e-6	1e-6
Adam beta weights	0.9, 0.98	0.9, 0.98
Dropout	0.1	0.1
Weight decay	0.01	0.01
learning rate decay	linear	linear

it may bring noisy information and disrupt the training of the entire language model.

In this work, we did not pay particular attention to the polysemy issue, because for most rare words, they often only have one meaning in the dictionary. For example, as mentioned in Section 4.2, there are a total of 252,581 rare words in the BERT pre-training corpus (i.e., Bookcorpus and Wikipedia). Among them, 228,658 (90.52%) words only have one meaning, and 21,721 (8.6%) words have two meanings. So, words less than three meanings account for more than 99% of words. To deal with the words having more than one meaning, we use the definition of their first etymology, i.e., the most commonly used meaning, in the Wiktionary.

Rare words during fine-tuning. One important advantage of Dict-BERT is that it can dynamically adjust the vocabulary of rare words, obtain and represent their definitions in a dictionary in a plug-and-play manner. As different domain datasets usually follow different word distributions, the pre-trained language model may still encounter many rare words when fine-tuned on the downstream tasks. To enhance the rare word representations during fine-tuning process, when encountering a rare word in the input text sequence, we append its definition to the end of input text sequence, just like what we did in pre-training.

Negative words sampling. The sentence-level definition discrimination task samples negative word for each input text sequence with rare words. In order to select harder negative words, we explored using the negative words with similar GloVe (Pennington et al., 2014) embeddings or taking the synonyms of rare words provided in the dictionary as negative samples. However, either of the two methods has the problem of extremely low coverage. Most of the rare words are not appeared in GloVe, and only about 10% of the words have synonyms in the Wiktionary. Thus, we chose to use the random negative sampling strategy.

A Feasibility Study of Answer-Agnostic Question Generation for Education

Abstract

We conduct a feasibility study into the applicability of *answer-agnostic* question generation models to textbook passages. We show that a significant portion of errors in such systems arise from asking irrelevant or uninterpretable questions and that such errors can be ameliorated by providing summarized input. We find that giving these models human-written summaries instead of the original text results in a significant increase in acceptability of generated questions (33% → 83%) as determined by expert annotators. We also find that, in the absence of human-written summaries, automatic summarization can serve as a good middle ground.

1 Introduction

Writing good questions that target salient concepts is difficult and time consuming. Automatic Question Generation (QG) is a powerful tool that could be used to significantly lessen the amount of time it takes to write such questions. A QG system that automatically generates relevant questions from textbooks would help professors write quizzes faster and help students stay engaged when reviewing course material.

Previous work on QG has focused primarily on answer-aware QG models. These models require the explicit selection of an answer span in the input context, typically through the usage of highlight tokens. This adds significant overhead to the question generation process and is undesirable in cases where clear lists of salient key terms are unavailable. We conduct a feasibility study[1] on the application of *answer-agnostic* question generation models (ones which do not require manual selection of answer spans) to an educational context. Our contributions are as follows:

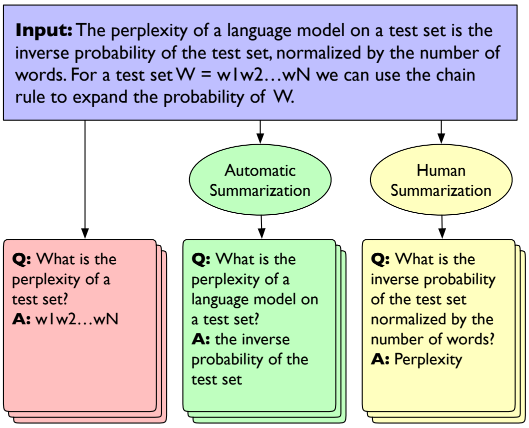

Figure 1: Relevance, interpretability, and acceptability of generated questions are significantly improved when using human-written summaries (yellow) or automatically-generated summaries (green) as input instead of the original text (red).

- We show that the primary way answer-agnostic QG models fail is by generating irrelevant or uninterpretable questions.
- We show that giving answer-agnostic QG models human-written summaries instead of the original text results in significant increases in question acceptability (33% → 83%), relevance (61% → 95%), and in-context interpretability (56% → 94%).
- We show that, in absence of human-written summaries, providing automatically generated summaries as input is a good alternative.

2 Related Work & Background

Early attempts to use QG for educational applications involved generating gap-fill or "cloze" questions[2] (Taylor, 1953) from textbooks (Agarwal and Mannem, 2011). This procedure has been shown to be effective in classroom settings (Zavala and Mendoza, 2018) and students' scores on this style

---

[2] For example, Q: "Dynamic Programming was introduced in ____" A: 1957

Findings of the Association for Computational Linguistics: ACL 2022, pages 1919 - 1926
May 22-27, 2022 ©2022 Association for Computational Linguistics

of generated question correlate positively with their scores on human-written questions (Guo et al., 2016). However, there are many situations where gap-fill questions are not effective, as they are only able to ask about specific unambiguous key terms.

In recent years, with the advent of large crowd-sourced datasets for extractive question answering (QA) such as SQuAD (Rajpurkar et al., 2018), neural models have become the primary methods of choice for generating traditional interrogative style questions (Kurdi et al., 2019). A common task formulation for neural QG is to phrase the task as *answer-aware*, that is, given a context passage $C = \{c_0, ..., c_n\}$ and an answer span within this context $A = \{c_k, ..., c_{k+l}\}$, train a model to maximize $P(Q|A, C)$ where $Q = \{q_0, ..., q_m\}$ are the tokens in the question. These models are typically evaluated using n-gram overlap metrics such as BLEU/ROUGE/METEOR (Papineni et al., 2002; Lin, 2004; Banerjee and Lavie, 2005) with the reference being the original human-authored question as provided by the extractive QA dataset.

The feasibility of using *answer-aware* neural QG in an educational setting was investigated by Wang et al. (2018), who used a BiLSTM encoder (Zhang et al., 2015) to encode C and A and a unidirectional LSTM decoder to generate Q. They trained on the SQuAD dataset (Rajpurkar et al., 2018) and evaluated on textbooks from various domains (history, biology, etc.). They showed that generated questions were largely grammatical, relevant, and had high n-gram overlap with human-authored questions. However, given that we may not always have a list of key terms to use as answer spans for an input passage, there is a desire to move past *answer-aware* QG models and evaluate the feasibility of *answer-agnostic* models for use in education.

Shifting to answer-agnostic models creates new challenges. As Vanderwende (2008) claims, the task of deciding what is and is not important is, itself, an important task. Without manually selected answer spans to guide it, an *answer-agnostic* model must itself decide what is and is not important enough to ask a question about. This is typically done by separately modeling $P(A|C)$, i.e., which spans in the input context are most likely to be used as answer targets for questions. The extracted answer spans are then given to an answer-aware QG model $P(Q|A, C)$. This modeling choice allows for more controllable QG and more direct modeling of term salience.

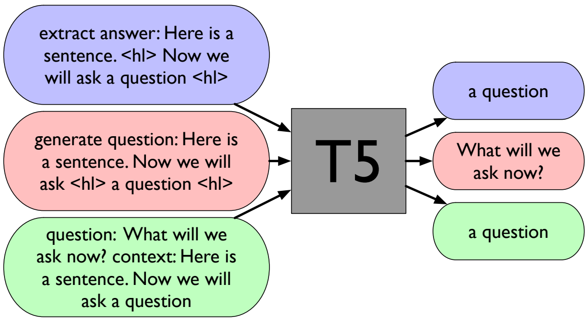

Figure 2: Diagram of the model's three different fine-tuning tasks: Answer extraction, question generation, and question answering

Previous work done by Subramanian et al. (2018) trained a BiLSTM Pointer Network (Vinyals et al., 2015) for this answer extraction task and showed that it outperformed an entity-based baseline when predicting answer spans from SQuAD passages. However, their human evaluation centered around question correctness and fluency rather than relevance of answer selection. Similar follow-up studies also fail to explicitly ask annotators whether or not the extracted answers, and subsequent generated questions, were relevant to the broader topic of the context passage (Willis et al., 2019; Cui et al., 2021; Wang et al., 2019; Du and Cardie, 2018; Alberti et al., 2019; Back et al., 2021).

In our study, we explicitly ask annotators to determine whether or not a generated question is relevant to the topic of the textbook chapter from which it is generated. In addition, we show that models trained for answer extraction on SQuAD frequently select irrelevant or ambiguous answers when applied to textbook material. We show that summaries of input passages can be used instead of the original text to aid in the modeling of topic salience and that questions generated from human-written and automatically-generated summaries are more relevant, interpretable, and acceptable.

3 Methodology

To perform answer-agnostic QG, we follow work done by Dong et al. (2019) and Bao et al. (2020) who show that language models, when fine-tuned for both QA and QG, perform better than models tuned for only one of those tasks. We assume that answer extraction will aid both QA and QG and thus use a model that was fine-tuned on all three. We considered using UniLM (Bao et al., 2020) or ProphetNet (Qi et al., 2020) but ultimately chose a T5 language model (Raffel et al., 2020) fine-tuned

	Key-Term Coverage (§5)	Total # Sents	Avg. Sent Length
A1's Summary	77.6%	279	17.56
A2's Summary	80.7%	243	19.28
A3's Summary	53.4%	148	15.37

Table 1: Analysis of summaries written by our three RAs. Key-Term Coverage is percentage of bolded textbook key terms present in the summary. Average sentence length reported in tokens (space-delimited).

on SQuAD due to the clean separation between tasks afforded by T5's task-specific prefixes such as "generate question:" and "extract answer:".[3]

The three fine-tuning tasks that were used to train the model we used are illustrated in Figure 2. For question generation, the model is trained to perform *answer-aware* question generation by modeling $P(Q|A,C)$. For question answering, the model is trained to perform extractive QA by modeling $P(A|C,Q)$. Finally, for answer extraction, instead of modeling $P(A|C)$, the model is trained to model $P(A|C')$ with $C' = \{c_0, ..., c_s, ..., c_e, ..., c_{n+2}\}$ where c_s and c_e are highlight tokens that denote the start and end of the sentence within which we want to extract an answer span.

To generate questions, we iteratively highlight the start and end of each sentence in a given passage and extract at most one answer span per sentence.[4] We then generate one question per extracted answer span using the same model in an answer-aware fashion. Passages longer than 512 tokens are split such that no sentences are divided between sub-passages and all sub-passages have a roughly equal number of sentences.

4 Experiments

Our first experiment evaluates the performance of the model on the original text extracted from Jurafsky and Martin (2020)'s textbook "Speech and Language Processing 3rd Edition."[5] To ensure proper comparison, we manually extracted the text from our three chapters of interest (Chapters 2, 3, and 4). When extracting text, all figures, tables, and equations were omitted and all references to them were either replaced with appropriate parenthetical citations or removed when possible. In total, we generated 1208 question-answer pairs from the original text.

Our second experiment evaluates the performance of the model on human-written summaries. We recruited three research assistants (RAs) as part of an undergraduate research experience to write abstractive summaries for each subsection of the same three chapters of the textbook.[6] They were encouraged to make their summaries easily readable by humans rather than to be easily understandable by machines but otherwise no specific guidelines were given. We report some statistics about these summaries in Table 1 and include examples in Appendix E. From these three sets of summaries we generated a total of 667 question-answer pairs.

Our final experiment evaluates the performance of the model on automatically generated summaries. To perform this automatic summarization we used a BART (Lewis et al., 2020) language model which was fine-tuned for summarization on the CNN/DailyMail dataset (Nallapati et al., 2016).[7] The same chunking procedure as described in Section 3 was performed on input passages that were larger than 512 tokens. The summarized output sub-passages were then concatenated together before running question generation. In total, we generated 318 question-answer pairs from our automatic summaries.

5 Evaluation

For evaluation, we randomly sampled 100 question-answer pairs from each of the three experiments to construct our evaluation set of 300 questions. We tasked the same set of RAs to evaluate the quality of the question-answer pairs. All 300 pairs were given to all three annotators. We asked the following yes/no questions:

(i). (Acceptable) Would you directly use this question as a flashcard?

(ii). (Grammatical) Is this question grammatical?

(iii). (Interpretable) Does the question make sense out of context?

(iv). (Relevant) Is this question relevant?

(v). (Correct) Is the answer correct?

We provided many example annotations to our annotators and wrote clear guidelines about each cat-

---

[3] https://huggingface.co/valhalla/t5-base-qa-qg-hl

[4] This comes from a limitation of the answer extraction model. The model is highly likely to extract the same answer span when run on a sentence multiple times. Future work should seek to improve this weakness. There are many cases where asking multiple questions on one sentence is desirable.

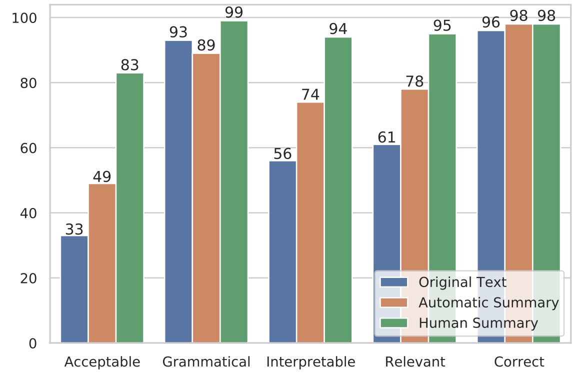

Figure 3: Results of our human evaluation for each input method. Numbers represent the proportion of questions that were labeled as having the given attribute (as determined by majority vote among our three annotators).

Source	n	Qs	As	Qs or As
Original Text	1209	70.9%	70.3%	88.6%
Auto Summary	318	44.9%	43.0%	60.1%
Human Summary	667	63.9%	68.4%	86.1%

Table 2: Coverage of bolded key terms from the textbook. Numbers represent percentage of bolded key terms present in any of the n question/answer pairs selected from the given source.

egory to ensure high agreement. Our full annotator guidelines can be found in Appendix B.

In Figure 3 we report the results of our evaluation across the three sources. We note that a majority of observed errors in the original text questions stem from them being either irrelevant or uninterpretable out of context. We also see that generating questions directly from human-written summaries significantly improves relevance and interpretability, resulting in over 80% being labeled as acceptable by annotators. Finally, in the case of automatic summaries, we see that relevance and interpretability are improved as compared to the original text questions while grammaticality suffers.

In Table 2 we evaluate the coverage of our generated questions. Coverage was calculated by extracting the bolded key terms from the textbook chapters and sub-string searching for each term among all questions and answers from a given source. Interestingly, if we think of the results from Figure 3 as precision scores and Table 2 as recall, we can see that human summaries have high precision high recall, original text has low precision high recall, and automatic summaries strike a balance between the two.

	A1	A2	A3	Pairwise IAA
Acceptable	69.7	48.7	47.7	(0.41, 0.50, 0.33)
Grammatical	98.3	90.7	86.3	(0.16, 0.49, 0.10)
Interpretable	79.7	70.7	59.7	(0.51, 0.43, 0.32)
Relevant	79.0	71.3	69.0	(0.41, 0.29, 0.25)
Correct	91.7	90.7	90.0	(0.03, 0.08, 0.06)

Table 3: Comparison between our three annotators (A1, A2, A3) on all 300 questions across all categories. Numbers represent percentages of "Yes" answers. Pairwise Inter-Annotator Agreement is calculated by Cohen κ and is reported in the order (A1-A2, A2-A3, A3-A1).

In Table 3 we report the pairwise inter-annotator agreement (IAA) as well as a per-annotator scoring breakdown. We use pairwise Cohen κ instead of Fleiss κ to better highlight the difference in agreement between certain pairs of annotators.[8]. While at first glance it may seem that agreement is low for grammaticality and correctness, this is somewhat expected for highly unbalanced classes (Artstein and Poesio, 2008). For the other three categories (relevance, interpretability, acceptability) we see pairwise agreement of approximately 0.4, suggesting a fair degree of agreement for such seemingly ambiguous categories.

6 Conclusion and Future Work

In this work we show that answer-agnostic QG models have difficulty both choosing relevant topics to ask about and generating questions that are interpretable out of context. We show that asking questions on summarized text ameliorates this in large part and that these gains can be approximated by the use of automatic summarization.

Future work should seek to further explore the relationship between summarization and QG. Work done concurrently to ours by Lyu et al. (2021) already has promising results in this direction, showing that training a QG model on synthetic data from summarized text improves performance on downstream QA.

Additionally, future work should focus on further refining and standardizing the metrics used for both automatic and human evaluation of QG. As noted by Nema and Khapra (2018) n-gram overlap metrics correlate poorly with in-context interpretability and evaluation on downstream QA fails to address the relevance of generated questions.

---

[8] Examples of questions for each category on which there was significant disagreement are listed in Appendix D

Acknowledgements

We graciously thank Suraj Patil for providing the fine-tuned question generation model used in this project. His training and inference code provided a great starting point for our experiments. We're very grateful for his support.

We would also like to thank Prof. Dan Jurafsky and Prof. James Martin for providing us with the raw latex files for their textbook. These files were very helpful for extraction purposes and saved us a lot of time.

Finally, we would like to thank the members of our lab for suggestions and feedback. In particular, Dan Deutsch and Alyssa Hwang were particularly influential in shaping the current version of this paper. Their great suggestions made the writing much clearer and much more understandable.

A Software and Data

The code and data used in this project can be found in our project repository.[9] The repository houses the 300 annotated questions, the 2,194 unannotated questions, the text sources used (three chapters of cleaned text from Jurafsky and Martin, three sets of human summaries, one set of automatic summaries), and the code used to generate the questions. We also provide scripts to reproduce the coverage analysis as well as the analysis of our annotations.

B Annotator Guidelines

In Table 4, we report the annotation guidelines given to our annotators. In the original document, under each category, 3 or more example annotations were given, each containing an explanation as to why the selection was made. Categories such as grammaticality had 10 or more examples given to ensure maximum agreement between annotators. Several discussion sessions were held between the authors and annotators to ensure that the guidelines were well understood.

During annotation, annotators were given the original textbook chapters to use as reference material and were allowed to use online search engines to check for grammaticality and correctness.

---

[9] https://github.com/liamdugan/summary-qg

Would you directly use this question as a flashcard? (Yes / No): A Yes answer to this question means that the generated question is salient, grammatically correct, non-awkwardly phrased and has one correct answer. If you answer Yes to this question you may skip the rest of the annotation for the given example – the answers for all other questions are assumed to be Yes. If you answer No, then please continue on to the rest of the questions. Importantly, if you *did* answer yes to all of the other questions, do not feel pressured to answer yes to this question. There are many reasons why you might not want to directly use a question as a flashcard (too easy, too general, etc.) that are not enumerated here.
Is this question grammatically correct? (Yes / No): A Yes answer to this question implies that a question has no grammatical errors. Awkwardly worded questions that are grammatical should be annotated as such (answer Yes for these questions).
Does this question make sense out of context? (Yes / No): This question asks if there are any references made by the question to other items that have been "previously discussed". For our use case, questions should never refer to other specific items in the text from which they were drawn. A Yes answer to this implies that the question is interpretable when taken on its own and is a question that someone would ask if there was no pre-existing context.
Is this question relevant? (Yes / No): A Yes answer to this question implies that the question being asked is important for understanding the main points that the chapter (and by extension the book) is attempting to teach. Questions that are relevant should be ones that would plausibly be asked on a quiz or a test from a fairly thorough course on computational linguistics. Questions that are about insignificant details or questions that are about specific illustrated examples that are not useful for understanding the main points of the chapter should be given a No. Anything that is relevant (or tangentially relevant) to computational linguistics should be given a Yes.
Is the answer to the question correct? (Yes / No): A Yes answer to this question implies that the answer given is one of a multitude of plausible correct answers to the question. If the question has multiple correct answers and the given answer is one of them, it should be annotated as a Yes. If the question is bad/ungrammatical or underspecified to such an extent that you cannot judge the answer properly, you should annotate Yes. However, irrelevant questions that are grammatical and reasonably interpretable should be annotated properly.

Table 4: Guidelines given to our human annotators before annotating for the acceptability, grammaticality, interpretability, relevance, and correctness of generated questions.

# Questions	Chapter 2 ($n = 139$)	Chapter 3 ($n = 93$)	Chapter 4 ($n = 66$)
Acceptable	54.0%	58.1%	53.0%
Grammatical	94.2%	93.5%	93.9%
Interpretable	74.1%	76.3%	72.7%
Relevant	72.7%	81.7%	83.3%
Correct	95.0%	100%	98.5%

Table 5: Distribution of human evaluation scores across the three chapters of annotation. Labels are determined via majority vote among our three annotators.

C Comparison Across Chapters

In Table 5 we report the distribution of scores across chapters. We note that scores are largely consistent across the three chapters, with lower average relevance for Chapter 2 questions possibly owing to the source material containing many worked examples of regular expressions.

D Example Disagreements

In Table 6, we list questions for which there was at least one dissenting annotator. We see that for categories such as "Relevant" and "Interpretable", annotations are often dependent on the level of granularity with which the topic is being discussed. For example, a question such as "Who named the minimum edit distance algorithm?" may or may not be relevant depending on how granular of a class the student is taking.

For categories such as "Correct" or "Acceptable" certain particularities about otherwise good questions can easily disqualify them from receiving a positive annotation. In the case of "What NLP algorithms require algorithms for word segmentation?", keen-eyed annotators would notice that the question is non-sensical, however others may note that both Japanese and Thai do, in fact, require word segmentation. Particularities such as these make this task very difficult, even for expert annotators.

E Example Summaries

In Table 7 we list two examples of textbook sections with their accompanying human and automatic summaries. We see that length of summary varies drastically between our annotators, each of them making different decisions on whether or not to keep or discard certain pieces of information. We also note that automatic summaries are much more extractive in nature while human summaries are generally more abstractive.

Acceptable	**Q**: What is another name for a corpus that NLP algorithms learn from? **A**: training corpus **Q**: What would happen if we accidentally trained the model on the test set? **A**: bias **Q**: What would give a lower cross-entropy? **A**: The more accurate model
Grammatical	**Q**: What are words like uh and um called fillers? **A**: filled pauses **Q**: What context do words that are in our vocabulary appear in a test set in? **A**: unseen **Q**: What word has the same lemma cat but are different wordforms? **A**: cats
Interpretable	**Q**: What gives us a way to quantify both of these intuitions about string similarity? **A**: Edit distance **Q**: What is another important step in text processing? **A**: Sentence segmentation **Q**: What seems to matter more than its frequency? **A**: whether a word occurs or not
Relevant	**Q**: What isn't big enough to give us good estimates in most cases? **A**: web **Q**: Who named the minimum edit distance algorithm? **A**: Wagner and Fischer **Q**: What do algorithms have to deal with? **A**: ambiguities
Correct	**Q**: What do square brackets not allow us to say? **A**: s or nothing **Q**: What NLP algorithms require algorithms for word segmentation? **A**: Japanese and Thai **Q**: What encode some facts that we think of as strictly syntactic in nature? **A**: Bigram probabilities

Table 6: Questions for which there was disagreement on the label for the given category

Original Text: What do we do with words that are in our vocabulary (they are not unknown words) but appear in a test set in an unseen context (for example they appear after a word they never appeared after in training)? To keep a language model from assigning zero probability to these unseen events, we'll have to shave off a bit of probability mass from some more frequent events and give it to the events we've never seen. This modification is called smoothing or discounting. In this section and the following ones we'll introduce a variety of ways to do smoothing: Laplace (add-one) smoothing, add-k smoothing, stupid backoff, and Kneser-Ney smoothing.	**Original Text**: As we saw in the previous section, naive Bayes classifiers can use any sort of feature: dictionaries, URLs, email addresses, network features, phrases, and so on. But if, as in the previous section, we use only individual word features, and we use all of the words in the text (not a subset), then naive Bayes has an important similarity to language modeling. Specifically, a naive Bayes model can be viewed as a set of class-specific unigram language models, in which the model for each class instantiates a unigram language model. Since the likelihood features from the naive Bayes model assign a probability to each word P(word|c), the model also assigns a probability to each sentence.
Automatic Summary: What do we do with words that are in our vocabulary (they are not unknown words) but appear in a test set in an unseen context? To keep a language model from assigning zero probability to these unseen events, we'll have to shave off a bit of probability mass from some more frequent events. This modification is called smoothing or discounting.	**Automatic Summary**: A naive Bayes Bayes model can be viewed as a set of class-specific unigram language models. The model for each class instantiates a language model. Since the likelihood features assign a probability to each word P(word|c), the model also assigns a probability to each sentence.
Human Summary (A1): We remove some probability mass for more frequent events and reassign it to unseen events with known words, and this is called smoothing or discounting. We study four 4 main methods of smoothing: Laplace smoothing, add-k smoothing, stupid backoff, and Kneser-Ney smoothing.	**Human Summary (A1)**: A naïve Bayes model can be viewed as a set of class-specific unigram language models.
Human Summary (A2): Smoothing or discounting is the procedure of transferring the probability mass of frequent events to other words that appear in the test set in an unseen context.	**Human Summary (A2)**: Naive Bayes models are similar to language modeling in that they can be viewed as a set of class-specific unigram language models. The probability of a sentence being positive is the total product of the individual probabilities that each word in the sentence is positive.
Human Summary (A3): Not assigning zero to the probability of an unseen word in the test set is called smoothing or discounting. There are different ways to do smoothing: Laplace, add-k smoothing, stupid backoff, Kneser-Ney smoothing.	**Human Summary (A3)**: A naive Bayes model can be viewed as a set of class-specific unigram language models, in which the model for each class instantiates a unigram language model.

Table 7: Examples of human and automatic summaries for two sections of "Speech and Language Processing". The left text is from Section 3.4 "Smoothing" and the right text is from Section 4.6 "Naive Bayes as a Language Model". We see that the automatic summaries tend to be more extractive while the human summaries are more abstractive.

Relevant CommonSense Subgraphs for "What if..." Procedural Reasoning

`kordjams@msu.edu`

Abstract

We study the challenge of learning causal reasoning over procedural text to answer "What if..." questions when external commonsense knowledge is required. We propose a novel multi-hop graph reasoning model to 1) efficiently extract a commonsense subgraph with the most relevant information from a large knowledge graph; 2) predict the causal answer by reasoning over the representations obtained from the commonsense subgraph and the contextual interactions between the questions and context. We evaluate our model on WIQA benchmark and achieve state-of-the-art performance compared to the recent models.

1 Introduction

In recent years, large-scale pre-trained language models (LMs) have made a breakthrough progress and demonstrate a high performance in many NLP tasks, including procedural text reasoning (Tandon et al., 2019; Rajagopal et al., 2020). There is a large amount of knowledge that is stored implicitly in language models that help in solving various NLP tasks (Devlin et al., 2019b). When we reason over text, sometimes, the knowledge contained in a given text is sufficient to predict the answer, as it is shown in the question 1 of Figure 1. This knowledge is directly encoded and used by LMs models (Tandon et al., 2019). However, there are many cases in which the required knowledge is not included in the procedural text itself. For example, for the question 2 in Figure 1, the information about the “nutrient” on the seeds does not exist in the procedural text. Therefore, the external commonsense knowledge is required.

There are several existing resources that contain world knowledge and commonsense. Examples are knowledge graphs (KGs) like ConceptNet (Speer et al., 2017) and ATOMIC (Sap et al., 2019). Looking back at the question 2, we observe that through providing the external knowledge triplets (nutrient, relatedto, soil) and (soil, relatedto, seed) derived from ConceptNet, we can build an explicit reasoning chain and choose an explainable answer.

Procedural Text:
1. A plant produces a seed.
2. The seed falls to the ground.
3. The seed is buried.
4. The seed germinates.
5. A plant grows.
6. The plant produces flowers.
7. The flowers produce more seeds

Questions and Answers:
1. suppose plants will produce more seeds happens, how will it affect less plants.
(A) More (B) **Less** (C) No effect
2. suppose the soil is rich in nutrients happens, how will it affect more seeds are produced.
(A) **More** (B) Less (C) No effect

Figure 1: WIQA contains procedural text, and different types of questions. The bold choices are the answers.

Two challenges exist in procedural text reasoning and using external KBs. The first challenge is effectively extracting the most relevant external information and reducing the noise from the KB. The second challenge is reasoning over the extracted knowledge. Several works enhance the QA model with commonsense knowledge (Lin et al., 2019; Lv et al., 2020). However, the noisy knowledge from KG will seriously mislead the QA model in predicting the answer. Moreover, using KBs is often investigated in the tasks that perform QA directly over KB itself, such as CommonsenseQA (Talmor et al., 2019), etc. There are less sophisticated techniques proposed for using external knowledge explicitly (i.e. not through training LMs) in reading comprehension for aiding QA over text. REM-Net (Huang et al., 2021) is the only work that uses commonsense for WIQA and uses a memory network to extract the external triplets to solve the first challenge. However, this work has no reasoning process over the extracted knowledge and uses a simple multi-head attention operator to predict the answer. EIGEN (Madaan et al., 2020) constructs an influence graph to find the chain of reasoning given

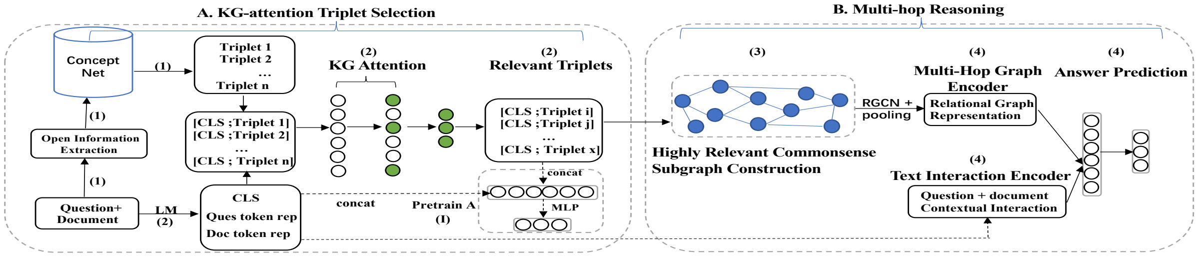

Figure 2: MRRG Model is composed of Candidate Triplet Extraction, KG Attention, Commonsense Subgraph Construction, Text encoder with contextual interaction, Graph Reasoning, and Answer prediction modules.

procedural text. However, EIGEN cannot deal with the challenge when the required knowledge is not in the given document.

To solve these two challenges, we propose a **M**ulti-hop **R**easoning network over **R**elevant ComMonSense SubGraphs (MRRG) for casual reasoning over procedural Text. Our motivation is to effectively and efficiently extract the most relevant information from a large KG to help procedural reasoning. First, we extract the entities, retrieve related external triplets from KG, and learn to extract the most relevant triplets to a given the procedure and question input by a novel KG attention mechanism. Then, we construct a commonsense subgraph based on the extracted KG triplets in a pipeline. We use the extracted subgraphs as a part of end-to-end QA model to help in filling the knowledge gaps in the procedure and performing multi-hop reasoning. The final model predicts the causal answer by reasoning over the contextual interaction representations over the question and the document and learning graph representations over the KB subgraphs. We evaluate our MRRG on the "what if" WIQA benchmark. MRRG model achieves SOTA and brings significant improvements compared to the existing baselines.

The contributions of our work are: **1)** We train a separate module that extracts the relevant parts of the KB given the procedure and question to avoid the noisy and inefficient usage of the information in large KBs. 2) We design an end-to-end model that uses the extracted QA-dependent KB as a subgraph to guide the reasoning over the procedural text to answer the questions. 3) Our MRRG achieves SOTA on the WIQA benchmark.

2 Model Description

2.1 Problem Formulation and Overview

Formally, the problem is to predict an answer a from a set of pre-defined answers given input question q, a document $\mathcal{C}$ which is composed of several sentences $\mathcal{C} = \{s_1, \dots, s_n\}$, and a large knowledge graph KG.

Figure 2 shows the proposed architecture. (1) We extract the entities from question and context in preprocessing step and use them to retrieve the set of **candidate triples** from the ConceptNet. (2) We train the **KG Attention** module to extract the most relevant triplets given the procedure and question and reduce the noisy concepts from candidate triplets. (3) We augment the **commonsense subgraph** based on the relevant triplets. (4) We train a model that uses two components, the commonsense subgraph as a relational graph network and a text encoder including question and document to do **procedural reasoning**. Below, we describe the details of each module.

2.2 Candidate Triplet Extraction from KG

Given the input q and $\mathcal{C}$, we extract the contextual entities (concepts) by a open Information Extraction (OpenIE) model (Stanovsky et al., 2018). For each extracted entity t_{in}, we retrieve the relational triplets $t = (t_{in}, r, t_{out})$ from KG, where t_{out} is the concept taken from ConceptNet and r is a semantic relation type. We then apply a pre-trained Language Model, RoBERTa, to obtain the representation of each triplet: $E^t = f_{LM}([t_{in}, r, t_{out}]) \in \mathbb{R}^{3\times d}$, where f_{LM} denotes the language model operation and the triplets are given as a sequence of concepts and relations to the LM.

2.3 KG Attention

The KG attention module is shown in Figure 2-A and Figure 3. We concatenate q and $\mathcal{C}$ to form $Q = [[CLS]; q; [SEP]; \mathcal{C}]$, where [CLS] and [SEP] are special tokens in the LMs tokenizer process (Liu et al., 2019). We use RoBERTa to obtain the list of token representations $E_{[CLS]}$, E_q, and $E_{\mathcal{C}}$. $E_{[CLS]}$ is the summary representation of the question and paragraph, E_q is the list of the question tokens embeddings, and $E_{\mathcal{C}}$ is the list of the paragraph tokens embeddings output of Roberta.

Given triplet E^t that is generated based on the triplet extraction described in Section 2.2, we build a context-triplet pair $E^t_z = [E_{[CLS]}; E^t_{in}; E^t_r; E^t_{out}]$, where E^t_{in} is the representation of the head entity from text, E^t_{out} is the representation of the tail entity from KG, and E^t_r is the representation of the relation. Afterwards, we compute context-triplet pair attention and a softmax layer to output the **C**ontext-**T**riplet pairwise importance **S**core CTS. The process is computed as follows: $\text{CTS}_t = \frac{\exp(MLP(E^t_z))}{\sum_{j=1}^{m} \exp(MLP(E^t_z))}$.

Then we choose the top-k relevant triplets with the top CTS scores and then use the relevant triplets to construct the subgraph. For each selected triplet, we obtain the triplet representation $E'^t = [E'^t_{in}, E^t_r, E'^t_{out}] \in \mathbb{R}^{3\times d}$, where $E'^t_{in} = f_{in}([CTS_t \cdot E^t_{in}; CTS_t \cdot E^t_r])$ and $E'^t_{out} = f_{out}([CTS_t \cdot E^t_{out}; CTS_t \cdot E^t_r])$. Notice that f_{in} and f_{out} are MLP layers, $[;]$ is the concatenation, and $[\cdot]$ is the scalar product.

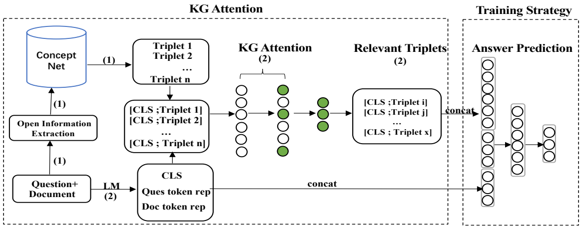

Figure 3: The architecture of training the KG Attention module.

2.4 Commonsense Subgraph Construction

We construct the subgraph G_s based on the relevant triplets from KG attention for each question and answer pair. We add more edges to the subgraph as follows: Two entities in the triplets will have an edge if a relation r in the KG exists between them. The assumption is that the augmented commonsense subgraph will contain the reasoning paths. We use E'^t_{in} and E'^t_{out} for the KG subgraph initial node representation $h^{(0)}$ which is used in RGCN formulation in Section 2.5.

2.5 Procedural Reasoning

Procedural Reasoning composes of two parts: Multi-Hop Graph Reasoning and Text Contextual Interaction Encoder.

(I) Multi-Hop Graph Reasoning: this is the Graph Reasoning part of Figure 2-B. Given the subgraph G_s, we use RGCN (Schlichtkrull et al., 2018) to learn the representations of the relational graph. RGCN learns graph representations by aggregating messages from its direct neighbors and relational semantic edges. The $(l+1)$-th layer node representation $h_i^{(l+1)}$ is updated based on the neighborhood node representations h_j^l from the l-layer multiplied by the relational matrices $W^{(l)}_{r_1}, \ldots, W^{(l)}_{r_{|R|}}$. The representation $h_i^{(l+1)}$ is computed as follows:

$$h_i^{(l+1)} = \sigma\Big(\sum_{r\in\mathcal{R}} \sum_{j\in N_i^r} \frac{1}{|N_i^r|} W_r^{(l)} h_j^{(l)} + W_0^{(l)} h_i^{(l)}\Big),$$

where σ denotes a non-linear activation function, N_i^r represents a set that includes neighbor indices of node i under semantic relation r. Finally, we obtain the E_{G_s} after several hops of message passing.

(II) Text Contextual Interaction Encoder: We have obtained the contextual token representations $E_{[CLS]}$, E_q, and $E_{\mathcal{C}}$ in the KG attention module that described in Section 2.3. Followed by Seo et al., we utilize Bi-DAF style contextual interaction module to feed E_q and $E_{\mathcal{C}}$ to Context-to-Question Attention $E_{\mathcal{C}\to q} = softmax(sim(E_q^T, E_{\mathcal{C}}))E_q$ and Question-to-Context Attention $E_{q\to\mathcal{C}}$ to obtain the contextual interaction between question and context. Then we use LSTM to obtain the hidden state representations: $F_{q\to\mathcal{C}} = LSTM(E_{q\to\mathcal{C}})$, and $F_{\mathcal{C}\to q} = LSTM(E_{\mathcal{C}\to q})$.

2.6 Answer Prediction

We concatenate $E_{[CLS]}$, $F_{q\to\mathcal{C}}$, $F_{\mathcal{C}\to q}$, and the compact subgraph representation E'_{G_s} obtained from attentive pooling, and use it as the final representation: $F = [E_{[CLS]}; F_{q\to\mathcal{C}}; F_{\mathcal{C}\to q}; E'_{G_s}]$. Then we utilize a classifier MLP (F) to predict the answer. Our MRRG has two separate training modules used in a pipeline for triplet selection and procedural reasoning.

(I) Training KG Attention for Triplet Selection: Figure 3 and the left block of Figure 2 show the same triplet selection model. The architecture of Figure 2.B is taken and 3 extra MLP layers added to it for training as shown in Figure 3. The MLP is applied on the concatenation of the concatenation of $[E_{[CLS]}; E_q; E_{\mathcal{C}}; E'^t_1; \ldots; E'^t_k]$ to predict the answer. We use the cross-entropy as the loss function to train the model.

(II) Training End-to-End MRRG: After pretraining the KG attention, we keep the learned parameters and extract the most relevant concepts and construct the multi-relational commonsense subgraph G_s. We combine subgraph representation and text interaction representation as input

to train the answer prediction module by cross-entropy loss.

3 Experiments and Results

We implemented our MRRG framework using PyTorch [1]. We use a pre-trained RoBERTa (Liu et al., 2019) to encode the contextual information in the input. The maximum number of triplets is 50 and the maximum number of nodes in the graph is 100. Further details of hyper-parameters of the graph are shown in Table 3. The maximum number of words for the paragraph context is 256. For the graph construction module, we utilize *open Information Extraction* model (Stanovsky et al., 2018) from AllenNLP[2] to extract the entities. The maximum number of hops for the graph module is 3. The learning rate is $1e-5$. The model is optimized using Adam optimizer (Kingma and Ba, 2015).

3.1 Datasets

WIQA is a large dataset for "what if" causal reasoning. WIQA contains three types of questions: 1) the questions can be directly answered based on the text, called in-paragraph questions. 2) the questions require external knowledge to be answered, called out-of-paragraph questions, and 3) irrelevant causes and effects, called no-effect questions. WIQA contains 29808 training samples, 6894 development samples, 3993 test samples (test V1), and 3003 test samples (test V2).

3.2 Baseline Description

We briefly describe the most recent baselines that use the Transformer-based language model as the backbone. We separately fine-tune the BERT and RoBERTa as the first two baselines.

EIGEN (Madaan et al., 2020) is a baseline that builds an event influence graph based on a document and leverages LMs to create the chain of reasoning to predict the answer. However, EIGEN does not use any external knowledge to solve the problem.

Logic-Guided (Asai and Hajishirzi, 2020) is a baseline that combines neural networks and logic rules. Specifically, the Logic-Guided model uses logic rules including symmetry and transitivity rules to augment the training data. Moreover, the base language model uses the rules as a regularization term during training to impose the consistency between the answers of multiple questions.

RGN (Zheng and Kordjamshidi, 2021) is the recent SOTA baseline that utilizes a gating network (Zheng et al., 2020) to effectively filter out the key entities and relationships in the given document and learns the contextual representations to predict the answer. RGN does not consider the external knowledge for procedural reasoning challenges.

REM-Net (Huang et al., 2021) proposes a recursive erasure memory network to find out the causal evidence. Specifically, REM-Net refines the evidence by a recursive memory mechanism and then uses a generative model to predict the causal answer. REM-Net is the only work that uses external knowledge for WIQA. REM-Net uses the external knowledge by training an attention mechanism that considers the KG triplet representations for finding the answer. It does not explicitly select the most relevant triplets as we do, and the graph reasoning is not exploited for finding the chain of reasoning.

Figure 4: Left: Case study of the MRRG Framework. "+interaction" means adding the contextual interaction module. "KG ATTN" means adding the KG Attention Triplet Selection module. 'X' indicates the model failed to predict the correct answer and "✓" means the prediction was successful with the included module. Right: Comparing the results over different number of hops.

4 Analysis

4.1 Effects of Using External Knowledge

In the WIQA, all the baseline models achieve significantly lower accuracy in the out-of-para than in-para and no-effect categories. MRRG achieves SOTA in the out-of-para category because of using the highly relevant commonsense subgraphs and the combination of reasoning over text interaction and the graph reasoning modules. As is shown in table 2, the advantage of the MRRG model is reflected on out-of-para questions. MRRG improves 4.61% over REM-Net. Notice that REM-Net is the only model that utilizes external knowledge on WIQA. Figure 4 shows a case in which the "soil" and "nutrient" only appear in the question and do not exist in the text. The baseline models fail to answer this out-of-para question due to missing external knowledge. However, our model predicts the correct answer by explicitly incorporating the (nutrient, relatedto, soil), (soil, relatedto, seed) that connects the critical information between the question and document.

Ablation	Model	Dev Acc
Text only	RoBERTa-base	75.51%
Text only	+ contextual interaction	76.85%
Text only	KG Attention Triplet Selection	77.39%
Text+Graph	- semantic relation	78.31%
	GNN dim=50	79.18%
	GNN dim=100	80.30%
	GNN dim=200	79.88%

Table 3: Ablation and hyper-para. choices on WIQA. "GNN dim" is the dimension of graph representation.

4.2 Relational Reasoning and Multi-Hops

Both in-para and out-of-para question types require multiple hops of reasoning to find the answer in the WIQA. As shown in the right side of Figure 4, the MRRG model accuracy improved 2% for 1 hop, 8% for 2 hops, and 2% for 3 hops compared to EIGEN. MRRG made a sharp improvement in reasoning with multiple hops due to the relational graph reasoning and the effectiveness of the extracted commonsense subgraph. We study some cases to analyze the multi-hop reasoning and the reasoning chains. In the third case in Figure 4, the extracted relevant triplets (land, relatedto, surface), (surface, relatedto, igneous rock) construct a two-hop reasoning chain "land→surface→igneous rock" that helps MRRG to find the correct answer.

4.3 Ablation Study

Table 3 shows the ablation study results of MRRG using WIQA. Firstly, we remove the commonsense subgraph and graph network. The accuracy decreases 3.4% compared to MRRG. Second, we remove the contextual interaction module and the accuracy decreases 1.3%. In an additional experiment, we use the KG attention triplet selection module to directly predict the answer without the pipeline of constructing the subgraph and using the graph reasoning module. We show the result as KG Attention Triplet Selection in Table 3. The result shows that removing the triplet selection module decreases the accuracy by 1.8%. In the same table 3, we report results about the impact of including the relation types in the RGCN graph and the influence of changing the dimensionality of the node representations in the model.

5 Conclusion

We propose MRRG model for using external knowledge graph in reasoning over procedural text. Our model extracts a relevant subgraph for each question from the KG and uses that knowledge subgraph for answering the question. The extracted subgraph includes the reasoning path for answering the question and helps multi-hop reasoning to predict an explainable answer. We evaluate MRRG on the WIQA and achieve SOTA performance.

Abstract

Training the deep neural networks that dominate NLP requires large datasets. These are often collected automatically or via crowdsourcing, and may exhibit systematic biases or *annotation artifacts*. By the latter we mean spurious correlations between inputs and outputs that do not represent a generally held causal relationship between features and classes; models that exploit such correlations may appear to perform a given task well, but fail on out of sample data. In this paper we evaluate use of different *attribution* methods for aiding identification of training data artifacts. We propose new hybrid approaches that combine *saliency maps* (which highlight "important" input features) with *instance attribution* methods (which retrieve training samples "influential" to a given prediction). We show that this proposed *training-feature attribution* can be used to efficiently uncover artifacts in training data when a challenging validation set is available. We also carry out a small user study to evaluate whether these methods are useful to NLP researchers in practice, with promising results. We make code for all methods and experiments in this paper available.[1]

1 Introduction

Deep networks dominate NLP applications and are being increasingly deployed in the real-world. But what exactly are such models "learning"? One concern is that they may be exploiting *artifacts* or spurious correlations between inputs and outputs that are present in the training data, but not reflective of the underlying task that the data is intended to represent.

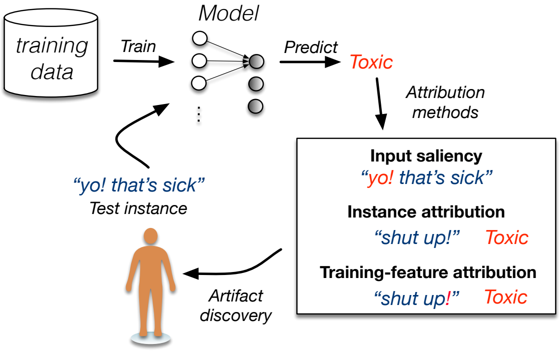

Figure 1: Use of different attribution techniques for artifact discovery in train data. Here attribution methods can reveal inappropriate reliance on certain tokens (e.g., *"!"*, *"yo"*) to predict Tweet toxicity; these are artifacts.

We assess the utility of *attribution methods* for purposes of aiding practitioners in identifying training data artifacts, drawing inspiration from prior efforts that have suggested the use of attribution methods for this purpose (Han et al., 2020; Zhou et al., 2021). Attribution methods are *model-centric*; our evaluation of them for artifact discovery therefore complements recent work on *data-centric* approaches (Gardner et al., 2021). We consider two families of attribution methods: (1) *feature-attribution*, which highlight constituent input features (e.g., tokens) in proportion to their "importance" for an output (Ribeiro et al., 2016; Lundberg and Lee, 2017; Adebayo et al., 2018), and; (2) *instance attribution*, which retrieves training instances most responsible for a given prediction (Koh and Liang, 2017; Yeh et al., 2018; Rajani et al., 2020; Pezeshkpour et al., 2021).

We also introduce new hybrid attribution methods that surface relevant *features within train instances* as an additional means to probe what the model has distilled from training data. This addresses inherent limitations of using either feature or instance attribution alone for artifact discovery. The former can only highlight patterns within a given input, and the latter requires one to inspect entire (potentially lengthy) training instances to

divine what might have rendered them influential.

Consider Figure 1. Here a model has learned to erroneously associate African American Vernacular English (AAVE) with *toxicity* (Sap et al., 2019) and with certain punctuation marks ("!"). For a hypothetical test instance "yo! that's sick", both input saliency and instance attribution methods may provide some indication of these artifacts. But combining these via *training-feature attribution* (TFA) can directly surface the punctuation artifact by highlighting "!" within a relevant training example ("shut up!"); this is not readily apparent from either input or instance attribution. Our goal in this work is to evaluate TFA and other attribution methods as tools for identifying dataset artifacts.

Contributions. The main contributions of this paper are as follows. (1) We propose a new hybrid attribution approach, training-feature attribution (TFA), which addresses some limitations of existing attribution methods. (2) We evaluate feature, instance and training-feature attribution for artifact detection on several NLP benchmarks with previously reported artifacts to evaluate whether and to what degree methods successfully recover these, and find that TFA can outperform other methods. We also discover and report previously unknown artifacts on a few datasets. Finally, (3) we conduct a small user-study to evaluate TFA for aiding artifact discovery in practice, and again find that combining feature and instance attribution is more effective at detecting artifacts than using either on its own.

2 Background and Notation

Assume a text classification setting where the aim is to fit a classifier ϕ that maps inputs $x_i \in \mathcal{X}$ to labels $y_i \in \mathcal{Y}$. Denote the training set by $\mathcal{D} = \{z_i\}$ where $z_i = (x_i, y_i) \in \mathcal{X} \times \mathcal{Y}$. Each x_i consists of a sequence of tokens $\{x_{i,1}, \dots, x_{i,n_i}\}$. Here we define a linear classification layer on top of BERT (Devlin et al., 2019) as ϕ, fine-tuning this on $\mathcal{D}$ to minimize cross-entropy loss $\mathcal{L}$. Two types of attribution methods have been used in prior work to characterize the predictive behavior of ϕ.

Feature attribution methods highlight *important features* (tokens) in a test sample x_t. Examples of feature attribution methods include input gradients (Sundararajan et al., 2017; Ancona et al., 2018), and model-agnostic approaches such as LIME (Ribeiro et al., 2016). In this work, we consider only gradient-based feature attribution.

Instance attribution methods retrieve training samples z_i deemed "influential" to the prediction made for a test sample x_t: $\hat{y}_t = \phi(x_t)$. Attribution methods assign scores to train instances z_i intended to reflect a measure of importance with respect to $\hat{y}_t$: $I(\hat{y}_t, z_i)$. Importance can reflect a formal approximation of the change in $\hat{y}_t$ when z_i is upweighted (Koh and Liang, 2017) or can be derived via heuristic methods (Pezeshkpour et al., 2021; Rajani et al., 2020). While prior work has considered these attribution methods for "train set debugging" (Koh and Liang, 2017; Han et al., 2020), this relies on the practitioner to abstract away potential patterns within the influential instances.

3 Artifact Detection and Training-Feature Attribution

3.1 What is an *Artifact*?

Models will distill observed correlations between training inputs and their labels. In practice, some of these correlations will be *spurious*, by which we mean specific to the training dataset used. Consider a particular feature function f such that $f(x)$ is 1 if x exhibits the feature extracted by f and 0 otherwise, a *training* distribution $\mathcal{D}$ over labeled instances z (often assembled using heuristics and/or crowdsourcing), and an ideal, hypothetical *target* distribution $\mathcal{D}*$ (the task we would actually like to learn; "sampling" directly from this is typically prohibitively expensive). Then we say that f is a *dataset* artifact if there exists a correlation between y and $f(x)$ in $\mathcal{D}$, but not in $\mathcal{D}*$. That is, if the mechanism by which one samples train instances induces a correlation between f and labels that would not be observed in an idealized case where one samples from the "true" task distribution.[2]

A given model may or may not exploit a particular dataset artifact; in some cases a *model-centered* view of artifacts may therefore be helpful. To accommodate this, we can extend our preceding definition by considering the relationship between model predictions $\hat{p}(y|x)$ and true conditional distributions $p(y|x)$ under D^*; we are interested in cases where the former differs from the latter due to exploitation of a dataset artifact f. Going further, we can ask whether this artifact was exploited *for a specific prediction*.

---

[2] As a proxy for realizing this, imagine enlisting well-trained annotators with all relevant domain expertise to label instances carefully sampled i.i.d. from the distribution from which our test samples will actually be drawn in practice.

In this work we consider two types of artifacts. *Granular* input features refer to discrete units, such as individual tokens (this is similar to the definition of artifacts introduced in recent work by Gardner et al. 2021). *Abstract* features refer to higher-level *patterns* observed in inputs, e.g., lexical overlap between the premise and hypothesis in the context of NLI (McCoy et al., 2019).

3.2 Training-Feature Attribution

Showing important training instances to users for their interpretation places the onus on them to determine *what* was relevant about these instances, i.e., which features (granular or abstract) in x_i were influential. To aid artifact detection, it may be preferable to automatically highlight the tokens most responsible for the influence that train samples exert, communicating *what made an important example important*. This hybrid training-feature attribution (TFA) can reveal patterns extracted from training data that influenced a test prediction, even where the test instance does not itself exhibit this pattern, whereas feature attribution can only highlight features within said test instance. And unlike instance attribution, which retrieves entire train examples to be manually inspected (a potentially time-consuming and difficult task), TFA may be able to succinctly summarize patterns of influence.

A high-level schematic of TFA is provided in Figure 2. We aim to trace influence back to features within training samples. We introduce training-feature attribution to extract influential features from training samples for a specific test prediction by considering a variety of combinations of feature and instance attribution and means of aggregating over these as TFA variants. For example, one TFA variant identifies features within the training point x_i that informed the prediction for a test sample z_t by taking the gradient of the influence with respect to inputs features, i.e., $\nabla_{x_i} \mathrm{I}(z_t, x_i, y_i)$ (Koh and Liang, 2017). After calculating the importance of features within a train sample for a test target, we either construct a heatmap to help users identify *abstract* artifacts, or take aggregate measures over features (described below) to detect *granular* artifacts and present them to users.[3]

Heatmaps We present the top and bottom k influential examples to users with *token highlights* communicating the relative importance of tokens within these k influential train instances. This may allow practitioners to interactively, efficiently identify potentially problematic abstract artifacts.

Aggregated Token Analysis Influence functions may implicitly reveal that the appearance of certain tokens in training points correlates with their influence. We might directly surface this sort of pattern by aggregating TFA over a set of training samples. For example, for a given test instance, we can retrieve the top and bottom $k\%$ most influential training instances according to an instance attribution method. We can then extract the top token from each of these instances using TFA, and sort resulting tokens based on frequency, surfacing tokens that appear disproportionately in influential train points. Returning to toxicity detection, this might reveal that punctuation marks (such as "!") tend to occur frequently in influential examples, which may directly flag this behavior.

Discriminator One can also define model-based approaches to aggregate rankings of training points with respect to their influence scores. As one such method, we train a logistic regression (LR) model on top of Bag-of-Words representations to distinguish between the most and least influential examples, according to influence scores for a given test point. This will yield a weight for each token in our vocabulary; tokens associated with high weights are correlated with influence for the test point, and we can show them to the practitioner.

4 A Procedure for Artifact Discovery

We now propose a procedure (Figure 2) one might follow to systematically use the above attribution methods to discover training artifacts.

(1) Construct a validation set, either using a standard split, or by intentionally constructing a small set of "difficult" samples. Constructing a useful (for dataset debugging) such set is the biggest challenge to using attribution-based approaches.

(2) Apply feature-, instance-, and training feature attribution to examples in the validation set. Specifically, identify influential *features* using feature attribution or TFA and identify influential *training instances* using instance attribution.

(3-a) **Granular artifacts**: To identify granular artifacts, aggregate the important features from the test points (via feature attribution) or from influential train points (using TFA) for all instances in the validation set to identify features that appear

---

[3] Many other strategies are possible, and we hope that this work motivates further exploration of such methods.

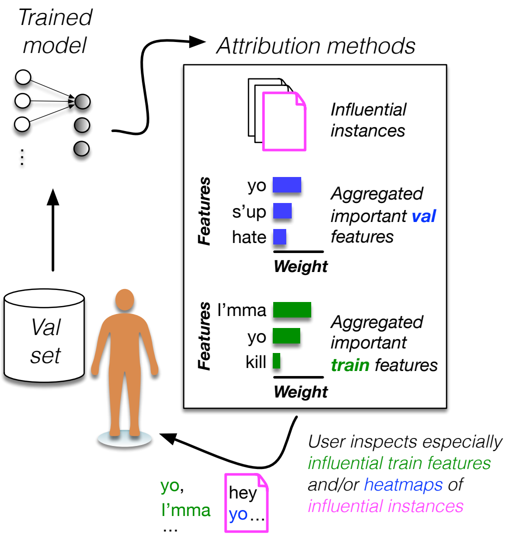

Figure 2: Finding artifacts via attribution methods. Staring from the validation set, we explain model prediction for every sample using different attribution methods. Then we either aggregate the explanations using frequency or rely on the heatmap analysis of explanations to detect artifacts.

disproportionately.
