Message from the General Chair

Welcome to ACL 2022, the 60th Annual Meeting of the Association for Computational Linguistics! The conference will be held in Dublin, the capital of Ireland, on May 22–27, 2022.

ACL 2022 will be a hybrid conference. After two fully virtual editions, ACL 2020 and ACL 2021, due to the covid-19 pandemic, this year we are gradually coming back to normality, estimating, at the moment of writing this message, that about 50% of the registered participants will be able to attend the conference in-person, enjoying the atmosphere of the CCD congress center, the social events of the conference, and the many opportunities in Dublin. On the other side, virtual attendees will have the possibility to interact almost like they were in Dublin, thanks to a sophisticated virtual conference platform.

There are few important innovations this year. The most relevant is that ACL 2022 adopted a new reviewing process, based on "rolling review" (ARR), with the goal of coordinating and making more efficient the paper reviews of the ACL conferences. This initiative was shared with NAACL 2022, resulting in a coordinated effort. As a side effect of moving to ARR, we have been working on a new version of the software, called ACLPUB2, used to produce both the conference proceedings and the conference schedule. I would like to thank all the people who contributed to those achievements. Finally, this year we celebrate the 60th anniversary of the ACL conference. Thanks to the enthusiastic contributions of many organizations, coordinated by the Diversity and Inclusion co-chairs, we are preparing a very special initiative for our community, which, at the time of writing this message, is still secret and that will be disclosed during the opening of the conference.

I was very lucky to work together with three fantastic Program Chairs: Preslav Nakov, Smaranda Muresan and Aline Villaviciencio. I could not thank you more for the dedication and the capacity with which you have organized a very exciting scientific program and for the help in all the phases of the conference organization.

Thanks to the local organizers in Dublin, Andy Way and John Kelleher, and to the PCO, who managed the local organization in a period in which we have had very few certainties, and many more uncertainties.

We are extremely grateful to all sponsors for their continuing and generous support to help our conferences be very successful. Thank you to Chris Callison-Burch, the ACL Sponsorship Director, for managing the relations between the sponsors and ACL 2022.

I am also very grateful to the chairs of the previous years' conferences, who were always ready to help and to provide advice, contributing to the transmission, from year to year, of all the know-how and collective memory. Thanks to all the members of The ACL Executive Committee, they were always supportive, particularly when feedback on delicate issues was needed.

Many thanks to the senior area chairs, the area chairs, the reviewers, our workshop organizers, our tutorial instructors, the authors and presenters of papers, and the invited speakers.

ACL requires a long process, involving a large team of committed people. It is an honor for me to have coordinated such a team of talented people, who kindly volunteered their time to make this conference possible. I would like to thank the members of the organizing committee for their dedication and hard work, often under a tight schedule:

- Workshop Co-Chairs: Elena Cabrio, Sujian Li, Mausam;
- Tutorial Co-Chairs: Naoaki Okazaki, Yves Scherrer, Marcos Zampieri;
- Demo Co-Chairs: Valerio Basile, Zornitsa Kozareva, Sanja Štajner;
- Student Research Workshop Co-Chairs: Samuel Louvan, Brielen Madureira, Andrea Madotto;

- SRW Faculty Advisors: Cecile Paris, Siva Reddy, German Rigau;
- Publication Co-Chairs (also publication co-chairs for NAACL 2022): Danilo Croce, Ryan Cotterell, Jordan Zhang;
- Conference Handbook Chair: Marco Polignano;
- Diversity & Inclusion Co-chairs: Mona Diab, Martha Yifiru Tachbelie;
- Ethic advisor committee: Su Lin Blodgett, Christiane Fellbaum;
- Technical OpenReview Chair: Rodrigo Wilkens;
- Publicity and Social Media Co-chairs: Isabelle Augenstein, Emmanuele Chersoni, Diana Maynard, Soujanya Poria, Joel Tetreault;
- Local Arrangement Committee: Fiona McGillivray, Greg Carew, Laird Smith;
- Student Volunteer Coordinators: Filip Klubicka, Vasudevan Nedumpozhimana, Guodong Xie, Pintu Lohar;
- Internal Communications Chair: Marcely Boito Zanon.

Let me deserve a special thanks to Priscilla Rasmussen. She has been the pillar not only of this year's ACL, but of the ACL conferences for many years. She has offered her invaluable experience to the organizing committee, and her presence has always given us a pleasant sense of security.

Finally, I would like to thank all the participants, both in-person and virtual, who will be the main actors from May 22 to May 27, 2022. I am convinced that we will experience a fantastic conference, scientifically exciting and full of fond memories.

Welcome and hope you all enjoy the conference!

Bernardo Magnini (FBK, Italy)
ACL 2022 General Chair

Message from the Program Chairs

Welcome to the 60th Annual Meeting of the Association for Computational Linguistics (ACL 2022). ACL 2022 has a special historical significance, as this is the 60th Anniversary edition. It is also the first hybrid ACL conference after two years of a fully virtual format for ACL in 2020 and 2021 due to the COVID-19 pandemic. Finally, it is the first *ACL conference to fully embrace the ACL Rolling Review (ARR) as a reviewing process. Below, we discuss some of these changes and we highlight the exciting program that we have put together with the help from our community.

Using ARR for Reviewing

In coordination with the NAACL 2022 team and the ACL executive committee, we decided to fully adopt the ACL Rolling Review (ARR) as the only reviewing platform for ACL 2022. ARR is a new review system for *ACL conferences, where reviewing and acceptance of papers to publication venues is done in a two-step process: (*i*) centralized rolling review via ARR, and (*ii*) commitment to a publication venue, e.g., ACL 2022. The purpose of the ACL Rolling Review is to improve the efficiency and the turnaround of reviewing in *ACL conferences while keeping diversity (geographic and otherwise) and editorial freedom.

As ACL 2022 is the first conference to fully adopt the ARR review process, we worked very closely with ARR and we coordinated our efforts with the NAACL 2022 PC chairs. In particular, given the short distance between ACL 2022 and NAACL 2022, we allowed authors to commit their papers to ACL 2022 and simultaneously to submit a revision to ARR in January, which were eligible for NAACL 2022. We also joined ARR as Guest Editors-in-Chief (EiCs) to help with the September–November submissions to ARR, which primarily targeted ACL 2022. We worked together to integrate ARR and some of the conference workflows to ensure scaling up, and to maintain the quality and the timely processing of the submissions for November, and thus to guarantee that all papers submitted by the November 15, 2021 ARR deadline could be considered for ACL 2022 if the authors decided to commit them. This required making sure we had all reviews and meta-reviews ready in time, which we managed to achieve thanks to the combined efforts of the ARR and the ACL 2022 teams. We would also like to note that this is a community effort, and we are grateful for the support of the authors, the reviewers, the Action Editors (AEs), and the Senior Area Chairs (SACs), who have been constructively engaging and helping with ARR and ACL 2022.

Committing to ACL 2022

The commitment form for ACL 2022 asked the authors to provide a link to their paper in ARR: we asked for a link to the latest version of the paper that had reviews and a meta-review. The authors also needed to select an area (including the Special Theme area) they were submitting their paper to (this was needed as ACL 2022 had areas, while ARR did not). Finally, the authors were allowed to submit optional comments to the ACL 2022 Senior Area Chairs (SACs). Note that these comments were only visible to the SACs, and they were not sent to the reviewers or to the Action Editors: the rationale was that responding to reviewers and Action Editors should be handled in a response letter if the authors decided to do a resubmission in ARR, which is a completely different process than committing a paper to ACL 2022. These comments to the SACs were designed mainly to raise concerns about objective misunderstandings by the reviewers and/or by the Action Editor about the technical aspect of the paper that the authors believed might help the SACs in their decision-making process.

Areas While ARR did not have areas, ACL 2022 did: it had 23 areas, including the 22 areas from ACL 2021 plus our Special Theme. Our special theme was on "*Language Diversity: from Low-Resource to Endangered Languages*," to commemorate the 60th anniversary of ACL with the goal of reflecting and stimulating a discussion about how advances in computational linguistics and natural language processing can be used to promote language diversity from low-resource to endangered languages. We invited papers that discuss and reflect on the "role of the speech and language technologies in sustaining language use" (Bird, 2020) for the large variety of world languages with focus on under-resourced, indigenous, and/or endangered languages. We were interested in the challenges for developing and scaling up the current NLP technologies for the rich diversity of human languages and in the ethical, cultural, and policy implications of such technologies for local communities. We also have a best Theme paper award category.

Acceptance to ACL 2022

As ACL 2022 submissions in ARR, we count all papers from September, October, and November, which we advertised as ACL 2022 months, after removing all re-submissions and also nine papers that selected NAACL 2022 as a preferred venue (a total of 3,360 papers) + the papers from the May–August period that were actually committed to ACL 2022 and that were not resubmissions (a total of 18 papers), for a total of 3,378 papers.

This number is on par with the number of submissions to ACL 2021, which received 3,350 submissions. Subsequently, 1,918 papers were committed to ACL 2022 (i.e., 57%). After the review process, 701 papers (604 long and 97 short) were accepted into the main conference.

Acceptance Rates for the Main Conference

The quality of a conference is often perceived based on the acceptance rate of the papers submitted there, and thus it is important to have an acceptance rate that adequately represents the difficulty of publishing a paper in the conference. Given the adoption of ARR, it is also important to allow for consistency across various conferences. Thus, ACL 2022 (and NAACL 2022) adopted the following two ways of calculating the acceptance rates:

(a) *(Number of accepted papers at ACL 2022) / (Number of papers that selected ACL 2022 as the preferred venue in ARR or were committed to ACL 2022).* For ACL 2022, for the denominator we consider the 3,378 papers as explained above. Thus, the acceptance rate is 701 / 3,378 = 20.75% for the Main conference.

(b) *(Number of accepted papers at ACL 2022) / (Number of papers committed to ACL 2022).* For the denominator, we had 1,918 papers committed to ACL 2022, and thus, the acceptance rate is 701 / 1,918 = 36.54% for the Main conference.

Note that option (a) is closer to the way the acceptance rate was computed at previous *ACL conferences, where submitting and committing a paper was done in one step and papers were rarely withdrawn after the reviews, the meta-reviews, and the corresponding scores were released. However, one issue with this option for ACL 2022 was that indicating a preferred venue was only enabled starting with the October ARR submissions, and it was not available for earlier months. As mentioned above, we removed a small number of papers from our denominator that selected NAACL 2022 as a preferred venue in October and November (a total of 9 papers) and we considered the ARR submissions only for the months of September, October, and November, as these months were advertised in our CFP, plus any papers that were committed to ACL 2022 from earlier months (May–July) and which were also not resubmissions.

Option (b) yields a higher "acceptance rate", as many authors with low reviewing scores chose not to commit their paper to ACL 2022.

Best Paper Awards

From the committed ACL 2022 papers, we selected 32 papers as candidates for the following Best Paper awards, based on nominations by the Senior Area Chairs: Best Research Paper, Best Special Theme

Paper, Best Resource Paper, and Best Linguistic Insight Paper. These papers were assessed by the Best Paper Award Committee. The selected best papers will be presented in a dedicated plenary session for Best Paper Awards on May 24, 2022.

Findings of ACL 2022

Given the success of the Findings at EMNLP 2020 and 2021 and ACL-IJCNLP 2021, we also have Findings of ACL 2022 papers, which are papers that were not accepted for publication in the main conference, but nonetheless were assessed by the Program Committee as solid work with sufficient substance, quality, and novelty. A total of 361 papers were offered to be included in the Findings of ACL 2022. Given the two ways of computing acceptance rates described above, this results in a 10.68% acceptance rate in option (a), and 19.82% in option (b). Out of the 361 papers, 30 papers declined the offer, leading to 331 papers to be published in the Findings of ACL 2022. In order to increase the visibility of the Finding of ACL 2022 papers, we offered the authors of these 331 papers the possibility to present their work as a poster at ACL 2022, in addition to making a 6-minute or a 3-minute video to be included in the virtual conference site (for long and for short papers, respectively). The authors of 305 of the 331 papers accepted our invitation to present their work as a poster at ACL 2022.

TACL and Computational Linguistics

Continuing the tradition from previous years, ACL 2022 also features 43 articles that were published at the Transactions of the Association for Computational Linguistics (TACL) and 8 papers from the Computational Linguistics journal.

Keynote and Invited Speakers

Another highlight of our program are the keynotes, which we run in three different formats:

- **a keynote talk** by Angela Friederici (Max Planck Institute for Human Cognitive and Brain Sciences) on "*Language in the Human Brain*";
- **a keynote fire-side chat** on "*The Trajectory of ACL and the Next 60 years*" with Barbara Grosz (Harvard University) and Yejin Choi (University of Washington and Allen Institute for Artificial Intelligence), moderated by Rada Mihalcea (University of Michigan);
- **a keynote panel** on "How can we support linguistic diversity?" led by Steven Bird (Charles Darwin University), with panelists representing a variety of world languages, including (currently confirmed) Teresa Lynn (Irish), Robbie Jimerson (Seneca), Heather Long (Creole languages), and Manuel Mager (Wixaritari).

We further had two additional invited talk initiatives:

- **Spotlight Talks by Young Research Stars (STIRS)** by Eunsol Choi (University of Texas at Austin), Ryan Cotterell (ETH Zurich), Sebastian Ruder (Google, London), Swabha Swayamdipta (Allen Institute for AI), and Diyi Yang (Georgia Tech);
- **Next Big Ideas Talks** by Marco Baroni (Pompeu Fabra University), Eduard Hovy (The University of Melbourne and Carnegie Mellon University), Heng Ji (UIUC), Mirella Lapata (University of Edinburgh), Hang Li (Bytedance Technology), Dan Roth (University of Pennsylvania and Amazon), and Thamar Solorio (University of Houston).

Thank You

ACL 2022 is the result of a collaborative effort and a supportive community, and we want to acknowledge the efforts of so many people who have made significant efforts into the organization of ACL 2022! First of all, we would like to thank our Program Committee (the full list of names is quite long and it is included in the Program Committee pages of the Proceedings):

- Our awesome 82 Senior Area Chairs who were instrumental in every aspect of the review process, from liaising with ARR, to supporting the implementation of a two-stage reviewing system, recommending Action Editors and reviewers, working on paper acceptance, and nomination of best papers and outstanding reviewers. For all of them, this involved familiarizing themselves with a new protocol to accommodate the integration of ARR reviews and a new system, and for many of them, the scope of their responsibilities was equivalent to chairing a small conference.
- The 363 ARR Action Editors (from the June–November ARR cycles), who had the role of ACL 2022 Area Chairs interacting with reviewers, leading paper review discussions, and writing meta-reviews.
- The 2,323 ARR reviewers (from the June–November ARR cycles), who contributed for the ACL 2022 reviewing cycles, providing valuable feedback to the authors.
- The emergency ARR Action Editors and reviewers, who provided their support at the last minute to ensure a timely reviewing process.
- The amazing ARR team, who collaborated in the challenge of managing and implementing the ARR reviewing needed for the scale of ACL 2022. In particular, we acknowledge Amanda Stent and Goran Glavaš as Guest ARR Editors-in-Chief for ACL 2022, Graham Neubig as Guest ARR Chief Technical Officer for ACL 2022, and Sara Goggi as Guest ARR Editorial Manager for ACL 2022.

ACL 2022 counted on the contributions of many wonderful committees, including:

- Our Best Paper Selection Committee, who selected the best papers and the outstanding papers: Tim Baldwin, Kathleen McKeown, David Chiang, Min-Yen Kan, and Taro Watanabe.
- Our Ethics Advisory Committee, chaired by Christiane Fellbaum and Su Lin Blodgett, for their hard work to ensure that all the accepted papers addressed the ethical issues appropriately, under a very tight schedule and on a new platform.
- Our amazing Publication Chair Danilo Croce, our Handbook Chair Marco Polignano, the Technical OpenReview Chair Rodrigo Wilkens, and the Scheduler Chair Jordan Zhang, who jointly with the NAACL 2022 Publication Chair, Ryan Cotterell, made an enormous contribution to the community by implementing the integration scripts for generating the proceedings, the handbook and the schedule from the OpenReview platform.
- Our Publicity Chairs Isabelle Augenstein, Emmanuele Chersoni, Diana Maynard, Soujanya Poria, and Joel Tetreault, for their work on managing the communications on social media platforms.
- The Internal Communications Chair Marcely Boito Zanon for streamlining the processes.
- The wonderful Technical OpenReview Chair Rodrigo Wilkens, who went above and beyond to ensure that the typical ACL conference functionalities were translated to a new environment.

We would also like to thank many people who helped us with various software used for the conference:

- The ARR Tech team, in particular Sebastin Santy and Yoshitomo Matsubara, who served as Guest ARR Tech Team for ACL 2022.

- The OpenReview team, in particular Nadia L'Bahy, Celeste Martinez Gomez, and Melisa Bok, who helped to implement the integration of ARR as a reviewing platform for ACL 2022.
- The whole Underline team, in particular Sol Rosenberg, Jernej Masnec, Damira Mršić, and Mateo Antonic, who created a virtual site for the conference.

As Program chairs, we had to deal with many tasks, including handling new protocols and situations and a new conference management environment. We would not be able to complete these tasks without the advice from our colleagues, including

- Our fantastic General Chair Bernardo Magnini, who provided invaluable support and feedback throughout the whole process, including collaborating on the efforts to take on the challenge of reengineering the conference reviewing processes and pipeline.
- The Program Co-Chairs of NAACL 2022 Marine Carpuat, Marie-Catherine de Marneffe, and Ivan Vladimir Meza Ruiz, and the NAACL 2022 General Chair, Dan Roth, for collaborating in the challenge of coordinated adoption of ARR reviewing in a full scale for ACL 2022 and NAACL 2022.
- The Program Co-Chairs of previous editions of *ACL conferences, in particular the ACL-IJCNLP 2021 PC chairs Roberto Navigli, Fei Xia, and Wenjie Li, as well as the EMNLP 2021 PC chairs Lucia Specia, Scott Wen-tau Yih, and Xuanjing Huang for providing amazing guidance and support, and sharing their experience and answering our many questions, often on short notice.
- The ACL Executive Committee, especially Tim Baldwin (the ACL President), Rada Mihalcea (the ACL Past President), Shiqi Zhao (Secretary), Priscilla Rasmussen (Business Manager), and the members of the ACL executive committee for providing invaluable feedback and for helping us sort through various issues.
- The Computational Linguistics Editor-in-Chief Hwee Tou Ng, the TACL Editors-in-Chief Ani Nenkova and Brian Roark, and the TACL Editorial Assistant Cindy Robinson, for coordinating the Computational Linguistics and the TACL presentations at ACL 2022.

We would also like to thank all the authors who submitted/committed their work to ACL 2022. Although we were only able to accept a small percentage of the submissions, your hard work makes this conference exciting and our community strong. Our huge thanks goes to the *ACL communities for the kind and patient support during a year of major changes in our submission and reviewing processes.
Last, but not least, we thank our students, interns, postdocs, colleagues, and families for being so understanding and supportive during this intense year, and especially when we were swamped by countless conference deadlines and meetings. Our deepest gratitude is to all of you. We hope you will enjoy this 60th Anniversary edition of ACL.

Smaranda Muresan (Columbia University and Amazon AWS AI Labs, USA)
Preslav Nakov (Qatar Computing Research Institute, HBKU)
Aline Villavicencio (University of Sheffield, UK)

ACL 2022 Program Committee Co-Chairs

Message from the Local Chairs

Back in March 2020, just after the first COVID-19 lockdown, we submitted our bid for Dublin to host ACL 2022, conference that you are currently attending. In November 2020, we learned that our bid had been successful, which we were of course delighted to hear. Of course, at that stage – and at many points in between – we have wondered whether we would be able to meet face-to-face at all, and it is great that we are able to host you in the wonderful city of Dublin where we are privileged to live, as well as accommodating many of you online.

ACL is an opportunity to welcome not just our European friends and colleagues, but also those from farther afield. Ireland punches above its weight in the areas of NLP and Machine Learning, principally through the SFI-funded €100 million ADAPT Centre for Digital Content Technology, which comprises experts from 4 local Dublin universities as well as 4 further universities from across the country in a range of disciplines in AI. We have internationally renowned groups in machine translation, information retrieval, speech technology, parsing and grammar Induction, among others, so we believe it is appropriate that ACL is being held in our country for the first time. We are of course grateful to everyone who submitted a paper; whether your work was selected for presentation or not, if no-one had submitted, we wouldn't have had a conference. For those of you whose work was selected for presentation, many thanks for coming to Dublin, or for presenting online.

Along the way, we have been helped greatly by the General Chair Bernardo Magnini, and by Priscilla Rasmussen and others from the ACL executive team, to whom we are extremely thankful. However, by far the biggest thanks are due to Greg Carew and his team in Abbey Conference and Events for their professional support of the conference. You will have met them at registration, and they are available throughout the event to ensure your needs are met. We have been engaging with them for 2 years now on ACL, and for longer as they helped Andy host the MT Summit in 2019. We could not have made a better choice of PCO to assist us with all the requirements involved in hosting the best-regarded conference in our area. This has been a true partnership that has made this journey an enjoyable one.

We are also extremely grateful to Fáilte Ireland for their extremely generous support of this conference, and to our PostDocs Guodong Xie & Pintu Lohar (with Andy at DCU), and Vasudevan Nedumpozhimana & Filip Klubička (with John at TUD) for their huge efforts to recruit and manage the small army of student volunteers. Finally, we really hope that you all enjoy the conference, that you benefit from the excellent programme that has been assembled, and that you go away from here having made new friends. We are fortunate indeed that many of our very best friends are in the computational linguistics community, and we will try our very best to meet as many of you as possible during the event.

Andy Way (Dublin City University, Ireland)
John Kelleher (TU Dublin, Ireland)

Abstract

Whole word masking (WWM), which masks all subwords corresponding to a word at once, makes a better English BERT model (Sennrich et al., 2016). For the Chinese language, however, there is no subword because each token is an atomic character. The meaning of a word in Chinese is different in that a word is a compositional unit consisting of multiple characters. Such difference motivates us to investigate whether WWM leads to better context understanding ability for Chinese BERT. To achieve this, we introduce two probing tasks related to grammatical error correction and ask pretrained models to revise or insert tokens in a masked language modeling manner. We construct a dataset including labels for 19,075 tokens in 10,448 sentences. We train three Chinese BERT models with standard character-level masking (CLM), WWM, and a combination of CLM and WWM, respectively. Our major findings are as follows: First, when one character needs to be inserted or replaced, the model trained with CLM performs the best. Second, when more than one character needs to be handled, WWM is the key to better performance. Finally, when being fine-tuned on sentence-level downstream tasks, models trained with different masking strategies perform comparably.

1 Introduction

BERT (Devlin et al., 2018) is a Transformer-based pretrained model, whose prosperity starts from English language and gradually spreads to many other languages. The original BERT model is trained with character-level masking (CLM). [1] A certain percentage (e.g. 15%) of tokens in the input sequence is masked and the model is learned to predict the masked tokens.

It is helpful to note that a word in the input sequence of BERT can be broken into multiple wordpiece tokens (Wu et al., 2016).[2] For example, the input sentence “`She is undeniably brilliant`” is converted to a wordpiece sequence “`She is un ##deni ##ably brilliant`”, where “`##`” is a special prefix added to indicate that the token should be attached to the previous one. In this case the word “`undeniably`” is broken into three wordpieces {“`un`”, “`##deni`”, “`##ably`”}. In standard masked language modeling, CLM may mask any one of them. In this case, if the token “`##ably`” is masked, it is easier for the model to complete the prediction task because “`un`” and “`##deni`” are informative prompts. To address this, Whole word masking (WWM) masks all three subtokens (i.e., {“`un`”, “`##deni`”, “`##ably`”}) within a word at once. For Chinese, however, each token is an atomic character that cannot be broken into smaller pieces. Many Chinese words are compounds that consisting of multiple characters (Wood and Connelly, 2009). [3] For example, “手机” (`cellphone`) is a word consisting of two characters “手” (`hand`) and “机” (`machine`). Here, learning with WWM would lose the association among characters corresponding to a word.

In this work, we introduce two probing tasks to study Chinese BERT model’s ability on character-level understanding. The first probing task is character replacement. Given a sentence and a position where the corresponding character is erroneous, the task is to replace the erroneous character with the correct one. The second probing task is character insertion. Given a sentence and the positions where

[†] Corresponding author.

[1] Next sentence prediction is the other pretraining task adopted in the original BERT paper. However, it is removed in some following works like RoBERTa (Liu et al., 2019). We do not consider the next sentence prediction in this work.

[2] In this work, wordpiece and subword are interchangeable.

[3] When we describe Chinese tokens, “character” means 字 that is the atomic unit and “word” means 词 that may consist of multiple characters.

Findings of the Association for Computational Linguistics: ACL 2022, pages 1 - 8
May 22-27, 2022

a given number of characters should be inserted, the task is to insert the correct characters. We leverage the benchmark dataset on grammatical error correction (Rao et al., 2020a) and create a dataset including labels for 19,075 tokens in 10,448 sentences.

We train three baseline models based on the same text corpus of 80B characters using CLM, WWM, and both CLM and WWM, separately. We have the following major findings. (1) When one character needs to be inserted or replaced, the model trained with CLM performs the best. Moreover, the model initialized from RoBERTa (Cui et al., 2019) and trained with WWM gets worse gradually with more training steps. (2) When more than one character needs to be handled, WWM is the key to better performance. (3) When evaluating sentence-level downstream tasks, the impact of these masking strategies is minimal and the model trained with them performs comparably.

2 Our Probing Tasks

In this work, we present two probing tasks with the goal of diagnosing the language understanding ability of Chinese BERT models. We present the tasks and dataset in this section.

The first probing task is character replacement, which is a subtask of grammatical error correction. Given a sentence $s = \{x_1, x_2, ..., x_i, ..., x_n\}$ of n characters and an erroneous span $es = [i, i+1, ..., i+k]$ of k characters, the task is to replace es with a new span of k characters.

The second probing task is character insertion, which is also a subtask of grammatical error correction. Given a sentence $s = \{x_1, x_2, ..., x_i, ..., x_n\}$ of n characters, a position i, and a fixed number k, the task is to insert a span of k characters between the index i and $i+1$.

We provide two examples of these two probing tasks with $k = 1$ in Figure 1. For the character replacement task, the original meaning of the sentence is "*these are all my ideas*". Due to the misuse of a character at the 7th position, its meaning changed significantly to "*these are all my attention*". Our character replacement task is to replace the misused character "主" with "注". For the character insertion task, what the writer wants to express is "*Human is the most important factor*. However, due to the lack of one character between the 5th and 6th position, its meaning changed to "*Human is the heaviest factor*". The task is to insert "要" after the 5th position. Both tasks are also extended to multiple characters (i.e., $k \geq 2$). Examples can be found at Section 3.2.

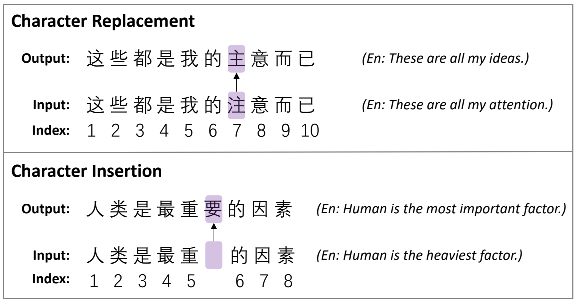

Figure 1: Illustrative examples of two probing tasks. For character replacement (upper box), the highlighted character at 7th position should be replaced with another one. For character insertion (bottom box), one character should be inserted after the 5th position. Translations in English are given in parentheses.

We build a dataset based on the benchmark of Chinese Grammatical Error Diagnosis (CGED) in years of 2016, 2017, 2018 and 2020 (Lee et al., 2016; Rao et al., 2017, 2018, 2020b). The task of CGED seeks to identify grammatical errors from sentences written by non-native learners of Chinese (Yu et al., 2014). It includes four kinds of errors, including insertion, replacement, redundant, and ordering. The dataset of CGED composes of sentence pairs, of which each sentence pair includes an erroneous sentence and an error-free sentence corrected by annotators. However, these sentence pairs do not provide information about erroneous positions, which are indispensable for the character replacement and character insertion. To obtain such position information, we implement a modified character alignment algorithm (Bryant et al., 2017) tailored for the Chinese language. Through this algorithm, we obtain a dataset for the insertion and replacement, both of which are suitable to examine the language learning ability of the pretrained model. We leave redundant and ordering types to future work. The statistic of our dataset is detailed in Appendix A.

3 Experiments

In this section, we first describe the BERT-style models that we examined, and then report numbers.

3.1 Chinese BERT Models

We describe the publicly available BERT models as well as the models we trained.

	Length = 1		Length = 2		Length > 3		Average	
Insertion	p@1	p@10	p@1	p@10	p@1	p@10	p@1	p@10
BERT-base	76.0	97.0	37.2	76.0	14.4	50.1	42.5	74.4
Ours-clm	**77.2**	**97.3**	36.7	74.4	13.3	49.3	42.4	73.7
Ours-wwm	56.6	80.1	**42.9**	79.1	19.3	**54.0**	39.6	71.1

Ours-wwm	34.8	68.2	25.7	65.3	7.4	35.2	22.6	56.2
Ours-clm-wwm	59.2	93.7	**26.5**	**66.4**	**12.4**	41.6	**32.7**	**67.2**

Table 1: Probing results on character replacement and insertion.

Character Replacement

Input: 我没有权利破害别人的生活
(En: I have no right to destroy other people's lives.)
Label: 坏 **Prediction:** 坏 (99.97%)

Input: 代沟问题越来越深刻。
(En: The problem of generation gap is getting worse.)
Label: 严重 **Prediction:** 严 (79.94%) 重 (91.85%)

Character Insertion

Input: 吸烟不但对自己的健康好，而且对非吸烟者带来不好的影响。
(En: Smoking is not only bad for your health, but also bad to non-smokers.)
Label: 不 **Prediction:** 不 (99.98%)

Input: 我下次去北京的时候，一定要吃北京烤鸭，我们在北京吃过的是越南料理等外国的。
(En: Next time I go to Beijing, I can not miss the Peking Duck. What we have eaten in Beijing are Vietnamese cuisine and other foreign dishes.)
Label: 饭菜 **Prediction:** 美 (40.66%) 食 (33.55%)

Figure 2: Top predictions of Ours-clm-wwm for replacement and insertion types. For each position, probability of the top prediction is given in parenthesis. The model makes the correct prediction for top three examples. For the bottom example, the prediction also makes sense, although it is different from the ground truth.

As mentioned earlier, BERT-base (Devlin et al., 2018)[4] is trained with the standard MLM objective.[5] To make a fair comparison of CLM and WWM, we train three simple Chinese BERT baselines from scratch[6]: (1) Ours-clm: we train this model using CLM. (2) Ours-wwm: this model only differs in that it is trained with WWM. (3) Ours-clm-wwm: this model is trained with both CLM and WWM objectives. We train these three models on a text corpus of 80B characters consisting of news, wiki, and novel texts. For the WWM task, we use a public word segmentation tool Texsmart (Zhang et al., 2020) to tokenize the raw data first. The mask rate is 15% which is commonly used in existing works. We use a max sequence length of 512, use the ADAM optimizer (Kingma and Ba, 2014) with a batch size of 8,192. We set the learning rate to 1e-4 with a linear optimizer with 5k warmup steps and 100k training steps in total. Models are trained on 64 Tesla V100 GPUs for about 7 days.

3.2 Probing Results

We present the results on two probing tasks here. Models are evaluated by Prediction @k, denoting whether the ground truth for each position is covered in the top-k predictions. From Table 1, we can make the following conclusions. First, Ours-clm consistently performs better than Ours-wwm on probing tasks that one character needs to be replaced or inserted. We suppose this is because WWM would lose the association between characters corresponding to a word. Second, WWM is crucial for better performance when there is more than one character that needs to be corrected. This phenomenon can be observed from the results of Ours-wwm and Ours-clm-wwm, which both adopt WWM and perform better than Ours-clm. Third, pretrained with a mixture of CLM and WWM, Ours-clm-wwm performs better than Ours-wwm in the one-character setting and does better than

---

[4] `https://github.com/google-research/bert/blob/master/README.md`

[5] We do not compare with RoBERTa-wwm-ext because the released version lacks of the language modeling head.

[6] We also further train these models initialized from RoBERTa and BERT and results are given in Appendix B.

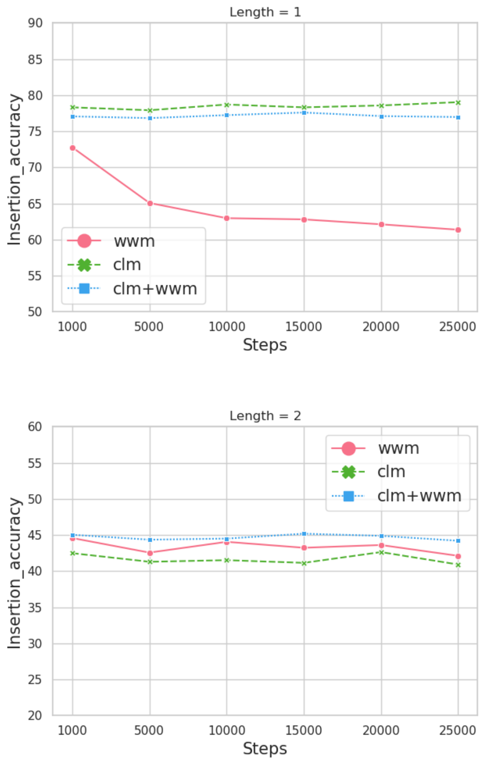

Figure 3: Model performance at different training steps on the probing task of character insertion. The top and bottom figures give the results evaluated on spans with one and two characters, respectively.

Ours-clm when more than one characters need to be handled. For each probing task, two examples with predictions produced by Ours-clm-wwm are given in Figure 2.

3.3 Analysis

To further analyze how CLM and WWM affect the performance on probing tasks, we initialized our model from RoBERTa (Cui et al., 2019) and further trained baseline models. We show the performance of these models with different training steps on the insertion task. From Figure 3 (top), we can observe that as the number of training steps increases, the performance of Ours-wwm decreases.

In addition, we also evaluate the performance of trained BERT models on downstream tasks with model parameters fine-tuned. The performance of Ours-clm-wwm is comparable with Ours-wwm and Ours-clm. More information can be found in Appendix C.

4 Related Work

We describe related studies on Chinese BERT model and probing of BERT, respectively.

The authors of BERT (Devlin et al., 2018) provided the first Chinese BERT model which was trained on Chinese Wikipedia data. On top of that, Cui et al. (2019) trained RoBERTa-wwm-ext with WWM on extended data. Cui et al. (2020) further trained a Chinese ELECTRA model and MacBERT, both of which did not have `[MASK]` tokens. ELECTRA was trained with a token-level binary classification task, which determined whether a token was the original one or artificially replaced. In MacBERT, `[MASK]` tokens were replaced with synonyms and the model was trained with WWM and ngram masking. ERNIE (Sun et al., 2019) was trained with entity masking, similar to WWM yet tokens corresponding to an entity were masked at once. Language features are considered in more recent works. For example, AMBERT (Zhang and Li, 2020) and Lattice-BERT (Lai et al., 2021) both take word information into consideration. ChineseBERT (Sun et al., 2021) utilizes pinyin and glyph of characters.

Probing aims to examine the language understanding ability of pretrained models like BERT when model parameters are clamped, i.e., without being fine-tuned on downstream tasks. Petroni et al. (2019) study how well pretrained models learn factual knowledge. The idea is to design a natural language template with a `[MASK]` token, such as “`the wife of Barack Obama is [MASK].`”. If the model predicts the correct answer “`Micheal Obama`”, it shows that pretrained models learn factual knowledge to some extent. Similarly, Davison et al. (2019) study how pretrained models learn commonsense knowledge and Talmor et al. (2020) examine on tasks that require symbolic understanding. Wang and Hu (2020) propose to probe Chinese BERT models in terms of linguistic and world knowledge.

5 Conclusion

In this work, we present two Chinese probing tasks, including character insertion and replacement. We provide three simple pretrained models dubbed Ours-clm, Ours-wwm, and Ours-clm-wwm, which are pretrained with CLM, WWM, and a combination of CLM and WWM, respectively. Ours-wwm is prone to lose the association between words and result in poor performance on probing tasks when one character needs to be inserted or replaced. Moreover, WWM plays a key role when two or more characters need to be corrected.

B Probing results from models with different initialization

We also verify the performance of models initialized from BERT (Devlin et al., 2018) and RoBERTa (Cui et al., 2019) on probing tasks. The results are detailed in Table 3, from which we can obtain consistent conclusions with the previous section.

C The evaluation on downstream tasks

We test the performance of BERT-style models on tasks including text classification (TNEWS, IFLYTEK), sentence-pair semantic similarity (AFQMC), coreference resolution (WSC), key word recognition (CSL), and natural language inference (OCNLI) (Xu et al., 2020a). We follow the standard fine-tuning hyper-parameters used in Devlin et al. (2018); Xu et al. (2020b); Lai et al. (2021) and report results on the development sets. The detailed results is shown in Table 4.

Abstract

Automatically generating compilable programs with (or without) natural language descriptions has always been a touchstone problem for computational linguistics and automated software engineering. Existing deep-learning approaches model code generation as text generation, either constrained by grammar structures in decoder, or driven by pre-trained language models on large-scale code corpus (e.g., CodeGPT, PLBART, and CodeT5). However, few of them account for compilability of the generated programs. To improve compilability of the generated programs, this paper proposes CompCoder, a three-stage pipeline utilizing compiler feedback for compilable code generation, including language model fine-tuning, compilability reinforcement, and compilability discrimination. Comprehensive experiments on two code generation tasks demonstrate the effectiveness of our proposed approach, improving the success rate of compilation from 44.18 to 89.18 in code completion on average and from 70.3 to 96.2 in text-to-code generation, respectively, when comparing with the state-of-the-art CodeGPT.

1 Introduction

Automated code generation (or program synthesis) has attracted much attention over the past few years (Lu et al., 2021), because of its potential to improve the productivity of developers, as well as to speed up the software development (Parvez et al., 2021; Wang et al., 2021). In the life cycle of software development, different types of code generation tasks are desired, including code completion (Liu et al., 2020b,a), text-to-code generation (Hashimoto et al., 2018), program translation (Chen et al., 2018), and program repair (Yasunaga and Liang, 2021).

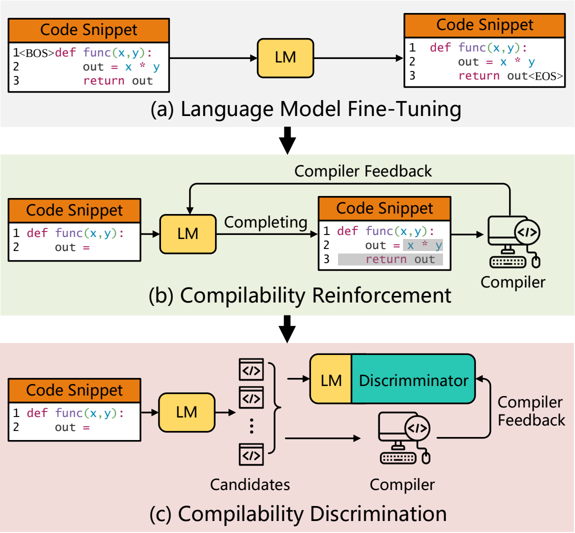

Figure 1: An illustration of Python code completion by CompCoder, utilizing the compiler feedback with three stages.

Recently, much effort has been made to advance the development of code generation (Li et al., 2018), using different logical forms of code, such as the abstract syntax tree (AST) (Kim et al., 2021; Yin and Neubig, 2017; Rabinovich et al., 2017), sketch (Nye et al., 2019) and graph (Yasunaga and Liang, 2020). Benefiting from the strong power of pre-training techniques (Devlin et al., 2019; Wang et al., 2021a) in natural language processing, several attempts have been made towards pre-training a language model on large-scale code corpus for code generation, such as CodeGPT (Lu et al., 2021), PLBART (Ahmad et al., 2021), and CodeT5 (Wang et al., 2021b).

However, to the best of our knowledge, most deep-learning approaches for code generation are still difficult to guarantee the compilability of the generated code, resulting in non-compilable code. For example, Chen et al. (2021) found that up to 67%-97% of patches generated by the most advanced deep-learning-based models are non-

May 22-27, 2022

compilable. We think this is because they generally do not directly optimize the compilability for code generation. The generation of non-compilable code will waste the time of programmers, as well as seriously reduce the trust and satisfaction of developers with the model. To improve the compilability of the generated code, some works attempt to repair the synthesized program which fails to compile (Kulal et al., 2019; Yasunaga and Liang, 2020, 2021). Recently, Korbak et al. (2021) attempt to directly generate compilable code using an energy model with compilability constraints.

This paper focuses on the task of compilable neural code generation. Different from previous works, we use compilability signals in two ways and design a novel method to jointly train the discriminator and generator for compilable code generation. Concretely, we propose COMPCODER, a novel three-stage pipeline utilizing compiler feedback for compilable code generation, including language model fine-tuning, compilability reinforcement, and compilability discrimination. Figure 1 shows an example of Python code completion by COMPCODER, which utilizes the compiler feedback in two ways. In Figure 1(b), we use the compiler feedback to optimize the generator. In Figure 1(c), we use the discriminator to check if the results generated by the generator can be successfully compiled. The joint training of the generator and discriminator significantly improves the compilability of the generated code.

Overall, the key contributions of this paper are as follows:

- We use compilability signals in two ways and design a novel method to jointly train the generator and discriminator for compilable code generation, called COMPCODER. We refine a pre-trained code generator using reinforcement learning and jointly learn a discriminator to enforce the generator to correct its own mistakes.
- Comprehensive experiments on two code generation tasks demonstrate the effectiveness of COMPCODER. It boosts the average compilation rate of CodeGPT from 44.18 to 89.18 in the code completion task and from 70.3 to 96.2 in the text-to-code generation task.

2 Preliminary

In this section, we set out notations for task formulation, as well as some preliminaries of compiler feedback. Let $s \in \mathcal{S}$ denote a given input, which can be a piece of partial code, natural-language description, or buggy program. Let $t \in \mathcal{T}$ denote the generated source code. Formally, the problem of code generation can be formulated as learning a mapping f between the input space and target code space, i.e. $f : \mathcal{S} \rightarrow \mathcal{T}$. In this paper, we investigate two specific code generation tasks, code completion and text-to-code generation, conditioned on different inputs.

Code Completion Let $c = \{c_1, c_2, \ldots, c_{|c|}\}$ denote a sequence of code tokens for program c, where $|c|$ denotes the length of the code. We use notation $c_{1:\,m} \in \mathcal{S}$ to refer to the previous code snippet $\{c_1, c_2, \ldots, c_m\}$ and notation $c_{m+1:\,|c|} \in \mathcal{T}$ to represent the subsequent code snippet $\{c_{m+1}, \ldots, c_{|c|}\}$. The code completion task can be defined as generating the subsequent (t) code token sequence $c_{m+1:\,|c|}$, given the previous (s) code sequence $c_{1:\,m}$.

Text-to-Code Generation Different from code completion, text-to-code generation aims to generate a whole program based on natural language description. Let $d = \{d_1, d_2, \ldots, d_{|d|}\}$ refer to a sequence of natural-language tokens. The text-to-code generation task can be defined as generating source code $c = t \in \mathcal{T}$, given the corresponding natural language description $d = s \in \mathcal{S}$.

Compiler Feedback As the whole program c is generated, no matter from partial code snippets or natural-language descriptions, we feed it into a compiler to test whether it can be compiled successfully. Formally, we define the the compiler feedback as:

$$\textit{feedback} = \mathbb{1}_{\text{Compiler}}(c)\,, \qquad (1)$$

where the compiler feedback is a binary value (compilable or non-compilable), and c denotes the code snippet fed into the compiler. As for the task of text-to-code generation, we simply feed the generated code t into the compiler, i.e., $c = t$. As for the task of code completion, we concatenate the partial code with generated code as a whole program, i.e., $c = [s; t]$, where ; is the concatenation operation.

3 COMPCODER

Figure 2 shows the overall architecture of COMPCODER on the code completion task, which covers three stages, i.e., language model fine-tuning (Stage 1), compilability reinforcement (Stage 2) and compilability discrimination (Stage 3). In the following

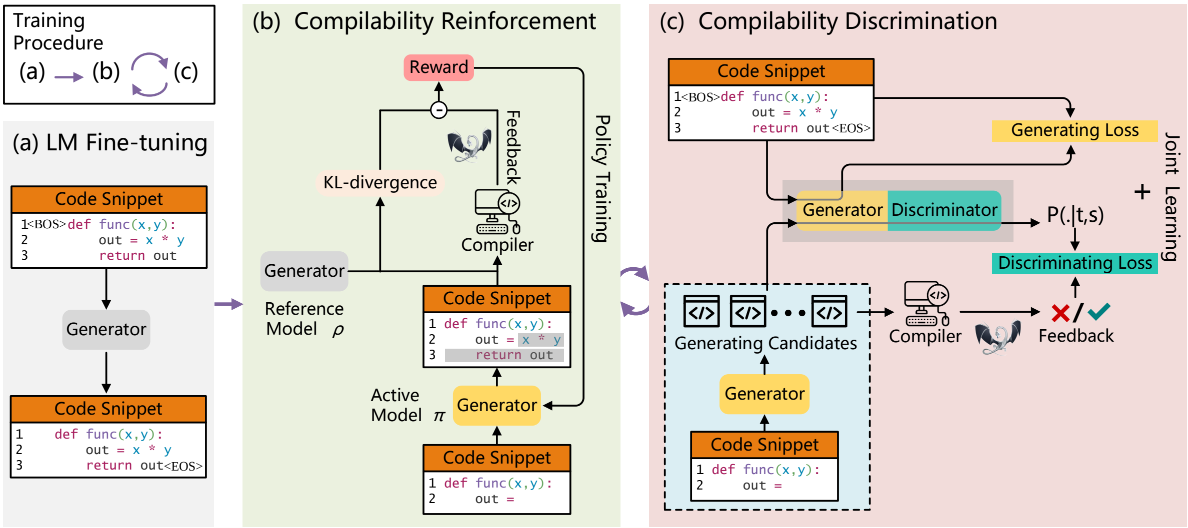

Figure 2: An illustration of our proposed three-stage pipeline for Python code completion. (a) We first fine-tune the generator based on pre-trained language models. (b) We take the compiler feedback into account as a reward via reinforcement learning. (c) We design a compilability discriminator which is jointly trained with the generator, to enforce the generator to correct its own mistakes. Stages 2 and 3 are performed alternately.

subsections, we will elaborate on each stage one by one. We alternately perform Stages 2 and 3, as described in Section 3.4.

3.1 Stage 1: Language Model Fine-Tuning

As shown in Figure 2(a), we adopt CodeGPT as the generator, which uses GPT-2 (Radford et al., 2019) as the starting point and is continually pre-trained on the large-scale code corpus. Our generator is then fine-tuned on the target task to minimize the cross-entropy loss:

$$\mathcal{L}_{\mathrm{G}} = -\frac{1}{|\mathcal{M}|}\sum_{i}^{|\mathcal{M}|}\sum_{j}^{|\mathcal{V}|} Y_{ij}\,\log P_{ij}\,, \qquad (2)$$

where $\mathcal{M}$ denotes the set of the generated code tokens, $\mathcal{V}$ represents the vocabulary, Y_{ij} denotes the label of the code token i in class j, and P_{ij} is the predicted probability of token i in class j.

During training, the generator takes $x = \{\texttt{<BOS>}, c, \texttt{<EOS>}\}$ as the input in the code completion task, and $x = \{d, \texttt{<BOS>}, c, \texttt{<EOS>}\}$ as input in the text-to-code generation task, correspondingly. Special tokens `<BOS>` and `<EOS>` indicate the start and end symbols of code sequences. After several epochs of supervised fine-tuning on the target task dataset, we save the trained generator, which will be used in the next stage.

3.2 Stage 2: Compilability Reinforcement

Reinforcement Learning (RL) is a method of learning the optimal policy by obtaining reward signals from the real environment (Sutton and Barto, 1998; Wan et al., 2018). As shown in Figure 2(b), we use the fine-tuned generator ρ (after Stage 1) as the *reference model*. Then we initialize a policy $\pi = \rho$. Given an input sequence $s \in \mathcal{S}$, our goal is to find a policy π that generates an output sequence $t \in \mathcal{T}$ with the objective of maximizing the compilability-based reward. We use RL (specifically PPO2 version of Proximal Policy Optimization (Schulman et al., 2017)) to directly optimize the expected reward as:

$$\mathbb{E}_{\pi}\left[r\right] = \mathbb{E}_{s\sim\mathcal{S},t\sim\pi(.|s)}\left[r(s,t)\right], \qquad (3)$$

where the policy π is rewarded by the compiler (Eq. 1), r is the reward function. We define $r(s,t) = 1.0$ iff the code can be compiled by the program compiler and $r(s,t) = -1.0$ otherwise.

It is worth mentioning that code compilability constraints can be strong or weak. *Strong constraint* is defined that a long piece of code snippet may not be correctly compiled if a certain token is changed. And *weak constraint* means a blank string consisting of whitespace characters can be correctly compiled by the compiler. Concretely, in the text-to-code generation task, if the generator generates a string composed of whitespace characters, the compiler will consider it as a good case. In the code completion task, if the previous code snippet is compilable, the generator can fool the compiler easily. The RL is good at making use of this, resulting in the generated code can be com-

```

Figure 3: An example of code completion. We mask the last five tokens of the code and let the generator complete them. Some minor mistakes prevent four candidates from being correctly compiled by the program compiler.

piled, but seriously deviating from the generation likelihood objective.

To avoid *active model* π being too far away from *reference model* ρ, we add a Kullback-Leibler (KL) penalty with expectation, e.g., $\beta\text{KL}(\pi, \rho)$ (Ziegler et al., 2019). Therefore, the modified reward will be reformulated as follows:

$$r(s,t) = r(s,t) - \beta \log \frac{\pi(t|s)}{\rho(t|s)}\,, \tag{4}$$

where β is a constant, which plays the role of an entropy bonus, preventing the policy from moving too far from the range where r is valid.

To alleviate the imbalance between the reward term and the KL penalty term and improve the stability of training, we use autoregressive fine-tuning (Causal Language Modeling) (Radford et al., 2019) to make the KL penalty term fluctuate within a small range after RL training. This fine-tuning process incorporates a compilability-aware discriminator that will be introduced in the next stage.

3.3 Stage 3: Compilability Discrimination

Figure 3 shows an example of code completion. We mask the last five tokens of a Python function and ask the generator to complete them. The generator generates five candidates with high probabilities. Some minor mistakes prevent four of them from being successfully compiled. We hope the generator can have more perception power to explicitly distinguish compilable and non-compilable code generated by itself. Therefore, at this stage, we design a compilability-aware discriminator to deal with this issue.

Concretely, we add a discriminator (a two-layer MLP equipped with the $\tanh$ activation function between layers) after the final hidden layer of the generator. As shown in Figure 2(c), given the input sequence (s), we perform beam search on the generator to generate top-k candidates (t). Each entire code $c \in \mathcal{Q}$ ($c = [s;t]$ in the code completion task) is labeled by the program compiler as positive (1) or negative (0), depending on whether it can be successfully compiled (see Eq. 1).

We use the hidden representation of the last token (`<EOS>`) as the final representation of the entire code c. Finally, the hidden representation of the last token (`<EOS>`) is fed into the discriminator for prediction:

$$\begin{aligned} h_{\texttt{<EOS>}} &= \text{CodeGPT}(s,t)\,, && (5)\\ h'_{\texttt{<EOS>}} &= \text{Discriminator}(h_{\texttt{<EOS>}})\,, && (6)\\ P(.|t,s) &= \text{softmax}(h'_{\texttt{<EOS>}})\,, && (7) \end{aligned}$$

where $h_{\texttt{<EOS>}}$ denotes the representation of the last token `<EOS>`. The training loss of the discrimination process can be defined as:

$$\mathcal{L}_{\text{D}} = -\frac{1}{|\mathcal{Q}^{+} \cup \mathcal{Q}^{-}|}\left[\sum_{c\in\mathcal{Q}^{+}} \log\ P(1|t,s) + \sum_{c\in\mathcal{Q}^{-}} \log\ P(0|t,s)\right], \tag{8}$$

where $\mathcal{Q}^{+}$ and $\mathcal{Q}^{-}$ represent positive and negative sets respectively. The parameters of the generator and discriminator will be jointly updated.

At this stage, we jointly train the generator and discriminator, including a generating objective (*to learn the generator only*) and a discriminating objective (*to learn the generator and discriminator together*), as shown in Figure 2(c). The joint training loss is defined as follows:

$$\mathcal{L} = \mathcal{L}_{\text{G}} + \mathcal{L}_{\text{D}}\,. \tag{9}$$

3.4 Overall Pipeline

Training Procedure We perform an interactive training procedure. Concretely, except that the first epoch contains Stages 1, 2, and 3, each subsequent epoch only consists of Stages 2 and 3. We update the *reference model* (at Stage 2), and *candidates* in Stage 3 is generated on the training dataset, which is time consuming, so we update the *candidates* in a preset frequency.

For better understanding, Stage 2 improves the compilability of generated code, Stage 3 distinguishes the compilable and non-compilable code generated by itself. Stage 2 and 3 refine each other and improve the performance iteratively, which is a basic idea of this training procedure. We think that the generator with high compilability (after Stage 2) facilitates the learning of the discriminator (discriminating objective at Stage 3). The autoregressive fine-tuning (generating objective at Stage 3) helps the KL penalty term (at Stage 2) fluctuate in a small range, improving the stability of RL training. At Stage 3, the discriminating objective is optimized by learning the generator and discriminator together, which makes the generator have more perception power to distinguish compilable and non-compilable code.

Inference Procedure The model inference consists of two stages. Given an input sequence (s), we perform the beam search on the generator to generate top-k candidates. The code (c in Eq. 1) with the highest compilability probability evaluated by the discriminator will be selected. Then the output (t) can be obtained as the final result.

4 Experiment Setup

4.1 Evaluation Tasks and Datasets

We conduct experiments on two tasks: code completion and text-to-code generation. To investigate the compilability of the generated code, we need to preserve the indentation and newline operations in code. We also need to make sure that the code and its version belong to the scope of the compiler. Existing datasets on both of the two tasks usually do not serve these considerations. For convenience, we choose Python for experiments, as it is very popular and used in many projects. We conduct all experiments based on Python 3 environment and adopt the `codeop`[1] module to simulate the program compiler. We remove code that could not be compiled correctly by the compiler.

Code Completion For the code completion task, we use the Python corpus in CodeSearchNet (Husain et al., 2019). We want to study the compilability of long enough code, while longer code means higher computational overhead. Therefore, we extract $50k$ compilable Python methods (Python 3 version) with eclectic token lengths ranging from 64 to 96. We randomly select $45k$ samples for training and the remaining $5k$ samples for testing. We mask a different number of tokens at the tail of the source code and let the model complete.

Text-to-Code Generation For the text-to-code generation task, we adopt the AdvTest dataset (Lu et al., 2021), which contains 251,820 text and Python code pairs. We only need code in Python 3 version. We expect code token lengths to range from 128 to 170, a moderate length, and text token lengths to be at least more than 5, containing sufficient semantics. Finally, we extract about $41k$ text-code pairs. We randomly select $40k$ text-code pairs for training, and the remaining $1k$ text-code pairs for testing.

4.2 Evaluation Metrics

To evaluate the quality of the generated code, we adopt two widely-used evaluation metrics: Levenshtein *Edit Similarity (ES)* (Svyatkovskiy et al., 2020; Lu et al., 2021) and *Compilation Rate (CR)* (Kulal et al., 2019). Levenshtein Edit Similarity measures the number of single-character edits required to transform one string into another. It is a critical evaluation metric for the code generation scenario, as it measures the effort required for the developer to correct the code. Compilation Rate measures how many code can be correctly compiled by the program compiler. For both of these metrics, bigger values indicate better performance.

4.3 Baseline Methods

We compare our approach with various state-of-the-art models in the code completion task and the text-to-code generation task:

- **BiLSTM** is a Seq2Seq model based on Bidirectional LSTM with an attention mechanism (Luong et al., 2015).
- **Transformer** (Vaswani et al., 2017) is the base architecture of CodeGPT. We use 6-layer Transformer decoder to conduct experiments.

---

(a) (b) (c) (d)

Figure 4: : Results in the code completion task (completing 30, 35, 40, 45 tokens respectively) evaluating with Edit Similarity (ES) and Compilation Rate (CR) metrics, using the CodeSearchNet-Python dataset.

- **GPT-2** (Radford et al., 2019) is an autoregressive pre-trained model trained on large-scale text corpus.
- **CodeGPT** (Lu et al., 2021) is pre-trained with source code corpus on the basis of GPT-2 vis causal language modeling objective (Radford et al., 2019).
- **PLBART** (Ahmad et al., 2021) is based on the BART (Lewis et al., 2020) architecture, which is pre-trained on large-scale Java and Python corpora via denoising autoencoding.
- **CodeT5** (Wang et al., 2021b) is based on the T5 (Raffel et al., 2020) architecture, which employs denoising sequence-to-sequence pre-training on multiple programming languages.

4.4 Implementation Details

In the code completion task, we set the learning rate as $1.5e$-5, the batch size as 32, the maximum fine-tuning epoch as 20, the maximum code sequence length as 96. We mask different numbers of code tokens (25, 30, 35, 40, and 45) and ask the model to complete them. We set the minimum generation length as 25, 30, 35, 40, and 45 accordingly. In the text-to-code generation task, we set the learning rate as $1.5e$-5, the batch size as 16, the maximum fine-tuning epoch as 20, the maximum text and code sequence length as 32 and 170. We set the minimum generation length as 96 (the generated code is slightly shorter than the ground-truth is allowed). In these two tasks, the generated sequence consisting of whitespace characters will be considered as a bad case.

We use the Adam optimizer to update model parameters. We train our model on the basis of CodeGPT checkpoint[2]. Our model is trained on 2 NVIDIA Tesla V100 with 32GB memory. We employ the same tokenizer as CodeGPT. To train the policy π, we use the PPO2 version of Proximal Policy Optimization (Schulman et al., 2017). In each epoch, we only randomly select 5% training data for the stability of RL training (Stage 2). In other stages (Stages 1 and 3), we use the full training data. To generate *candidates* (at Stage 3), we set the beam size as 5 in beam search. For efficiency, we update the *candidates* every 5 epochs.

Models	ES	CR
BiLSTM	55.32	36.34
Transformer	61.47	40.22
GPT-2	63.02	43.26
CodeGPT	64.47	46.84
COMPCODER	**64.53**	**94.48**

Table 1: Results in the code completion task (completing 25 tokens) evaluating with Edit Similarity (ES) and Compilation Rate (CR) metrics, using the CodeSearchNet-Python dataset.

5 Results and Analysis

5.1 Code Completion

Table 1 shows the results of the code completion task. We mask 25 tokens at the tail of code functions and ask the generation model to complete. We can observe that: (1) The code generated by existing autoregressive models has a low Compilation Rate. CodeGPT and GPT-2 only achieve 46.84 and 43.26 scores respectively on the Compilation Rate, which means that more than half of the code generated by them cannot be correctly compiled by the program compiler. (2) COMPCODER significantly improves the Compilation Rate. It obtains 94.48 scores on the Compilation Rate, which is 47.64 points higher than the closest competitor

---

[2] `https://huggingface.co/microsoft/CodeGPT-small-py-adaptedGPT2`

(CodeGPT). (3) When our approach significantly improves the Compilation Rate, it does not sacrifice the fluency of the generated code. COMPCODER obtains a comparable and even slightly better Edit Similarity score than other baselines, indicating that it effectively preserves the code fluency.

Figure 4 presents more results of the code completion task in the setting of completing 30, 35, 40, and 45 tokens. COMPCODER still effectively improves the Compilation Rate when generating longer code. As the completion length increases, our approach outperforms CodeGPT by 49.66, 47.68, 46.64, and 33.36 points in the setting of completing 30, 35, 40, and 45 tokens, respectively. On average, our approach outperforms CodeGPT by *45* points across a different number of tokens for the task of code completion.

Models	ES	CR
BiLSTM	54.86	48.7
Transformer	57.47	55.6
GPT-2	60.54	63.3
CodeGPT	61.82	70.3
PLBART	62.43	71.9
CodeT5	62.58	73.1
COMPCODER	**62.74**	**96.2**

Table 2: Results in the text-to-code generation task evaluating with Edit Similarity (ES) and Compilation Rate (CR), using the AdvTest dataset.

5.2 Text-to-Code Generation

Table 2 presents the results of the text-to-code generation task. We could see that: (1) COMPCODER significantly outperforms all other models w.r.t. the Compilation Rate. E.g., COMPCODER achieves 23.1 points and 24.3 points improvements when compared with PLBART and CodeT5 respectively. (2) Compared to code completion task (Table 1), all models in the text-to-code generation task have relatively higher Compilation Rate. One of the main reasons we think may be: code completion requires the generated code to be constrained by the existing (previous) code, which is a much stronger restriction than the text-to-code generation.

5.3 Ablation Study

We compare several simplified versions of our model to understand contributions of different components, including the Reinforcement Learning (RL) component and the discriminator's effect for both model training (D_{train}) and model inference (D_{test}). As a case study, we take the code completion task as an example in the setting of completing 25 tokens and present the results in Table 3.

Models	ES	CR
(1) CodeGPT	64.47	46.84
(2) w/ D_{train}	65.46	64.88
(3) w/ RL	64.71	76.48
(4) w/ RL+D_{train}	64.43	83.14
(5) w/ D_{train}+D_{test}	65.24	81.96
(6) w/ RL+D_{train}+D_{test} (Ours)	64.53	94.48

Table 3: Ablation study in the code completion task in the setting of completing 25 code tokens.

Several meaningful observations can be drawn: **First**, both RL (Row 2) and D_{train} (Row 3) effectively increase the code Compilation Rate of the generation model (CodeGPT in Row 1), which confirms that the two components we designed can indeed improve the ability of the generator for compilable code generation. **Second**, applying RL and D_{train} together (Row 4) further improves the Compilation Rate over their individual contributions. **Third**, using the discriminator to select the output during model inference stage (D_{test}) is beneficial. It further boosts the Compilation Rate of vanilla "D_{train}" by 17.08% (Row 5 v.s. Row 2) and boosts "RL+D_{train}" by 11.34% (Row 6 v.s. Row 4). **Forth**, these three components (RL, D_{train}, D_{test}) that effectively improve the Compilation Rate do not compromise the generation capability measured by the Edit Similarity.

5.4 Case Study

To better understand the effectiveness of our proposed approach, we present two cases for code completion and text-to-code generation tasks respectively. For both CodeGPT and COMPCODER, we present top-1 result in Figure 5. For code completion, we observe that CodeGPT can not complete code with high quality (non-compilable), while COMPCODER can complete the code well, and it is *exactly the same* for the reference solution. For text-to-code generation, we observe that although both models can not generate exactly the same code as the reference solution, COMPCODER generates a compilable code at the function level. These results reveal the effectiveness of our proposed approach for compilable code generation.

Text-to-Code Generation

Figure 5: Case study for code completion and text-to-code generation tasks.

6 Related Work

Neural Code Generation With the rapid development of Deep Learning (DL), some researchers attempt to use DL for code generation tasks. Liu et al. (2020a) proposed a neural architecture for code completion task with multi-task learning based on the architecture of Transformer-XL Dai et al. (2019) and BiLSTM (Schuster and Paliwal, 1997). Kim et al. (2021) presented several ways of feeding the code structure to Transformer (Vaswani et al., 2017) and further improved the accuracy of the code prediction (next token prediction) task. Wei et al. (2019) adopted an encoder-decoder architecture and utilized the relations between code generation and code summarization to improve the performance of both tasks. Yasunaga and Liang (2021) proposed a new training approach for program repair. They used the critic to check a fixer's output on real bad inputs and add good outputs to the training data, and trains a breaker to generate realistic bad code from good code. Yasunaga and Liang (2020) used compiler error messages to repair programs. They designed a program-feedback graph and then applied a graph neural network on top to model the reasoning process. Many unlabeled programs are used for program repair with self-supervised learning.

Benefiting from the strong power of pre-training techniques (Devlin et al., 2019; Wang et al., 2021a) in natural language processing, such as GPT (Radford and Narasimhan, 2018), BART (Lewis et al., 2020), and T5 (Raffel et al., 2020), some recent works attempt to pre-train language models on the corpus of source code for code generation. Lu et al. (2021) proposed CodeGPT follows the architecture of GPT-2 (Radford et al., 2019), which is pre-trained with a causal language modeling (CLM) objective on large-scale source code. Ahmad et al. (2021) proposed PLBART follows the architecture of BART (Lewis et al., 2020), which is pre-trained on Java and Python functions paired with code comments via denoising autoencoding. Wang et al. (2021b) proposed CodeT5 based on the T5 (Raffel et al., 2020) architecture, which employs denoising sequence-to-sequence pre-training on multiple programming languages.

Reinforced Text Generation Reinforcement learning (Sutton and Barto, 1998) has shown great success in various tasks. It focuses on how agents ought to take actions in an environment to maximize the cumulative reward, is well suited for decision-making tasks. Ranzato et al. (2016) were among the first to apply REINFORCE algorithm (Williams, 1992) to train recurrent neural networks on sequence generation tasks, suggesting that directly optimizing the metric used at the test phase can lead to better results. Chen and Bansal (2018) proposed a hybrid extractive-abstractive architecture with policy-based reinforcement learning. They used an extractor agent to select salient sentences and then employed an abstractor network to rewrite these extracted sentences. Wan et al. (2018); Wang et al. (2022) incorporated the tree structure and sequential content of code snippets and designed a deep reinforcement learning framework optimized by the metric of BLEU to improve the performance of the code summarization task. Yao et al. (2019) proposed a reinforcement learning framework, which encourages the code annotation model to generate annotations that can be used for code retrieval tasks. Korbak et al. (2021) proposed an energy-based model with an imposed constraint of generating only compilable sequences to improve compilation rates of generated code.

7 Conclusion and Future Work

In this paper, we use the compilability signals in two ways and design a novel method to jointly train the generator and discriminator for compilable code generation, called COMPCODER. Comprehensive experiments on two code generation tasks demonstrate the effectiveness of COMPCODER, improving the average compilation rate of state-of-the-art CodeGPT from 44.18 to 89.18 in the code completion task and from 70.3 to 96.2 in the text-to-code generation task.

This work presents our preliminary attempt to generate compilable code. Yet, considering the compilation rate is not the whole story as it still cannot guarantee the correctness of generated code. As a future work, we would like to utilize unit tests to evaluate the code correctness towards building more useful code generation models.

Abstract

The aspect-based sentiment analysis (ABSA) is a fine-grained task that aims to determine the sentiment polarity towards targeted aspect terms occurring in the sentence. The development of the ABSA task is very much hindered by the lack of annotated data. To tackle this, the prior works have studied the possibility of utilizing the sentiment analysis (SA) datasets to assist in training the ABSA model, primarily via pretraining or multi-task learning. In this article, we follow this line, and for the first time, we manage to apply the Pseudo-Label (PL) method to merge the two homogeneous tasks. While it seems straightforward to use generated pseudo labels to handle this case of label granularity unification for two highly related tasks, we identify its major challenge in this paper and propose a novel framework, dubbed as Dual-granularity Pseudo Labeling (DPL). Further, similar to PL, we regard the DPL as a general framework capable of combining other prior methods in the literature (Rietzler et al., 2019; Bai et al., 2020). Through extensive experiments, DPL has achieved state-of-the-art performance on standard benchmarks surpassing the prior work significantly (Liu et al., 2021).

1 Introduction

1.1 Aspect-based Sentiment Analysis

The aspect-based sentiment analysis (ABSA) task aims to recognize the sentiment polarities centered on the considered aspect terms occurring in the sentence. The establishment of the ABSA task echoes the long-standing literature of conventional sentence-level sentiment analysis (SA). For instance, as shown in Figure 1, a normal ABSA data annotation tags sentiment score on specific aspect terms in the sentence, like "surroundings" as positive and "food" as negative. Meanwhile, in the conventional sentence-based sentiment analysis, the whole sentence is labeled as negative at a coarser granularity.

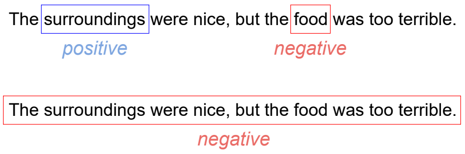

Figure 1: Sentiment Analysis (SA) and Aspect-based Sentiment Analysis (ABSA). The sample on the above is the ABSA task, while the sample on the bottom is the SA task. Both tasks aim at analyzing the sentiments carried by the objects in the box.

Due to its much finer granularity, the annotation cost is significantly higher than its conventional counterpart. Essentially, many of the existing SA datasets (He et al., 2018) can be crawled and curated straightforwardly from the review websites such as Amazon[1] or Yelp[2]. The five-star rating system comes in handy to accomplish the annotation. Thus, the SA datasets are often presented at a large scale. By contrast, the ABSA annotation has no such "free lunch". It has to require human annotators to participate. Coupling with its higher complexity on labeling, the ABSA datasets are ubiquitously at considerably smaller scales (Pontiki et al.; He et al., 2018; Yu et al., 2021b). To this date, the available datasets for conventional sentiment analysis are generally larger to several orders of magnitude than the ABSA.

For instance, the commonly used ABSA benchmark SemEval 2014 task 4 has less than 5000 samples (Pontiki et al.), while there are 4,000,000 sentences in the Amazon Review dataset[3] for SA. Due to the similarity between the SA task and the ABSA task, it is natural to use SA datasets as auxiliary datasets for the ABSA task (He et al., 2018). Most, if not all, previous work has focused on pretraining and multi-task learning methods (He et al., 2018,

May 22-27, 2022

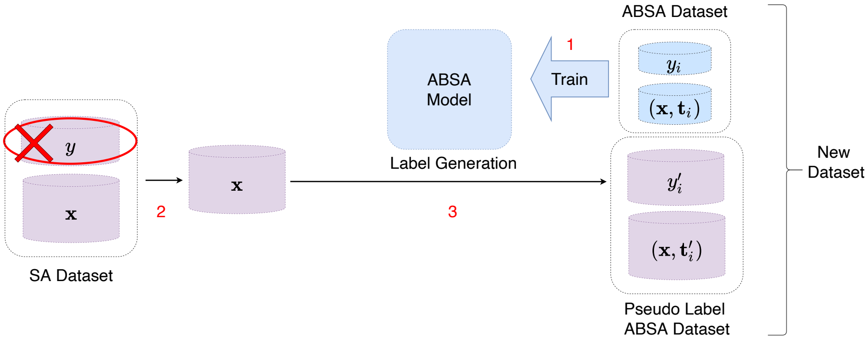

Figure 2: Dataset Generation in the Pseudo-Label (PL) Method. This figure shows a pipeline of the traditional Pseudo-Label method. $\mathbf{x}$ is the input data, a sentence in the SA dataset, while y is the sentiment carried by a sentence. $\mathbf{t}_i$ indicates the position of an aspect term in a sentence, and y_i is the label for that aspect term. $\mathbf{t}_i'$ and y_i' are pseudo labels generated by the ABSA model. As we can see, in the PL method, the sentence sentiment labels are dropped, and the SA dataset is regarded as an unlabeled dataset.

2019b). In this paper, we first take the Pseudo-Label method to utilize the SA datasets to solve the challenge faced by the ABSA task.

1.2 Pseudo-Label

The family of Pseudo-Label methods has had wide success in multiple fields (Pham et al., 2020; Ge et al., 2020; Mallis et al., 2020; Zoph et al., 2020; He et al., 2019a). The core of this family is to “trust” the generated fake labels by running the unlabeled samples through a teacher network that is trained by using the limited number of labeled samples. The generated labeled samples are then combined with the original set of supervised datasets and fed to the final model training.

In this article, our core mission is to incorporate the large-scale datasets into the sentiment analysis with the targeted ABSA task. While there have been works on this line, such as He et al. (2018) and He et al. (2019b), exploring the Pseudo-Label methods has been very much untapped. Indeed, a very straightforward technological solution is depicted in Figure 2. One can apply the traditional Pseudo-Label method to generate a bunch of pseudo-aspect-based sentiment labels from the SA or even the unlabeled datasets. However, a consequence of this is the total abandonment and waste of the provided coarse-grained labels. While seemingly acceptable, we argue that due to the homogeneous root for the ABSA and SA tasks, the under-exploiting of the sentence-level coarse-grained sentiment labels is sub-optimal. It will be unnecessary if the traditional framework throws away the coarser-grained labels containing finer-grained task-relevant information. We argue that the Pseudo-Label family of approaches is limited to fit a *uniform granularity* situation. They ought to evolve and further adapt to the discrepancy of granularity in the label space.

1.3 Dual-granularity Pseudo Labels

To solve the aforementioned problem, we propose the Dual-granularity Pseudo Labeling framework (DPL). In essence, the DPL augments the original PL framework and is capable of leveraging the labels drawn from both granularities. Briefly, the DPL relies on two teacher models obtained from datasets from both granularities, respectively, then generates pseudo labels for both sides. As a result, datasets from both granularity levels can be merged into a whole, with every sentence sample being tagged by both finer- and coarser-set of labels. To facilitate the employment of both sets of labels, we set a few standard conditions as the design principle of DPL. Slightly more concretely, DPL establishes two separate pathways leading to prediction for both granularities. Together, the two pathways interact in the representation space and ideally may possess controlled information flow that respectively corresponds and only correspond to the considered granularity. We incorporate an adversarial module to accomplish this functionality.

On the widely used benchmarks, SemEval 2014 task 4 subtask 2 (Pontiki et al.), the DPL method significantly surpasses the current state-of-the-art method. We deem our simple but effective framework DPL pioneering a bi-granularity level dataset merging. In what follows, we empirically validate that DPL is a framework that can be seamlessly combined with the previous pre-training or multi-task learning methods in terms of ABSA and SA dataset merging.

To sum up, we make the following contributions in this paper:

1. Among those works to solve the lack of labeled data in the ABSA task, we pioneer to adopt and enhance a pseudo-label framework to leverage the coarser-grained SA labels.

2. We propose a novel general framework called Dual-granularity Pseudo Labels (DPL). Just like the vanilla PL method, the DPL is established as a general framework. We validate that DPL is also compatible with previous work on this line, such as pre-training or multi-task learning (MTL). DPL has achieved excellent performances on the standardized ABSA benchmarks such as SemEval 2014, which significantly outperforms the prior works.

2 Related Works

2.1 Aspect-based Sentiment Analysis (ABSA)

ABSA is a finer-grained task of Sentiment Analysis (SA). It is a pipeline task, including aspect term extraction and aspect term sentiment classification. Aspect term sentiment classification is the true target task in this paper. For convenience, we use ABSA to refer to this task in the remaining parts.

Like other application tracks in NLP, the family of neural network models has wide successes in this task (Jiang et al., 2011; Vo and Zhang, 2015; Zhang et al., 2016; Ma et al., 2017; Li et al., 2018; Wang et al., 2018; Huang et al., 2018; Song et al., 2019). Wang et al. (2016) introduce attention mechanism into an LSTM to model the inter-dependence between sentence and aspect term. Tang et al. (2016) apply Memory Networks in this task.

Syntax-based models have also been explored widely in this domain (Dong et al., 2014; Tai et al., 2015; Nguyen and Shirai, 2015; Liu et al., 2020; Li et al., 2021; Pang et al., 2021). Sun et al. (2019) and Zhang et al. (2019) introduced graph convolution networks (GCN) to leverage the structured information from the dependency tree. Huang and Carley (2019) used graph attention networks (GAT) to improve the performance. Bai et al. (2020) and Wang et al. (2020) took the syntax relations as edge features and introduced them into the Relational Graph Attention Network (RGAT).

In addition, pretrained language models like BERT (Devlin et al., 2018) have greatly promoted the development of ABSA (Li et al., 2018; Gao et al., 2019; Song et al., 2019; Rietzler et al., 2019; Yang et al., 2019).

2.2 Using Extra Dataset for ABSA

Due to the dataset scale challenge of the ABSA task, there have been some methods exploring how to utilize the auxiliary dataset.

Some of them (Xu et al., 2019; Rietzler et al., 2019; Yu et al., 2021b) achieve decent ABSA performance by post-processing or fine-tuning BERT (Devlin et al., 2018) with an additional unlabeled dataset. For these methods, we argue that the cost of computation is too high. Moreover, DPL does not conflict with it and can accommodate the results of these works. We take Rietzler et al. (2019)'s work as an example for comparison in experiments.

The others (He et al., 2018, 2019b; Chen and Qian, 2019; Liang et al., 2020; Yang et al., 2019; Oh et al., 2021; Yu et al., 2021a; Yan et al., 2021) utilize some labeled datasets and propose (later extend) a framework applying multitask learning methods. These auxiliary labeled datasets mainly include the sentiment analysis (SA) task and other subtasks of ABSA, such as Aspect Term Extraction, Opinion Term Extraction, and so on (Yan et al., 2021). DPL is more similar to these methods, using labeled datasets. However, we argue that the datasets of other subtasks can't solve the problem of the high annotation cost. Thus, DPL utilizes the SA task as auxiliary datasets and is the first to apply the PL method to this problem.

2.3 Pseudo-Label

Pseudo-label (PL), often associated with self-training, is a semi-supervised learning method. PL has been utilized and further developed by many studies (Ge et al., 2020; Mallis et al., 2020; Zoph et al., 2020; He et al., 2019a). It has been successfully applied in many tasks, such as image classification (Pham et al., 2020; Xie et al., 2020), object detection (Ge et al., 2020), text classification (Mukherjee and Awadallah, 2020), Etc.

However, these PL methods are inapplicable under a non-uniform granularity situation; that is, there are massive available coarse-grained datasets for fine-grained tasks. These existing methods can only discard the coarse-grained labels and treat them as unlabeled datasets. Thus, we argue that these PL methods cause loss of information and are definitely unreasonable.

3 Preliminary

3.1 Pseudo-Labels

The traditional PL method generally involves a labeled set denoted by D and an unlabeled set D_u. A teacher model is trained on D by cross-entropy loss:

$$\mathcal{L}(\Theta_T) = \sum_{(x,y)\in D} [-\log P_{\Theta_T}(y|x)] \tag{1}$$

where Θ_T denotes the parameters of the teacher model. The cross-entropy loss function is adopted for general classification problems, including image classification, detection, and semantic segmentation (Ge et al., 2020; Pham et al., 2020; Xie et al., 2020; Zoph et al., 2020).

In what follows, on the unlabeled dataset D_u, one can obtain the corresponding labels via running the unlabeled input through an inference procedure of the teacher model. The yielded label set for D_u forms a pseudo-labeled dataset that can later be combined with the original dataset with gold annotations. A student model M_S is trained by the newly merged dataset:

$$\begin{aligned}\mathcal{L}(\Theta_S) = & \sum_{(x,y)\in D} [-\log P_{\Theta_S}(y|x)]+ \\ & \lambda \sum_{(x_u,y')\in D'_u} [-\log P_{\Theta_S}(y'|x_u)]\end{aligned} \tag{2}$$

where y' indicates the pseudo label corresponding to the sample x_u generated by the teacher model. D'_u are the pseudo-label augmented version of D_u. λ is a weighing term.

4 Dual-granularity Pseudo Labeling

In short, our work focuses on expanding the traditional PL method to utilize coarse-grained datasets. To achieve this goal, we draw inspiration from the multi-task learning community and augment the PL method with a different modeling pathway. Consequently, we obtain a framework where two separate pathways are trained synergistically targeted at labels of both granularities.

4.1 Setup

Our work is based on two datasets, the fine-grained and the coarse-grained datasets in the same domain. Let us use D_{fine} and D_{coarse} to denote two datasets respectively. For the coarse-grained dataset D_{coarse}, the task is to learn a mapping:

$$f_{\text{coarse}}(\mathbf{x}) \rightarrow y, \tag{3}$$

For the fine-grained dataset D_{finer}, the target mapping is:

$$f_{\text{fine}}(\mathbf{x}, \mathbf{t}_i) \rightarrow y_i, i \in \{1, ..., m\} \tag{4}$$

where $(\mathbf{x}, y) \in D_{\text{coarse}}$ and $(\mathbf{x}, \mathbf{t}_i, y_i) \in D_{\text{fine}}$. $\mathbf{x}$ is the input data, and y is the corresponding label for $\mathbf{x}$. $\mathbf{t}_i \subseteq \mathbf{x}$. m means that $\mathbf{x}$ has m sub-parts totally, and y_i is the corresponding label for $\mathbf{t}_i$.

The traditional PL method is limited to fit a uniform granularity situation. The first step to resolve this limitation is to merge the coarse-grained dataset with the fine-grained dataset. Like the traditional PL method, we train a teacher model on one dataset and generate pseudo labels for the other dataset. We repeat this process at two granularities. Here, we suppose that $\mathbf{x}_i$ for each $\mathbf{x}$ in the D_{coarse} have been extracted. After pseudo labels generation, two new datasets are generated, donates as D'_{fine} and D'_{coarse}, and a new dataset D' are merged by these two datasets. Specifically,

$$D' = D'_{\text{fine}} \cup D'_{\text{coarse}}, \tag{5}$$

where $(\mathbf{x}, \mathbf{t}_i, y, y'_i) \in D'_{\text{coarse}}$ and $(\mathbf{x}, \mathbf{t}_i, y', y_i) \in D'_{\text{fine}}$. y' and y'_i are the generated pseudo labels.

Up to now, we get a new dataset with a much larger scale. Our goal translates into obtaining a model trained by the new dataset D' with high performance on the fine-grained task. In other words, compared with the traditional PL method, the key problem is: how to utilize the coarse-grained labels to improve the model's performance on the fine-grained task.

4.2 DPL Skeleton

As we mentioned, the core challenge for adapting the vanilla PL method is to utilize coarse-grained labels. As displayed in Figure 3, we set dual pathways corresponding to each granularity. Both pathways are finished by setting a proper softmax-based classifier. Using $\mathbf{z}$ and $\mathbf{h}$ to denote the internal representation vectors for both pathways, we decompose the design philosophy of DPL by the following three conditions:

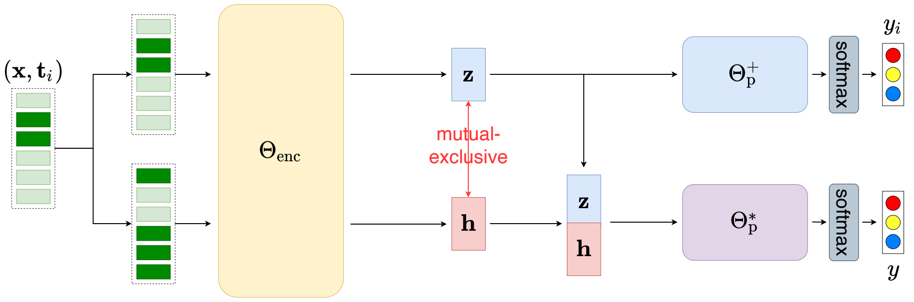

Figure 3: The Model for the DPL Framework. $(\mathbf{x}, \mathbf{t}_i)$ is the input data. $\mathbf{t}_i$ indicates the aspect terms, which are painted by the dark green. We first generate $(\mathbf{x}, \mathbf{t}_i)$ and $(\mathbf{x}, \mathbf{1} - \mathbf{t}_i)$ as the input of the upper and lower pathways, respectively. In this case, $\mathbf{t}_i = (0, 1, 1, 0, 0, 0)$ and $\mathbf{1} - \mathbf{t}_i = (1, 0, 0, 1, 1, 1)$. "$\Theta_{\text{enc}}$" is an encoder that outputs $\mathbf{z}$ and $\mathbf{h}$. "Θ_{p}^{+}" is a predictor for the fine-grained task, and "Θ_{p}^{*}" is a predictor for the coarse-grained task. Correspondingly, y_i is the prediction for the fine-grained task, and y is the prediction for the coarse-grained task. "mutual-exclusive" means the information carried by $\mathbf{z}$ and $\mathbf{h}$ has little overlap.

- $\mathbf{z}$ carries adequate information to determine the label at the fine-grained level. More formally, there exists a function $f_{\Theta_{\text{p}}^{+}}$ in the overall functional space that is able to map the $\mathbf{z}$ to y_i.

- The union set of $\mathbf{h}$ and $\mathbf{z}$ is capable of determining the label at the coarse level. There exists another function $f_{\Theta_{\text{p}}^{*}}$ in the overall functional space that is sufficient to map the $[\mathbf{z} \circ \mathbf{h}]$ to y.

- $\mathbf{h}$ and $\mathbf{z}$ are mutually exclusive in terms of the carried information. That means we cannot train a function $f_{\Theta_{\text{p}}^{*}}$ to map $\mathbf{h}$ to y_i, due to the lack of information contributed from $\mathbf{z}$.

The main rationale behind these three conditions may include but is not limited to: (i)-the information passing through the pathway with $\mathbf{z}$ is only required in the fine-grained task; (ii)-the other information needed by the coarse-grained task passes through the pathway with $\mathbf{h}$; (iii)-the prediction at coarse-grained level is based on the concatenation of $\mathbf{h}$ and $\mathbf{z}$, while either of them is insufficient to accomplish the prediction of coarse-grained labels.

In order to satisfy the model to these three conditions, our loss function consists of three terms. Among them, the two terms are the classification loss terms for the fine- and coarse-grained tasks, respectively, fulfilling conditions 1&2. For condition 3, we draw inspiration from adversarial training (Lample et al., 2017) to reduce the fine-grained task-relevant information carried by $\mathbf{h}$.

4.2.1 Fine- and Coarse-grained Tasks

As shown in Figure 3, the model consists of an encoder, Θ_{enc}, together with two predictors, Θ_{p}^{*} and Θ_{p}^{+}. In particular, Θ_{enc} encodes each input data $(\mathbf{x}, \mathbf{t}_i)$ into two intermediate results, $\mathbf{z}$ and $\mathbf{h}$. In the figure, the top line with $\mathbf{z}$ is the pathway for the fine-grained task-relevant information flow, while the bottom line with $\mathbf{h}$ is the pathway for the fine-grained task-irrelevant information flow.

The fine-grained predictor Θ_{p}^{+} spits out prediction based on $\mathbf{z}$, with a cross-entropy loss:

$$\begin{aligned} &\mathcal{L}_{\text{fine}}(\Theta_{\text{enc}}, \Theta_{\text{p}}^{+}) \\ &= \sum_{(\mathbf{x}, \mathbf{t}_i, y, y_i) \in D'} [-\log P_{\Theta_{\text{p}}^{+}}(y_i | \mathbf{z})], \end{aligned} \tag{6}$$

Another crucial design in the DPL is that the concatenation of $\mathbf{h}$ and $\mathbf{z}$, $[\mathbf{h} \circ \mathbf{z}]$, is fed to decide the prediction of the sequence-level prediction:

$$\begin{aligned} &\mathcal{L}_{\text{coarse}}(\Theta_{\text{enc}}, \Theta_{\text{p}}^{*}) \\ &= \sum_{(\mathbf{x}, \mathbf{t}_i, y, y_i) \in D'} [-\log P_{\Theta_{\text{p}}^{*}}(y | \mathbf{h} \circ \mathbf{z})]. \end{aligned} \tag{7}$$

The gradient of this loss will update the model parameters on both pathways. To prevent the degenerated case where the two pathways act completely separately, we introduce another crucial part to DPL in the next subsection.

4.2.2 Adversarial Training

The current version of DPL could still work as two separate systems, which is deemed a degenerated case. Therefore, to guarantee the mutual exclusiveness between the $\mathbf{h}$ and the $\mathbf{z}$, we introduce an adversarial training loss term to maximally reduce the fine-grained task-relevant information carried by $\mathbf{h}$:

$$\mathcal{L}_{\text{enc}}(\Theta_{\text{enc}}) = \sum_{(\mathbf{x},\mathbf{t}_i,y,y_i)\in D'} [-\log P_{\Theta_{\text{p}}^{+}}(1-y_i|\mathbf{h})], \tag{8}$$

$$\mathcal{L}_{\text{dis}}(\Theta_{\text{p}}^{+}) = \sum_{(\mathbf{x},\mathbf{t}_i,y,y_i)\in D'} [-\log P_{\Theta_{\text{p}}^{+}}(y_i|\mathbf{h})], \tag{9}$$

$$\mathcal{L}_{\text{adv}}(\Theta_{\text{enc}},\Theta_{\text{p}}^{+}) = \mathcal{L}_{\text{dis}}(\Theta_{\text{p}}^{+}) + \lambda\mathcal{L}_{\text{enc}}(\Theta_{\text{enc}}), \tag{10}$$

where λ weighs the trade-off between Θ_{enc} and Θ_{p}^{+}. The adversarial training was first introduced in Lample et al. (2017) and has been widely used (Zhao et al., 2018; Fu et al., 2018; Shen et al., 2017; Melnyk et al., 2017). The loss term trains Θ_{enc} to fool Θ_{p}^{+} by removing fine-grained task relevant information from $\mathbf{h}$. Considering that $\mathbf{z}$ is only required by the fine-grained task, the less fine-grained task-relevant information the $\mathbf{h}$ has, the less overlap there is between the $\mathbf{h}$ and $\mathbf{z}$. As a result, the adversarial training makes h and z more mutually exclusive in terms of the carried information.

4.2.3 Loss Function

The overall loss function to optimzie DPL combines as below:

$$\begin{aligned}\mathcal{L}(\Theta_{\text{enc}},\Theta_{\text{p}}^{*},\Theta_{\text{p}}^{+}) =& \mathcal{L}_{\text{fine}}(\Theta_{\text{enc}},\Theta_{\text{p}}^{+})\\ &+\alpha\mathcal{L}_{\text{coarse}}(\Theta_{\text{enc}},\Theta_{\text{p}}^{*})\\ &+\beta\mathcal{L}_{\text{adv}}(\Theta_{\text{enc}},\Theta_{\text{p}}^{+})\end{aligned} \tag{11}$$

where α and β are weighing terms. With this design of the loss functions, we posit that all three philosophies should be satisfied. The ideal result for it is that (i)-$\mathbf{z}$ only carries information dedicated at the fine-level; (ii)-$\mathbf{h}$ carries the information of the entire coarse level (i.e., the whole sequence) excluding the information of $\mathbf{z}$; (iii)-neither $\mathbf{h}$ nor $\mathbf{z}$ is sufficient on deciding the whole-sequence coarse-level prediction, but with the concatenation of them, $\mathbf{h} \circ \mathbf{z}$, the information is just adequate.

4.3 Grounding DPL to ABSA

4.3.1 Document-level Sentiment Analysis.

The task aims to analyze the sentiments reflected by sentences. Given an ordinary labeled document-level dataset $D = \{(\mathbf{x}^0, y^0), (\mathbf{x}^1, y^1) \dots (\mathbf{x}^N, y^N)\}$, where $\mathbf{x}^i$ donates a sentence and y^i donates the sentiment polarity of the sentence. The goal of the task is to learn a mapping function: $f_{\text{sent}}(\mathbf{x}^i) \rightarrow y^i$.

Dataset	**positives**		**neutral**		**negative**	
	Train	Test	Train	Test	Train	Test
Rest	2164	727	637	196	807	196
Laptop	976	337	455	128	851	167

Table 1: Statistics of SemEval 2014 task 4 subtask 2.

4.3.2 Aspect-based Sentiment Analysis.

The ABSA task is to derive the sentiment polarity attached to specific aspect terms in the given sentence. Formally, one can draw a data point $(\mathbf{x}^i, \mathbf{y}^i)$ from the dataset D. We assign a separate variable indicating the aspect terms annotation, $\{\mathbf{t}^{i,1}, \dots, \mathbf{t}^{i,N_i}\}$, where N_i denotes the number of total aspect terms in $\boldsymbol{\tau}^i$. In addition, the label $\mathbf{y}$ is a combination of polarities corresponding to aspect terms, $\mathbf{y}^i = \{y^{i,1}, \dots, y^{i,N_i}\}$. The goal for the ABSA is to learn the mapping $f_{\text{aspect}}(\mathbf{x}^i, \mathbf{t}^{i,k}) \rightarrow y^{i,k}$, where $k \in \{1, \dots, N_i\}$.

4.3.3 Implementation

Before implementing a specific DPL model, we first map the task objectives of the SA and ABSA tasks to the coarse- and fine-grained tasks in the DPL framework. The coarse-grained task is the SA task, while the fine-grained task is the ABSA task. In another word, the mapping $f_{\text{sent}}(\mathbf{x}^i) \rightarrow y^i$, is considered as the coarse-grained mapping $f_{\text{coarse}}(\mathbf{x}) \rightarrow y$, and the mapping $f_{\text{aspect}}(\mathbf{x}^i, \mathbf{t}^{i,k}) \rightarrow y^{i,k}$ is considered as $f_{\text{fine}}(\mathbf{x}, \mathbf{t}_i) \rightarrow y_i$.

Then we choose the model for Θ_{enc}, Θ_{p}^{+} and Θ_{p}^{*}. Θ_{p}^{+} and Θ_{p}^{*} are simple multilayer perceptron (MLP). It is worth noting that Θ_{enc} can be a prior ABSA model. Thus, we argue that the DPL framework can be applied to most ABSA methods. Typically, we choose Bai et al. (2020)'s and Rietzler et al. (2019)'s works and a multi-task learning baseline as examples to verify. The results are shown in Table 3.

5 Experiments

5.1 Experimental Setup

5.1.1 Dataset

The experiments of the DPL framework require at least two datasets at different granularities. For the

ABSA task, we select the SemEval dataset (Pontiki et al.) as the fine-grained sentiment task dataset and the Amazon reviews dataset from Kaggle[4] as the coarse-grained sentiment task dataset. The SemEval datasets are used as our core task dataset, and the Amazon reviews dataset is used as an auxiliary dataset.

Dataset SemEval. This dataset is SemEval 2014 task 4 subtask2 (Pontiki et al.). It has two subdatasets, the reviews in the restaurant and laptop domains. We show more details in Table 1.

Dataset Amazon Reviews. The dataset contains 3.6 million sentences in the training set and 0.4 million sentences in the test set. Considering the huge data volume gap, we only chose the test set as the auxiliary dataset for this experiment.

5.1.2 Generation of Pseudo Labels

Here we provide some details of the pseudo labels generation process.

As a result of the PL generation, the ABSA dataset has true aspect-level sentimental labels and pseudo-sentence-level sentimental labels, while the SA dataset has true sentence-level sentimental labels and pseudo-aspect-level sentimental labels.

To get aspect terms from the sentence in the SA dataset, we first performed aspect extraction using the model proposed by Li et al. (2019) and discarded sentences without aspect terms.

We train the model proposed by (Bai et al., 2020) as the teacher models on the aspect-level dataset with the accuracy scores of 86.05% and 79.53% respectively on the domain of Restaurant and Laptop.

We train a BERT+Linear as the teacher model on the document-level dataset, with a 94.45% accuracy score in the restaurant Domain and a 93.35% accuracy score in the laptop domain.

5.1.3 Implementation Details

In addition to the above introduction, some more important details of our experiments need to be clarified for ease of understanding.

Evaluate Matrix

The model for **ABSA** is tested on SemEval's test set. Like those who have performed this work before, we use the model classification accuracy (ACC) and macro-F1 (F1) scores as the evaluation criterion.

Model		Restaurant		Laptop	
		Acc	F1	Acc	F1
Auxiliary	**He et al. (2018)**	78.73	68.63	71.91	68.79
	Chen and Qian (2019)	79.55	71.41	73.87	70.10
	He et al. (2019b)	83.89	75.66	75.36	72.02
	Liang et al. (2020)	84.93	76.66	77.51	73.42
BERT	**Bai et al. (2020)***	86.04	80.27	79.53	74.54
	Pang et al. (2021)	87.66	82.97	80.22	77.28
	Li et al. (2021)	87.13	81.16	81.80	78.10
	Rietzler et al. (2019)	87.89	81.05	80.23	75.77
Ours	**DPL**	**89.54**	**84.86**	**81.96**	**78.58**

Table 2: Results of different methods. "BERT" represents the works that are also based on the BERT (Devlin et al., 2018), "Auxiliary" represents the methods that also utilize auxiliary datasets to help the ABSA task. "*" means our replication results. The results show that our method achieves state-of-the-art in this benchmark.

Batch Loader

Since the size of the current auxiliary dataset is much larger than the existing dataset. To avoid the large auxiliary dataset changing the original dataset distribution, we adopt two asynchronous loaders and define the step ratio k, i.e., whenever the model is trained on the original dataset by 1 step, it is trained on the auxiliary dataset by k steps. In general, we set $k = 1$.

Model Implementation

The encoder has three main structures for the **ABSA** task: BERT (Devlin et al., 2018), Relational Graph Attention Networks (RGAT) (Wang et al., 2020), and masking embedding module. The BERT and RGAT have been proved to have a good effect on this task. The mask embedding module is used to generate $\mathbf{z}$ and $\mathbf{h}$. It is similar to the implementation of "segment_id" in the code of BERT.

5.2 Main Results

Table 2 shows that the DPL has achieved a state-of-the-art (SOTA) performance in terms of the average accuracy and F1-scores on the SemEval 2014 task 4 subtask 2 dataset. The group denoted as "Auxiliary Dataset is multi-task learning methods based on labeled datasets. Compared with them, our work shows the advantage of the PL method. "BERT-based" are some recently published works with good results. Obviously, our method achieves significant improvements over them.

It should be noted that our design is based on the BERT. Thus the comparison is not made with the methods based on a more powerful pre-trained model, such as Roberta (Liu et al., 2019), DeBERTa (Silva and Marcacini), and GPT-3 (Floridi and Chiriatti, 2020).

---

Improvement	**+1.65**	**+3.71**	**+1.73**	**+2.81**
MultiBERT	84.54	78.52	78.32	73.87
MultiBERT+DPL	85.52	79.61	79.75	75.80
Improvement	**+0.98**	**+1.09**	**+1.43**	**+1.93**

Table 3: Results of Combining DPL with Other Methods. Restaurant and Laptop are two benchmarks same as those in Table 2. RGAT (Bai et al., 2020), Adapter (Rietzler et al., 2019) are typical ABSA methods. MultiBERT is a multi-task baseline implemented by us. It predicts the SA label based on the "[cls]" and predicts the ABSA task based on the specific word vector. We add the DPL framework to them, denoted as "+DPL", and achieve significant improvements.

5.3 DPL as a General Framework

As we mentioned, we promote DPL as a general framework capable of combining other methods on the ABSA task. Table 3 shows the performances of some typical methods before and after they combine the DPL framework. On the one hand, RGAT (Bai et al., 2020) is a model architecture based on GAT and BERT. Thus the improvement shows that the DPL framework fits other architectural designs, even without auxiliary datasets. On the other hand, for those methods involving auxiliary datasets, we take Adapter (Rietzler et al., 2019) and MultiBERT for demonstration. Previous works are mainly divided into two categories, pretraining and multi-task learning. Adapter (Rietzler et al., 2019) can be categorized into the pretraining class while MultiBERT is a multi-task learning baseline inspired by He et al. (2018). Since the previous works using the multi-task method to combine the SA and the ABSA datasets were LSTM based, we implemented a better model based on the BERT. All the improvements verify that the DPL framework does not conflict with these methods and exhibits full compatibility for further performance gains.

5.4 Ablation Study

We set up several sets of ablation experiments and present the results in Table 4 to explore the role of adversarial training and pseudo labels in the DPL framework.

The above experiments contain two types of BERT on the SemEval Restaurant dataset. To ensure the fairness of the ablation experiments, we use the same parameters when training the same group, and the parameter configurations are shown in Appendix.

Model	Restaurant+Pre		Restaurant	
	Acc	F1	Acc	F1
DPL	89.54	84.86	86.68	80.44
Traditional Pseudo-Label	-1.43	-2.09	-1.60	-2.73
- adversarial training	-1.96	-3.31	-1.96	-3.60
- coarse-grained pseudo labels	-1.60	-2.74	-1.34	-1.35
- fine-grained pseudo labels	-1.96	-2.84	-0.79	-1.79

Table 4: Results of ablation study. "Restaurant" takes plain BERT as the initial model while "Restaurant+Pre" takes Rietzler et al. (2019)'s BERT as the initial model. "DPL" denotes our method. "Traditional Pseudo-Label" represents we take the PL method for fine-grained tasks dropped out the coarse-grained labels. The last three cases named in the form of "- X" means that we deleted the "X" from the original DPL to evaluate the effect of "X".

The comparison with "Traditional Pseudo-Label" shows the advantages of our method. From the item "- adversarial training", the significant decline on F1 reflects that adversarial training plays an important role in the DPL framework. The items, "- coarse-grained pseudo labels" and "- fine-grained pseudo labels", show that only adding adversarial training at one granularity has less effect than adding it both ways.

Furthermore, we also take Chamfer Distance (CD) between the set of $\mathbf{h}$ and the set of $\mathbf{z}$ to provide an insight into the effect of the mutual exclusiveness. And the CD of the model with the adversarial training process is 30% larger than that of the model without this process. That means the adversarial training process increases the distance between the variable $\mathbf{h}$ and $\mathbf{z}$.

6 Conclusion

In this paper, we propose Dual-granularity Pseudo Labeling (DPL). DPL extends from the vanilla Pseudo-Label method and augments it to a dual-pathway system. It additionally enforces strong control of information flow directing to the data at different granularities of annotation. The results demonstrate the state-of-the-art performance of DPL on the data-scarce ABSA task. As a pioneering framework design, we also show that the DPL is compatible with pre-training and multi-task learning methods as published before. In the future, we hope to explore the possibility of DPL in other domains, such as computer vision problems where the discrepancy of granularities possesses.

Abstract

Self-attention heads are characteristic of Transformer models and have been well studied for interpretability and pruning. In this work, we demonstrate an altogether different utility of attention heads, namely for adversarial detection. Specifically, we propose a method to construct input-specific attention subnetworks (IAS) from which we extract three features to discriminate between authentic and adversarial inputs. The resultant detector significantly improves (by over 7.5%) the state-of-the-art adversarial detection accuracy for the BERT encoder on 10 NLU datasets with 11 different adversarial attack types. We also demonstrate that our method (a) is more accurate for larger models which are likely to have more spurious correlations and thus vulnerable to adversarial attack, and (b) performs well even with modest training sets of adversarial examples.

1 Introduction

Self-attention heads are characteristic of Transformer models. Individual attention heads are interpretable in different ways. One, for a token in an input sentence, we can visualize the attention paid by a head to all other tokens. Such attention patterns are attractive linguistically and have come to define roles for attention heads (Pande et al., 2021). Two, the output of attention heads from various layers can be probed for their ability to encode information related to the "NLP pipeline" (Jawahar et al., 2019; Tenney et al., 2019; van Aken et al., 2019). Three, attention patterns of heads can represent knowledge learnt by a teacher model when distilling to a smaller student model (Jiao et al., 2020). While individual attention heads are interpretable in the above ways, it is found that attention heads in models such as BERT are over-provisioned and can be pruned. For instance, Michel et al. (2019) showed that a model with 16 attention heads per layer can be pruned to just one. Voita et al. (2019) and Budhraja et al. (2020) have shown similar results with different pruning techniques across tasks.

In the above methods, while interpretation of attention heads is input-specific, pruning of heads is input-agnostic. Can these two be combined, i.e., can we prune attention heads in an input-specific manner creating opportunities for interpretation? We explore this idea to identify an altogether different utility of attention heads - namely *adversarial detection* which is the task of differentiating between authentic and adversarial inputs. Specifically, we propose a method to obtain an *input-specific attention subnetwork* (IAS), which is a subnetwork where a subset of attention heads is masked without affecting the output of the model for that input. Such subnetworks could vary across inputs representing how the model works for each input. This is particularly important for adversarial detection, as adversarial inputs do not reveal themselves in *what* the model outputs but may leave tell-tale signs in *how* the model computes this output.

In this work, we present a technique to efficiently compute IAS and demonstrate its utility in adversarial detection with significantly improved accuracy over all current methods. To this end, we propose three sets of features from IAS. The first feature, F_{mask}, is simply the attention mask that identifies if an attention head is retained or pruned in IAS. The second feature, F_{flip}, characterizes the output of a "mutated" IAS obtained by toggling the mask used for attention heads in the middle layers of IAS. The third feature, F_{lw}, characterizes the outputs of IAS as obtained layer-wise with a separately trained classification head for each layer. We train a classifier, called AdvNet, with these features as inputs to predict if an input is adversarial.

We report results on 10 NLU tasks from the GLUE benchmark (SST2, MRPC, RTE, SNLI, MNLI, QQP, QNLI) and elsewhere (Yelp, AG News, IMDb). For each of these tasks, we first create a benchmark of adversarial examples com-

Findings of the Association for Computational Linguistics: ACL 2022, pages 31 - 44
May 22-27, 2022 ©2022 Association for Computational Linguistics

bining 11 attack methodologies like Word order swap (Pruthi et al., 2019), embedding swap (Mrkšić et al., 2016), word deletion (Feng et al., 2018), etc. In total, the benchmark contains 5,686 adversarial examples across tasks and attack types. To the best of our knowledge, this dataset is the most extensive benchmark available on the considered tasks. Across all these tasks and attack types, we compare our adversarial detection technique against state-of-the-art methods such as DISP (Zhou et al., 2019), NWS (Mozes et al., 2021), and FGWS (Mozes et al., 2021). Our method establishes the best results in all tasks and attack types, with an average improvement of 7.45% over the best method for each task. Our detector achieves an accuracy of 80–90% across tasks suggesting effective defense against adversarial attacks.

Having established the utility of attention heads for adversarial detection, we perform several ablation studies. First, we compare different combinations of the features demonstrating that they are mutually informative and thus combining them all works best. Second, we show that CutMix data augmentation (Yun et al., 2019) improves accuracy, demonstrating the first use of this method in adversarial detection in NLP tasks. Third, we show that the detector is more accurate as the size of the language model scales. This is encouraging because larger language models are expected to have increased spurious correlations and thus are more vulnerable to adversarial attacks. Fourth, we show that the detector performs well even for modest training sizes of adversarial examples, suggesting effective generalization. In summary, we propose a novel relation between attention heads and adversarial detection. The effectiveness of the resultant detector establishes that the mask of attention heads captures critical information about *how* a Transformer model works for a given input.

The rest of the paper is organized as follows. We detail our core method of computing IAS in the next section. In Section 3 we discuss the features from IAS for adversarial detection. We detail the experimental setup along with the dataset creation process in Section 4. We present our results in Section 5 and conclude in Section 6.

2 Input-Specific Attention Subnetworks

In this section, we describe Input-specific Attention Subnetworks (IAS) and the computational approach to identify IAS for a given input.

2.1 Notation

We consider a BERT-style encoder model where each layer consists of multi-headed self-attention and position-wise FFN. Let an input x consist of T tokens each represented by d_v-dimensional vectors. Let $X_j \in \mathbb{R}^{T \times d_v}$ be the representation at the input of the j^{th} layer. Let $W_{ji}^Q, W_{ji}^K, W_{ji}^V$ be the projection matrices of the i^{th} self-attention head in the j^{th} layer. We define $Q_{ji} = X_j W_{ji}^Q, K_{ji} = X_j W_{ji}^K, V_{ji} = X_j W_{ji}^V$ as the query, key, and value corresponding to the head respectively. Each self-attention head performs a scaled dot-product attention on the query, key, and value to generate the head's output. The output of all the heads in a layer are concatenated and passed through the FFN.

$$\mathrm{Head}_{ji}(X_j) = \mathrm{softmax}\left(\frac{Q_{ji}K_{ji}^T}{\sqrt{d_k}}\right)V_{ji} \quad (1)$$

$$\mathrm{Layer}_j(X_j) = \mathrm{concat}_i[\mathrm{Head}_{ji}(X_j)]W_j^O \quad (2)$$

where d_k is the dimensionality of each key vector and W_j^O is a learnable parameter.

A pre-trained model is fine-tuned on a specific task, such as sentiment classification. Let θ be the set of trainable network parameters which are optimized to minimize a task-specific training loss for each input x:

$$\mathcal{L}^\theta(x) = \mathcal{L}_{CE}(f(x,\theta), y), \quad (3)$$

where $f(\cdot)$ is the function computed by the model with parameters θ for input x, $\mathcal{L}_{CE}$ is the standard cross-entropy loss function and y is the expected model output for input x. The overall training loss is averaged across all $|x|$ inputs, i.e., $\mathcal{L}^\theta = \frac{1}{|x|}\sum_x \mathcal{L}^\theta(x)$. Let $\widehat{f}(\cdot)$ represent the output class generated from $f(\cdot)$ and θ^* be the set of optimal network parameters obtained after training.

2.2 Representing IAS

In an IAS, a subset of attention heads are pruned. We represent a continuous relaxation of pruning by modifying Eqn. 1 to weigh the output of each head by a scalar gating value $g_{ji} \in [0,1]$. The j^{th} layer of the modified network is given by

$$\mathrm{Layer}_j^m(X_j) = \mathrm{concat}_i[g_{ji} \cdot \mathrm{Head}_{ji}(X_j)]W_j^O \quad (4)$$

During inference, we constrain the gating values to be binary to characterize either exclusion or inclusion of a head: g_{ji} is replaced by $g_{ji}^b \in \{0,1\}$ which defines the attention mask for the input x: $g^b(x) = \{g_{ji}^b\} \in \{0,1\}^{nm}$, where n is the number

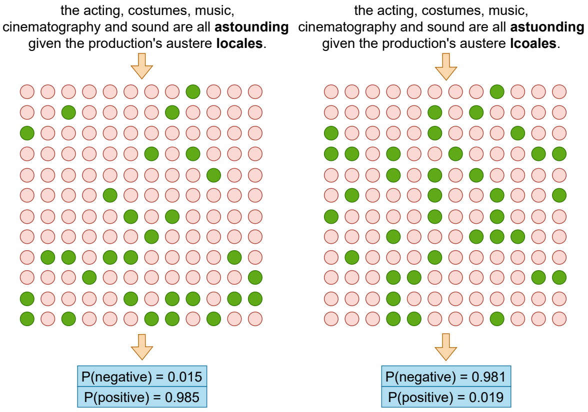

Figure 1: The IAS (with active heads in green) computed for two inputs on the SST-2 task, left is authentic while right is adversarial. Notice how a small adversarial perturbation in the input leads to very distinct subnetworks being computed. The class predicted by each IAS agrees with the prediction of the full network.

of layers and m is the number of heads per layer. We represent the output class predicted by the IAS for an input x by $\widehat{f_g}(x, \theta^*, g^b)$. We call the subset of attention heads that are assigned a gating value of 1 as *active* heads and note that the active heads jointly define a subnetwork, called IAS. We illustrate IAS with an example. Figure 1 shows the BERT-Base model with 12 layers and 12 heads per layer. For two specific inputs, the corresponding attention masks are shown with their active heads in green. Thus, IAS is input-specific and characterizes how the model processes the input in a relatively low-dimensional space of $[0, 1]^{144}$.

2.3 Computing IAS

We compute IAS by treating the gating values as free variables to optimize the task-specific loss (Eqn. 3) for a given input x. In this optimization, the network parameters θ are frozen. Each gating value, g_{ji} is defined as $g_{ji} = f_{HC}(p_{ji})$, where p_{ji} is the free variable that is optimized and f_{HC} is a version of the hard concrete distribution (Louizos et al., 2017) given as $\frac{1}{1+e^{\alpha\cdot(log(1-p_{ji})-log(p_{ji}))}}$, where, α=6 gave the best results for our work. Let g be the gating vector as optimized by minimizing the loss for a specific input. We need to enforce that g is binary. Unlike approaches by Voita et al. (2019) and Wang et al. (2020), we do not include a regularization term in the training objective. Instead, we retain only those heads for which the gating values ascend the fastest towards 1, as measured after a certain η number of epochs. Specifically, each binary value g^b_{ji} is derived from g_{ji} after η epochs as:

$$g^b_{ji}(x) = \begin{cases} 1, & \text{if } g_{ji}(x) \geq \beta \cdot \max(g(x)) \\ 0, & \text{otherwise} \end{cases} \tag{5}$$

where, $\beta(< 1)$ is a thresholding parameter and $\max(g(x))$ is the largest among nm gating values. For our work, we set $\eta = 10$ and $\beta = 0.8$.

Two exceptional cases may arise. First, if the binary gating values of all heads in a layer are thresholded to 0, then the largest gating value in that layer is forced to 1 to ensure information flows through the network. Second, if the IAS predicts the wrong class for that input, then β is reduced successively in steps of 0.2 until the output of the IAS is correct. For 98% of the inputs, the subnetwork predicted the target class within $\beta = 0.6$.

3 Model for Adversarial Detection

In this section, we explain how we extract features from the IAS and the design of the classifier for adversarial detection. We use the term *target class* to refer to the class predicted by the complete fine-tuned network for an input. For authentic inputs, this translates to the true class while for adversarial inputs, this refers to the adversarial class that the model is fooled into predicting.

3.1 Attention mask F_{mask}

The IAS identifies a subnetwork through which important information flows for a particular input. We hypothesize that this flow could be different for authentic and adversarial inputs. Thus, the first feature we extract, F_{mask}, is just the pre-activation value p for the gating values of each head in the IAS. Thus, for a BERT-base model with 12 layers and 12 heads per layer, F_{mask} is a 144 dimensional vector. We also define F_{bmask} which uses the binary gated values g^b instead of the real-values.

3.2 Features from flipping heads in IAS F_{flip}

Adversarial inputs rely heavily on the network architecture and specific parameter combinations to fool the model (Wang et al., 2019). Hence, slight changes to network parameters can render an adversarial perturbation non-adversarial. We thus hypothesize (and later illustrate in Section 5.2) that if we flip some of the heads in the IAS, it could significantly change the output for adversarial inputs but not by as much for authentic inputs. Which heads should we flip? We take motivation from studies that show that middle layers of BERT capture syntactic relations (Hewitt and Manning, 2019;

Goldberg, 2019) and are multi-skilled (Pande et al., 2021), making them crucial for prediction. In contrast, the initial layers are responsible for phrase-level understanding while the last few layers are highly task-specific (Jawahar et al., 2019). Hence, we choose to flip the gating values g^b of heads in the *middle layers* of IAS, specifically, the middle $\lceil \frac{n}{3} \rceil$ layers, i.e., we drop heads that were earlier active and include earlier inactive heads. We denote the modified gating vector after flipping as g^f.

$$g^f_{ji} = \begin{cases} g^b_{ji}, & \text{if } j \leq \lfloor \frac{n}{3} \rfloor \text{ or } j \geq 2\lceil \frac{n}{3} \rceil \\ 1 - g^b_{ji}, & \text{if } \lceil \frac{n}{3} \rceil \leq j < 2\lceil \frac{n}{3} \rceil \end{cases} \quad (6)$$

We run each input x through this mutated subnetwork and obtain a 4-dimensional feature vector, F_{flip} consisting of the predicted class given by $\widehat{f}_g(x, \theta^*, g^f)$, the target class y, the confidence of prediction, and a flag asserting equality between predicted and target classes.

3.3 Layer-wise auxiliary features F_{lw}

Studies (Wang et al., 2020; Xie et al., 2019) have shown that intermediate representations of adversarial inputs diverge from those of authentic inputs as we progress into deeper layers. This indicates that layer-wise information may be discriminative of adversarial inputs. Hence, instead of having a single classifier head processing the output of the final layer, we propose to train a classifier head at the output of each layer and use the classes predicted by them as features in adversarial detection. Specifically, on the fine-tuned complete model, we freeze the standard model parameters to θ^* and train $n-1$ classifiers separately with a classifier head attached to each of the first $n-1$ layers to predict the target class. Following the convention in Eqn. 3, the training loss for the l^{th} classifier head with parameters Ω^l on input x is given by:

$$\mathcal{L}^{\Omega^l}(x) = \mathcal{L}_{CE}(f^l_g(x, \theta^* \cup \Omega^l, \{1\}^{nm}), y), \quad (7)$$

where $f^l_g(\cdot)$ gives the output class computed by the l^{th} classification head of a network with gating vector g. The overall training loss is given by $\mathcal{L}^{\Omega} = \frac{1}{(n-1)|x|} \sum_x \sum_l \mathcal{L}^{\Omega^l}(x)$. Let Ω^* be the set of optimal parameters obtained after training.

Then for a given input, we construct the IAS after flipping heads as given by the gating vector g^f and compute the outputs of the $n-1$ layer-wise classifiers, i.e., the output of the l^{th} classifier head is given by $\widehat{f}^l_g(x, \theta^* \cup \Omega^{*l}, g^f)$. We then create an $n+1$ dimensional feature, F_{lw}, which consists of the $n-1$ output labels with two other scalars: (a) the number of these outputs that match the target class, and (b) the number of times these outputs change when traversed in the order of layers.

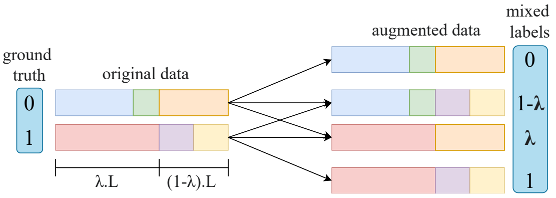

Figure 2: Demonstration of CutMix used to mix patches from two input feature vectors of length L each.

In summary, we compute the features as follows. First, the model is fine-tuned on the task. Then, layer-wise classification heads are trained while keeping the model parameters frozen. Thus, given an input, we first optimize and compute IAS from which we extract F_{mask}. Then, the gating values of the middle layers are flipped and we extract F_{flip}. Finally, on the IAS with flipped heads, layer-wise classifier outputs are used to extract F_{lw}.

3.4 Classifier for adversarial detection

We refer to our classifier as *AdvNet*, which takes as input, an $(nm+n+5)$-dimensional vector $F(x)$ which is the concatenation of F_{mask}, F_{flip}, F_{lw} and generates a binary output classifying if a given input is authentic or adversarial. AdvNet consists of two 1-D convolutional layers with ReLU activation, two fully connected layers with sigmoid activation, and a final classification layer with softmax activation. Since adversarial inputs are slow and computationally expensive to generate, we employ the CutMix algorithm (Yun et al., 2019) for data augmentation. In CutMix, we slice out patches from feature vectors of multiple inputs in the training set, each of which could be authentic or adversarial, and combine them to generate new feature vectors. Their respective ground truth labels are mixed in proportion to the length contributed by each patch (see Figure 2). Formally, if $\{x_i\}_{i=1}^R$ is a random subset of training set samples, an augmented feature vector from CutMix is defined by $F(\widetilde{x}) = \text{concat}_i[F(x_i)[p_i : p_{i+1}]]$, where $0 = p_1 < p_2 < \ldots < p_{R+1} = nm + n + 5$ and the mixed ground truth label is given by $\widetilde{y} = \sum_i y_i(p_{i+1} - p_i)$. Using soft labels by mixing ground truth labels also offers better generalization and learning speed (Müller et al., 2019).

4 Experimental Setup

4.1 NLU tasks for evaluation

We choose the following 10 standard NLU tasks for performing our experimental studies: SST-2 (Socher et al., 2013), Yelp polarity (Zhang et al., 2015a), IMDb (Maas et al., 2011), AG News (Zhang et al., 2015b), MRPC (Dolan and Brockett, 2005), RTE (Wang et al., 2018), MNLI (Williams et al., 2018), SNLI (Bowman et al., 2015), QQP[1] and QNLI (Wang et al., 2018; Rajpurkar et al., 2016). We refer the reader to Appendix A for further details on these datasets.

4.2 Dataset creation

To perform adversarial detection, we require a combined set of authentic and adversarial samples for each task. First, we fine-tune a BERT-based model for each task using its publicly available training set. Then, samples from its test set for which the fine-tuned model makes correct predictions constitute the set of authentic samples for that task. Second, we generate adversarial samples by attacking the fine-tuned model using a broad set of 11 hard attack types to comprehensively test AdvNet's performance and its generalizability to diverse perturbations. The attacks include **word-level attacks:** deletion (Feng et al., 2018), antonyms, synonyms, embeddings (Mrkšić et al., 2016), order swap (Pruthi et al., 2019), PWWS (Ren et al., 2019), TextFooler (Jin et al., 2020) and **character-level attacks:** substitution, deletion, insertion, order swap (Gao et al., 2018). We use the popular TextAttack framework (Morris et al., 2020) for implementations of these attacks. Resulting perturbed samples that successfully fool our complete fine-tuned model constitute the set of adversarial samples for that task. On the combined authentic and adversarial set, we make a 70-10-20 split for creating training, validation and test sets for adversarial detection using AdvNet. Our dataset contains a total of 5,686 adversarial inputs across tasks and attack types and is publicly available at `https://github.com/emilbiju/Bert-Paths`.

4.3 Implementation details

Our adversarial detection model, AdvNet, contains two 1D convolutional layers followed by two fully connected layers. The two convolutional layers have a kernel size of 3 and generate 32 and 16 output feature maps. The two fully connected layers have output dimensions of 32 and 16 with dropout rates of 0.1. We use the binary cross-entropy loss function and the Adam optimizer with a learning rate of 0.001. We train the model for 100 epochs with early stopping on an NVIDIA K80 GPU.

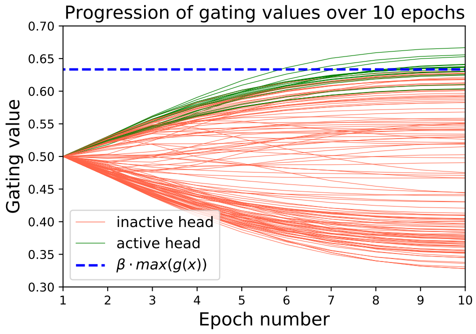

Figure 3: The trajectory of gating values of individual heads during the optimization to compute IAS. Only a few heads (in green) reach the threshold and remain active in IAS.

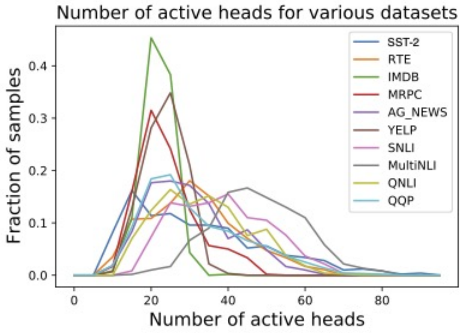

Figure 4: Fraction of inputs with a given number of active heads from BERT-Base. Notice that in most cases, only 20-40 heads out of 144 remain active.

5 Results & Discussion

In this section, we first analyse the IAS (Section 5.1) and the constituent features of AdvNet (Section 5.2). We then perform a comparative study with state-of-the-art adversarial detection methods (Section 5.3). Lastly, we perform ablation studies to understand the effect of task, model size, feature combinations and training set attacks on the performance of AdvNet (Section 5.4). Unless otherwise stated, the plots pertain to experiments on the SST-2 dataset with the BERT-Base model.

---

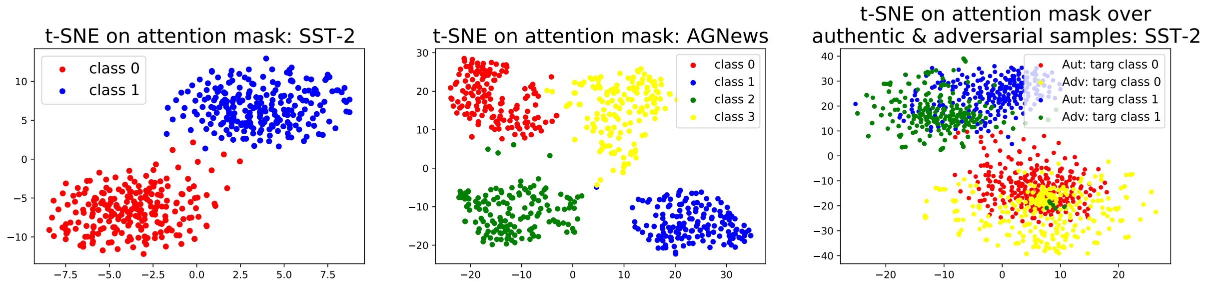

Figure 5: Projections with t-SNE on the attention mask for (a) SST-2, (b) AG News, and (c) authentic and adversarial inputs. Projection of attention masks are strongly discriminative of class and weakly of adversarial inputs.

5.1 Active heads in IAS

We first check the number of active heads in IAS for a given input. To do so, we plot the progression of gating values with epochs when optimizing them for a given input (see Figure 3). We observe that only a small fraction of heads (shown in green) are active at the end of the optimization process, thus resulting in a sparse vector. The green curves that are below the blue (threshold) line correspond to the two exceptional cases discussed at the end of Section 2.3. While the above plot was for a single randomly selected input, in Figure 4 we show the fraction of inputs with a given number of active heads for all the datasets used in this work. The relatively small modes and the right skew distributions imply that the extracted IAS are often sparse.

5.2 Feature-specific analysis

We now analyze the individual effectiveness of the three features proposed in Section 3.

Attention mask (F_{mask}). We first show that the attention mask is strongly correlated with the input's target class. To do so, we project the binary vector $g(x)$ for each authentic input x onto a 2D-plane using the t-SNE method (van der Maaten and Hinton, 2008) as shown in Figure 5(a), (b). We observe that inputs from different classes separate into distinctly separate clusters. Thus, the attention mask is discriminative of an input's target class as the choice of active heads depends on it. Interestingly, even if the attention computed for the same word location in two distinct inputs are the same, the heads attending to each word and responsible for generating different output classes are different.

We present a similar plot with both authentic and adversarial inputs in Figure 5(c). We note that adversarial inputs group together with the authentic inputs whose true class is the same as their adversarial/target class. Within clusters of the same target class, there is a only a moderate distinction between adversarial and authentic inputs. But we show in further experiments that a better separation is possible when the complete nm-dimensional vector is used as opposed to a 2D projection.

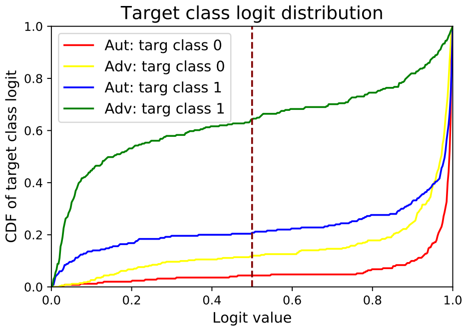

Figure 6: CDF over the target class output logit of the mutated IAS. The large area below the green curve with logit value<0.5 corresponds to a large number of adversarial inputs whose mutated IAS predict a non-target class.

Features from flipping heads in IAS (F_{flip}). For each of the datasets, we compute the percentage of authentic and adversarial inputs which generated non-target class predictions. We find that the mutated IAS after flipping heads in the middle layers is more likely to predict the correct target class output for an authentic input than an adversarial one. We also study the confidence of the mutated IAS in making these predictions using a CDF plot (Figure 6) over the output logit corresponding to the target class.

We observe that F_{flip} predicts the target class with higher confidence in case of authentic inputs than adversarial ones. Specifically, only 9% of authentic inputs had prediction confidence lower than 0.85 as compared to 20% of adversarial inputs. Further, it predicts a non-target class with high confidence for some adversarial inputs. For

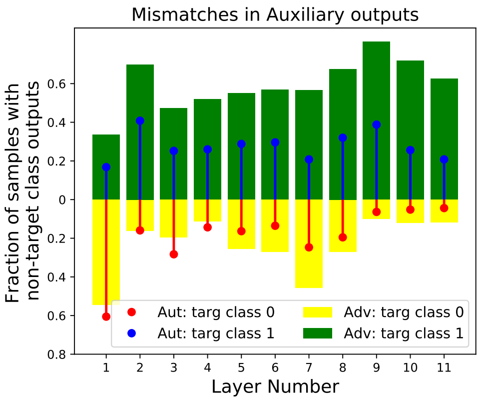

Figure 7: Fractions of authentic and adversarial inputs that generate a non-target class prediction at each layer-wise classification head.

example, 30% of adversarial inputs with prediction confidence higher than 0.85 gave the wrong prediction. In contrast, flipping the initial/final layers of the IAS instead of the middle layers did not significantly change the model prediction for either authentic or adversarial samples, making it difficult it to distinguish them.

Layer-wise auxiliary features (F_{lw}). In Figure 7, we plot the distribution of auxiliary output mismatches (non-target class predictions) across network layers. We observe that for most layers, the fraction of authentic inputs having target class predictions is higher than adversarial inputs. The differences are particularly large for the last few layers. On average across datasets, we observed that 52.5% of adversarial inputs generate more than 2 auxiliary output predictions that do not match the target class while only 23.1% of authentic inputs do the same. Additionally, when traversing the layer-wise outputs in order, we observed that the output predictions of adversarial inputs switch among possible classes more often than for authentic inputs (see Appendix D). These observations justify the features that we include in F_{lw}.

Based on the above analyses, we have demonstrated that all 3 features of IAS are informative for adversarial detection. Our results in the next section corroborate these findings.

5.3 Performance on Adversarial Detection

Following the observations in the previous section, we use AdvNet with the identified features for adversarial detection. We compare the performance of AdvNet with the current state-of-the-art approaches for detecting adversarial inputs for BERT-based models, *viz.*, **FGWS** (Mozes et al., 2021), **NWS** (Mozes et al., 2021), **DISP** (Zhou et al., 2019) and **FreeLB** (Zhu et al., 2019). We briefly describe these methods in Appendix C.

As seen in Table 1, AdvNet significantly outperforms existing approaches across all 10 datasets with an average improvement of 7.45%. We report an improvement of 6.53% for the 3 sentiment analysis datasets (SST-2, Yelp, IMDb), 8.05% for the 4 NLI datasets (RTE, SNLI, MNLI, QNLI) and 6.98% for the 2 paraphrase detection datasets (MRPC, QQP) over the respective best methods.

Another baseline that we compare with is **Certified Robustness Training** (Jia et al., 2019). While this work is not aimed at adversarial detection, it provides bounds on model robustness for word substitution perturbations. For making a comparison with our work, we note that the fraction of adversarial samples that are correctly detected as adversarial translates to robustness for binary classification tasks. We report robustness of 87% for word substitution-based attacks and 81% across all 11 attacks for IMDb, while the best upper bound obtained through certified robustness training is 75%.

When comparing across datasets, we observe that AdvNet performs better on simpler sentence labelling datasets like SST-2 and AG News when compared to more complex tasks like RTE and MRPC which require comparison between sentences. Existing work (Pande et al., 2021) shows that for simpler tasks, the BERT heads perform discrete non-overlapping roles, while for complex tasks, there is greater overlap in head roles and a few heads perform more than one role. We hypothesize that this nature implies that the attention masks for different inputs even belonging to the same type (authentic or adversarial) can vary widely. This reduces the consistency of features across input types making the detection harder. Nevertheless, AdvNet establishes state-of-the-art results across datasets. A detailed analysis of the performance of AdvNet across tasks and attack types is provided in Appendix E.

5.4 Ablation studies

We now evaluate how variations in model size, training set size, and the choice of feature combinations effect performance of AdvNet.

Effect of model size. IAS can be computed for Transformer networks of any size. We compare BERT-Small and BERT-Base models in terms of

Model	**SST-2**	**Yelp**	**AG News**	**MRPC**	**IMDb**	**SNLI**	**RTE**	**MNLI**	**QQP**	**QNLI**
FGWS	71.93	78.36	70.41	69.85	75.98	75.41	71.23	60.23	73.52	78.14
NWS	70.31	74.72	65.62	68.02	65.72	71.82	64.27	56.94	70.20	74.58
DISP	68.73	70.15	66.38	62.22	75.23	72.92	66.40	59.34	69.86	76.92
FreeLB	77.60	82.54	75.55	72.41	79.85	79.80	64.29	58.10	65.69	76.40
AdvNet										
w/ BERT-Small	78.57	76.72	78.63	75.05	74.09	72.07	73.64	64.26	68.71	74.47
w/ BERT-Base	**90.74**	**87.68**	**91.78**	**84.61**	**81.18**	**82.50**	**80.43**	**72.61**	**75.27**	**86.07**

Table 1: Comparison of the adversarial detection accuracy of AdvNet using features extracted from fine-tuned BERT-Small and BERT-Base models with other state-of-the-art approaches for adversarial detection.

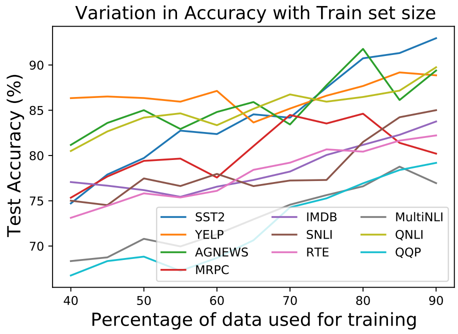

Figure 8: Effect of training set size on accuracy of adversarial detection with AdvNet.

Datasets	F_{mask}	F_{flip}	F_{lw}	**Bin**	**w/o CM**
SST-2	82.87	74.07	64.79	85.59	82.23
Yelp	80.23	62.08	66.01	84.30	83.57
AG News	83.11	76.41	57.14	90.47	83.11
MRPC	76.35	68.82	59.40	80.27	77.35
IMDb	74.54	60.00	55.45	73.78	74.23
SNLI	80.83	57.91	58.83	75.64	70.41
RTE	74.44	60.88	56.67	77.21	74.06
MNLI	66.95	51.30	60.00	66.85	69.95
QQP	66.41	61.63	62.64	71.88	64.50
QNLI	79.65	55.69	59.36	81.42	73.11

Table 2: Results on feature combinations.

performance of AdvNet as shown in Table 1. We observe that, across datasets, AdvNet performs better in detecting adversarial inputs fed to the larger BERT-Base model (108M parameters) as opposed to the smaller BERT-Small model (25M parameters). The increase in accuracy averaged across tasks is a significant 10.76%. We hypothesize that this is because models with more layers encode more information and allow for a better build-up of semantic information which means that individual heads play more discrete roles. This better performance for the larger model is encouraging as the more accurate and larger language models are expected to be more vulnerable to adversarial attacks.

Effect of training set size. In Figure 8, we show how the performance of AdvNet changes as the amount of training data changes. We observe that AdvNet performs well even when it uses only a fraction of the training set. Specifically, even at 40% of the training examples used, AdvNet outperforms the results obtained with existing state-of-the-art models on most tasks. This suggests that the CutMix data augmentation is effective and the AdvNet model is sample-efficient. This is particularly important because designing adversarial examples for each dataset remains a challenging task.

Using different feature combinations. We had shown that each of the three features are informative in Section 5.2. In Table 2, we report the performance of AdvNet by ablating various model components. The first 3 columns report accuracies when only one of the three features is passed at a time to the model. We observe that F_{mask} performs better than F_{flip} and F_{lw}. This suggests that the attention mask is the most important feature input to the model. We analyze the roles of individual gating values using GradCAM (see Appendix F). Next, we test the performance when the boolean attention mask F_{bmask} is used instead of the real-valued vector F_{mask} along with F_{flip} and F_{lw}. The lower accuracy indicates that the real values are more informative. Finally, we test the model performance when CutMix is not used and conclude that augmenting the training set using CutMix provides higher accuracy as seen in the last row of Table 1 which uses all 3 features along with CutMix.

Defense Transferability Analysis. Next, we perform a study to understand how well the model can perform on unseen attack types. For this purpose, we train AdvNet with samples from only $x\%$ of the 11 attack types and report results both on test samples from the remaining attack types and the complete test set for $x \in \{25, 50, 75\}$ in Table 3. We observe that even when AdvNet is trained with only 75% of the attack types, the test results on new attacks outperform existing approaches for most datasets, thus showing that our model can generalize to unseen attack methods. Besides, at all three values of x, the results on the complete test set closely agree with the results on the new attack types. This indicates that the reduction in accuracy at lower x values can largely be attributed to a smaller training set than to a lack of defense transferability.

Dataset	25%	50%	75%
SST-2	(57.8, 58.9)	(69.9, 68.4)	(82.7, 80.7)
Yelp	(63.1, 61.8)	(70.3, 69.9)	(77.8, 78.4)
AG News	(63.7, 62.1)	(71.4, 69.9)	(83.6, 78.4)
MRPC	(63.2, 60.1)	(73.2, 74.5)	(81.5, 82.3)
IMDb	(66.8, 64.8)	(71.6, 73.1)	(77.4, 79.1)
SNLI	(57.9, 57.6)	(67.2, 66.6)	(73.4, 72.3)
RTE	(63.8, 62.4)	(70.8, 69.7)	(76.4, 75.5)
MNLI	(57.4, 58.8)	(62.3, 61.3)	(67.0, 68.9)
QQP	(59.7, 60.2)	(64.0, 64.2)	(69.0, 69.6)
QNLI	(61.8, 60.6)	(69.3, 67.2)	(75.7, 77.5)

Table 3: Defense transferability study of AdvNet with varying percentages of attack types included in the train set. Each tuple contains the test accuracy on new attack types and on all attack types respectively.

In summary, our results show that (a) the 3 IAS features are individually informative, (b) AdvNet significantly improves on baseline methods across datasets, (c) AdvNet performance improves with model size and does not drop much on reducing training sets, (d) AdvNet achieves the best performance when all 3 features are used along with CutMix augmentation, and (e) AdvNet generalizes well to new attack types.

6 Conclusion and future work

In this work, we present an altogether new utility of attention heads in Transformer networks - to detect adversarial attacks. We defined input-specific attention subnetworks (IAS) and proposed a method to compute them efficiently. We extracted 3 features from IAS and showed their utility in distinguishing adversarial samples from authentic ones. We demonstrated that our approach significantly improves the state-of-the-art accuracy across datasets and attack types. Our work suggests that input-specific model perturbations provide strong signals to interpret Transformer-based models such as large language models. Further, the sparse nature of the identified IAS indicate opportunities for input-specific model optimization. In future work, we would like to extend this study to tasks beyond NLU, including vision and speech-related tasks.

Discussion on Ethics and broader impact

One of the main challenges with deep neural models is their lack of explainability. These models typically have inherent biases resulting from the training data, parameter combinations and other factors that lead to unexpected responses to certain inputs. This is further complicated when adversarial agents target to manipulate the output of deep neural models. We see our work on creating and using attention subnetworks for adversarial detection as a part of the broader effort towards Responsible AI. Such a solution is particularly important in situations where deep neural models make decisions that affect physical safety, digital security and equal opportunity. However, we acknowledge that this additional visibility into the model comes at an added cost - inference under uncertainty of adversarial detection is more expensive. We encourage system designers to trade-off computational and runtime considerations for security when deploying such solutions.

A Datasets used for authentic examples

The 10 datasets used in this work were listed in Section 4.1. Here, we provide additional details about these datasets. SST-2 (Socher et al., 2013), Yelp polarity (Zhang et al., 2015a) and IMDb (Maas et al., 2011) are binary sentiment classification datasets. AG News (Zhang et al., 2015b) consists of news headlines classified into one of 4 categories (world, sports, business, sci/tech) and MRPC (Dolan and Brockett, 2005) is a paraphrase dataset which contains sentence pairs with binary labels indicating whether they are semantically equivalent or not. RTE (Wang et al., 2018), MNLI (Williams et al., 2018), SNLI (Bowman et al., 2015) contain sentence pairs with labels indicating whether one sentences entails, contradicts or is neutral with respect to the other sentence. QQP is again a paraphrase dataset but unlike MRPC which contains sentences, it contains question pairs taken from Quora with binary labels indicating whether they are semantically equivalent or not. QNLI contains question-context pairs with a binary label indicating whether the context sentence contains the answer to the question or not.

B Examples of adversarial attacks

In Table 4, we provide examples for each of the 11 attack types that we use to generate adversarial inputs for this work.

C Other methods for Adversarial Detection

We briefly describe the four methods that we compare with in Table 1.

- **FGWS** (Mozes et al., 2021): Here, a word frequency-guided approach is used to identify infrequent words in an input sentence and replace them with more frequent, semantically similar words. Then, the difference in prediction confidence of the Transformer-based model between the original and substituted sentences is considered. If this value is above a threshold, the sentence is predicted to be adversarial.
- **NWS**: This is the *naive word substitution* baseline used in Mozes et al. (2021). Here, each out-of-vocabulary word in an input sentence is replaced with a random word from a set of semantically related words, following which the same process as above is used to predict input authenticity.
- **DISP** (Zhou et al., 2019): In this approach, a BERT-based perturbation discriminator predicts whether each token in the input sentence is authentic or perturbed. If none of the tokens are predicted to be perturbed, the input sentence is considered authentic.
- **FreeLB** (Zhu et al., 2019): This is an adversarial training approach where adversarial perturbations are added to word embeddings and the resulting adversarial loss is minimized to promote higher invariance in the embedding space.
- **Certified Robustness Training** (Jia et al., 2019): This approach uses Interval Bound Propagation (IBP) to obtain an upper bound on the worst-case loss resulting from any word substitution-based perturbation. This has been applied to CNN and LSTM-based language models.

D Analysing F_{flip} and F_{lw}

In the second column of Table 5, for each of the datasets, we show the percentage of authentic and adversarial inputs which generated non-target class predictions. Further, in the third column of Table 5 we show the percentage of (authentic, adversarial) inputs whose layer-wise outputs showed more than one switch. These results show that the F_{flip} and F_{lw} are individually informative.

E Adversarial detection accuracy for different attack types

In Table 6, we present the breakup of model accuracy across individual attack types. We observe that for text classification tasks like SST-2, Yelp and AG News the accuracy for Embedding and Synonym swap attack types are much higher compared to other datasets. We also note that in case of both word and character-level attacks, Deletion and Substitution operations are the ones with least detection accuracy across almost all datasets. Finally, we observe that the performance for detecting adversarial inputs generated by PWWS and TextFooler attacks remain fairly consistent across datasets.

F Refereeing heads in adversarial detection

In this section, we explore the influence of each gating value in generating the prediction for our adversarial detection model. We make use of the Grad-CAM (Selvaraju et al., 2017) approach to identify critical neurons in the input layer of AdvNet that

Attack Type	**Perturbed Text**
Original Text	**it 's a charming and often affecting journey.**
Word-level attacks	
Deletion	it's a _ and often affecting journey.
Antonyms	it's a repulsive and often affecting journey.
Synonyms	it's a charming and often affecting passage.
Embeddings	it's a charming and quite affecting journey.
Order Swap	it's charming and affecting a often journey.
PWWS	it's a entrance and often strike journey.
TextFooler	it's a charming and _ affecting journey.
Original Text	**a sometimes tedious film.**
Character-level attacks	
Substitution	a sometimes tidious fylm.
Deletion	a som_times tedio_s film.
Insertion	a sometimeDs tvedious film.
Order Swap	a smoetimes tedoius film.

Table 4: Examples of 11 attack types used for adversarial data creation. '_' represents a deleted character and there is no character present at that position in the adversarial sample.

Dataset	**Non-target o/p (Mutated)**	**Switches>1 (Layer-wise)**
SST-2	(12.3, 34.2)	(37.9, 54.8)

have large gradients from the target class (authentic or adversarial) flowing through them. Among these, we consider neurons that correspond to the gating values, i.e, F_{mask} and call the heads corresponding to them as *refereeing* heads. From Figure 9, we observe that word swap attacks like antonyms, synonyms, and embeddings require a greater number of refereeing heads, while character-level attacks need fewer. This is because character-level changes make the token invalid, i.e, the model treats it as a unknown token absent in the vocabulary. Since this changes the input embedding sequence more dramatically (Biju et al., 2020), small deviations from standard gating patterns are sufficient to mislead the model leading to fewer refereeing heads. Since introducing synonym and embedding based perturbations change the embeddings input to the model by a smaller extent, larger deviations from the gating pattern are required to block or pass selective chunks of information to mislead the model.

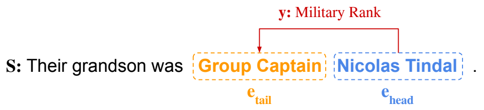
Abstract

Despite the importance of relation extraction in building and representing knowledge, less research is focused on generalizing to unseen relations types. We introduce the task setting of Zero-Shot Relation Triplet Extraction (ZeroRTE) to encourage further research in low-resource relation extraction methods. Given an input sentence, each extracted triplet consists of the head entity, relation label, and tail entity where the relation label is not seen at the training stage. To solve ZeroRTE, we propose to synthesize relation examples by prompting language models to generate structured texts. Concretely, we unify language model prompts and structured text approaches to design a structured prompt template for generating synthetic relation samples when conditioning on relation label prompts (RelationPrompt). To overcome the limitation for extracting multiple relation triplets in a sentence, we design a novel Triplet Search Decoding method. Experiments on FewRel and Wiki-ZSL datasets show the efficacy of RelationPrompt for the ZeroRTE task and zero-shot relation classification. Our code and data are available at github.com/declare-lab/RelationPrompt.

1 Introduction

Relation extraction aims to predict relationships between entities in unstructured text, which has applications such as knowledge graph construction (Lin et al., 2015) and question answering (Xu et al., 2016). However, existing approaches often require large datasets of annotated samples which are costly to annotate and have a fixed set of relations. Currently, less research is focused on the zero-shot setting (Wang et al., 2019) where models need to generalize to unseen relation sets without available annotated samples (Wang et al., 2019). Although there are existing zero-shot relation task settings, they do not require extracting the full relation triplets. The task setting of Zero-Shot Relation Classification[1] (ZeroRC) was previously introduced by Chen and Li (2021) to classify the relation between a given head and tail entity pair for unseen labels. However, it is not always practical or realistic to assume that the ground-truth entities are readily available. Zero-Shot Relation Slot-Filling (Levy et al., 2017) aims to predict the tail entity based on the provided head entity and relation, but also relies on other methods for entity detection. Thus, it also faces the challenge of error propagation in practice (Zhong and Chen, 2021).



Task Setting	Input	Output	Supervision
Relation Classification	S, e_{head}, e_{tail}	y	Full
Zero-Shot Relation Classification	S, e_{head}, e_{tail}	y	Zero-Shot
Zero-Shot Relation Slot-Filling	S, e_{head}, y	e_{tail}	Zero-Shot
Relation Triplet Extraction	S	e_{head}, e_{tail}, y	Full
Zero-Shot Relation Triplet Extraction	S	e_{head}, e_{tail}, y	Zero-Shot

Table 1: Comparison of task settings with our proposed Zero-Shot Relation Triplet Extraction (ZeroRTE). To our knowledge, ZeroRTE is the first task to extract full relation triplets in the zero-shot setting.

Hence, we propose a new and challenging task setting called Zero-Shot Relation Triplet Extraction (ZeroRTE). The goal of ZeroRTE is to extract triplets of the form (head entity, tail entity, relation label) from each sentence despite not having any annotated training samples that contain the test relation labels. For a clear comparison between task settings, we provide a summary in Table 1. To our knowledge, this is the first work to extend the task of Relation Triplet Extraction to the zero-shot setting. For example in Figure 1, the training samples may belong to the seen relation set {Sibling, Man-

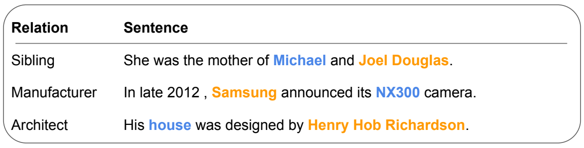
ufacturer, Architect}, while the test samples may belong to the unseen relation set {Military Rank, Position Played, Record Label}. Given the annotated training samples in Figure 1a, ZeroRTE aims to extract triplets such as (Nicolas Tindal, Military Rank, Captain) in Figure 1b.

To solve the challenges of data scarcity, there are several existing approaches. Although distant supervision (Ji et al., 2017) can be used to construct a relation corpus with a many relation types, this approach generally results in lower annotation quality than human annotation. Furthermore, distant supervision remains limited to a fixed set of relation types in the existing knowledge base (Smirnova and Cudré-Mauroux, 2018). Another approach is to formulate the task objective such that the label space is unconstrained. For instance, zero-shot sentence classification can be reframed as entailment (Puri and Catanzaro, 2019) or embedding similarity (Pushp and Srivastava, 2017) objectives. However, the existing formulations are designed for sequence classification tasks, which cannot be directly applied to structured prediction tasks such as relation triplet extraction. A third direction is to leverage pre-trained language models using task-specific prompt templates (Liu et al., 2021) which enables the models to generalize to new tasks with little to no training samples, such as zero-text classification (Zhong et al., 2021). This zero-shot potential is possible by leveraging the semantic information in prompts to query the language comprehension capabilities of pre-trained language models (Radford et al., 2019).



Relation	Sentence
Sibling	She was the mother of Michael and Joel Douglas.
Manufacturer	In late 2012 , Samsung announced its NX300 camera.
Architect	His house was designed by Henry Hob Richardson.

Record Label	Deadsy signed onto Immortal Records to release "Phantasmagore".

(b) Annotation samples of unseen relations for evaluation.

Relation	Sentence
Military Rank	She is the wife of Lieutenant Colonel George Hocham.
Position Played	However, it was Dario Argentino who defended the midfield.
Record Label	"The Sun" was first recorded by Pavement in 1982.

(c) Generated synthetic samples of unseen relations.

Figure 1: Example relation triplet data for ZeroRTE and our formulation as synthetic sentence generation. The head and tail entities are shown in blue and orange, respectively. The ZeroRTE train samples (a) and test samples (b) contain triplets that belong to disjoint relation label sets. We formulate ZeroRTE as generating synthetic samples (c) for the unseen test relation labels. The synthetic data can then be used to train another model to extract relation triplets from the test sentences. We also present more data samples in Appendix A.1.

Hence, we propose RelationPrompt which reframes the zero-shot problem as synthetic data generation. The core concept is to leverage the semantics of relation labels, prompting language models to generate synthetic training samples which can express the desired relations. The synthetic data can then be used to train another model to perform the zero-shot task. This capability is supported by the finding that language models can be prompted to control task-specific aspects of the generated text, such as domain and content (Keskar et al., 2019). For instance, given the relation label "Military Rank" in Figure 1c, it is reasonable to condition the language model and compose a sentence demonstrating the relationship that a person has been bestowed with a certain position in the armed forces. Hence, a possible sentence could be "She is the wife of Lieutenant Colonel George Hocham.", where the head entity is "George Hocham" and the tail entity is "Lieutenant Colonel". Given generated samples of sufficient quality and diversity, the synthetic dataset can effectively supervise another model to perform ZeroRTE.

To encode the relation triplet information as text sequences which can be generated by language models, we unify prompt templates with structured text formats (Paolini et al., 2020). Structured texts use special markers to encode the structured information which can be easily decoded as triplets. However, it is challenging to generate sentences which contain multiple different relation triplets. Designing a complex structured prompt template to encode multiple triplets may compromise the generation quality as the language model needs to manipulate multiple relations at once. Hence, we focus on generating single-triplet samples and explore how this limitation can be overcome by the downstream relation extractor model. Concretely, we propose a method named Triplet Search Decoding which allows the extraction of multiple triplets at prediction time despite training on synthetic samples which contain a single triplet each.

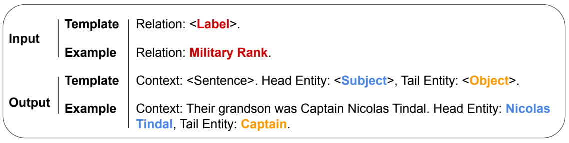
Contributions. In summary, our main contributions include: (1) We introduce the ZeroRTE task setting which overcomes limitations in prior task settings by extending the Relation Triplet Extraction task to the zero-shot setting. ZeroRTE is released as a publicly available benchmark based on the reorganized FewRel (Han et al., 2018) and Wiki-ZSL (Chen and Li, 2021) datasets. (2) In order to make ZeroRTE solvable in a supervised manner, we propose RelationPrompt to generate synthetic relation examples by prompting language models to generate structured texts. (3) We propose Triplet Search Decoding to overcome the limitation for extracting multiple relation triplets in a sentence. (4) RelationPrompt surpasses prior ZeroRC methods and baselines on ZeroRTE, setting the bar for future work. Our analysis shows that the generated samples are reasonable and diverse, hence serving as effective synthetic training data.

2 RelationPrompt: Methodology

To extract triplets for unseen relation labels in ZeroRTE, we propose a framework called RelationPrompt which uses relation labels as prompts to generate synthetic relation examples of target unseen labels. The synthetic data can then be used to supervise any downstream relation extraction model. Hence, our framework requires two models: a Relation Generator for synthetic relation samples, and a Relation Extractor that will be trained on the synthetic data and used to predict triplets for unseen relations. In order to represent the relation triplet information to be processed by language models, we design structured prompt templates. The relation extractor is designed to support both ZeroRTE and ZeroRC tasks. We further propose Triplet Search Decoding to overcome the challenge of generating relation samples with multiple triplets.

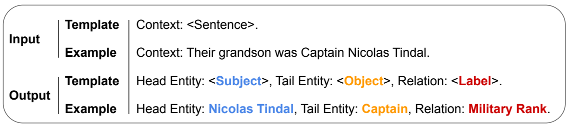
2.1 Task Formulation

In ZeroRTE, the goal is to learn from the seen dataset D_s and generalize to the unseen dataset D_u. The datasets D_s and D_u are used for training and testing respectively, and are originally split from the full dataset which is defined as $D = (S, T, Y)$ where S denotes the input sentences, T denotes the output triplets and Y denotes the set of relation labels present in D. The seen and unseen label sets are predefined and denoted as $Y_s = \{y_s^1, ..., y_s^n\}$ and $Y_u = \{y_u^1, ..., y_u^m\}$ respectively, where $n = |Y_s|$ and $m = |Y_u|$ are the size of seen and unseen label sets respectively. Hence, the label sets of D_s and D_u are disjoint, i.e., $Y_s \cap Y_u = \emptyset$. Each data sample contains the input sentence $s \in S$ which corresponds to a list $t \in T$ which can contain one or more output triplets. A relation triplet is defined as (e_{head}, e_{tail}, y) which denotes the head entity, tail entity and relation label respectively. To solve ZeroRTE, we formulate the following algorithm:



Input	Template	Relation: <Label>.
	Example	Relation: Military Rank.
Output	Template	Context: <Sentence>. Head Entity: <Subject>, Tail Entity: <Object>.
	Example	Context: Their grandson was Captain Nicolas Tindal. Head Entity: Nicolas Tindal, Tail Entity: Captain.

(a) Structured template for relation generator.



Input	Template	Context: <Sentence>.
	Example	Context: Their grandson was Captain Nicolas Tindal.
Output	Template	Head Entity: <Subject>, Tail Entity: <Object>, Relation: <Label>.
	Example	Head Entity: Nicolas Tindal, Tail Entity: Captain, Relation: Military Rank.

(b) Structured template for relation extractor.

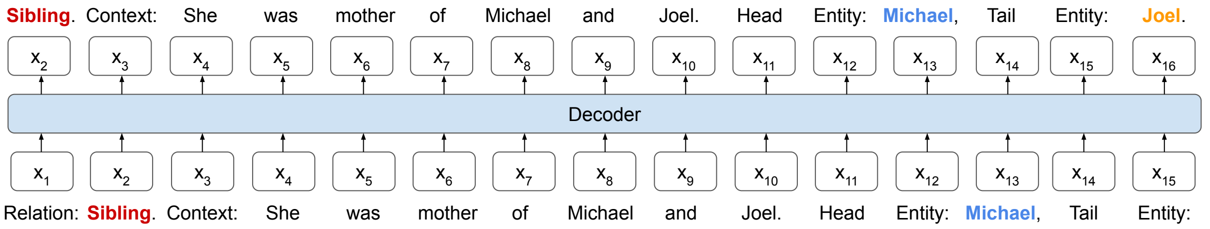
Figure 2: RelationPrompt structured templates. The head entities, tail entities and relation labels are shown in blue, orange and dark red respectively. The relation generator (a) takes the relation label as input and outputs the context and entity pair. The relation extractor (b) takes the sentence as input and outputs the relation triplet which consists of entity pair and relation label.

Algorithm 1 RelationPrompt: Prompting language models to generate synthetic data for ZeroRTE.

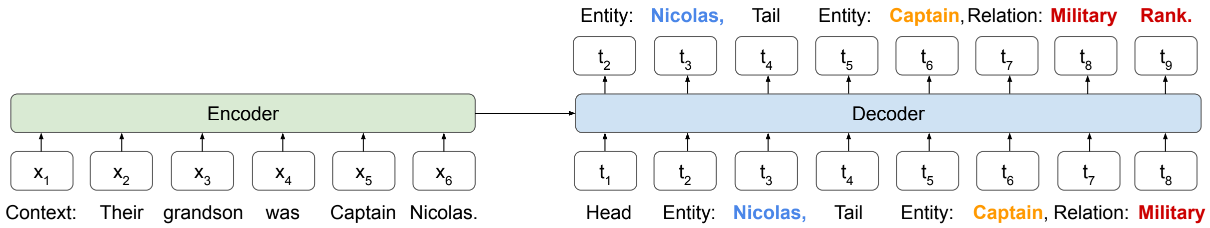
```
Define:
Dataset $D = (\text{Sentences } S, \text{Triplets } T, \text{Labels } Y)$
Require: Train Dataset $D_s$, Test Dataset $D_u$, Relation Generator $M_g$, Relation Extractor $M_e$.
Ensure: $Y_s \cap Y_u = \emptyset$.
1: $M_{g,finetune} \leftarrow Train(M_g, D_s)$
2: $M_{e,finetune} \leftarrow Train(M_e, D_s)$
3: $D_{synthetic} \leftarrow Generate(M_{g,finetune}, Y_u)$
4: $M_{e,final} \leftarrow Train(M_{e,finetune}, D_{synthetic})$
5: $\hat{T}_u \leftarrow Predict(M_{e,final}, S_u)$
6: return Extracted Triplets $\hat{T}_u$
```

2.2 Relation Generator

Language models are implicitly capable of zero-shot generalization based on their general and large-scale pre-training (Radford et al., 2019). Furthermore, text generation has been shown to be effectively controllable (Keskar et al., 2019). Hence, we prompt the language model to generate synthetic samples by conditioning on the target unseen relation labels. As shown in Algorithm 1, relation generator M_g is first fine-tuned on samples for the seen dataset D_s (line 1) and then prompted by relation labels Y_u to generate the synthetic sam-



(a) Training process for relation generator.



(b) Training process for relation extractor.

Figure 3: Model training process. Each head entity, tail entity and relation label is shown in blue, orange and dark red respectively. To conserve space, the sentences shown are shortened and punctuation is not separated. The relation generator (a) is trained with the standard language modeling objective to condition on the relation label and generate the sentence and entity pair. The relation extractor (b) is trained with the standard sequence-to-sequence objective to condition on the input sentence and output the relation triplet of entity pair and relation label.

ples $D_{synthetic}$ (line 3). As shown in Figure 2a, the relation generator takes as input a structured prompt in the form of “Relation: y” and outputs a structured output in the form of “Context: s. Head Entity: e_{head}, Tail Entity: e_{tail}.”. We employ a causal language model as our relation generator to sample the structured sequence in an autoregressive manner. As shown in 3a, the model M_g is trained using the standard language modeling objective of next-word prediction (Bengio et al., 2001). Given each sequence $x = [x_1, x_2, ..., x_n]$, the goal is to learn the conditional generation probability:

$$p(x) = \prod_{i=1}^{n} p(x_i|x_{<i}) \tag{1}$$

To generate diverse output sequences for each input relation prompt, we use sampling with temperature t (Hinton et al., 2015) over the output logits o and vocabulary size V with temperature tp:

$$p(x_i|x_{<i}) = \frac{exp(o_i/tp)}{\sum_{j=1}^{|V|} exp(o_j/tp)} \tag{2}$$

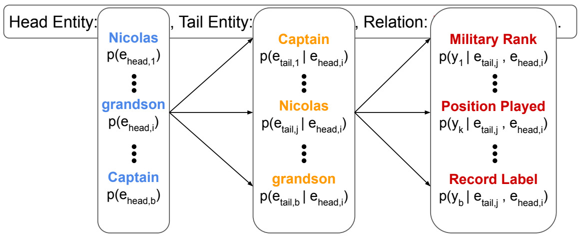
The output sequences are decoded into relation triplets by splitting on the special terms “Context:”, “Head Entity:” and “Tail Entity:”. In case of decoding errors where an entity is not found in the generated context, we discard that sample and continue generating until a fixed amount of valid samples is reached.

2.3 Relation Extractor

Given the generated samples of unseen relations, we can train a relation extractor model M_e to predict the relation triplets in a zero-shot setting. As shown in Algorithm 1, relation extractor M_e is first fine-tuned on samples for the seen dataset D_s (line 2) and finally tuned on the synthetic samples $D_{synthetic}$ (line 4). Lastly, M_e is used to predict and extract relation triplets $\hat{T}_u$ from the test sentences S_u (lines 5 and 6). We adopt a sequence-to-sequence learning approach which is flexible and effective for structured prediction tasks (Cui et al., 2021; Paolini et al., 2020). As shown in Figure 2b, the relation extractor takes as input a structured prompt containing the sentence s in the form of “Context: s”. It then generates a structured output sequence containing a single pair of entities e_{head} and e_{tail} satisfying the relation y, in the form of “Head Entity: e_{head}, Tail Entity: e_{tail}, Relation: y”. As shown in Figure 3b, we use a standard sequence-to-sequence objective (Lewis et al., 2020) for training and greedy decoding for generation. To predict a single relation triplet in a given sentence s, we can generate the model outputs without any initial decoder input, as seen in Figure 4a. In case of invalid entity or relation, we treat it as null prediction for that sample. On the other hand, prediction for ZeroRC is easily supported by providing the entity information as the initial decoder input. As shown

(a) Unconditional decoding for single-triplet extraction.

(b) Entity-conditioned decoding for relation classification.



(c) Triplet search decoding for multi-triplet extraction.

Figure 4: Comparison of generation decoding methods with our proposed Triplet Search Decoding. The head entities, tail entities and relation labels are shown in blue, orange and dark red respectively. Unconditional decoding (a) can be used to predict one relation triplet in each sentence for ZeroRTE. Entity-conditioned decoding (b) can be used to predict only the relation label between the given entity pair for ZeroRC. Our proposed triplet search decoding (c) can be used to predict multiple triplets in each sentence for ZeroRTE.

in Figure 4b, the model takes "Context: s, Head Entity: e_{head}, Tail Entity: e_{tail}, Relation:" as decoder input to generate "y" as output. Hence, our method naturally encompasses both ZeroRTE and ZeroRC as this change affects model prediction and not training.

2.4 Extracting Multiple triplets using Triplet Search Decoding

We further propose a generation decoding method in order to improve the zero-shot extraction performance on sentences which contain multiple triplets. For the RelationPrompt generation of synthetic data, each sample is limited to contain a single relation triplet. Hence, conventional models for triplet extraction most likely cannot perform well with our framework for multi-triplet ZeroRTE as they normally assume that the training samples may contain multiple triplets per sentence. The inference method of multi-turn question answering (Li et al., 2019) may mitigate this issue, but cannot scale easily to unseen relations as it relies on hand-crafted question templates which are specific to certain relation and entity types. Hence, we propose Triplet Search Decoding which improves multi-triplet ZeroRTE for the relation extractor.

Given the relation extractor which takes a sentence as input and generates output sequences in an autoregressive fashion, greedy decoding as in Figure 4a can output a single sequence. However, Triplet Search Decoding as shown in Figure 4c can output multiple sequences that each correspond to a different candidate relation triplet. We then apply a likelihood threshold to filter the final output sequences. The core concept is enumerating multiple output sequences during generation by considering multiple candidates for the head entity, tail entity and relation label respectively. Starting from the special sub-sequence "Head Entity:", it follows from our template in Figure 3b that the next generated token should be the first token of the head entity, such as "Nicolas". For the i^{th} possible first token of the head entity, we denote the softmax probability as $p(e_{head,i})$. We only consider the probability of the first token as it can mostly determine the following generated tokens of the entity (Zhao et al., 2021). Instead of greedily decoding the entire sequence, we branch the generation into b sequences based on the tokens with the top b highest $p(e_{head,i})$. Thereafter, the sequence is greedily decoded until the special sub-sequence "Tail Entity:" is generated. The following token will then be the first token of the tail entity, such as "Captain". The j^{th} tail entity first token probability is denoted as $p(e_{tail,j}|e_{head,i})$. Hence, the generation is branched such that for each head entity, there will be another b sequences based on the tokens with the top b highest $p(e_{tail,j}|e_{head,i})$. Thereafter, the sequence is greedily decoded until the special sub-sequence "Relation:" is generated. The next generated token will be the first token of the relation label, such as "Military" in "Military Rank". The k^{th} relation first token probability is denoted as $p(y_k|e_{head,i}, e_{tail,j})$. We branch the generation such that for each pair of head entity and tail entity, there will be another b sequences based on the tokens with the top b highest $p(y_k|e_{head,i}, e_{tail,j})$. For each sequence, the generation proceeds greedily until the end token is reached, and the overall inference probability is aggregated as:

$$\begin{aligned} p(triplet_{i,j,k}) &= p(e_{head,i}, e_{tail,j}, y_k) \\ &= p(y_k|e_{head,i}, e_{tail,j}) \\ &\quad \cdot p(e_{tail,j}|e_{head,i}) \\ &\quad \cdot p(e_{head,i}) \end{aligned} \tag{3}$$

We note that the conditional assumption does not directly consider the other context tokens as they consist of the special sub-sequences which are fixed as part of our generation template. The input sentence s is also not included in the formulation as it is the same when considering multiple output triplets for one sample. At this point, there will be b^3 sequences, each corresponding to a different candidate relation triplet. To filter the final output sequences, we use a probability threshold over that is tuned on the validation F_1 metric, with hyperparameter details in Section A.2. Compared to previous generative extraction methods (Paolini et al., 2020; Nayak and Ng, 2020), Triplet Search Decoding allows the probability $p(triplet_{i,j,k})$ of each output triplet to be directly calculated and hence control the number of output triplets using the threshold. Compared to other decoding methods such as beam search, Triplet Search Decoding leverages the specific relation triplet structure in our structured text templates. Hence, it can ensure that each output sequence corresponds to a different relation triplet. Furthermore, Triplet Search Decoding is more interpretable than existing generative methods for triplet extraction as it can directly provide the prediction probability for each triplet. More importantly for ZeroRTE, this decoding process allows the relation extractor to naturally predict multiple triplets at test time despite training on synthetic samples which have a single triplet each.

3 Experiments

3.1 Datasets

We use the following two datasets for our experiments. FewRel (Han et al., 2018) was hand-annotated for few-shot relation extraction, but we made it suitable for the zero-shot setting after data splitting into disjoint relation label sets for training, validation and testing. Wiki-ZSL (Chen and Li, 2021) is constructed through distant supervision over Wikipedia articles and the Wikidata knowledge base. The dataset statistics are shown in Table 2. To partition the data into seen and unseen label sets, we follow the same process as Chen and Li (2021) to be consistent. For each dataset, a fixed number of labels are randomly selected as unseen labels while the remaining labels are treated as seen labels during training. To study the performance of methods under different settings of unseen label set size m, we use $m \in \{5, 10, 15\}$ in our experiments. In order to reduce the effect of experimental noise, the label selection process is repeated for five different random seeds to produce different data folds. For each data fold, the test set consists of the sentences containing unseen labels. Five validation labels from the seen labels are used to select sentences for early stopping and hyperparameter tuning. The remaining sentences are treated as the train set. Hence, the zero-shot setting ensures that train, validation and test sentences belong to disjoint label sets.

	Samples	Entities	Relations	Sentence Length
Wiki-ZSL	94,383	77,623	113	24.85
FewRel	56,000	72,954	80	24.95

Table 2: Dataset statistics. “Sentence Length” refers to the average number of words in each sentence.

3.2 Experimental Settings

For the relation generator, we fine-tune the pre-trained GPT-2 (Radford et al., 2019) which has 124M parameters. For the relation extractor, we fine-tune the pre-trained BART (Lewis et al., 2020) which has 140M parameters. In both cases, the fine-tuning is performed on the training set for up to five epochs and early stopping is based on the validation loss. The learning rate is 3e-5 with linear warm up for the first 20% of training steps and batch size is set to 128. During the training process, we use the AdamW optimizer (Loshchilov and Hutter, 2019). The relation generator is used to generate synthetic samples based on the validation and test set label names. A fixed amount of sentences will be generated for each relation. The relation extractor is fine-tuned again on the synthetic relation sentences and then used for evaluation on the test set.[2]

To perform evaluation for ZeroRTE, we evaluate the triplet extraction results separately for sentences containing single triplets and multiple triplets. To evaluate multiple triplet extraction, we use the Micro F_1 metric which is standard in structured prediction tasks (Paolini et al., 2020) and report the precision (P.) and recall (R.). Evaluating single triplet extraction involves only one possible triplet for each sentence, hence the metric used is Accuracy (Acc.). We evaluate on ZeroRC using the Macro F_1 metric to be consistent with Chen and Li (2021). Table 3 and 4 report the average results across five data folds as detailed in Section 3.1.

3.3 Baseline Methods

ZeroRTE As ZeroRTE is a new task setting, we provide two baseline methods for comparison with our RelationPrompt method. Firstly, our relation

Table 3: Results for Zero-Shot Relation Triplet Extraction (ZeroRTE).

extractor can be made to perform ZeroRTE without fine-tuning on synthetic samples as it is trained to extract triplets on the sentences of the seen relation set. At prediction time, we constrain the generated labels to be selected from the target label names by masking the generated token probabilities. We denote this model as **"NoGen"** to indicate that it does not use generated synthetic samples for training. Secondly, we use an existing triplet extraction model known as **TableSequence** (Wang and Lu, 2020). As it is normally unable to perform ZeroRTE, we provide supervision using synthetic samples from our relation generator.

ZeroRC There are three main categories of competing methods for ZeroRC. Firstly, **R-BERT** (Wu and He, 2019) is a relation classification model but can be adapted to the zero-shot setting by using the sentence representations to perform nearest neighbor search over label embeddings. Next, **CIM** (Rocktäschel et al., 2016) is an entailment-based method which takes the sentence and each possible relation as input to perform binary classification whether the label matches the sentence semantically. Lastly, **ZS-BERT** (Chen and Li, 2021) generates sentence representations that are conditioned on the provided entity pair information, and performs nearest neighbor search over embeddings of the candidate relation descriptions.

3.4 Experimental Results

Triplet Extraction We compare RelationPrompt with the baselines on ZeroRTE for Wiki-ZSL and FewRel datasets in Table 3. In both single-triplet and multi-triplet evaluation, our method consistently outperforms the baseline methods in terms of Accuracy and F_1 metrics respectively. Although we do not observe a consistent advantage in precision and recall scores for multi-triplet extraction, the baseline methods cannot achieve a balanced precision-recall ratio, leading to poor overall F_1 results. The results difference between NoGen and RelationPrompt also indicate that using the synthetic samples from the relation generator is critical, as the F_1 score can be improved by more than two times in some cases. This also suggests that the relation generator can produce reasonable-quality synthetic sentences as training data for the downstream relation extractor. We also observe that the choice of relation extractor for ZeroRTE is not trivial, as the third-party TableSequence (Wang and Lu, 2020) has significantly worse performance when compared to RelationPrompt, especially for multi-triplet extraction. Although the TableSequence model is able to perform multi-triplet extraction by design, it assumes that the training data may contain multi-triplet sentences, whereas our synthetic data is limited to single triplet samples. On the other hand, our proposed relation extractor and decoding method effectively overcomes this chal-

lenge by naturally enumerating and ranking multiple triplets at inference time.

Relation Classification RelationPrompt naturally supports the ZeroRC task without additional training by providing the entity pair information in the prompt. In Table 4, we observe consistent improvements compared to the prior state-of-the-art method ZS-BERT (Chen and Li, 2021). Notably, our method is able to maintain a relatively high classification F_1 performance when the unseen label set size m increases, whereas ZS-BERT shows a sharper drop in performance. The trend suggests that RelationPrompt is able to scale better to larger unseen label sets, which is more important for open-domain applications. This advantage may further indicate that our method can leverage the semantic information of relation labels more effectively through the token-level conditional generation and extraction stages. On the other hand, ZS-BERT relies on sequence-level representations which can only preserve the high-level label semantics.

4 Analysis

4.1 Ablation Study

We conduct an ablation study to examine the performance of our decoding method and task-specific fine-tuning on the seen relation set for multi-triplet ZeroRTE, and the results are shown in Table 5. The comparison is conducted on the Wiki-ZSL validation set with 10 unseen labels. The large performance gap shows that Triplet Search Decoding is critical for multi-triplet ZeroRTE, and suggests that the enumeration and ranking of relation triplet candidates are of sufficiently high quality. Secondly, we observe a significant drop in performance when the relation extractor is not fine-tuned on seen relation samples from the train set before the final tuning on generated synthetic samples for unseen labels. This case suggests that the initial fine-tuning on sentences for seen relations is useful for learning the general task of relation triplet extraction. The learned representations can then be further fine-tuned on the synthetic samples to adapt specifically for the unseen relations to achieve optimal results.

4.2 Effect of Generated Data Size

We further study how the number of generated synthetic samples effects the multi-triplet ZeroRTE performance. The evaluation is based on Wiki-ZSL validation set with 10 unseen labels, and the results are shown in Figure 6. Increasing the amount from 125 to 250 samples per label improves F_1 score. However, further increasing the generated size up to 2000 does not improve the final performance. This indicates that although the synthetic data is beneficial for ZeroRTE, excessive amounts can lead to over-fitting due to noise. We further analyze the generation diversity in Appendix A.3.

4.3 Qualitative Analysis

To assess how the relation data generator generalizes to relations in the wild, we present several samples of real and generated samples in Figure 5. The relation labels and real sentences were collected from factual articles. Given the relations "Investor", "Defeated By" and "Currency Of", the generator is able to determine the correct semantic meaning of the relations and compose reasonable sentences. In most cases, the generated head and tail entity pairings can match the given relations and have a similar context to the real sentences. However, in the last case for relation "Political Partner", the generated entity pair does not match the relation meaning despite being grounded in a political context. Instead, the generated sentence expresses a relationship that is closer to "Political Party". This suggests that a future area of improvement could be to match the generated head and tail entity more closely to the given relation.

5 Related Work

Zero-Shot Relation Extraction Zero-shot relation extraction was previously framed as a slot-filling task and solved by reading comprehension methods (Levy et al., 2017). However, their approach requires manual template design for each relation label, which cannot scale well to new relation types. Another approach to zero-shot relation extraction is the formulation into an entailment task (Obamuyide and Vlachos, 2018), which is not constrained to a fixed relation label space. Instead, the entailment approach determines if arbitrary pairs of sentences and relation labels are compatible. However, it is designed for sentence classification and cannot be applied to ZeroRTE.

Relation	Real Sentence	Generated Sentence
Investor	In October 1999, Alibaba received a US $25 million investment from Goldman Sachs and SoftBank.	In 2001, CSC announced that it is investing in a record 65 plants in South Africa and plans to invest $2 billion in hydropower, hydrological services and agriculture.
Defeated By	National shuttler Loh Kean Yew recorded a 24-22, 21-14 win over All-England champion Lee Zii Jia.	The team lost three consecutive draws to the New York Knicks, including a 9–2 win against the Lakers
Currency Of	El Salvador, on the other hand, has accepted Bitcoin (BTC) as a legal currency.	In 2001, as the euro strengthened, Italy introduced an extension of the Eurobill (Eurobills), the currency of the Eurozone.
Political Partner	Beijing and the Holy See reached a provisional agreement in 2018 on the appointment of Chinese bishops.	His son, Thomas, was a leading Republican, elected to the Massachusetts State Senate in 1881.

Figure 5: Case study between real and generated samples for relations in the wild. The head and tail entities are shown in blue and orange respectively.

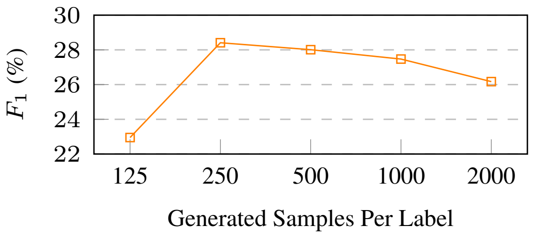

Figure 6: Effect of generated data size on ZeroRTE.

Data Augmentation A popular method for improving model performance in supervised low-resource tasks is data augmentation. Simple heuristics such as token manipulation (Kobayashi, 2018) were initially developed, new methods in language modeling improved the quality of augmented samples (Xie et al., 2020; Wei and Zou, 2019). Although there are data augmentation methods that can be applied to structured tasks such as named entity recognition (Ding et al., 2020) and relation extraction (Papanikolaou and Pierleoni, 2020; Lee et al., 2021), they require existing training samples and cannot be easily adapted to zero-shot tasks.

Knowledge Retrieval RelationPrompt also leverages the knowledge stored in language models (Roberts et al., 2020) to compose relation samples that are grounded in realistic contexts. To ensure that the generated samples are factually accurate, the language model requires strong knowledge retrieval capabilities (Petroni et al., 2019).

Language Model Prompts Prompting-based methods have shown promise as a new paradigm for zero-shot or few-shot inference in natural language processing (Liu et al., 2021). Another advantage is the potential to adapt very large language models (Reynolds and McDonell, 2021) to new tasks without relatively expensive fine-tuning. Concurrent works (Meng et al., 2022; Ye et al., 2022) also show that language models can generate synthetic training data. However, such methods have not yet proven effective for more complex tasks such as triplet extraction.

Structured Prediction RelationPrompt generates synthetic data for relation triplet extraction, which is a structured prediction task. Hence, it can be widely applicable to other structured prediction tasks such as named entity recognition (Aly et al., 2021), event extraction (Huang et al., 2018) or aspect sentiment triplet extraction (Xu et al., 2021).

6 Conclusions and Future Work

In this work, we introduce the task setting of Zero-Shot Relation Triplet Extraction (ZeroRTE) to overcome fundamental limitations in previous task settings and encourage further research in low-resource relation extraction. To solve ZeroRTE, we propose RelationPrompt and show that language models can effectively generate synthetic training data through relation label prompts to output structured texts. To overcome the limitation for extracting multiple relation triplets in a sentence, we propose the Triplet Search Decoding method which is effective and interpretable. Results show that our method surpasses prior ZeroRC methods as well as strong baselines on ZeroRTE, setting the bar for future work. As mentioned in Section 4.3, a future direction for improvement could be to ensure that the generated entity spans are more compatible with the semantics of the relation in the language model prompt.

A Appendix

A.1 Additional Data Samples

Dataset Samples To further illustrate the datasets used, we show test samples in Figure 7. The samples are taken from the FewRel (a) and Wiki-ZSL (b) test sets respectively with 10 unseen relation labels.

Synthetic Samples To further examine the output of the relation generator, we show test samples in Figure 8. The samples are generated from the FewRel (a) and Wiki-ZSL (b) test set labels respectively with 10 unseen relation labels.

A.2 Implementation Details

Generating Structured Texts We use the relation generator model to generate synthetic sentences in an autoregressive fashion. To convert the structured text outputs to relation triplet samples, we perform simple string processing on the output templates shown in Figure 3a to separate the structured content from the natural text. In case of a small amount of conversion errors, we continue to generate samples until the amount of sentences generated per label is reached. For the relation extractor model, we perform a similar processing on the output templates in Figure 3b to extract the predicted relation triplets. However, in case of processing errors, we do not continue generation and instead treat it as a prediction failure for that input sample.

Hyperparameters We show more detailed hyperparameters used in Table 6. We run a grid search on the Wiki-ZSL validation set with 10 unseen labels for multi-triplet ZeroRTE F_1 metric. A grid search is used to tune the hyperparameters. For number of generated samples per label, we consider the values $\{125, 250, 500, 1000, 2000\}$. To tune the Triplet Search Decoding threshold, we consider fifty evenly-spaced values from the interval over the minimum and maximum output scores of all candidate triplets on the validation set. Due to computational constraints, we consider the number of branches to consider at each stage a fixed value, and do not tune it as a hyperparameter.

Computing Infrastructure The experiments are conducted on NVIDIA V100 GPUs, and each experiment is run on a single GPU with 32 GB of

	Value
Generator Maximum Sequence Length	128

Generated Data	3461	4949	10558

Table 7: Data diversity comparison.

memory and mixed precision settings.

A.3 Further Analysis

Generated Sample Diversity Our method for ZeroRTE heavily depends on the quality of the generated data. Hence, we compare the diversity of real and synthetic data samples. Concretely, we measure the number of unique words and entities present in the texts. We used the Wiki-ZSL validation set sentences with five unique labels and generate an equal amount of synthetic sentences for comparison. Table 7 shows that the diversity of unique entities is actually greater for the generated sentences. However, the generated sentences have lower diversity of overall unique words. This may be explained by the fact that entity names tend to be unique, and the generator language model has seen a vast number of unique entity names during the large-scale pre-training. On the other hand, the total unique words are mostly determined by the non-entity words. By using prompts to condition the generation of sentences specifically for unseen relation labels, this may constrain the diversity of contextual information in the output sentences.

Performance Across Relations To study how the performance varies across different relation labels, we evaluate single-triplet ZeroRTE on the Wiki-ZSL test set with 10 unseen labels. Figure 9 shows that the model is able to perform well for relations such as "Drafted By" and "Sports Discipline Competed In". However, it performs more poorly for relations such as "Official Language" and "Employer". This suggests that RelationPrompt performs best for relations which are highly specific to constrain the output context more effectively.

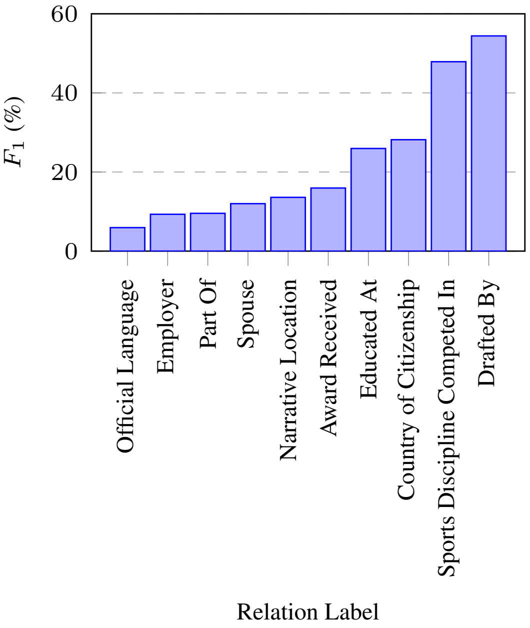

Figure 9: Separate evaluation on relation labels.

Pre-Trained Multilingual Sequence-to-Sequence Models: A Hope for Low-Resource Language Translation?

Abstract

What can pre-trained multilingual sequence-to-sequence models like mBART contribute to translating low-resource languages? We conduct a thorough empirical experiment in 10 languages to ascertain this, considering five factors: (1) the amount of fine-tuning data, (2) the noise in the fine-tuning data, (3) the amount of pre-training data in the model, (4) the impact of domain mismatch, and (5) language typology. In addition to yielding several heuristics, the experiments form a framework for evaluating the data sensitivities of machine translation systems. While mBART is robust to domain differences, its translations for unseen and typologically distant languages remain below 3.0 BLEU. In answer to our title's question, mBART is not a low-resource panacea; we therefore encourage shifting the emphasis from new models to new data[1].

1 Introduction

Pre-trained multilingual sequence-to-sequence (PMSS) models, such as mBART (Tang et al., 2021) and mT5 (Xue et al., 2021), are pre-trained on large general data, then fine-tuned to deliver impressive results for natural language inference, question answering, and text simplification (Hu et al., 2020). Their performance on machine translation shows promise for translating low-resource languages (Liu et al., 2021b; Adelani et al., 2021; Thillainathan et al., 2021), which remains an open challenge (Lopez and Post, 2013; Koehn and Knowles, 2017; Mager et al., 2021; Ranathunga et al., 2021).

When can mBART and mT5 succeed in translating a low-resource language? Despite their promise, the specific conditions for their practical application are not yet clear. Understanding their sensitivities is crucial to guide data acquisition efforts and apply PMSS models to new languages.

We introduce a framework for assessing data-dependency of performance of machine translation systems. We then apply it in a large-scale study of mBART's viability for low-resource machine translation on 10 typologically and geographically varied languages. Eight languages are low-resource, and four are unseen by mBART during pre-training. Through our results, we gauge the importance of five dimensions of the training data:

1. Amount of fine-tuning data
2. Noise in fine-tuning data
3. Amount of pre-training data
4. Domain mismatch
5. Language typology

The closest work to ours (Liu et al., 2021b) considers only the first two.

For the seen languages, mBART reaches acceptable performance with either 10k high-quality, in-domain sentence pairs or 100k noisy ones. However, mBART's BLEU score for unseen languages is often below 3.0—far below usability. For these unseen, low-resource languages, the fact that even mBART—which has already seen billions of sentences—cannot succeed in virtually any of our conditions speaks to the need for appropriate in-domain data. Therefore, the analytical framework in our experimental design can help to target new data acquisition efforts.

2 Models and Data

mBART and mT5 are PMSS models that rely on the encoder–decoder Transformer architecture (Vaswani et al., 2017) trained on Common Crawl–derived data with variants of a monolingual autoencoding objective: they must recreate the input text that they are provided. Neither is trained with an explicit objective encouraging similar tokens or sentences to have similar representations.

After model weights have been learned, the models can be fine-tuned on parallel text for translation.

Table 3: Parallel corpora used in our study.

The ideal fine-tuning scenario would be vast, clean data matching the language and domain of interest. Because this scenario is unlikely for low-resource languages, we test the relaxation of these assumptions for PMSS models.

In a preliminary experiment comparing mBART and mT5, mBART performed better than mT5 on 11 of the 18 translation directions, especially the EN→xx directions (Table 1), corroborating Liu et al. (2021b). Because mBART performed better both in number of translation directions and average BLEU, we focus hereafter on it.

2.1 Languages

To assess mBART's translation ability, we selected a set of high- and low-resource languages with high typological and geographical diversity (Table 2). Five of the ten languages do not use the Latin script, so that we can evaluate mBART's generalization to non-Latin scripts (see Pires et al., 2019). Eight are considered low-resource languages by Joshi et al. (2020), while two high-resource languages (FR and HI) give a skyline of performance.[2] Four are unseen during mBART's pre-training. Together, these languages let us probe the effects of pre-training data size and language typology on translation.

2.2 Corpora

Selecting suitable parallel corpora enables us to probe the remaining three factors: amount of fine-tuning data, noise in the fine-tuning data, and domain mismatch.

For each of our 10 languages, we use three training corpora: data from Common Crawl, the Bible, and one other domain-specific dataset (Table 3; complete details in Appendix A). Common Crawl is large and open-domain, while the others are smaller curated translations. We use FLORES (which is also open-domain) and the two domain-specific corpora for testing. Comparing on these lets us assess the impact of domain mismatch.

To evaluate consistently across differently sized corpora, we sampled fixed-size training sets from each corpus. For the Common Crawl data, we used two sizes: 25k and 100k sentence pairs. For the Bible, we used a 1k-sentence-pair sample. Finally, for each language's other domain-specific dataset, depending on the amount of parallel text available, we used up to four sizes (1k, 10k, 50k, 100k).

The Common Crawl datasets are large open-domain parallel corpora, but their construction by automatic alignment invites substantial noise. This problem is especially severe for low-resource languages (Kreutzer et al., 2022). Noisy data often harm translation models (Khayrallah and Koehn, 2018), but it is possible to use them effectively (McCarthy et al., 2020a). This raises the question of whether mBART can do so. Among our experiments, we can see whether and when a smaller, clean parallel corpus would be preferable.

3 Experimental Setting

We fine-tune mBART models on each of the training corpora and sizes listed above, and we evaluate their performance using the development and test sets from the domain-specific corpora and FLORES.

---

[2] Joshi et al. (2020)'s taxonomy is out-of-date. Because SI is used to train mBART, it must be at least class 3. We believe that, according to Joshi et al. (2020)'s definition, no language in our study is below class 2.

Table 5: Experimental results for French, reported in SacreBLEU. Values <1.0 grey; values >10.0 bold.

We additionally train a standard Transformer baseline (Vaswani et al., 2017) to compare pre-training versus training from scratch.

We score translations with SacreBLEU (Post, 2018). Details of training and evaluation are given in Appendix B.

4 Results and Analysis

The results of our empirical study are given in Table 4, with FR given in Table 5. By contrasting specific groups of rows, we probe our five factors.

4.1 Amount of fine-tuning data

To assess this dimension, we compare the Transformer and mBART models trained on varying sizes of the same corpus with their corresponding open-domain and domain-specific evaluation sets.

In the open-domain case (training on Common Crawl), for languages seen during pre-training, mBART fine-tuned with 25k sentence pairs outperforms the Transformer trained with 100k parallel sentences; this pattern holds for 18 of the 20 language directions. This indicates that pre-trained mBART is at least four times as data-efficient. Although it also outperforms the Transformer on unseen languages in terms of BLEU, the scores are often below 3.0—a far cry from even the BLEU score needed for gisting.

On the other hand, we observe a similar trend when training with domain-specific datasets (JW300, Gov't, and DGT). For the government-domain dataset, mBART trained with 10k sentences of SI or TA achieves a higher BLEU than the Transformer trained with 50k sentences (+3.4 to

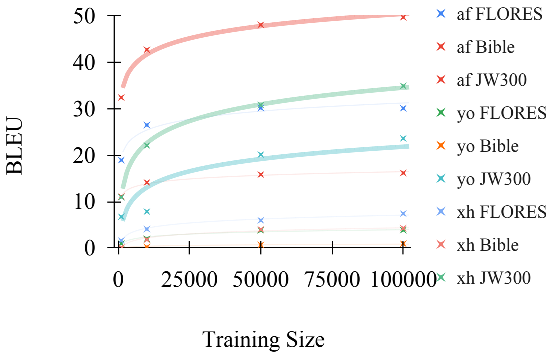

Figure 1: Impact of fine-tuning dataset size on mBART performance translating into English on JW300.

+6.8); this suggests at least a fivefold data efficiency. The exception is SI→EN, where the difference in scores is 0.1 BLEU. For JW300, mBART trained with 10k parallel sentences outperforms the Transformer trained with 100k for some translation tasks tenfold. Further, mBART trained with 50k sentences outperforms the Transformer model for all languages by a large margin[3]. Of note, YO begins to perform well in-domain on JW300 with tens of thousands of sentences.

When do we reach diminishing returns on fine-tuning size? Figure 1 shows how fine-tuning size affects translation of JW300 into EN from AF, XH, and YO. Although training with more data improves BLEU, the gain saturates as the dataset size reaches approximately 50k sentence pairs. Liu et al. attribute this to the limit of the model's capacity: that the pre-trained weights are "washed out" (2020) when fine-tuning with more parallel data.

4.2 Noise in fine-tuning data

At what point is a small-but-clean corpus more useful than an automatically mined one like from Common Crawl? Comparing mBART trained on Common Crawl versus domain-specific data, we see that for several languages both in and not in mBART, 10k high-quality in-domain sentences leads to better performance than 100k sentences from Common Crawl.

4.3 Amount of pre-training data

The improvement of mBART over the Transformer is more prominent for languages with more pre-training data. The correlation between BLEU and number of pre-training sentences is $R^2 = 0.31$ for open-domain (Figure 2), and the effect in the domain-specific case is similar. This shows that mBART effectively leverages the pre-training data. Taken with the results of §4.1, the contrasting behavior between seen and unseen languages belies a "rich-get-richer" phenomenon.

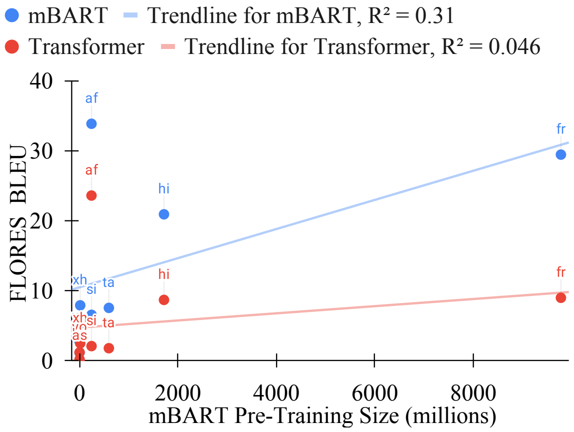

Figure 2: Effect of pre-training open-domain dataset size, using 100k Common Crawl sentence pairs for fine-tuning, translating from English

4.4 Domain mismatch

This section compares the performance of models when trained and tested on matching versus mismatched domains.

Unsurprisingly, taking a training set from the same domain as the test set consistently yields higher BLEU than a mismatched training set. This pattern repeats across domains and directions.

Of greater interest is that Common Crawl–trained models often do better on domain-specific test sets than open-domain test sets. For languages with JW300 or Gov't, testing BLEU on these was higher than on the open-domain FLORES data.

Further, for SI and TA, mBART trained on 10k sentences achieved higher BLEU than the Transformer trained on 100k data, suggesting the pre-training gain was able to compensate the lack of in-domain data. This may indicate that mBART is valuable for domain-specific translation with low amounts of high-quality data.

Results for FR on DGT and the Bible and HI on PMI show that mBART can excel with even 1k parallel sentences for languages with sufficient pre-training. If data from a different domain is available in sufficient quantities, an acceptable translation can be expected, as evident from the Gov't 50k and JW300 100k settings. Noticeably, issues related to domain difference and fine-tuning dataset size

---

[3] The only exceptions are AF-EN and EN-XH in-domain testing, with less than or equal to 1.0 BLEU point difference.

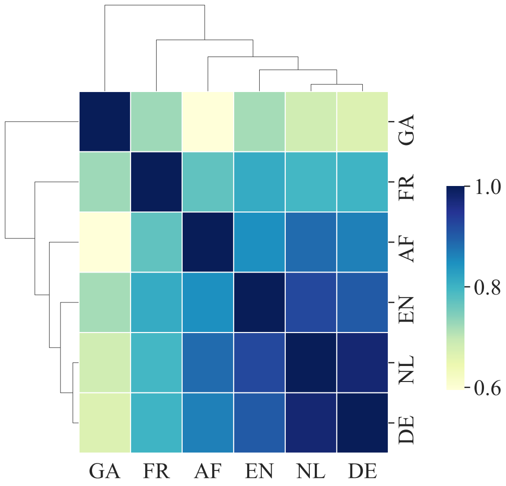

Figure 3: Cosine similarities of syntactic features

are less pronounced for FR (see results for 1k Bible data and 1k DGT). This reiterates the impact of language coverage in the mBART model.

4.5 Language typology

This analysis relates properties of the languages to their performance.

Foremost, AF regularly achieves the highest BLEU among low-resource languages used to pre-train mBART. This observation is consistent with Zhou and Waibel (2021). We attribute this to AF's relationship with EN: both are Germanic and share the Latin script, with large lexical overlap. Multilingual machine translation systems can learn shared representations for linguistically similar languages (Dabre et al., 2017; Neubig and Hu, 2018; Kudugunta et al., 2019; Hokamp et al., 2019); we expect that mBART taps into this relationship. Further, a smaller token set may help explain this improved generalization (Arivazhagan et al., 2019).

For unseen languages that share the Latin script with English, explaining mBART's performance is less trivial, so we turn to a computational analysis. GA reaches lower BLEU than YO, despite being Indo-European like most of mBART's training data. It could be a result of its rare VSO word order (Liu et al., 2021a), its initial consonant mutations, or other rare syntactic phenomena. To explain the divergent behavior of AF and GA, we use syntactic features estimated by the k nearest neighbors (Littell et al., 2017) of their WALS features (Dryer and Haspelmath, 2013). Figure 3 shows the syntactic similarities between AF, GA, and four high-resource languages (EN, DE, FR, and NL). This confirms that AF is more syntactically similar to these high-resource languages than GA is.

Finally, we consider the interplay of translation direction and BLEU. Translating into EN regularly outperforms translating from EN, which we may attribute to mBART and the Transformer learning a strong EN language model in the decoder (Voita et al., 2021). But it may also come from BLEU's ignorance of subword phenomena. When translating into a morphologically rich language like SI or TA, no partial credit is awarded for partially correct sets of morphemes. We see this as bolstering the movement toward character-aware metrics (Popović, 2015; Mager et al., 2021).

5 Conclusion

We have assessed the value of PMSS models like mBART for low-resource machine translation. We designed a reusable framework of experiments, capturing mBART's sensitivity to five facets of data. Consistently, mBART fails in learning to translate new under-resourced languages—those unseen in the pre-trained model. For languages used in monolingual pre-training, we find four- to tenfold data efficiency over a from-scratch Transformer, plus robustness to domain differences.

For domain-specific datasets, mBART might outperform standard Transformers by an efficiency of five to ten times; future work can pinpoint the saturation size. Fine-tuned mBART is robust to domain differences, while the Transformer flounders for out-domain datasets. However, the performance on unseen languages is generally not indicative of usable translation system.

Taken in tandem, these results point to the paramountcy of monolingual pre-training for the bilingual task of translation. The biggest open issue, though, is not how to tune PMSS models on limited data; instead, *greater data acquisition* is the hope for truly low-resource machine translation.

Acknowledgments

This project has been supported by the ICLR Co-Submitting Summer (CSS) program 2022 initiated by ICLR DEI co-chairs Rosanne Liu and Krystal Maughan. David Adelani acknowledges the support of the EU funded Horizon 2020 project ROXANNE under grant agreement No. 833635. Lastly, we thank the Spoken Language Systems Chair, Dietrich Klakow at Saarland University for providing GPU resources to train the models.

A Supplementary Material on Corpora

Here we give details of the corpora used in our study.

Bible. The JHU Bible Corpus (McCarthy et al., 2020b) is a recently released corpus of Bible translations in over 1600 languages. In several low-resource languages, the Bible is the only available text parallel with another language; moreover, its verse structure makes it multi-parallel across thousands of languages. It has been used to assess multilingual translation at massive linguistic scale (Mueller et al., 2020), develop new morphological tools (Nicolai et al., 2020), and fine-tune pre-trained language models to new low-resource languages (Ebrahimi and Kann, 2021).

Gov't. The government document corpus of Fernando et al. (2020) is a multilingual corpus for Sinhala, Tamil, and English. It contains official Sri Lankan government documents: annual reports, crawled content from government institutional websites, committee reports, procurement documents, and acts.

PMI. PMIndia (Haddow and Kirefu, 2020) is a parallel corpus of news updates for English and 13 other languages in India, extracted from the Prime Minister of India's website.

JW300. The JW300 corpus (Agić and Vulić, 2019) is another parallel corpus, spanning 343 languages. It is obtained from `jw.org` and includes Jehovah's Witness magazines like *Awake* and *Watchtower*. The domain is highly religious, but it includes other societal topics such as reports about persecution of their disciples around the world. While JW300 was automatically aligned, Abbott and Martinus (2019) and Alabi et al. (2020) have verified its quality for African languages. For languages with non-Latin scripts in our study, the alignment has been judged to be poor by native speakers.

DGT. The European Commission's Directorate-General for Translation–Translation Memory (Tiedemann, 2012) covers 25 languages and corresponds to the 'Summaries of EU legislation'. They are short explanations of the main acts passed by the European Union. The legislation included in the dataset includes directives, regulations, decisions, and international agreements.

Common Crawl. CCAligned (El-Kishky et al., 2020) and CCMatrix (Schwenk et al., 2021) are web-scraped corpora that were automatically aligned using LASER sentence embeddings (Schwenk, 2018). CCAligned is newer, and it has more text in low-resource languages. The dataset, albeit noisy (Kreutzer et al., 2022), has been used to develop highly multilingual machine translation models like M2M100 (Fan et al., 2021) and mBART multilingual MT (Tang et al., 2021); a modified version is used to train mT5 (Xue et al., 2021).

Data splits For FLORES and the Bible, we always use 1000 sentence pairs for development (see Kann et al., 2019) and 1000 sentence pairs for test. For the second in-domain dataset, the size varies between 1000 and 2000 sentence pairs based on availability.

B Supplementary Material on Experimental Setup

mBART and mT5. We compared mBART50 and `mT5-base` because they have comparable numbers of parameters. For both the mBART50 and `mT5-base` models (Tang et al., 2021), we train up to 3 epochs with a learning rate of 5×10^{-5}, dropout of 0.1, maximum lengths of 200 for the source and target, and a batch size of 10. We decode using beam searh with a beam size of 5. We use the implementations in the HuggingFace Transformers library, and we leverage hardware-level parallelism by training on NVIDIA Tesla V100 GPUs.

We perform bilingual fine-tuning on the 10 selected language pairs. For each language direction, we initialize the encoder–decoder model's parameters from the pre-trained mBART model's corresponding encoder and decoder. After initialization, we continue training.

Because mBART requires a target language to be specified during decoding from amongst those that the model has seen, we follow past work in selecting languages related to our target languages for unseen languages (Madaan et al., 2020; Cahyawijaya et al., 2021). Considering syntactic and phylogenic closeness of languages (Dryer and Haspelmath, 2013; Littell et al., 2017), we chose BN for AS, TE for KN, FR for GA, and SW for YO.

mT5. Considering memory bottlenecks, we use the `mT5-base` model. It supports over 100 languages, including five of the six from our preliminary experiment. Because Irish (GA) is not among these, we use the French language code for fine-tuning the model.

Transformer. We train Transformer models implemented in FAIRSEQ using the same datasets as we used for fine-tuning mBART. We use two Transformer architectures, depending on the data size. When there are fewer than 10k parallel sentences, the model consists of 3 encoder layers and 3 decoder layers, with embedding dimension of 512 and 2 attention heads. When there are 10k or more parallel sentences, we instead use a model that consists of 6 encoder layers and 6 decoder layers, with an embedding dimension of 256 and 2 attention heads. In each case, we have an initial learning rate of 1×10^{-3}, a weight decay of 1×10^{-4}, dropout of 0.4, and batch size of 32. We use early stopping based on the validation loss. We train the models from scratch with segmentation into subword tokens performed by SentencePiece. When decoding, we use beam search with a beam size of 5.

Evaluation. To ease the comparison of future work with ours, we report that the SacreBLEU settings we use are represented by the signature `BLEU+c.mixed+#.1+s.exp+tok.13a+v.1.5.0`.

Multi-Scale Distribution Deep Variational Autoencoder for Explanation Generation

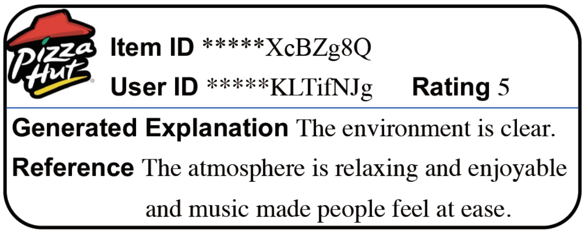
Abstract

Generating explanations for recommender systems is essential for improving their transparency, as users often wish to understand the reason for receiving a specified recommendation. Previous methods mainly focus on improving the generation quality, but often produce generic explanations that fail to incorporate specific details of user and item. To resolve this problem, we present **M**ulti-Scale Distribution Deep **V**ariational **A**utoencoders (MVAE). A deep hierarchical VAE with a prior network that eliminates noise while retaining meaningful signals in the input, coupled with a recognition network serving as the source of information to guide the learning of the prior network. Further, the **M**ulti-scale distribution **L**earning **F**ramework (MLF) along with a **T**arget Tracking **K**ullback-**L**eibler divergence (TKL) mechanism are proposed to employ multiple KL divergences at different scales for more effective learning. Extensive empirical experiments demonstrate that our methods can generate explanations with concrete input-specific contents.

1 Introduction

Due to the massive demand for convincing high-quality recommendations, researchers from both academic and industrial communities have paid increasing attention to the topic of enhancing the explainability of recommender systems (Wang et al., 2018b,a; Xian et al., 2019; Chen et al., 2019). Explanations for recommendations in real-world scenarios are presented in a variety of different forms, among them, the most popular and natural form is that of free-text explanations given in natural language (Zhang and Chen, 2020).



Item ID *****XcBZg8Q
User ID *****KLTifNJg **Rating** 5
Generated Explanation The environment is clear.
Reference The atmosphere is relaxing and enjoyable and music made people feel at ease.

Figure 1: An example of explanation generation.

As shown in Fig. 1, this task requires a machine to generate a textual explanation based on a given user ID, item ID, and the rating score from a recommender system. Previous models attempt to embed these IDs in a similar way as normal words. However, since the IDs appear far less frequently than the words, most approaches typically fail to account for specific features of the users and item. Hence, it is a very common phenomenon to obtain explanations without concrete characteristics about the given user and item as shown in Table 4. A probable reason for this phenomenon is that these models fail to utilize the input embeddings effectively. Specifically, in most models, the user and item information is merely provided as randomly initialized input embeddings, which barely contain meaningful information, but introduce noise that may be indistinguishable from more meaningful information. Here, we refer to noise from the similarities of randomly initialized input embeddings that are conflated with implicit patterns contained in our data. For example, there may be two user embedding similar to each other while in our data they represent users very different from each other. Importantly, as the recommendation data is sparse, some of the noisy embeddings are not able to be adequately trained, resulting in that the noise dominates the representation of those embeddings, as shown in Section 4.5. Since the presence of noise disturbs the model's ability to interpret the input embeddings at the inception of training, the model may tend to generate explanations in an unconditional manner. Moreover, such noisy inputs may still exist even after training. A common phenomena is that some users or items have very limited

---

[*] Corresponding author. Email: llwang@cs.ecnu.edu.cn.

Findings of the Association for Computational Linguistics: ACL 2022, pages 68 - 78

relevant training instances. Consequently, their corresponding representation embeddings are insufficiently trained and remain noisy. Therefore, it is vital to overcome such noise, so as to ensure the model can generate in a conditional manner.

To deal with this problem, we present **M**ulti-Scale Distribution Deep **V**ariational **A**uto**e**ncoders (MVAE). They consist of three modules, namely a recognition network, prior network, and a reconstruction network. The prior network in our model can filter out the noise contained in input embeddings, while retaining meaningful information for generation through information compression. Moreover, to help the prior network learn to generate fine-grained information, the recognition network is leveraged to provide the prior network with suitable guiding information. Thus, the decoder tends to generate explanations in a conditional manner with a substantially more informative generation signal.

However, with strong guiding signals available during training, generation becomes much simpler, which may result in a degradation of performance when such information is no longer available during testing. Thus, we propose a **M**ulti-scale distribution **L**earning **F**ramework (MLF) along with a target **T**racking **K**ullback-**L**eibler divergence (TKL) mechanism to reduce this performance gap between training and testing. The optimization effectiveness of the prior network can further be boosted when this method is employed at multiple different scales.

Overall, our contributions are as follows:

- We highlight the problem of noise in the input embeddings that current approaches suffer from. To the best of our knowledge, MVAE is the first model that aims to overcome such noisy input embeddings in explanation generation for recommender systems.

- We propose MVAE, a novel VAE model for explanation generation, which can utilize the input embedding effectively for generating high-quality explanations. The prior network in our model filters the noise contained in the input embeddings, while retaining meaningful information for generation. Moreover, we propose multi-scale distribution learning framework along with a target tracking Kullback–Leibler divergence mechanism to improve the optimization of the prior network, yielding better generalization performance.

- Extensive experiments show that our approach yields state-of-the-art results on three real-world datasets, demonstrating its effectiveness in generating high-quality explanations. A series of in-depth analyses shed further light on its ability to overcome noise contained in input embeddings in the training process.

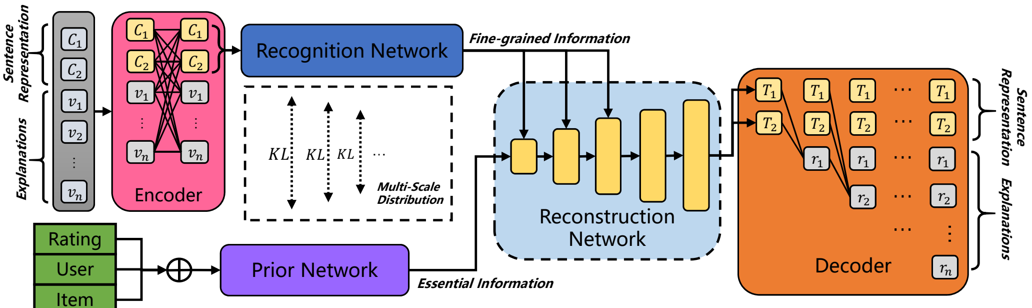
2 Related Work

For generation of textual explanations, mainstream research can be divided into two categories: template-based and natural language generation approaches. Template-based approaches generate explanations by filling the slots of predefined templates (Zhang et al., 2014), which are typically manually specified in advance. Natural language generation approaches, in contrast, adopt an encoder–decoder framework such as a recurrent seq-to-seq model (Li et al., 2020) or a Transformer-based architecture (Li et al., 2021) to learn to generate more diverse explanations based on the respective input.

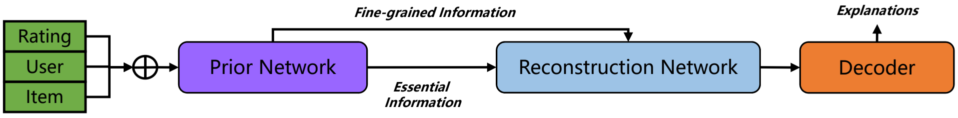
In recent years, the latter strategy has received considerable attention, mainly owing to advances in neural generation along with the massive availability of text from online review systems.

Still, existing natural language generation methods may generate overly generic sentences that fall short at providing concrete information and are thus less useful for users (Cao et al., 2018). Indeed, explanation generation goes beyond mere generation, as it is expected to improve the transparency of the recommendation engine (Tintarev and Masthoff, 2015). Thus, technical ideas to encourage the generation process to account for more conditional signals are crucial to enable models to generate more specific explanations that are custom-tailored for particular user–item pairs.

Variational autoencoders (VAE) were proposed by Kingma and Welling (2014) based on the idea of autoencoding, which has been used for noise reduction (Vincent et al., 2008, 2010). VAEs have been studied extensively in a variety of language generation tasks, including text summarization (Li et al., 2017a) and dialogue generation (Serban et al., 2017; Wen et al., 2017; Zhao et al., 2017). A VAE maximizes the mutual information between the input and latent variables (Barber and Agakov, 2003; Alemi et al., 2017), requiring the network to retain the information content of the input data to the extent possible (Shwartz-Ziv and Tishby, 2017). Hence, VAEs are qualified to overcome



a) Training of explanation generation



b) Testing of explanation generation

Figure 2: Overview of the Proposed Model.

the overly generic explanations caused by uninformative noisy input embeddings and prompt the construction of more meaningful outputs.

3 Proposed Model

An overview of our model is given in Fig. 2. The recognition network encodes the explanations and generates fine-grained information for the reconstruction network. The prior network encodes the input embeddings and generates essential information for the reconstruction network. The essential information here refers to the general semantics of a reason, which can be described in multiple ways, while the fine-grained information here refers to information that determines the details in the explanations, thus narrowing down and customizing the essential information to a specific form.

Finally, the reconstruction component decodes the given information and generates explanations. Additionally, the proposed MLF employs KL divergence at multiple different scales, which improves the optimization of the prior network. The TKL applied in every KL divergence can aid the learning of the prior network even further. We will present the details of each network in the following sections.

3.1 Input Encoding

To achieve a suitable transformation for compression and reconstruction of information, we design a basic component called the representation transformation module, which is used repeatedly in our model. Formally, it can be defined as follows:

$$\begin{aligned} f_{d_x,d_y}(x) &= \mathrm{SN}(W_{d_x \times d_y}\mathrm{GELU}(x) + b_{d_x}) \\ T_{d_1,d_2,d_3}(x) &= f_{d_2,d_3} \circ f_{d_2,d_2} \circ f_{d_1,d_2} \circ f_{d_1,d_1} \\ x' &= \mathrm{LayerNorm}(T_{d_1,d_2,d_3}(x) + x) \\ y &= f_{d_3,d_4}(x') \end{aligned} \tag{1}$$

Here, $x \in \mathbb{R}^{d_x}$ is the input and $y \in \mathbb{R}^{d_y}$ is the output of this module. The subscripts d_x, d_y of f and d_1, d_2, d_3 of any F are the dimensionalities of the matrices or vectors used in the corresponding function. T is a composite module consisting of four different f, where $\circ$ denotes composition, SN is the spectral normalization introduced by Yoshida & Miyato (2017). GELU (Hendrycks and Gimpel, 2016) is an activation function based on the cumulative distribution function for a Gaussian Distribution.

For simplicity, we denote this module as $\mathrm{Block}(\cdot)$. Moreover, our notation assumes that its output is split into equal-sized partitions if the output is assigned to more than one variable.

Recognition Network The recognition network serves to provide guidance to the prior network to enable it better generate fine-grained information, while supplying fine-grained information to the reconstruction network in training, as shown in Fig. 2(a). With the ground-truth explanations as input, the recognition component can generate valuable guiding information.

We first employ Transformer (Vaswani et al., 2017) encoder layers to encode input tokens $v_i \in \mathbb{R}^{d_v}$ into compact hidden states. The two special tokens C_1 and C_2 represent the overall input. The encoders are represented by B_b and the encoding process can be described as follows:

$$O_1, O_2, \ldots, O_{n+2} = B_b(C_1, C_2, v_1, \ldots, v_n) \tag{2}$$

Here, O_i is the i-th output of B_b. We concatenate O_1 and O_2 as the initial sentence-level representation $C'_0 = [O_1, O_2]$. Then the input information is compressed and the distributions of fine-grained information can be obtained as follows:

$$\begin{aligned} C'_i &= \text{Block}^R_{di}(C'_{i-1}) \\ \mu_{rz_j}, \sigma_{rz_j}, C'_j &= \text{Block}^R_{sj}(C'_{j-1}) \end{aligned} \tag{3}$$

Here, $i \in \{1, 2, \ldots, n_{rd}\}$, $j \in \{n_{rd}+1, \ldots, n_{rd}+n_{rs}\}$, while n_{rd} and n_{rs} are the number of Block^R_d and Block^R_s instances in the recognition network, respectively. Further, $\mu_{rz_j} \in \mathbb{R}^{d_{z_j}}$ is the mean and $\sigma_{rz_j} \in \mathbb{R}^{d_{z_j}}$ is the variance of the posterior distribution $q_{\theta_j}(z|x)$, where θ denotes the parameters of the recognition network. The reparameterization trick (Kingma and Welling, 2014) is used to sample a rz_j from $q_{\theta_j}(z|x)$.

Prior Network As for the prior network, its key aim is to filter out uninformative noise in the given input embeddings while retaining the essential signals for later reconstruction. The given user ID, item ID and rating are first mapped to their representation embeddings E_u, E_i, E_r and are then concatenated. After that, we employ a compression block Block^P_d to filter out noise in the input and an additional Block^P_s to generate fine-grained information:

$$\begin{aligned} E'_0 &= [E_u, E_i, E_r] \\ E'_i &= \text{Block}^P_{di}(E'_{i-1}) \\ \mu_{pz_j}, \sigma_{pz_j}, E'_j &= \text{Block}^P_{sj}(E'_{j-1}) \end{aligned} \tag{4}$$

Here, $i \in \{1, 2, \ldots, n_{pd}\}$, $j \in \{n_{pd}+1, \ldots, n_{pd}+n_{ps}\}$, while n_{pd}, n_{ps} refer to the number of Block^P_d and Block^P_s instances in the recognition network, respectively. Further, $\mu_{pz_j} \in \mathbb{R}^{d_{z_j}}$ and $\sigma_{pz_j} \in \mathbb{R}^{d_{z_j}}$ are the mean and variance of $q_{\phi_j}(z|E')$, where ϕ denotes the parameters of the prior network.

After suitable training, the prior network will be able to replace the recognition network to supply fine-grained signals to the reconstruction network in the testing phrase, as illustrated in Fig. 2(b).

3.2 Multi-Scale Learning

In our model, it is crucial to ensure that the prior network can learn suitable fine-grained information at different scales from the recognition network effectively. To this end, we further propose the MLF and TKL techniques.

Target Tracking KL Regularizations (TKL) Our TKL mechanism serves to improve the representation of the output latent variable z with regard to fine-grained information and thus ease the difficulty of learning a prior network for generation of specific fine-grained information. For simplificity, the subscripts to represent the index of layers are omitted here, but this mechanism is applied to every pair of distributions of prior network and recognition network with the same input variable scale. The TKL consists of two KL divergences: the first is $\text{KL}(q_\theta(z|x) \parallel q_\phi(z|E'))$ and the second is $\text{KL}(\mathcal{N}(0, I_{d_z}) \| q_\theta(z|x))$. Here, I_{d_z} denotes a diagonal matrix. Traditionally, VAE models directly apply KL divergence $\text{KL}(p(z|x) \| \mathcal{N}(0, I))$ on the final posterior distribution ($q_\phi(z|E')$ in our model), which is not suitable for our case, as the distribution $q_\phi(z|E')$ is learnt with $q_\theta(z|x)$ during the training phase. If we directly apply KL regularization between $\mathcal{N}(0, I_{d_z})$ and $q_\phi(z|E')$, the lagging problem (He et al., 2019) would cause posterior collapse. To resolve this problem, we use $\text{KL}(\mathcal{N}(0, I_{d_z}) \parallel q_\theta(z|x))$ to improve the quality of representation of latent variables z, as we find if both $\text{KL}(q_\theta(z|x) \parallel q_\phi(z|E'))$ and $\text{KL}(\mathcal{N}(0, I_{d_z}) \parallel q_\theta(z|x))$ are small enough, we can then obtain a small $\text{KL}(\mathcal{N}(0, I_{d_z}) \parallel q_\phi(z|E'))$. Finally, we can obtain:

$$\text{KL}(\mathcal{N}(0, I_{d_z}) \parallel q_\phi(z|E')) \approx \text{KL}(\mathcal{N}(0, I_{d_z}) \parallel q_\theta(z|x)) \tag{5}$$

Therefore, the first KL divergence term supports the second KL divergence term to implicitly apply disentangled regularization to improve the representation of fine-grained cues (Shao et al., 2020). Overall, the TKL mechanism applied to pairs of distributions can be expressed as

$$\begin{aligned} &\text{TKL}(\mathcal{N}(\mu_{rz}, \sigma_{rz}) \parallel \mathcal{N}(\mu_{pz}, \sigma_{pz})) = \\ &\quad \beta \text{KL}(\mathcal{N}(\mu_{rz}, \sigma_{rz}) \parallel \mathcal{N}(0, I_{d_z})) \\ &\quad + \text{KL}(\mathcal{N}(\mu_{rz}, \sigma_{rz}) \parallel \mathcal{N}(\mu_{pz}, \sigma_{pz})), \end{aligned} \tag{6}$$

where β is a hyperparameter originally from β-VAE (Higgins et al., 2017) to balance between reconstruction and disentangled regularization.

Multi-Scale Learning Framework (MLF) The multi-scale distributions are originally proposed by Sønderby et al. (2016) to improve the flexibility of prior distribution and thus improve the generation

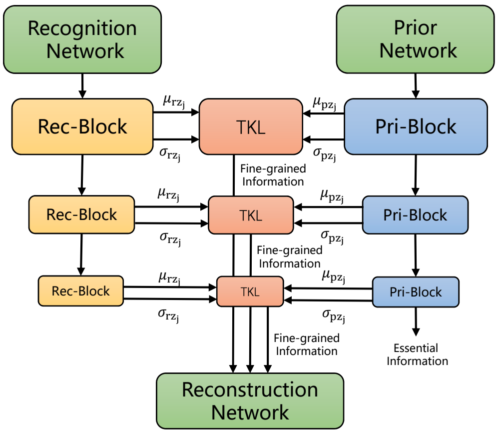


Figure 3: Multi-Scale Learning Framework. The Rec-Block represents the Block_s^R in the recognition network and Pri-Block represents the Block_s^P in the prior network.

quality of a VAE. We extend this architecture and the overall structure is shown in Fig. 3. Our MLF can also improve the flexibility of prior distributions and controls the fine-grained information to aid the reconstruction network. During training, rz_j from the recognition network is provided to the reconstruction network, delivering fine-grained information to assist the latter in achieving the reconstruction. During testing, the μ_{pz_j} from the prior network come into play. For simplicity and consistency, we refer to both with the same symbol z_j in the following.

More importantly, MLF decides how the prior block network is optimized according to the recognition network. Since multi-scale information is leveraged, the prior network can be better optimized. The sampling process from the distributions of the recognition network add appropriate noise into the supplementary information during training, which improves the denoising ability of the reconstruction network. Therefore, when the μ_{pz} without sampling noise but with noise from the input signals are used in testing, the reconstruction network can better cope with the situation of noisy supplementary information. This results in a reduction of the performance gap between training and testing. The overall regularization loss can be represented as:

$$\mathcal{L}_{\mathrm{MLF}} = \sum_{n_{pd}+1}^{n_{ps}} \mathrm{TKL}(\mathcal{N}(\mu_{rz}, \sigma_{rz})_j \,\|\, \mathcal{N}(\mu_{pz}, \sigma_{pz})_j) \quad (7)$$

3.3 Reconstruction Network

Reconstruction Network The reconstruction network is responsible for explanation generation according to received fine-grained information and essential information. The mechanism of the reconstruction network can be described as follows:

$$\begin{aligned} H'_0 &= E'_{n_{pd}+n_{ps}} \\ H'_j &= \mathrm{Block}_j^D(H'_{j-1} + z_k) \\ H'_i &= \mathrm{Block}_i^D(H'_{i-1}) \\ T_1, T_2 &= \mathrm{chunk}(H_{n_{ps}+n_{pd}}) \end{aligned} \quad (8)$$

where $j \in \{1, \ldots, n_{ps}\}$, $i \in \{n_{ps}+1, n_{ps}+n_{pd}\}$, $k = n_{ps} + n_{pd} + 1 - j$. Block_*^D are used to reconstruct the information. The sentence representations $T \in \mathbb{R}^{d_v}$ are fed into a GPT decoder (Floridi and Chiriatti, 2020) as initial tokens. $\mathrm{chunk}(\cdot)$ denotes splitting the input into two equal-sized parts.

The negative log-likelihood function is used as the objective function, which can be expressed as

$$\mathcal{L}_{\mathrm{rec}} = -\sum_{t=1}^{n} \log(p(r_t^*)), \quad (9)$$

where r_t^* is the ground-truth review word at step t and n is the total length of the output token sequence.

3.4 Overall Objective Function

Ultimately, the optimization of our model is achieved using the following overall objective function:

$$\mathcal{L} = \mathcal{L}_{\mathrm{rec}} + \mathcal{L}_{\mathrm{MLF}} \quad (10)$$

4 Experiments

4.1 Dataset

For the evaluation, we use three large-scale datasets, including Yelp[1] for restaurants, Amazon 5-core Movie & TV[2] for movies, and TripAdvisor[3] for hotels. In contrast to prior work, we only select and use challenging samples where related users or items have fewer than 15 reviews for Yelp and TripAdvisor, 20 reviews for Amazon movies. Our setting is suitable for advancing the research on this task. The statistics of the resulting ***Yelp***, ***Amazon***, and ***TripAdvisor*** datasets are given in Table 1.

---

[1] http://www.yelp.com/dataset
[2] http://www.jmcauley.uscd.edu/data/amazon
[3] http://www.tripadvisor.com

Entries	*Amazon*	*Yelp*	*TripAdvisor*
# of users	161,434	451,937	333,409
# of items	118,862	154,951	304,954
# of reviews	653,568	1,033,823	1,311,676
Avg. # of reviews/user	4.04	2.28	3.93
Avg. # of reviews/item	5.49	6.67	4.30
Avg. # of words/explanation	14.81	15.03	14.84

Table 1: Statistics of three processed datasets.

4.2 Evaluation Metrics

We employ five metrics to evaluate the quality of generated explanations, including BLEU-1, BLEU-4, ROUGE-1, ROUGE-L, and METEOR. BLEU-1 and BLEU-4 are BLEU (Papineni et al., 2002) scores with 1-grams and 4-grams, respectively. ROUGE-1 refers to ROUGE (Lin, 2004) scores with 1-grams, while ROUGE-L finds the longest common subsequence and takes the sentence level structure similarity into account. METEOR (Banerjee and Lavie, 2005; Sharma et al., 2017) is a metric that correlates better at the sentence level with human evaluations. For all metrics, higher scores indicate better results.

4.3 Baselines

Various recent approaches serve as strong baselines in our experiments[4]. In addition, we consider several variants of our model to ascertain the effectiveness of our proposed techniques.

NRT (Li et al., 2017b): In this model, a multi-layer perceptron (MLP) is used to predict a rating based on the given user ID and item ID. It formulates the explanation generation task as a text summarization task and trains in a multi-task learning framework. In our case, the explanation sentence is used as the tip.

Att2Seq (Dong et al., 2017): This model employs a MLP to encode three attributes and adopts a two-layer LSTM to decode representations for generating textual explanations.

NETE (Li et al., 2020): A neural template explanation generation framework design with a gated fusion recurrent unit (GFRU) to generate neural templates and explanations in parallel. It combines advantages of both templates and neural networks.

PETER (Li et al., 2021): PETER is a Transformer-based model that reforms the attention mask to combine different kinds of input embedding and finally be able to generate natural language explanations, which resulted in the previous state-of-the-art.

MVAE-NoKL: The second KL divergence regularization in TKL is removed, in order to investigate whether TKL can effective apply disentangled regularization to latent variables for helping the reconstructing network to decode latent variable and easing the difficulty with which the prior network learns from the recognition network.

MVAE-NoMLF: In this variant, distributions of all scales of MLF are removed except for the smallest one. This allows us to investigate whether MLF can promote the learning of the prior network and supply suitable amounts of fine-grained information to the reconstruction network.

4.4 Implementation Details

Following common practice in recommender systems, we map a rating greater than or equal to 3 to positive sentiment, and consider it a negative sentiment otherwise. The final results are the average of 5 experiments with different random data splits. In the training phase, if the decrease ratio of the validation loss is larger than 0.98, we decrease the learning rate by a factor of 0.8. We set the longest generation length to 20, while the average length of sentences is about 15. For all of the models, we set a fixed vocabulary size of 20,000. For the hyper-parameters of other models in the experiments, we adopt the default settings in their published code to ensure the proper performance.

For our model, we set the hidden sizes of the Transformer encoder and decoder layers to 768 and each consist of two layers. For the prior and recognition networks, we stack 6 Block units to compress the input by a factor of 0.5 in each Block. Another 6 layers of Block units are stacked for reconstruction in the reconstruction network. We use AdamW optimization (Kingma and Ba, 2015).

The β used in our TKL is set to 0.001 with the following annealing schedule:

$$\beta' = \beta \cdot \frac{1}{1 + \exp(-k\,(n_{\text{step}} - a_0))} \tag{11}$$

To select suitable hyperparameters for the annealing function, we first disable the second KL regularization and record how many steps our model needs to reach convergence. Then half of this amount of steps is chosen as a_0. The weight $k = 0.0025$

---

[4] Note that our model can be adapted to arbitrary recommender systems, while some explainable recommendation baselines require access to specific internal information of the recommender system and are thus omitted for a fair comparison.

Table 2: Performance comparison of explanations generation of different methods on three datasets. Improvements are computed as relative gains compared with the previous state-of-the-art method. Best results are highlighted in boldface, and the statistical significance over the best baseline is $p < 0.05$ via a t-test.

is selected without any tuning. The learning rate warm-up step count is set to 5,000 for all datasets.

In training phase, the teacher-force strategy is employed for the decoder network to accelerate the training. The dropout rate used in the encoder network and decoder network is set to 0.3 and gradient clipping is applied with 5.0. For the multi-scale learning framework, n_{rd} is equal to n_{pd} and n_{rs} is equal to n_{ps}. The n_{rd} is set to 4 and n_{rs} is set to 3. In both the prior network and recognition network, the variable is compressed by the ratio of 0.5. In our model, the dimensionality of the input variable is 1,536 and the dimensionality of resulting encoding is 12 after 7-fold compression. Similarly, in the reconstruction network, the latent variable is reconstructed from size 16 to size 1,536 after 7 reconstruction blocks. In addition, the word embedding used in the encoder Transformer layers and decoder Transformer layers are shared.

4.5 Existence of Initial Noise

To show the existence of initial noise, we first conduct an additional experiment on the ***Yelp*** dataset.

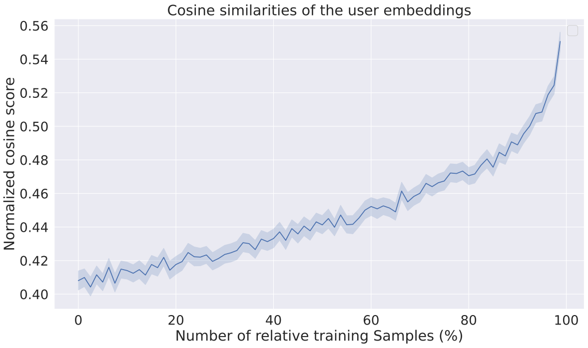

Figure 4: Illustration of the existence of initial noise.

Specifically, we randomly sample half of all examples, then duplicate them and all involved input embeddings to build a new dataset. In this dataset, there are two different instances of each user with their corresponding respective examples. Subsequently, we train a naive VAE model on the dataset. We sorted the user embeddings based on the number of their relevant training examples and calculate normalized cosine similarity between the two instances of the same user. We cluster them into 80 bins to enable a clearer presentation of the extensive data. The results are shown in Fig. 4. Intuitively, the difference of two instances of the same user represents the noise contained in the embeddings, and we can see that as increasing the number of relevant training samples, the noise becomes smaller and smaller. We believe that this is because user embeddings with more training samples are updated more frequently, while we can see there is still substantial noise remaining on the embeddings with few relevant training samples. This motivates the necessity of employing our model to eliminate such noise.

4.6 Explanation Generation Performance

As shown in Table 2, MVAE outperforms all previous methods across all three datasets, which demonstrates the effectiveness of our proposed model. Inspecting the samples generated by previous methods, we discover that their poor BLEU scores stem mainly from the occasional generation of descriptions without concrete meaning or lack of details, suggesting that their methods lack the ability to capture more specific characteristics of users or items, and corroborating our intuition that noisy embeddings may cause a model to generate unconditional natural language expressions without concrete meaning, since all the explanations are generated by the same decoder but different input embeddings. Moreover, we find that such low-quality predicted explanations usually correspond to users or items with fewer pertinent training samples, demonstrating our assumption that some user or item embeddings remain insufficiently trained.

We further provide a detailed evaluation assessing the quality of explanations for users with different amounts of training samples in Fig. 5. As we can see, our methods improve the quality of explanations with a larger absolute improvement when fewer relevant training samples are present (note the different slope of means of different methods), which suggests that our model can better handle less well trained user and item embeddings. This confirms that our VAE architecture is able to filter out noise and retain meaningful information for the decoder to generate more specific explanations.

4.7 Ablation Study

For an in-depth analysis of the effectiveness of our proposed techniques, as shown in Table 3, we compare our model with two variants introduced earlier. As we can see, the performance of MVAE-NoMLF drops substantially. We believe this is because MLF decides how the prior network can be optimized by learning from the recognition network. Also, it controls the fine-grained information that is provided to the reconstruction network. Removing the MLF significantly harms the effectiveness of learning the prior network for fine-grained information. For MVAE-NoKL, with the optimization of representing fine-grained information removed, it is hard for the prior network to model the fine-grained information from the recognition network. Therefore, the model may obtain poor results in testing. In fact, we observe that MVAE-NoKL attains lower training losses in training but has higher testing losses, indicating a significant disparity of distributions between the prior and recognition networks, which degrades the model performance in testing.

Figure 5: The mean and 95% confidence interval of BLUE-1 and ROUGE-L scores of explanantions generated by PETER and MVAE on the ***Yelp*** dataset. The x-axes represent the count of relevant training samples.

4.8 Analysis of MLF

We further examine in detail the necessity and rationality of our proposed MLF. In previous methods, the randomly initialized input embeddings are leveraged by the model directly. However, noisy inputs in the initial training may impede the ability of the model to leverage them and lead to convergence to a sub-optimal solution. We suspect the alternative of simply supplying additional information directly may facilitate the training of the model but result in a large performance gap between training and testing. To confirm our conjecture, we further propose two variants of our model named MVAE-NoRN and MVAE-NoKL. For MVAE-NoRN, we train our model with the testing phase architecture illustrated in Fig. 2(b), i.e., it is trained without the help of ground-truth information directly. For MVAE-NoKL, we replace the rz_j with μ_{rz_j} to supply fine-grained information to the reconstruction network and replace the TKL with the mean squared error between μ_{rz_j} and μ_{pz_j}. Under this setting, the additional noise injected into ground-truth information is removed. We compare the re-

	BLEU-1	BLEU-4	ROUGE-1	ROUGE-L	METEOR
MVAE-NoKL	21.03 (↓1.82%)	2.02 (↓10.26%)	18.67 (↓0.55%)	15.15 (↓0.82%)	7.01 (↓3.44%)
MVAE-NoMLF	19.12 (↓10.74%)	1.56 (↓30.70%)	17.95 (↓4.38%)	14.57 (↓4.66%)	6.73 (↓7.30%)
MVAE	21.42	2.25	18.77	15.28	7.26

Table 3: Performance comparison of variants of our model on ***Yelp*** dataset. Deterioration of the performance is calculated as the relative drop compared with MVAE.

Reference	The staffs are super knowledgeable and obviously care very deeply about the needs and preferences of their customers.
NETE	The service is great.
PETER	The staffs are very friendly and willing to help.
MVAE	The staffs are knowledgeable and the customer service is impressive.
Reference	The atmosphere is relaxing and enjoyable and music made people feel at ease.
NETE	The environment is clear.
PETER	The food is good and the staffs are friendly.
MVAE	The atmosphere and the music are pleasant.

Table 4: Examples of generated explanation by various methods. Fine-grained features are underlined.

sulting training and validation losses in Fig. 6. The training losses of MVAE-NoRN decrease faster in the early stage of optimization, but this soon stagnates and barely improves any further, suggesting that external guided signals are necessary to overcome this plateau, as the prior network without the guidance of the recognition may be unable to distinguish meaningful information from noisy inputs. The MVAE-NoKL model has much lower training losses but higher validation losses, reflecting a large performance gap between training and validation. In contrast, MVAE has reasonable training losses and the lowest validation losses, which implies that the MLF in our model narrows the performance gap between training and validation, proving the effectiveness of our proposed MLF.

4.9 Qualitative Case Study

To further compare the generation quality of explanations generated by previous work and our model, we provide examples in Table4. We observe that our methods can capture more specific characteristics, thus generating more concrete explanations. For instance, the generated explanation of our model describes fine-grained aspects such as “staff” and “customer service”, which are possible reasons of a recommendation. In contrast, the previous state-of-the-art model PETER only emphasizes the “staff” without a high-level summary on “service”.

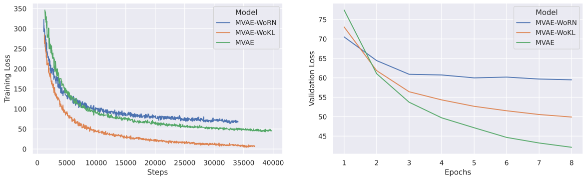

Figure 6: Loss plots: (a) is the training loss and (b) is the validation loss of each model on the ***Yelp*** dataset.

5 Conclusion

We present MVAE, a novel model for explanation generation in recommender systems, which has a prior network that eliminates noise while retaining meaningful signals in the input and a recognition network serving as the source of information to guide the learning of the prior network. Further, we propose a Multi-scale distribution Learning Framework along with TKL to prompt this process. Extensive experiments demonstrate the effectiveness of our method and confirm that it can generate high-quality explanations.

Dual Context-Guided Continuous Prompt Tuning for Few-Shot Learning

Abstract

Prompt-based paradigm has shown its competitive performance in many NLP tasks. However, its success heavily depends on prompt design, and the effectiveness varies upon the model and training data. In this paper, we propose a novel dual context-guided continuous prompt (DCCP) tuning method. To explore the rich contextual information in language structure and close the gap between discrete prompt tuning and continuous prompt tuning, DCCP introduces two auxiliary training objectives and constructs input in a pair-wise fashion. Experimental results demonstrate that our method is applicable to many NLP tasks, and can often outperform existing prompt tuning methods by a large margin in the few-shot setting.

1 Introduction

With the rise of pretrained language models(PLMs), natural language processing(NLP) shifted from the fully-supervised paradigm to pretrain and fine-tune paradigms (Radford et al., 2018; Devlin et al., 2019; Liu et al., 2019). To further utilize the large capacity of PLMs, a prompt-based paradigm is proposed to reformulate downstream tasks into an LM-like task upon the context and task-specific prompt.

There are some issues with the prompt-based paradigm, especially prompt engineering. Discrete prompts (a.k.a hard prompts) (Petroni et al., 2019; Wang et al., 2021) need expert-level experience to manually discover templates. To address this problem, automatic prompt design is conducted on gradient-based search (Shin et al., 2020), generation (Ben-David et al., 2021), ensembles (Schick and Schütze, 2021) and scoring (Davison et al., 2019). ADAPET (Tam et al., 2021) provide a denser supervision during fine-tuning based on the label-conditioned language modeling task. However, these methods might get sub-optimal templates and require adequate validation data (Zhao et al., 2021; Perez et al., 2021).

What's more, it is unnecessary to limit prompts to hard-crafting text. Continuous prompts (a.k.a soft prompts) (Liu et al., 2021b; Li and Liang, 2021) take templates as additional trainable parameters. Thus, prompt search can be simplified as optimizing parameters based on downstream task. Recent works add layer-wise adaptive prompt parameters (Qin and Eisner, 2021; Liu et al., 2021a), data-dependent mixture (Qin and Eisner, 2021) and hard-soft hybrid prompt (Han et al., 2021) based on adequate training data. When it comes to the few-shot learning scenario, it remains unclear how to effectively learn continuous prompts. Previous works mainly improve continuous prompts by additional prompt and target encoder (Gao et al., 2021; Zhang et al., 2021; Liu et al., 2021a).

This paper presents a new model-agnostic perspective of further utilizing deep LM features. We propose a novel **D**ual **C**ontext-guided **C**ontinuous **P**rompt (DCCP) tuning approach that makes PLMs better few-shot learners. Our main concern is how to learn better continuous prompts with only a few samples, averting dependency on hand-craft engineering and large validation samples.

Considering that prompt-based models predict based on both prompt and context, the vanilla models learn about $P(Y|X_{context}, H_{Prompt})$. Notably, additional prompt embeddings H_{prompt} are optimized based on the given context $X_{context}$ with LM decoding task on the downstream target Y in previous works. We give an insight into better continuous prompt tuning throughout the dual view of context-aware prompt and label-aware context representations. Technically, we introduce a new label-aware context-masked input aligning with the vanilla context-aware prompt-masked input. We add two auxiliary training objectives for coupling layer-wise linguistic features. The dual view makes the model learn $P(X_{context}|Y, H_{prompt})$ and $P(H_{context}|Y, H_{prompt})$ throughout LM inner features, further optimizing the prompt embed-

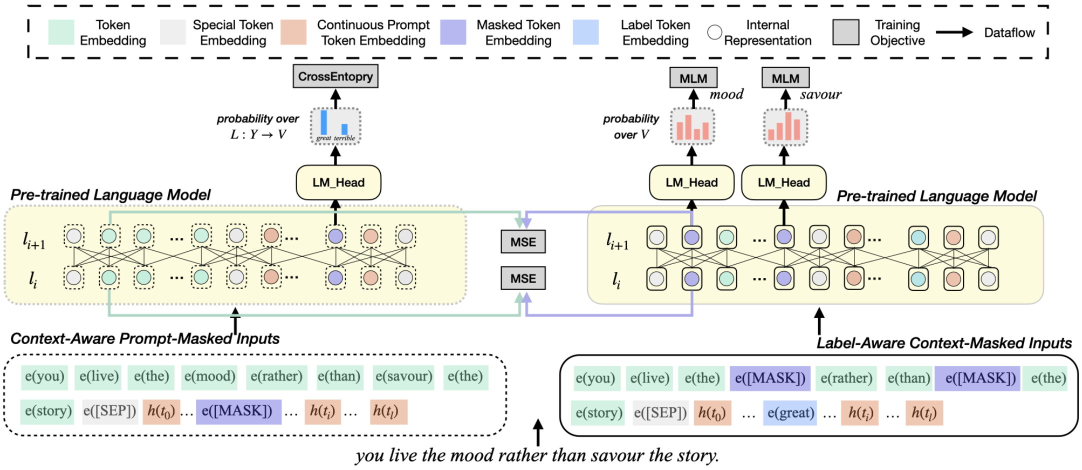

Figure 1: The Architecture of Dual Context-Guided Continuous Prompt Tuning.

dings. In a nutshell, DCCP goes deep into PLMs representations for better continuous prompt tuning.

We conduct experiments on 10 NLP datasets in the few-shot learning setting. DCCP significantly outperforms conventional fine-tuning, discrete prompts, and previous works on continuous prompts. DCCP achieves 89.6% (on average) of the full-supervised fine-tuning performance across all datasets with only 16 training samples. It obtains gain 11.8%, 2.5%, and 1.6% absolute improvement on average compared to conventional fine-tuning, vanilla continuous prompts (Gao et al., 2021), and state-of-the-art continuous prompts (Zhang et al., 2021). We empirically demonstrate that DCCP makes LM a better few-shot learner.

2 Methodology

In this section, we first introduce the vanilla continuous prompt tuning model and then clarify our dual context-guided prompt tuning method.

2.1 Vanilla Continuous Prompt Tuning

Given a pretrained language model, a context input sequence $X_{context} = (x_0, \ldots, x_n)$ is tokenized as $[\text{CLS}]X_{context}[\text{SEP}]$. The conventional fine-tuning model predicts based on [CLS] output. For prompt-based methods, a task-specific prompt $\widetilde{X}_{prompt} = (t_0, \ldots, [\text{MASK}], \ldots, t_l)$ is added into the input as $X_{in} = [\text{CLS}]X_{context}[\text{SEP}]\widetilde{X}_{prompt}[\text{SEP}]$. t_i is represented by a trainable pseudo token embedding h_i. It takes downstream tasks as a masked language modeling(MLM) task. Assume that verbalizer $L : Y \rightarrow V$ maps the class set Y to vocabulary set V, the probability of predicting $y_j \in Y$ is:

$$p(y_j|X_{in}) = p([\text{MASK}] = V_j|\widetilde{X}_{prompt}, X_{content}) \quad (1)$$

where X_{prompt} is represented by the additional trainable embedding parameters. Here we discard the prompt and target encoders used in (Liu et al., 2021b,a), retaining origin LM architectures. Based on downstream tasks, the vanilla model is optimized based on cross-entropy loss:

$$L_c = -\frac{1}{N}\Sigma_i^N \Sigma_j^{|Y|} y_{ij} \log p_{ij}. \quad (2)$$

2.2 Dual Context-Guided Prompt Tuning

Continuous prompt tuning simply introduces a trainable pseudo template for automatic prompt searching. It faces optimization challenges of word embedding discreteness and prompt embedding association (Liu et al., 2021b), which makes it hard tune continuous prompt with only a few samples.

Although continuous prompts are pseudo tokens and not referred to any real word, we propose that continuous prompt tuning should be consistent with natural language modeling. It could take more language modeling constraints into account, thus further reducing the gap between pretraining and fine-tuning. Vanilla continuous prompt tuning has considered an MLM-like objective L_c for matching target verbalizer and masked token output, focusing on prompt and downstream tasks. Furthermore, we propose two auxiliary language modeling tasks for both pluggable prompt and origin context.

We aim to further leverage context information for better guiding prompt tuning. The auxiliary

Table 1: Main results using RoBERTa-large. † refers to using the full training set while ‡ refers to using no training samples. The others involve $K = 16$ (per class) for few-shot experiments. Note that the mean (and standard deviation) performances are reported over 5 different splits. "GPT-3" in-context learning: using the in-context learning proposed in (Brown et al., 2020) with RoBERTa-large (no parameter updates).

tasks are constructed for context language modeling. Technically, a label-aware context-masked input $\widetilde{X}_{in}$ is fed as another model input aligning with origin context-aware prompt-masked X_{in}. Given the ground-truth label y, we obtain a semantically intact prompt X_{prompt}. A masked context input $\widetilde{X}_{context}$ is generated by randomly masking context tokens at position of $z_i \in Z$ in the same manner as the pretrained MLM task. The new input is:

$$
\begin{aligned}
&\widetilde{X}_{in} = \text{[CLS]}\widetilde{X}_{context}\text{[SEP]}X_{prompt}\text{[SEP]},\\
&\widetilde{X}_{context} = (x_0, \ldots, \text{[MASK]}, \ldots, \text{[MASK]}, \ldots, x_n),\\
&X_{prompt} = (t_0, \ldots, L(y), \ldots, t_l).
\end{aligned} \tag{3}
$$

As depicted in Fig 1, we obtain a couple of model inputs. The origin context-aware prompt-masked input has intact context information but lacks downstream label information. On the contrary, the label-aware context-masked input is aware of the ground-truth label but misses partial context features. Although these two dual inputs separately lack partial semantic information, they should be semantically paraphrased.

Specifically, the first auxiliary constraint L_{mlm} is for the masked language modeling task of label-aware masked context tokens Z. It is calculated as:

$$
\begin{aligned}
&\ell_{mlm}^{i,j} = -\log(p(\widetilde{x}_c^{i,j} = x_c^{i,j}|y_i, X_p, \widetilde{X}_c, j \in Z)),\\
&L_{mlm} = \frac{1}{N}\Sigma_i^N \frac{1}{|Z|}\Sigma_j^{|Z|}\ell_{mlm}^{i,j},
\end{aligned} \tag{4}
$$

where c and p refer to the context and prompt. The origin text token $x_c^{i,j}$ serves as the hard label of this label-aware context cloze task.

In addition, paraphrased texts can be closely related to each other throughout the language structure. We further exploit different-level linguistic features for aligning the dual context input as a paraphrased couple. According to the large capacity of PLMs, the LM encoder could be directly utilized as a linguistic feature encoder. We add a metric constraint on internal representations of the pairwise masked context tokens Z. It aligns the label-aware masked context $\widetilde{X}_{context}$ with the origin context $X_{context}$ upon linguistic features across LM layers. The training objective is calculated based on internal representations as a mean square error loss L_{mse}.

$$
\begin{aligned}
&\ell_{mse}(\widetilde{x}_c^{i,j}, x_c^{i,j}) = \frac{1}{S}\Sigma_k^S||\widetilde{h}_c^{i,j,k} - h_c^{i,j,k}||_2^2,\\
&L_{mse} = \frac{1}{N}\Sigma_i^N \frac{1}{|Z|}\Sigma_j^{|Z|}\ell_{mse}(\widetilde{x}_c^{i,j}, x_c^{i,j})
\end{aligned} \tag{5}
$$

where h is the hidden state, S indicates the depth of the LM model, j refers to the masked context

tokens, and i means the i-th sample. The overall training objective is $L = L_c + L_{mlm} + L_{mse}$. These two auxiliary constraints are trained in a self-supervised learning manner, which leverages more information than the vanilla prompt tuning within the same dataset size. In the other words, this model-agnostic training method makes full use of the current training data from the view of going deep into the internal representations.

All in all, the vanilla model predicts downstream task via filling the blank of prompts based on the context information. Our proposed auxiliary tasks reconstruct the masked context based on the ground-truth label and prompt semantics. Therefore, our dual context-guided continuous prompt (DCCP) tuning method would advance few-shot learning based on the dual implementation of prompt and context features.

3 Experiments

We experiment our proposed architecture on 10 NLP tasks in the few-shot setting (k=16) according to LMBFF (Gao et al., 2021). The datasets involve sentiment analysis (SST-2, MR, CR), subjective analysis (SUBJ), question type (TREC), natural language inference (MNLI, SNLI, QNLI), paraphrase detection (MRPC, QQP).

3.1 Experimental Settings

The experiment is conducted in the same setting as (Gao et al., 2021; Zhang et al., 2021), which is based on RoBERTa-large (Liu et al., 2019). We conduct a grid search on multiple hyper-parameters for each set, and choose the best setting on the development subset. We use AdamW (Loshchilov and Hutter, 2019) as the optimizer. We average the performance on the test set with five fixed random few-shot training datasets for each task. The verbalizer and pseudo prompt template can be referred to Tab 2.

3.2 Results and Analysis

Main Result In Table 1, we compare the performance of our DCCP to the state-of-the-art prompt-based methods and conventional fine-tuning method. Our model achieves great performance gain compared to the conventional fine-tuning and vanilla continuous prompt tuning model over all 10 tasks. DCCP outperforms the SOTA prompt-based methods (Gao et al., 2021; Zhang et al., 2021) across 9 datasets, which indicates the great advancement of our DCCP on few-shot learning. Especially, in the condition of only 16 training and development samples, DCCP could obtain a competitive result compared to the full training set in SST-2, MR and CR dataset. Our results obtain up to 5% and 4% absolutely improvement when compared to DART (Zhang et al., 2021) and LMBFF (Gao et al., 2021).

Ablation Study According to Table 3, both auxiliary tasks outperform the vanilla model and previous works. It denotes that the context-view language modeling tasks are beneficial for the continuous prompt tuning approach in the few-shot learning scenario. The results reveal that the metric constraint on internal representation is complementary to the masked language modeling.

Our overall methodology achieves 2.5% perfor-

Method	Avg. Performance
Fine-tuning	74.51
LMBFF (Gao et al., 2021)	80.31
PTuning (Liu et al., 2021b)	79.79
DART (Zhang et al., 2021)	80.74
DCCP	**82.3**
w/o MLM	81.02
w/o MSE	80.97

Table 3: Ablation Study of DCCP. The score refers to the average performance across all datasets.

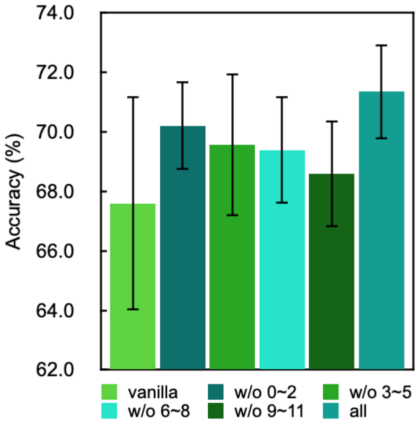

Figure 2: Average Performance on QNLI of arious supervised layers for dual context constraint. Note that "w/o k-i" denotes "not supervise on k-th to i-th LM layer". "w/o 9-11" additionally averts the masked language modeling.

mance gain upon the vanilla model without modifying the model architecture or leveraging more external data.

Will the layers of metric constraint affects performances? Referring to Fig 2, it is necessary to consider internal representations at different LM layers as we couple the dual context linguistic features. It could get more stable and better results by comparing all linguistic features of the label-aware masked context and origin context.

Performance on various training dataset size. Fig 3 illustrates our stable improvement compared to conventional fine-tuning and vanilla prompt tuning as the number K of training samples increases. Even though it converges with vanilla prompt tuning around $K = 256$, it retains better stability and performance.

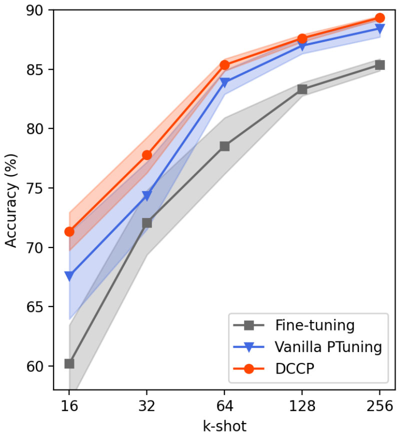

Figure 3: Conventional Fine-tuning vs Vanilla PTuning vs our DCCP across various K-shot (i.e. # instances per class) settings on QNLI.

4 Conclusion

In this paper, we present a model-agnostic approach for advancing continuous prompt. Specifically, we propose a novel dual context-guided continuous prompt tuning method for few-shot learning. Our approach constructs a couple of dual inputs, including the origin context-aware prompt-masked input and label-aware context-masked one. Then, we go deep into the language model to leverage linguistic features for two auxiliary constraints on the pairwise context inputs. The empirical results show that continuous prompts can be further revised during the procedure of reconstructing context.

Abstract

Nested named entity recognition (Nested NER) aims to identify named entities which may overlap. Span-based approaches regard nested NER as a two-stage task—span extraction and classification, thus having the innate ability to handle this task. However, they face the problems of error propagation, ignorance of span boundary, difficulty in long entity recognition and requirement on large-scale annotated data. In this paper, we propose *Extract-Select*, a span selection framework for nested NER, to tackle these problems. Firstly, we introduce a span selection framework in which nested entities with different entity categories would be separately extracted by the extractor, thus naturally avoiding error propagation in prior two-stage approaches. In the inference phase, the trained extractor selects final results specific to the given entity category. Secondly, we propose a hybrid selection strategy in the extractor, which not only makes full use of both span boundary and span content, but also improves the ability of long entity recognition. Thirdly, we design a discriminator to evaluate the extraction result, and train both extractor and discriminator with generative adversarial training (GAT). The use of GAT greatly alleviates the stress on the dataset size. Experimental results on four benchmark datasets demonstrate that *Extract-Select* outperforms competitive nested NER models, obtaining state-of-the-art results. The proposed model also performs well with less labeled data, proving the effectiveness of GAT.

1 Introduction

Named entity recognition (NER) aims at detecting the spans and semantic categories of entities from the text. Previous studies usually treat NER as a sequential labeling problem (Ma and Hovy, 2016; Chiu and Nichols, 2016). These studies restrict each token belonging to at most one entity mention, and hence it is unable to handle nested NER (Huang et al., 2015), where one token may belong to multiple mentions. For example in Figure 1, a LOC (i.e., Location) entity "western Canadian" is nested in another GPE (i.e., Geo-Political Entity) entity "the western Canadian province of British Columbia".

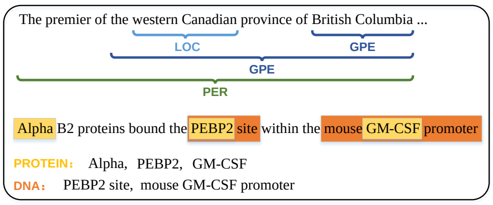

Figure 1: Examples for nested entities from ACE2005 and GENIA corpora.

Some studies seek to reconcile sequential labeling with nested NER (Alex et al., 2007; Ju et al., 2018). However, sequential labeling is naturally unsuitable for assigning multiple labels to a single token. Considering that, some studies turn to adopt the two-stage framework, including transition-based approaches (Wang et al., 2018a; Lin et al., 2019), hypergraph-based approaches (Wang and Lu, 2018; Katiyar and Cardie, 2018; Luo and Zhao, 2020) and span-based approaches (Sohrab and Miwa, 2018; Shen et al., 2021; Zhong and Chen, 2021). Among them, span-based approaches handle nested NER by extracting possible spans and classifying their categories. Although these approaches have the innate ability to cope with this task, they have the following problems: (1) Span-based approaches follow the two-stage framework, which inevitably has the problem of error propagation; (2) These approaches usually rely on span content for classification. However, span boundary information is not fully utilized, which is important for precise entity span extraction; (3) It is difficult for span-based approaches to recognize long entities because the span length in the span extraction phase is limited; (4) These approaches usually rely heavily on large size of training data for obtaining competitive results.

Findings of the Association for Computational Linguistics: ACL 2022, pages 85 - 96

In this paper, we propose a novel nested NER approach, named *Extract-Select*, which is able to cope with the above shortcomings. Specifically, the proposed *Extract-Select* works as follows. Firstly, an extractor is proposed to *extract* all possible entity spans specific to a particular typed entity marker, with a novel hybrid selection strategy. Then, a discriminator is introduced to evaluate and score entity span candidates predicted by the extractor. The extractor and the discriminator are iteratively trained with generative adversarial training (GAT). In the inference phase, the iteratively trained extractor *selects* final entity spans of the given entity marker from the contexts.

Extract-Select solves the above shortcomings from the following three aspects:

- To address Problem (1), we adopt a span selection framework in *Extract-Select*, which aims to separately train the extractor for each entity category. Motivated by Zhong and Chen (2021), we design entity markers that encodes category knowledge and use it to clarify the extractor what to extract. For example in Figure 1, the nested entities "PEBP2" (type PROTEIN) and "PEBP2 site" (type DNA) would be separately extracted. As two nested entities with different categories are separately selected by the extractor in one step, the problems of error propagation in two-stage approaches can be naturally solved.
- To solve Problems (2) and (3), we design a hybrid selection strategy in our extractor. This strategy makes full use of boundary information by detecting the start and end positions of entity span, followed with span content matching. Then, the span boundary as well as content information are fully used in the training of the extractor. As this strategy detects entity spans with boundary extraction, it does not require the setting of maximum span length, thus overcoming the difficulty in long entity recognition.
- To solve Problem (4), we design a discriminator to evaluate the extractor and train the extractor and discriminator with GAT. Through min-max training, the extractor can additionally learn from the discriminator to get higher scores, meanwhile greatly reducing the demand on training data size. What is more, the well designed entity markers provide informative prior knowledge for the extractor, which also contributes to better performance with less labeled data.

To evaluate our *Extract-Select*, we conduct experiments on four standard nested NER benchmarks, including ACE04, ACE05, KBP17 and GENIA datasets. Experimental results show that our model can effectively detect nested entities and achieve state-of-the-art results on the above four datasets. The ablation study on entity marker, GAT and hybrid selection strategy reveals that these components are indispensable and all of them contribute to our model. Moreover, our model only requires half amount of labeled data to achieve the same performance as baselines, indicting the effectiveness of our approach with less training data.

2 Related Work

Sequential labeling-based approaches solve the nested NER by designing suitable labeling schema. Shibuya and Hovy (2020) provide a second-best path decoding method to iteratively find nested entities. Straková et al. (2019) propose a linearized encoding scheme to model multiple named entity labels. Wang et al. (2020) design a pyramid framework to identify nested entities. Sequential labeling approaches is naturally unsuitable for nested NER.

Transition-based approaches model nested structure through state transition and construct nested entities through actions. Wang et al. (2018a) introduce a scalable transition-based model. Lin et al. (2019) propose an Anchor-Region architecture which models the head-driven phrase structures. However, these approaches rely heavily on hand-crafted features.

Hypergraph-based approaches construct hypergraphs by the structure of nested NER and decode results on hypergraphs. Muis and Lu (2017) introduce a mention hypergraph for nested NER. Wang and Lu (2018) propose a hypergraph representation, which is free from structural ambiguity. Luo and Zhao (2020) propose to capture bidirectional information interactions between hypergraph layers. However, these hypergraphs should be well designed to prevent ambiguous structure.

Span-based approaches extract entity spans and then classify their categories. Luan et al. (2019) select the most confident entity spans for classification. Fisher and Vlachos (2019) propose to merge entities and tokens into entities, and then assign labels. Shen et al. (2021) regards this task as an object detection task, locating and then labeling spans. Nevertheless, these two-stage approaches have the problem of ignorance of span boundary, difficulty in long entity recognition and error propagation.

Li et al. (2020b) formalizes NER as a machine reading comprehension (MRC) task, which uses

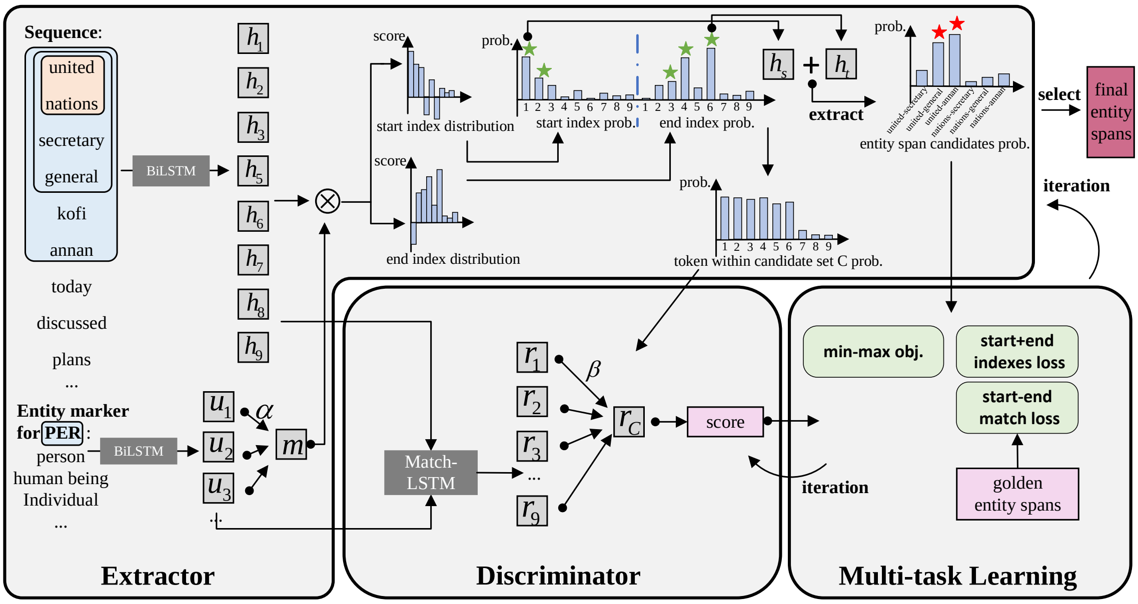

Figure 2: Overview of *Extract-Select*. It follows a span selection framework and contains an extractor which adopts a hybrid selection strategy to extract entity span candidates and a discriminator which aims to score the extractor. The extractor and discriminator are trained with multi-task learning including span boundary extraction and generative adversarial training.

BERT as backbone and extracts spans of given queries. However, this work relies heavily on training data size. Besides, it extracts entity spans based on boundary information but ignores content information. In contrast to their work, we use GAT to iteratively train extractor to get better results, and adopt hybrid selection strategy to make full use of both boundary and content information.

Generative adversarial training (GAT) gives a way to learn deep representations without extensively labeled data. It is proposed by Goodfellow et al. (2014) and is characterized by training a generator and a discriminator in competition with each other. GAT has been applied in different NLP subtasks, including dialogue generation (Li et al., 2017) and relation extraction (Qin et al., 2018). In these studies, GAT proves to be effective in reducing the usage of training data. Motivated by these work, we propose to apply GAT in NER task to reduce the demand on labeled data.

3 Problem Definition

The input of the span selection framework is a sequence $X = \{x_1, x_2, ..., x_{|X|}\}$, where $|X|$ denotes the length of the sequence. The possible entity span $x_{s,e} = \{x_s, x_{s+1}, ..., x_{e-1}, x_e\}$ is a continuous sub-string of X satisfying $s \leq e$. Let Y denote the predefined list of all entity categories and y^* be the entity marker specific to type $y \in Y$ (e.g., “LOC” has an entity marker “location”). The aim of span selection framework is to find all entities in X for each category y.

4 Extract-Select: Nested NER with GAT

4.1 Overview

In this section, we introduce *Extract-Select* in detail. As shown in Figure 2, *Extract-Select* consists of two main components: an extractor and a discriminator. In particular, given the input sequence X and the entity marker y^*, the extractor adopts a hybrid selection strategy to extract the entity span candidate set C and calculates its representation p_C, i.e., $(C, r_C) = f_E(y^*, X)$. Afterwards, the discriminator is fed with r_C to evaluate the correctness of C, i.e., $score = f_D(y^*, X, r_C)$. After iterative training of both extractor and discriminator, the extractor selects the final result (a set of entity spans), i.e., $final\ result = f_{E_{final}}(y^*, X)$.

4.2 Extractor

Given the entity type y and the input sequence $X = \{x_j\}_{j=1}^{|X|}$, the extractor aims to extract the entity span candidate set $C = \{C_1, C_2, ...C_i\}$ specific to y^* from X. Then, the extractor needs to compute a continuous latent variable p_C to represent C.

1) Sequence representation: We first represent all tokens $\{x_i\}_{i=1}^{|X|}$ in the input sentence X as a sequence of embeddings $\{w_i\}_{i=1}^{|X|}$. Each embedding w_i is the concatenation of character embedding, word embedding, contextualized word embedding and part-of-speech (POS) embedding. The character embedding is generated by a bi-directional

LSTM (BiLSTM) module with the same setting as Ju et al. (2018). For the contextualized word embedding, we obtain the context-dependent embedding for a target token with one surrounding sentence on one side. Then, the concatenation is fed into another BiLSTM to obtain the final token representation:

$$\{h_i\}_{i=1}^{|X|} = \text{BiLSTM}(\{w_i\}_{i=1}^{|X|}), \tag{1}$$

where h_i is the hidden state.

2) Entity marker representation: Entity category is an important prior knowledge as it makes the extractor know what to extract, and its effectiveness has been demonstrated in prior work (Li et al., 2020b). Besides, the usage of entity marker can avoid the error propagation issue in two-stage framework. Therefore, we propose to design an entity marker for each category, where the entity marker is its fine-grained explanation and would be used as the input of the extractor. We experiment on different types of entity marker and finally choose the combination of *Keywords* and *Synonyms*. Specifically, *Keywords* mean that entity markers are keywords describing entity type, e.g., the entity marker for type ORG is "organization", and *Synonyms* mean that entity markers are words or phrases which mean nearly the same as terms extracted from the Oxford Dictionary, e.g., the entity marker for type ORG is "institution body group company firm business corporation".

We concatenate word embeddings of *Keywords* and *Synonyms*, and feed embeddings $\{w_i\}_{i=1}^{|y^*|}$ into a BiLSTM to obtain $\{u_i\}_{i=1}^{|y^*|} =$ Bi-LSTM$(\{w_i\}_{i=1}^{|y^*|})$, where $|y^*|$ is the length of entity marker. Then, we use self attention to integrate the entity marker information:

$$\alpha_i = \frac{exp(W_a u_i)}{\sum_k exp(W_a u_k)}, \tag{2}$$

$$m = \textstyle\sum_{i=1}^{y^*} \alpha_i u_i, \tag{3}$$

where α_i is the attention weight of u_i and $W_a \in \mathbb{R}^d$ is a learned weight vector.

3) Hybrid selection: Prior span-based approaches extract spans by predicting whether each token is within the entity span with n two-class classifier, which only considers the span content. These methods need to set maximum span length parameter to avoid high computational costs. As a result, it is hard for them to identify long entities. What is more, they ignore the span boundary which is also important for entity recognition.

In view of this, we propose a hybrid selection strategy, which makes full use of both boundary and content of span. It first predicts the probability of tokens being the boundary of entity spans, and produce the entity span candidate set. Later, it uses the content of span candidates, i.e., calculates content representation of candidates, to enable the training of extractor and the golden entity spans could be selected eventually.

Given the representations of sequence and entity marker, the extractor first predicts the probabilities of token i being the boundary (i.e., start and end index) of entity spans:

$$\begin{aligned} p_s(i|y,X) &= \frac{exp(h_i W_s m)}{\sum_k exp(h_k W_s m)}, \\ p_e(i|y,X) &= \frac{exp(h_i W_e m)}{\sum_k exp(h_k W_e m)}, \end{aligned} \tag{4}$$

where $W_s, W_e \in \mathbb{R}^{d\times d}$ are learnable parameters.

In the input sequence X, there may be multiple entities of a particular category. This means that multiple start and end indexes could be predicted. To match them, we first get the indexes that might be the starting or ending positions:

$$\begin{aligned} I_s&=\{i|\arg\max(p_s(i|y,X))=1, i=1,..,n\}, \\ I_e&=\{j|\arg\max(p_e(j|y,X))=1, j=1,..,n\}. \end{aligned} \tag{5}$$

For any given start index $i_s \in I_s$ and end index $j_e \in I_e$ ($i_s \leq j_e$), we calculate the probability of entity span candidate:

$$p_{s,e}(i_s, j_e|y,X)=sigmoid(W_C \cdot concat(h_{i_s}, h_{j_e})), \tag{6}$$

where $W_C \in \mathbb{R}^{1\times 2d}$ is a learned parameter. The entity span candidate C_i is added into the candidate set C if its span probability $p_{s,e}$ is larger than a pre-defined threshold.

Then the content of candidate set C is utilized. We calculate $p_C(i|y,X)$ as the probability of the ith token appearing in C, which can be considered as the probability of the ith token within the span candidates. Specifically, $p_C(i|y,X)$ can be calculated through p_s and p_e:

$$p_C(i|y,X) = \sum_{s=1}^{i}\sum_{e=i}^{|X|} p_s(s|y,X)p_e(e|y,X), \tag{7}$$

where $p_C(i|y,X)$ also means the frequency of the ith token appearing in C. In other words, the more frequent the ith token appears in C, the higher $p_C(i|y,X)$ would be. In this way, the content information p_C can be used in candidate set scoring process to enable the training of extractor.

Finally, with both the boundary and content information, the extractor could be well trained to select the final golden entity span. This strategy does not set the maximum span length. As a result, long entity span can also be recognized.

4.3 Discriminator

After the extractor has obtained the entity span candidate set C, the discriminator aims to evaluate and score C, so as to train the extractor with GAT. This process consists of two steps as follows.

1) Candidate set representation: To represent the entity span candidate set C, we propose to encode the information of both entity type y and sequence X into p_C. Specifically, we build entity-aware sequence representation with Match-LSTM (Wang et al., 2018b), by matching the entity marker up with the sequence:

$$\{r_i\}_{i=1}^{|X|} = \text{Match-LSTM}(\{h_i\}_{i=1}^{|X|}, \{u_i\}_{i=1}^{|y^*|}). \tag{8}$$

Then the representation of entity span candidate set r_C is calculated with r_i and the probability $p_C(i|y, X)$ through weighted sum:

$$\begin{aligned} \beta_i &= \frac{p_C(i|y, X)}{\Sigma_{k=1}^{|X|} p_C(k|y, X)}, \\ r_C &= \Sigma_{k=1}^{|X|} \beta_k r_k. \end{aligned} \tag{9}$$

2) Candidate set scoring: The score f_D of entity span candidate set C can be calculated:

$$f_D(C) = sigmoid(W_D r_C), \tag{10}$$

where $W_D \in \mathbb{R}^d$ is a learned weight vector and the score $f_D \in [0, 1]$ would be used to iteratively train the extractor to get higher span candidate set score from the discriminator through min-max training in the GAT process.

4.4 Multi-task Learning with GAT

In the training process, we train the extractor by multi-task learning, and train the extractor and discriminator together with GAT.

The first task is to train the extractor by minimizing the negative log probabilities of the true start and end indexes of the golden entity span:

$$\ell_E^{boundary} = -\log p_s(s|y, X) - \log p_e(e|y, X), \tag{11}$$

where s and e denote the start and end indexes of the golden entity in the sequence X.

The second is to train the extractor by minimizing the start-end index matching loss:

$$\ell_E^{span} = -\log p_{s,e}. \tag{12}$$

The third is to train the extractor and discriminator together with GAT. We train the extractor to obtain a higher score from the discriminator:

$$\ell_E^{GAT} = \log(1 - f_D(y, X, p_C)). \tag{13}$$

Meanwhile, we train the discriminator to maximize $\log f_D(y, X, p_C)$ and minimize $\log(1 - f_D(y, X, p_C))$:

$$\ell_D^{GAT} = z \log f_D(C) + (1 - z) \log(1 - f_D(C)), \tag{14}$$

where $z \in \{1, 0\}$ denotes whether the golden entity appears in the entity span candidate set or not.

The overall training objective ℓ_E of the extractor is defined as follows:

$$\ell_E = \gamma_1 \ell_E^{boundary} + \gamma_2 \ell_E^{span} + (1 - \gamma_1 - \gamma_2) \ell_E^{GAT}, \tag{15}$$

where γ_1,$\gamma_2 \in [0,1]$ are learnable hyper-parameters to control the contributions towards the overall training objective.

In each training iteration, we use the extractor to select the new entity span candidate set through Eq.(4)-(6). The new entity span candidate set would then be scored by the discriminator. Such training procedure will be conducted iteratively so that the extractor can select spans having high score from discriminator. In the inference phase, the trained extractor would first select the start and end indexes and then match the start indexes with end indexes, getting the final results. The pseudo-code of the training procedure is given in Appendix A.

Our model differs from *BERT-MRC* in the following ways: (1) Different from *BERT-MRC* which uses bert-based machine reading comprehension model as the backbone, we design an *Extract-Select* model which iteratively trains the extractor to select the golden entity spans specific to the entity marker. (2) We propose a hybrid selection strategy for better entity span selection. This strategy makes full use of both boundary and content information of the span. However, *BERT-MRC* only conducts entity decoding based on the span boundary. (3) We propose to incorporate GAT in our model to train the extractor to learn additional information from the discriminator, meanwhile greatly reducing the demand on training data size. (4) We use easily-obtained entity markers to achieve competitive performance, avoiding complex query designing.

5 Experimental Setup

5.1 Benchmarks and Evaluations

We evaluate *Extract-Select* on four NER benchmarks — ACE2004[1], ACE2005[2], GENIA[3], and KBP2017[4]. Please refer to Appendix B.1 for the statistics and the detailed processing of the datasets, and refer to Appendix B.2 for implementation details.

Table 1: Results for nested NER tasks. Bold indicates the best scores

As for the evaluation metrics, we use strict evaluation that an entity is considered correct when both span and category are correctly predicted. We use span-level micro-averaged Precision (P), Recall (R) and F1 scores (F1) for evaluation.

5.2 Baselines

We choose the following models as baselines.

Sequential labeling-based models. *Second-Path* (Shibuya and Hovy, 2020) regards the tag sequence as a path and searches for results with the second-best path decoding. *Seq2seq* (Straková et al., 2019) views the nested NER as a sequence-to-sequence problem. *Pyramid* (Wang et al., 2020) is based on BERT and decodes nested mentions by its length in a bottom-up manner.

Transition-based models. *Transition* (Wang et al., 2018a) constructs forests for nested mentions through an action sequence. *ARN* (Lin et al., 2019) builds the Anchor-Region networks by using the head-driven structures of nested entities.

Hypergraph-based models. *Seg-Graph* (Wang and Lu, 2018) utilizes a segmental hypergraph representation for the modeling of nested mentions. *BiFlat-Graph* (Luo and Zhao, 2020) constructs a hypergraph module and uses the representation of it to improve inner entity predictions.

Span-based models. *Merge-Label* (Fisher and Vlachos, 2019) first merges tokens and entities to form nested structures and then labels them. *Locate-Label* (Shen et al., 2021) is based on BERT and generates span proposals by filtering and doing regression on seed spans. *BERT-MRC* Li et al. (2020b) formulates NER as a MRC task.

6 Results and Discussions

6.1 Overall Evaluation

Table 1 presents the performance of *Extract-Select* as well as the above baselines on four datasets. From the table, we observe that: (1) *Extract-Select* can effectively deal with nested NER, achieving the state-of-the-art performance. Specifically, *Extract-Select* gains at least 0.98%, 0.88%, 0.27%, 0.75% F1 scores improvements on ACE2004, ACE2005, GENIA and KBP2017, respectively. This verifies the effectiveness of our span selection architecture. (2) *Extract-Select* brings much higher recall value improvements than other methods, especially on KBP2017 and GENIA datasets. We notice that KBP2017 and GENIA contain much more entities than the other two datasets and the number of entities on test set of KBP2017 is over four times more than that of ACE2005. *Extract-Select* has significant advantages on such dataset, proving the effectiveness of GAT. (3) Compared with most of the baselines, *Extract-Select* can well balance precision and recall, maintaining precision value with high recall improvement. The reason may be that entity markers highlight the category information, clarifying which to extract. (4) With conventional word embeddings, *Extract-Select* method performs better that those BERT-based models (e.g., *Locate-Label* and *Pyramid*), which further proves the advantage of span selection framework. We also evaluate our model on two flat NER datasets, as shown in Appendix C.

6.2 Ablation Study

We then conduct ablation study to elucidate the effectiveness of main components of our *Extract-Select* method. Likewise, we only present the results on ACE2005. We compare *Extract-Select* with the following three internal baselines:

w/o EntityMarker: To verify the effectiveness of entity marker, this variation removes entity marker representations and only uses the index (i.e., "one", "two", *et al.*) of entity category for span selection.

w/o GAT: To evaluate the effectiveness of GAT, this variation only retains the extractor. Extractor

---

[5] *Transition* (Wang et al., 2018a) did not report precision and recall scores. Instead, Wang and Lu (2018) reported these scores for *Transition*.

[6] *Seq2seq* (Straková et al., 2019) did not report precision and recall scores. We use the reported F1 scores in this article.

Model	ACE2005		
	P	R	F1
w/o EntityMarker	85.82	86.03	85.92
w/o GAT	85.75	85.12	85.43
w/o HybridSelect	84.96	87.21	86.07
Extract-Select	**87.15**	**88.37**	**87.76**

Table 2: Results of internal baselines on the test set of ACE2005.

is trained by Eq.(11) and Eq.(12):

$$\ell_E = \lambda \ell_E^{boundary} + (1-\lambda)\ell_E^{span}, \tag{16}$$

where $\lambda \in [0,1]$ is a hyper-parameter that controls the weights of two tasks.

w/o HybridSelect: To verify the effectiveness of hybrid selection strategy, this variation only considers the boundary information and leaves out the content. Specifically, we still calculate the probabilities of tokens being start and end indexes of entity spans, but use the boundaries of entity candidates to represent the candidate set. Thus, Eq.(9) can be rewritten as follows: $r_{C_j} = r_{j_s} + r_{j_e}$, where j_s and j_e are the start and end indexes of the j^{th} entity span candidate C_j, obtained through Eq.(5). And $r_{j_{s(e)}}$ is obtained through Eq.(8).

In the training process, the extractor is trained with the policy gradient method. Thus, the training objective of the extractor in Eq.(13) can be modified as follows:

$$\begin{aligned}\nabla \ell_E^{GAT} \approx & -\sum_{j=1}^{k} [f_D(y,X,C_j) \nabla(log p_s(j_s|y,X)) \\ & + log p_e(j_e|y,X))],\end{aligned} \tag{17}$$

Results are shown in Table 2. From the table, we find that: (1) *Extract-Select* outperforms three internal baselines on the test set of ACE2005. Compared with *w/o GAT*, the F1 scores of full model improve by up to 2.33%, which means it is useful to introduce the discriminator to train the extractor through min-max training. (2) *w/o HybridSelect* suffers from much more precision decrease than recall compared to full model. The reason may be that the policy gradient adopted in *w/o HybridSelect* produces noise when sampling the span candidates, whereas ours can avoid such noise by training the extractor using back-propagation. Such intuition reveals the effectiveness of our hybrid selection strategy in enabling the extractor to be trained by back-propagation from the discriminator. (3) Experimental results also demonstrate that entity markers are effective. This allows the model to take advantage of the prior knowledge of categories, improving the F1 score by 1.84% on ACE2005. (4) *w/o EntityMarker* shows significant or comparable performance improvements compared to the baselines presented in Table 1. This validates the effectiveness of our span selection framework.

Setting	**ACE2005** (F1)
Keywords	87.12
Synonyms	87.34
Wikipedia	86.71
w/o EntityMarker	85.92
Extract-Select	**87.76**

Table 3: Results of the model with different entity markers on ACE2005 dataset.

6.3 Analysis of Entity Marker

To explore the influence of using different types of entity marker in *Extract-Select*, we investigate the performance of our model with different entity marker settings. Three experimental settings are considered: *Keywords*, *Synonyms*, *Wikipedia*. *Keywords* means the entity marker is the keyword describing the category, whereas *Synonyms* represents entity markers as synonymous words of keywords that are extracted from the Oxford Dictionary. *Wikipedia* means entity markers are constructed using the Wikipedia definition. For example, the entity marker for type ORG is “an entity comprising multiple people, such as an institution or an association”. Besides, we also include *w/o EntityMarker*, for which entity markers are replaced with the position index of the category.

The results of our model with different input entity markers on ACE2005 are presented in Table 3. From the table, we find that our *Extract-Select* (with Keywords+Synonyms as entity marker) achieves the highest F1 scores. In all settings, *w/o EntityMarker* that do not contain any entity information underperforms the others, indicting that meaningful prior knowledge contributes to superior performance. We also observe that *Wikipedia* underperforms *Keywords* and *Synonyms*. The reason may be that descriptive words from *Wikipedia* may not precisely describe entity categories compared to other settings.

6.4 Analysis of Training Data

Since entity markers encode useful prior knowledge and the min-max training also learns from unlabeled data, we expect that the proposed model works better with less training data. We test our model, *w/o EntityMarker* and *w/o GAT* on randomly sub-sampled labeled data of ACE2005 training set. As shown in Figure 3, the performance of three models drops with the decline of training sample size. However, our full model only requires half amount of training data to achieve comparable performance with two internal base-

Sentence 1	The US Supreme Court will hear arguments from both sides on Friday and Florida ’ s Leon County Circuit Court will consider the arguments on disputed state ballots on Saturday .
Gold Label	ORG:{The US Supreme Court, both sides, Florida ’ s Leon County Circuit Court}; GPE:{Florida, Leon County, state}
Locate-Label	ORG:{The US Supreme Court, Florida ’ s Leon County Circuit Court}; GPE:{US, Florida, Leon County, state};PER: {both sides}
Extract-Select	ORG:{The US Supreme Court, both sides, Florida ’ s Leon County Circuit Court}; GPE:{US, Florida, Leon County, state}
Sentence 2	Separatists have fought since 1975 for independence in Aceh , which is rich in oil and gas and has a population of about 4 . 1 million people .
Gold Label	PER:{Separatists, a population of about 4 . 1 million people}; GEP:{which, Aceh , which is rich in oil and gas and has a population of about 4 . 1 million people}
Locate-Label	PER:{Separatists, about 4 . 1 million people, a population of about 4 . 1 million people} ; GEP: {which, Aceh , which is rich in oil and gas and has a population of about 4 . 1 million peoople}
Extract-Select	PER:{Separatists, a population of about 4 . 1 million people}; GEP:{which, Aceh , which is rich in oil and gas and has a population of about 4 . 1 million people}
Sentence 3	united nations secretary general kofi annan today discussed plans for the summit with the host , egyptian president hosni mubarak .
Gold Label	ORG:{united nations}; PER:{united nations secretary general, united nations secretary general kofi annan, the host, egyptian president, egyptian president hosni mubarak}; GPE:{egyptian}
Locate-Label	ORG:{united nations}; PER:{united nations secretary general, united nations secretary general kofi annan, the host, egyptian president, egyptian president hosni mubarak}; GPE:{egyptian}
Extract-Select	ORG:{united nations}; PER:{united nations secretary general, united nations secretary general kofi annan, secretary general kofi annan, the host, egyptian president, egyptian president hosni mubarak} ; GPE:{egyptian}

Table 4: Examples of predicted results of our model and Locate-Label. Blue highlights indicate wrong predictions by Locate-Label, red highlights indicate wrong predictions by our model, colored words indicate wrongly predicted entity references.

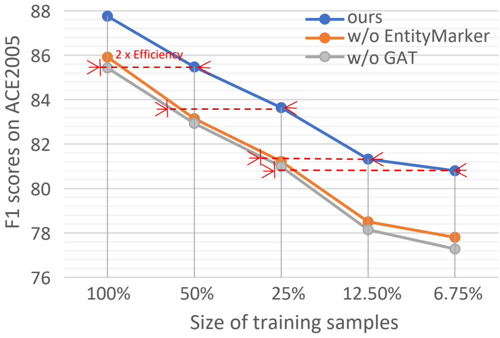

Figure 3: Effect of varying training sample size on ACE2005.

Model	ACE2004 (F1)			
	$1 \le L \le 5$	$5 < L \le 10$	$L > 10$	ALL
support	2719	219	97	3035
Locate-Label-reg	88.43	66.12	37.11	85.18
Locate-Label	88.55	82.78	61.72	87.41
Extract-Select	**89.52**	**84.06**	**66.20**	**88.39**

Table 5: A comparison of recognition F1 score on entities of different lengths, we divide the entities into three groups: $1 \le L \le 5$, $5 < L \le 10$, and $L > 10$, where L denotes entity length. Support denotes the number of entities in each length group on the test set of ACE2004.

lines (removing the entity marker and the GAT, respectively). Besides, the observation from the vertical line reviews that the degree of performance decrease of the full model is much less than that of other two internal baselines. In sum, the above observations indicate that both the entity marker and the GAT contributes to the better performance when less training data is given.

6.5 Analysis of Long Entity Recognition

To illustrate the performance of model on entities of different lengths, we divide the entities into three groups according to their lengths. We compare *Extract-Select* with two-stage models: *Locate-Label* (Shen et al., 2021) which adopts boundary regressors to enable long entity recognition and *Locate-Label-reg* which is a two-stage baseline. The results are shown in Table 5. We notice that the F1 score of *Locate-Label-reg* has a sharp decrease for long entities ($L > 10$) by 29.09% compared to our model. This may because *Locate-Label-reg* set maximum span length in span extraction, limiting the ability of recognizing long entities. *Locate-Label* faces a large F1 score decrease (5.77% and 21.06%) when the entity length increases from $1 \le L \le 5$ to $5 < L \le 10$ and from $5 < L \le 10$ to $L > 10$, respectively. Compared with them, *Extract-Select* maintains a good performance when the entity length increases, with only 5.46% and 17.86% F1 score decrease. This verifies that our model is more effective in recognizing long entities.

6.6 Case Study

Examples of predictions are shown in Table 4. The first part illustrates that *Extract-Select* has the ability of resolving ambiguous entity references, as span selection framework separately extracts entities for each category rather than conducts multi-classification for every entity. As shown in the fourth line, *Extract-Select* accurately recognizes the reference phrase "both sides" as ORG category, whereas *Locate-Label* incorrectly classifies it into PER category due to the ambiguity. The second part reveals that *Extract-Select* can recognize long entities well. As shown in the second part, the long entities "Aceh , which is rich in oil and gas and has a population of about 4 . 1 million people" of GEP category can be extracted. However, this framework may also incorrectly recall some entities, especially for entities with multi-level nested structures. For example in the third part, the multi-level nested entities "secretary general kofi annan" is incorrectly recognized. The reason may be that the extracted multi-level nested entities confuses the discriminator.

7 Conclusion

This paper proposes *Extract-Select*, a span selection framework to solve nested NER. It contains an extractor which aims to extract entities specific to a particular entity category with a hybrid selection strategy, and a discriminator scoring the extractor. The extractor and discriminator are trained with GAT to reduce the demand on labeled data. Comprehensive experiments performed on four widely used nested NER datasets demonstrate the superiority of *Extract-Select*. In future, we will (1) attempt to overcome the deficiency issue and (2) investigate in discontinuous and joint NER.

A The Training Procedure of Extract-Select

The full pseudo-code for the learning procedure of *Extract-Select* is given in Algorithm 1.

Algorithm 1 The learning procedure of *Extract-Select*.

```
Require: An extractor E; A discriminator G; the input sequence $S$; an entity type $y \in Y$
Output: Trained extractor with multi-task leaning
Initialize E, D parameters;
Generate entity span candidate set $C$ using E for training D;
Pre-train D via min-max training by Eq.(14);
repeat
    for E-step do
        Extract a set and its representation $(C, r_C) = f_E(y, S)$ using Eq.(1)-(9);
        Compute the score of $C$ using Eq.(10);
        Compute joint objective $\ell_E$ using Eq.(11)-(13);
        Update Extractor parameters via policy gradient;
    end for
    for D-step do
        Use current E to generate entity span candidate set $C$;
        Represent $C$ and calculate its score $f_D(y, S)$ using Eq.(10);
        Train discriminator for k epochs by Eq.(14);
    end for
until Extract-Select converges
```

B Experiments on Nested NER

B.1 Datasets Processing

Dataset statistics are listed in Table 6. For ACE2004 (Doddington et al., 2004) and ACE2005 (Walker et al., 2006), we follow the same settings as Lin et al. (2019), and splitting files into training, development and test sets

	ACE2004			**ACE2005**			**GENIA**			**KBP2017**

by 8:1:1. For GENIA (Ohta et al., 2002), we use GENIA v3.0.2 corpus, and follow the split of Wang et al. (2020), i.e., first collapse all subtypes into five types, and then split files into training, development, and test sets by 8.1:0.9:1. For KBP2017, we follow Lin et al. (2019) and evaluate the model on the 2017 English evaluation dataset, using previous RichERE annotated datasets as the training set except 20 randomly sampled documents reserved as development set. Finally, there are 866/20/167 files for training, development and test set.

B.2 Implementation Details

We initialize word embeddings of the input sequence and entity marker with 100-dimensional GLoVE vectors for extractor and discriminator. The dimensions of contextualized word embedding, POS embedding, and character embedding are 1024, 50, and 50, respectively. The hidden size is set to 1024. For GENIA dataset, we replace GLoVE vectors with word vectors pre-trained on biomedical corpus (Chiu et al., 2016), which are in 200 dimensions. During the training process, we employ the Adam Optimizer with the initial learning rate as 0.002 and the minibatch size as 64. We use a dropout rate of 0.35 in each training process. We set the threshold in Line 325 through grid search among $(0.2, 0.5, 0.8)$, and it is set to 0.5 for having the best performance.

C Experiments on Flat NER

We also choose two flat NER datasets, i.e., CoNLL2003 and Weibo, to evaluate *Extract-Select*. CoNLL2003 is an English dataset (Sang and Meulder, 2003) with four types of flat entities. We follow the data processing in Lin et al. (2019). Weibo is a Chinese dataset (Peng and Dredze, 2015) sampled from Weibo web pages. We use the same settings in Li et al. (2020a) to evaluate our model.

For English flat NER, we use several taggers as baselines: *BiLSTM-CRF* (Ma and Hovy, 2016), *ELMo-Tagger* (Peters et al., 2018), and *Bert-Tagger* (Devlin et al., 2019). For Chinese flat NER, we use the following models as baselines: *SLK-NER* (Hu and Wei, 2020) which incorporates second-order lexicon knowledge, *Glyce* (Meng et al., 2019) which combines glyph information, and *FLAT* (Li et al., 2020a) which uses phrases.

Table 7 presents comparisons between *Extract-Select* and the baselines on two flat NER datasets. On Weibo dataset, our model outperforms the baselines, improving the F1 score by 1.09%. On CoNLL2003, our model also gains comparable results, with 0.25% performance improvement compared to *Bert-Tagger*. In general, *Extract-Select* achieves good performance on not only nested NER but also flat NER.

Controlled Text Generation Using Dictionary Prior in Variational Autoencoders

Abstract

While variational autoencoders (VAEs) have been widely applied in text generation tasks, they are troubled by two challenges: insufficient representation capacity and poor controllability. The former results from the posterior collapse and restrictive assumption, which impede better representation learning. The latter arises as continuous latent variables in traditional formulations hinder VAEs from interpretability and controllability. In this paper, we propose Dictionary Prior (DPrior), a new data-driven prior that enjoys the merits of expressivity and controllability. To facilitate controlled text generation with DPrior, we propose to employ contrastive learning to separate the latent space into several parts. Extensive experiments on both language modeling and controlled text generation demonstrate the effectiveness of the proposed approach.

1 Introduction

As one of the representative deep generative models, variational autoencoders (VAEs) (Kingma and Welling, 2014) have been widely applied in text generation tasks, such as dialog generation (Wu et al., 2020; Zhao et al., 2017), machine translation (Shah and Barber, 2018; McCarthy et al., 2020; Sheng et al., 2020) and poetry generation (Li et al., 2018b; Yi et al., 2020). Despite the success, VAEs still suffer from two challenges: insufficient representation capacity and poor controllability.

The challenge of insufficient representation capacity in variational models arises from two aspects. One is the posterior collapse, a notorious issue that generally exists in VAEs especially serious in autoregressive text generation (Bowman et al., 2016), which leads to degenerate local optimums during the training of VAEs (He et al., 2019). Another is the restrictive assumption for priors and variational posteriors (Ding and Gimpel, 2021), which generally follow Gaussian distribution and spherical Gaussian distributions with diagonal co-variance matrices, respectively (Higgins et al., 2017; He et al., 2019; Li et al., 2019a). Such predefined forms would hinder VAEs from larger optimization space (Fang et al., 2019), thus restricting the expressivity of the model (Ding and Gimpel, 2021) and further leading to the posterior collapse (Fang et al., 2019). Therefore, a potential solution is to try more expressive distribution forms for priors and variational posteriors to improve the representation capacity (Fang et al., 2019; Tomczak and Welling, 2018; Ding and Gimpel, 2021).

Attributes	Samples
Positive	this is followed by good movies, great food.
Negative	for me it looks crappy and understaffed.
Present	this restaurant has an excellent view.
Past	i was able to get the delicious sushi!

Table 1: Examples of controlled text generation in second column where sentence attributes indicated by colored words are consistent with user-specified attributes in the first column.

Another challenge of VAEs is poor controllability. The challenge is rooted in the continuous latent variables that hinder VAEs from interpreting the discrete attributes like sentiments or topics (Zhao et al., 2018; Shi et al., 2020). Thus it is difficult to generate text with user-specified attributes, as the examples in Table 1. To approach controlled text generation in variational models, Hu et al. (Hu et al., 2017) propose to disentangle the latent representations by separately modeling discrete attribute and continuous content representations. Nevertheless, it is hard to completely disentangle attribute and attribute-independent content, resulting in poor readability in text generation (Wang et al., 2019; Higgins et al., 2017). A natural choice is to employ discrete representations as each of them could well correspond to one of the discrete attributes. Recent studies also reveal learned discrete representations by K-means and self-organization map (Kohonen,

1995) display great clustering performance and interpretability (van den Oord et al., 2017; Fortuin et al., 2019), showing the potential to be manipulated and split latent space for controlled text generation.

In this paper, we follow the practice of learning discrete representations and propose a new data-driven prior that enjoys the merits of expressivity and controllability. Specifically, we deploy a set of learnable vectors and interpolate the learnable vectors to form the prior, which we call *Dictionary Prior (DPrior)*. Each learnable vector is dubbed an atom in the dictionary. To facilitate generative models with DPrior, dual-form KL-divergence (Dai et al., 2018) is employed to make the prior distribution spanned by dictionary atoms approximate the posterior distribution. Our DPrior is model-agnostic and could be combined with pre-trained models such as BERT/GPT to enrich posterior representations (Li et al., 2020a). To enforce controllability to the DPrior, we separate the dictionary atoms into several disjoint subsets according to the natural language attributes. Then, we propose to employ contrastive learning to incorporate the attribute information, which can cluster different subsets of dictionary atoms into different semantic subspaces.

We demonstrate the superiority of DPrior against recent VAE variants on the language modeling task. We also validate our DPrior in controlled text generation where DPrior shows its effectiveness over several advanced counterparts. The main contributions of this paper can be summarized as:

- We propose an expressive Dictionary Prior (DPrior) within VAEs framework, which consists of learnable dictionary atoms and interpolating the atoms as latent variables.
- DPrior is model-agnostic and can be combined with pre-trained language models. By doing so, DPrior achieves SOTA language modeling performance on four benchmarks.
- We enforce controllability to DPrior by separating dictionary atoms into disjoint subsets and applying contrastive learning to incorporate attribute information.

2 Related Work

Controlled Text Generation Controlled text generation is a task aiming to generate realistic sentences with desired attributes, e.g., sentiments or topics. Most efforts for controlled text generation are based on conditional pre-trained language models (Keskar et al., 2019; Dathathri et al., 2020). CTRL (Keskar et al., 2019) employs a GPT-2 like pre-trained language model and trains it from scratch on a large corpus containing various control codes. Subsequently, controlled generation is accomplished by using the control codes as prompting words. PPLM (Dathathri et al., 2020) seeks to avoid the further training process and combines the GPT-2 model with several simple attribute classifiers whose gradients can update the latent representations.

Another line of work tries to explore limited labeled data via learning latent representations (Hu et al., 2017). Hu et al. (Hu et al., 2017) propose to approach controlled text generation by learning disentangled latent representations including independent content and attribute parts. In this paper, we learn entangled latent representations and approach controlled text generation by separating prior space into several parts.

Expressive Prior and Posterior In VAEs VAEs usually employ simple Gaussian distribution as the prior and spherical Gaussian distributions with diagonal co-variance matrices as the variational posteriors (Higgins et al., 2017; He et al., 2019; Fu et al., 2019). Such predefined forms in traditional formulations hinder VAEs from the expressivity of the model (Ding and Gimpel, 2021), thus further inducing the posterior collapse (Fang et al., 2019).

To improve the representation capacity, some efforts try more expressive priors. MoG-VAE (Ding and Gimpel, 2021) considers a uniform mixture of Gaussians as the prior, Vamp-VAE (Tomczak and Welling, 2018) introduces "Variational Mixture of Posteriors" prior (VampPrior). APo-VAE (Dai et al., 2021) adopts VampPrior to learn a hyperbolic latent space. FlowPrior (Ding and Gimpel, 2021) tries a new prior through normalizing flows. It is noted that VQ-VAE (van den Oord et al., 2017) introduces an auto-regressive prior via learning discrete representations, which enjoys the merits of learnability and expressivity. Nevertheless, the auto-regressive prior has low generation efficiency and no ability of latent manipulation (Fang et al., 2021). In this paper, we propose a data-driven prior via learning discrete representations but have same generation efficiency and the ability of latent variable manipulation to traditional VAEs.

Another line of work is to seek more expressive posteriors. Fang et al. (Fang et al., 2019) adopts implicit posterior representation. APo-VAE (Dai et al., 2021) and our DPrior also employ the implicit posterior representations to match the flexible priors thus further improve representation capacity.

3 Methodology

In this section, we first review the basics of deep generative models in Section 3.1, then introduce Dictionary Prior (DPrior) in Section 3.2 which is built on a set of learnable vectors. We further approach controlled text generation in Section 3.3. The overall illustration of our proposed approach is shown in Figure 1. More details will be explained in the following sections.

3.1 Deep Generative Models

VAEs are one of the most representative deep generative models for language modeling. Given a text $\mathbf{x} = x_{1:T}$ with length T, VAEs seek to infer latent variable $\mathbf{z}$ that explains the observation. Towards this end, VAEs maximize the marginal log-likelihood $\log p_\theta(\mathbf{x})$, which is usually intractable due to the complex true posterior $p(\mathbf{z}|\mathbf{x})$. Consequently an approximate posterior $q_\phi(\mathbf{z}|\mathbf{x})$ (i.e. the *encoder*) is introduced, and the evidence lower bound (ELBO) of the marginal likelihood is maximized as follows:

$$\begin{aligned}\log p_\theta(\mathbf{x}) \geq & \mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] \\ & - D_{KL}(q_\phi(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})), \quad (1)\end{aligned}$$

where $p_\theta(\mathbf{x}|\mathbf{z})$ represents likelihood function conditioned on $\mathbf{z}$, also known as the *decoder*.

VAEs usually adopt simple Gaussian distribution as the prior and spherical Gaussian distributions with diagonal co-variance matrices as the variational posterior. However, predefined distribution forms in traditional formulations of VAEs restrict representation capacity. As discussed before, we turn to learning an expressive prior via discrete representations instead of predefined prior.

3.2 Data-driven Dictionary Prior

We define the prior via a set of learnable vectors, i.e., $\psi = \{\mathbf{e}_1, ..., \mathbf{e}_m\}$, and each vector is dubbed as a dictionary atom. Intuitively, we could sample one dictionary atom and feed it to the decoder, i.e., $p_\theta(\mathbf{x}|\mathbf{e})$. However, the generation capacity is always restricted by the dictionary size m. To facilitate larger generation capacity, we further introduce a continuous random variable $\boldsymbol{\pi} = (\pi_1, \ldots, \pi_m)^\top$ that follows the Dirichlet distribution parameterized by an m-dimensional vector $\boldsymbol{\gamma}$:

$$\boldsymbol{\pi} \sim Dir(\boldsymbol{\pi}|\boldsymbol{\gamma}) = \frac{\Gamma(\sum_k \gamma_k)}{\Pi_k \Gamma(\gamma_k)} \Pi_k \pi_k^{\gamma_k - 1}. \quad (2)$$

Then we interpolate all dictionary atoms with $\boldsymbol{\pi}$ to form the latent variable: $\mathbf{z} = \sum_i \pi_i \cdot \mathbf{e}_i$. Although atoms in ψ are discrete and finite, the latent variable $\mathbf{z}$ is continuous and has infinitely possible realizations via sampling $\boldsymbol{\pi}$ according to the Dirichlet distribution. We call the prior defined on these dictionary atoms as Dictionary Prior (DPrior), or $p_\psi(\mathbf{z}|\boldsymbol{\gamma})$. Note that $\boldsymbol{\gamma}$ is a hyper-parameter and we set $\boldsymbol{\gamma}$ the same in each dimension. Dirichlet distribution would approximate one hot distribution when $\gamma_k \rightarrow 0$, and approximate uniform categorical distribution when $\gamma_k \rightarrow \infty$. In general, The smaller γ_k, produces more diverse text from our proposed DPrior.

As part of the network parameters, the dictionary ψ would be differentially updated according to various training samples. Such a data-driven prior would produce larger optimization space, enforcing to learn better representations.

Dual Form of KL divergence It is intractable to deploy vanilla KL divergence to train DPrior as in Equation 1, since learnable discrete atoms in ψ make it difficult to explicitly estimate the density of $p_\psi(\mathbf{z}|\boldsymbol{\gamma})$. To address the issue, we propose to employ its dual form based on Fenchel duality theorem (Rockafellar et al., 1966), which can effectively narrow the distribution gap between the prior $p_\psi(\mathbf{z}|\boldsymbol{\gamma})$ and posterior $q_\phi(\mathbf{z})$ when the density of the priors and/or variational posterior are unknown (Fang et al., 2019; Dai et al., 2021).

Specifically, we follow (Fang et al., 2019) and introduce an auxiliary dual function $v(\cdot)$, parameterized by a neural network with weights φ, to optimize the KL divergence as:

$$\begin{aligned}&L_D^{\phi,\psi,\varphi} = D_{KL}(q_\phi(\mathbf{z})\|p_\psi(\mathbf{z}|\boldsymbol{\gamma})) \quad (3)\\ &= \max_\varphi \mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z})} v_\varphi(\mathbf{z}) - \mathbb{E}_{\mathbf{z}\sim p_\psi(\mathbf{z}|\boldsymbol{\gamma}))} \exp(v_\varphi(\mathbf{z})),\end{aligned}$$

where $q_\phi(\mathbf{z}) = \int q(\mathbf{x}) q_\phi(\mathbf{z}|\mathbf{x}) d\mathbf{x}$ is the *aggregated posterior*. To make the posterior match the expressive DPrior, we also employ implicit posterior representations as (Fang et al., 2019). Specially, we adopt white noise $\epsilon_i \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ and concatenate it with hidden representations of $\mathbf{x}$ to obtain i-th latent variable as $\mathbf{z}_i = G_\phi(\mathbf{x}, \epsilon_i)$.

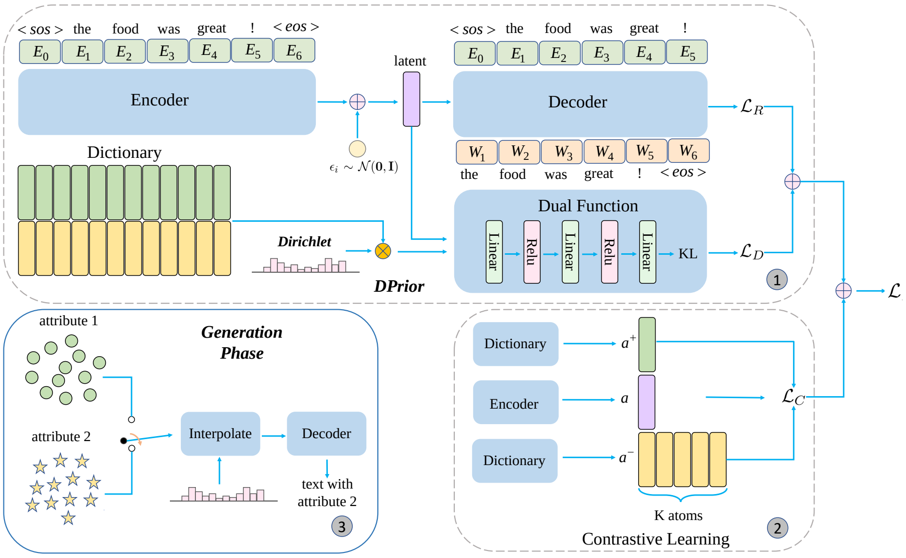

Figure 1: The overall illustration of our proposed method, which consists of an encoder-decoder network, a learnable dictionary, and a deep dual function network. $\otimes$ and $\oplus$ represent interpolation and sum operator respectively. Different colors in the dictionary denote different attributes. Block 1 represents the training process of DPrior, consisting of the reconstruction loss $\mathcal{L}_R$ and the dual-form KL divergence $\mathcal{L}_D$. Block 2 denotes contrastive learning applied to the dictionary with the contrastive loss $\mathcal{L}_C$. Block 3 denotes the controlled text generation after training.

During training, we choose γ near 0 as it consistently performs better than other values in our experiments. Together with the reconstruction loss, i.e., $\mathcal{L}_R^{\phi,\theta} = -\mathbb{E}_{\mathbf{z}\sim q_\phi(\mathbf{z}|\mathbf{x})} \log p_\theta(\mathbf{x}|\mathbf{z})$, the objective function of DPrior for language modeling can be summarized as:

$$\min_{\phi,\psi,\theta} \max_{\varphi} \mathcal{L}_R^{\phi,\theta} + \beta_1 * \mathcal{L}_D^{\varphi,\phi,\psi}, \tag{4}$$

where β_1 is a regularization parameter.

Combined with Pre-trained Models Our DPrior is model-agnostic and could be combined with various neural networks such as LSTM (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017). To improve representation capacity, we propose the combination of DPrior and a large-scale pre-trained deep latent variable model, i.e., OPTIMUS (Li et al., 2020a), which adopts the pre-trained BERT and GPT-2 as the encoder and decoder, respectively. Since extra large-scale text corpus was exploited, more diverse and even out-of-domain sentences that exploit more words are able to be generated.

3.3 DPrior for Controlled Text Generation

In this section, we enforce interpretability and controllability to DPrior to approach controlled text generation. Specifically, we separate the dictionary ψ into L disjoint subsets, i.e. $\psi_1, \psi_2, ..., \psi_L$, given L different attributes in the dataset. For example, we have two subsets to represent positive and negative sentiments as in Figure 1. The number of atoms in each subset is set according to the attribute proportion in the dataset. To accomplish controlled text generation, we can then choose a certain dictionary subset and interpolate atoms in this subset as the latent variable $\mathbf{z}$ for decoder generation.

To effectively incorporate the attribute information into dictionary atoms, we propose to employ *contrastive learning* such that sentences generated from a certain subset accurately correspond to the desired attribute. During the training of DPrior, The semantic space of the dictionary could be gradually clustered into several parts according to the natural language attributes.

Contrastive Learning for DPrior Given a latent variable $\mathbf{z}$ from encoder $q_\phi(\mathbf{z}|\mathbf{x})$ with its attribute label $c \in \{1, ..., L\}$, we denote $\mathbf{z}$ as an anchor a. Therefore, atoms in the subset ψ_c with the same attribute constitute *positive samples* (denoted as a^+) of anchor a, and atoms in other subsets $\psi_{\{-c\}}$ are *negative samples* (denoted as a^-) of anchor a. A contrastive loss (van den Oord et al., 2018; Hoffer and Ailon, 2015) is a distance metric to enforce the anchor a to be similar to positive samples a^+ and dissimilar to negative samples a^-. With the supervised attribute information contained in anchor a, the positive samples would learn to cluster into the same semantic subspace with the anchor while negative samples into other semantic subspaces. The contrastive loss will gradually enlarge the gap among different subspaces.

As shown in Block 2 of Figure 1, we employ InfoNCE loss (van den Oord et al., 2018) where we randomly sample one positive sample from ψ_c and K negative samples from $\psi_{\{-c\}}$ for each anchor a. Then the objective is to produce the log loss of a (K+1)-way softmax-based classifier that tries to classify a as a^+:

$$\mathcal{L}_C^{\phi,\psi} = -\mathbb{E}_S \log \frac{e^{\tau \cdot a \cdot a^+}}{e^{\tau \cdot a \cdot a^+} + \sum_{i=1}^{K} e^{\tau \cdot a \cdot a_i^-}}, \quad (5)$$

where $S = \{a, a^+, a^-\}$ and τ is a temperature hyper-parameter and we set $\tau = 1$ in all experiments. Together with the loss function of DPrior introduced in Equation 4, the overall objective for controlled text generation can be summarized as:

$$\min_{\phi,\psi,\theta} \max_{\varphi} \mathcal{L}_R^{\phi,\theta} + \beta_1 * \mathcal{L}_D^{\varphi,\phi,\psi} + \beta_2 * \mathcal{L}_C^{\phi,\psi}, \quad (6)$$

where $\mathcal{L}_R$ denotes the reconstruction loss, $\mathcal{L}_D$ denotes the dual-form KL-divergence, $\mathcal{L}_C$ denotes the contrastive loss, β_1 and β_2 are the hyper-parameters.

Controlled Text Generation from DPrior After the training phase of DPrior, as Block 3 of Figure 1, given any attribute label $c \in \{1, ..., L\}$, we select all atoms from the corresponding subset ψ_c, sample $\boldsymbol{\pi}$ from the Dirichlet distribution, interpolate these atoms with $\boldsymbol{\pi}$ to produce a latent variable $\mathbf{z}$, and finally feed it to the decoder for text generation. In this way, controlled text generation with the user-specified attributes can be achieved.

4 Experiments

In this section, we apply DPrior model to two tasks: (i) language modeling, where DPrior shows its advantage in expressive prior in comparison with state-of-the-art VAE methods. (ii) controlled text generation, where DPrior shows its superiority in controllability with desired attributes. We also conduct a series of analyses and visualizations to shed more light on the proposed approach.

4.1 Language Modeling

Following (Li et al., 2020a), we consider four benchmark datasets of language modeling for evaluation: Penn Tree (Marcus et al., 1993), SNLI (Bowman et al., 2015), Yahoo Answers (Xu and Durrett, 2018) and Yelp corpora (Yang et al., 2017). A summary of dataset statistics is shown in Appendix A.

Baselines We compare the proposed DPrior against following baselines: (i) auto-regressive models such as LSTM-LM (Mikolov et al., 2010) and GPT-2 (Radford et al., 2019). (ii) VAE (Kingma and Welling, 2014) with simple Gaussian prior, and its advanced variants for bettering training and avoiding posterior collapse, including Annealing VAE (Bowman et al., 2016), Free Bits (FB)-VAE (Kingma et al., 2017), Lag-VAE (He et al., 2019), and AE-FB (Li et al., 2019a). (iii) VAEs with expressive prior choices, including MoG-VAE (Ding and Gimpel, 2021), Vamp-VAE (Tomczak and Welling, 2018), APo-VAE (Dai et al., 2021), FlowPrior (Ding and Gimpel, 2021). (iv) iVAE (Fang et al., 2019) considers implicit posterior representation instead of explicit form. (v) OPTIMUS (Li et al., 2020a), a large-scale pre-trained VAE model.

Metrics We evaluate language modeling from two perspectives: Generation capacity measured by *perplexity* (PPL) and representation learning capacity measured by Active Units (AU) of $\mathbf{z}$ and its Mutual Information (MI). Note that LSTM-LM and GPT-2 has exactly PPL, while VAEs do not. Following (Fang et al., 2019), our calculation of PPL is slightly different from exact PPL in two ways: (i) we approximate $\log p(\mathbf{x})$ to report PPL; (ii) the KL term in the bound is estimated via samples, rather than a closed-form. We also report results with ELBO, KL, and Reconstruction in Appendix B.

Main Results As the results shown in Table 2, our proposed DPrior achieves state-of-the-art language modeling performance in terms of PPL and MI in all datasets. In comparison with vanilla VAE and its variants in the middle block that employ explicit posterior representations, iVAE, APo-VAE, and DPrior that adopt implicit posterior representations achieve better performance, indicating the importance of expressive posterior representations. Moreover, our DPrior achieves further improvements upon iVAE, which we attribute to the proposed data-driven prior and improving the representation capacity.

In comparison with VAEs implemented by LSTM layers in the middle block of Table 2, VAEs based on the OPTIMUS framework in the bottom block achieve impressive results by large margins.

Table 2: Language modeling performance comparison on PTB, Yelp, Yahoo, and SNLI datasets. "LSTM" indicates autoencoder architectures are built with two-layer LSTMs, while "OPTIMUS" employs pre-trained BERT and GPT-2 as the encoder and decoder. [†]: results from (Li et al., 2020a). [‡]: results from (Fang et al., 2019). [§]: results from (Li et al., 2019a). [⋆]: results from (Dai et al., 2021). [◇]: results from (Ding and Gimpel, 2021). "-" indicates the models are improper to report these values. Empty cells indicate the results were not reported in the literature.

A potential explanation is that the latter could incorporate natural language understanding knowledge into generation tasks, and then learn a more structured semantic latent space with the combination of strengths of VAE, BERT, and GPT-2. Overall, DPrior achieves the lowest PPL and highest MI among all datasets based on the OPTIMUS framework, which further verifies the superiority of the data-driven prior via learnable dictionary atoms.

Analysis We conduct a set of analyses including the influence of the dictionary size, atom analysis, latent interpolation, and sentence transfer. We find that the results on the PTB dataset are insensitive to the size of the dictionary. To gain a comprehensive understanding of the prior, we also conduct atoms analysis. Specifically, we randomly choose an atom from the dictionary and search top-9 nearest atoms via euclidean distance to this atom. Then we feed the sampled atom and top-9 nearest atoms to the decoder for sentence generation. The results are illustrated by the red and blue sentences in Table 3. We conduct latent interpolation to demonstrate DPrior could learn a smooth latent space. We also conduct sentence transfer to imply DPrior has great ability of high-level sentence editing in latent space. More details are illustrated in Appendix C.

a dog is running on the plant

4.2 Controlled Text Generation

In this section, we conduct controlled text generation on the Yelp (Li et al., 2018a) and Arxiv (Sergio, 2019) datasets. Yelp dataset (Yelp-s) consists of business reviews that are labeled as either positive or negative according to their sentiment. To gain the tense attributes (present or past) from Yelp, we use the Stanford Parser to extract the main verb from a sentence to constitute a new dataset (Yelp-t). We also consider the combination of sentiment and tense attributes (Yelp-st) for multi-set controlled text generation. Arxiv dataset extracts the abstract from `arxiv` articles regarding three topics: artificial intelligence, computer vision, and natural language process. Appendix A shows the detailed dataset statistics.

Baselines We compare the proposed DPrior with constrastive loss (denoted as DPrior+c) against several baselines:(i) **CVAE**, the conditional-VAE model (Sohn et al., 2015) where each attribute is

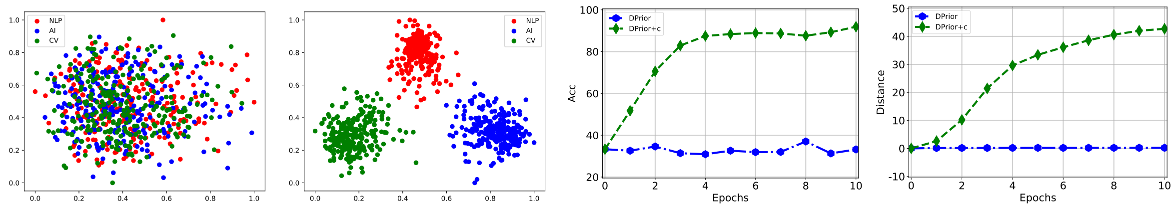
represented by a separated Gaussian distribution. (ii) **CVAE+c**, which applies constrastive loss as DPrior+c to the conditional-VAE model. (iii) **Disentagle** (Hu et al., 2017), which disentangles the latent representations into content and attribute parts for controlled text generation; (iv) **Semi-VAE** (Kingma et al., 2014), semi-supervised VAE model with independent discrete and continuous latent variables; (v) a fine-tuned **GPT-2** (Radford et al., 2019) model using attribute labels as the the prompt. We deploy the test dataset as **Reference** for comparison. To demonstrate the influence of constrative loss, we also consider an ablation where no constrative loss is applied on DPrior. Implementation details are discussed in Appendix D.

Metrics We evaluate the performance of controlled text generation from three aspects, i.e., *controllability*, *fluency* and *diversity*. For controllability, we fine-tune a BERT classifier (Devlin et al., 2019) on the training data as attribute predictor, which measures the accuracy (Acc) of correctly generated sentences with desired attributes. Note that the BERT classifier achieves an accuracy of 98.4%, 99.5%, 98.0%, and 86.2% on Yelp-s, Yelp-t, Yelp-st, and Arxiv respectively, being a good automatic evaluator. For fluency, we adopt a pre-trained GPT-2 model (Radford et al., 2019) as the fluency evaluator, which takes the generated sentences as input and returns the corresponding perplexity scores (PPL). For diversity, distinct metric (Dist) is employed which calculates the number of distinct bigrams in generated sentences (Li et al., 2016). A better-controlled generation generally has higher Acc, lower PPL, and higher Dist.

Main Result The results are listed in Table 4, 5, and 6, including automatic evaluation and human evaluation. From the results, we can conclude that: (i) in terms of **controllability**, our proposed DPrior+c consistently achieves the best generation accuracies (Acc) on all four datasets via either automatic evaluation or human evaluation. (ii) In terms of **fluency**, there is no doubt that GPT-2 produces the best PPL scores since it is pre-trained on language modeling tasks. Though not the best, our



(a) DPrior (b) DPrior+c (c) Accuracy of items (d) Distance between subsets

Figure 2: Illustration of subspace separations on the Arxiv dataset.

DPrior+c also achieves better PPL scores against other methods. Note that fluency is a very subjective metric, and the use of the GPT-2 PPL score may not be a reliable measurement. We also conduct human evaluation, reported in Table 5, and our DPrior+c always achieves the best fluency excluding the reference. (iii) In terms of **diversity**, our DPrior+c can also attain comparable distinct metrics (Dist) against other methods. Note that DPrior+c achieves the best distinct metrics (Dist) in the Arxiv dataset, as shown in Table 6. With the help of pre-trained OPTIMUS, DPrior+c could generate more diverse long sentences with more words exploited in the vocabulary.

In comparison with DPrior+c, DPrior always attains the worst controllability as shown in the top block of Table 4, which can be explained that dictionary atoms cannot receive supervised information without contrastive learning. We also find that Transformer-based models always achieve a little better controllability but worse diversity compared with pretrain-based models, as shown in Table 4. A possible explanation is that pretrain-based models can always leverage extra large-scale text corpus and generate out-of-domain sentences that exploit more words, even their attributes cannot be distinguished by the BERT classifier.

Visualizations To gain a better understanding of how contrastive learning benefits the prior subspace separations, we visualize dictionary atoms with different attributes. Specifically, we focus on the Arxiv dataset and sample all atoms from DPrior and DPrior+c models. We reduce the dimensionality from 32 to 2 using PCA and plot them in Figure 2. As shown in Figure 2(a), the subspace for AI, CV, and NLP parts are highly overlapped without contrastive loss. This can also explain the poor controllability of DPrior in Table 4. By contrast, DPrior+c model clearly separates the prior space into the AI, CV, and NLP parts, as shown in Figure 2(b), indicating that the contrastive loss could effectively enlarge the gap among different subspaces. Therefore, text generated from the interpolation of the disjoint dictionary subsets will be highly consistent with the desired attributes.

We further analyze the advantages of contrastive learning from two perspectives: the accuracy of dictionary atoms, where we directly feed all atoms to the decoder and measure the accuracy of predicted attributes by the BERT classifier; and the distance between the mean of the three disjoint subsets. As shown in Figure 2(c) and Figure 2(d), when no contrastive loss is applied, the atom accuracy and subset distance keep almost unchanged, i.e., 33% and 0 respectively. By contrast, when contrastive learning is deployed, the atom accuracy quickly increases to 91.9%, and the distance gradually enlarges during the model training.

Other Analysis We show some sampled sentences from DPrior+c including short controlled text generation trained on Yelp dataset in terms of sentiment, tense, and the combination of them, and long controlled text generation trained on Arxiv dataset. All samples can be found in Appendix E.

We also analyze the influence of Dirichlet distribution for text generation in terms of controllability, fluency, and diversity. Details can be found in Appendix G.

5 Conclusion

In this paper, we propose the Dictionary Prior (DPrior), a new data-driven prior that enjoys the merits of expressivity and controllability. The proposed prior deploys a set of learnable vectors dubbed as dictionary atoms and interpolate the atoms to form the prior. We apply dual-form KL-divergence to make the prior distribution spanned by dictionary atoms approximate the posterior distribution. Contrastive learning is further deployed to the disjoint dictionary subsets to enable controllability and interpretability. Empirical results on benchmark datasets demonstrate the superiority of our approach in both language modeling and controlled text generation.

Nevertheless, the proposed approach has limitations. While the Gaussian distribution employed in standard VAEs has an infinite support region, the support region of DPrior is finite as it corresponds to the convex hull of the dictionary atoms. Therefore, future work considers extending our framework to the more general infinite support region. We will also apply DPrior to more text generation tasks like poetry generation (Yi et al., 2020) and machine translation (Li et al., 2020b, 2019b).

A Dataset Statistics

We list the data statistics of all experiments in Table 7. PTB, Yelp, Yahoo, and SNLI datasets are used in the language modeling experiments in Section 4.1. Yelp-s, Yelp-t, Yelp-st, and Arxiv datasets are used in the controlled text generation experiments in Section 4.2.

B Language Modeling Results

The language modeling performance was evaluated by perplexity(PPL), Mutual Information(MI), Active Units(AU), Evidence Lower Bound(ELBO), KL divergence(KL), and Reconstruction(Rec) on PTB, SNLI, Yelp, and Yahoo datasets are shown in Table 8 and 9.

C Analysis on Language Modeling

The Influence of Dictionary Size To analyze how the dictionary size m influences the language modeling performance, we vary $m = 2^k, k \in \{8, 9, 10, 11, 12, 13, 14, 15\}$, and conduct experiments on the PTB dataset. The curves shown in Figure 3 present slight fluctuations in terms of PPL, MI, ELBO, and Rec, indicating the experiment results are insensitive to the size of the dictionary. We set m to 2048 for all language modeling experiments in Table 2, 8 and 9 for the highest MI.

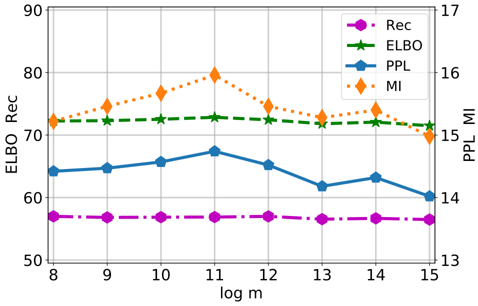

Figure 3: Influence of various dictionary sizes m for language modeling on PTB dataset.

Atoms Analysis To gain a better understanding of the prior space, we conduct atoms analysis on the SNLI dataset, i.e., we randomly choose an atom from the dictionary and search top-9 nearest atoms via euclidean distance to this atom, and then feed the sampled atom and top-9 nearest atoms to the decoder to obtain red and blue sentences respectively, as shown in Table 3 and 10, which show similar semantics, grammar and text length are well clustered in the prior space.

Latent Interpolation To demonstrate DPrior can learn a smooth latent space that captures sentence semantics, we implement linear interpolation between latent vectors on the SNLI dataset, i.e., we take two sentences $\mathbf{x}_1$ and $\mathbf{x}_2$, and use their posterior as the latent features $\mathbf{z}_1$ and $\mathbf{z}_2$, respectively. We interpolate a path $\mathbf{z}_\tau = \mathbf{z}_1 \cdot (1 - \tau) + \mathbf{z}_2 \cdot \tau$ with τ increases from 0 to 1 by a step size of 0.1. As shown in Table 11, the interpolated sentences using greedy decoding conditioned on $\mathbf{z}_\tau$ exhibit smooth semantic evolution.

Sentence Transfer To testify the ability of high-level sentence editing in latent space, we also conduct a one arithmetic latent vector operation on the SNLI dataset. Specially, given source sentence $\boldsymbol{x}_A$ and target sentence $\boldsymbol{x}_B$, the goal is to re-write the input sentence $\boldsymbol{x}_C$ as output in analogy to the transition from $\boldsymbol{x}_A$ to $\boldsymbol{x}_B$. We take encoded latent features $\mathbf{z}_A, \mathbf{z}_B, \mathbf{z}_C$ from $\boldsymbol{x}_A, \boldsymbol{x}_B, \boldsymbol{x}_C$, then apply the arithmetic operator $\mathbf{z}_D = \mathbf{z}_B - \mathbf{z}_A + \mathbf{z}_C$, and generate $\boldsymbol{x}_D$ conditioned $\mathbf{z}_D$ using greedy decoding. As shown in Table 12, two style transitions are well achieved, i.e., from singular to plural subject and from daily-life activity to sport, indicating DPrior can well support the sentence editing.

D Implementations for Controlled Text Generation

We implement all the baselines on our own under the same protocols as there is hardly any reference code for controlled text generation. For transformer-based models, reported in the top block of Table 4, all encoders and decoders are stacked by two transformer layers. These models share the same hyper-parameter settings, including the dimension of latent space, word embedding, and self-attention module. The dimension of latent variable and dictionary atom is set to 32. Adam (Kingma and Ba, 2015) optimizer is employed with an initial learning rate of 0.001. Among pretrained-based models in the bottom block, CVAE+c and DPrior+c adopt OPTIMUS framework (Li et al., 2020a) that employs BERT as the encoder and GPT-2 as the decoder with an initial learning rate of 1e-5. GPT-2 model is fine-tuned on the above datasets with an initial learning rate of 1e-5 directly. We prepend the attribute label words (e.g., positive, negative) to each sentence such that GPT-2 learns to treat them as prompt words. For Yelp-s, Yelp-t, and Yelp-st datasets, the size of the subset for each attribute in the dictionary is set to 2048, and $\gamma = 1/2^9$, and we sample 1000 sentences each attribute for automatic evaluation. Similarly, the size of each subset in the dictionary is set to 256 for Arxiv dataset, and $\gamma = 1/2$, and we sample 200 sentences each attribute for automatic evaluation.

E Case Study on Controlled Text Generation

We show some sampled sentences from DPrior+c trained on the Yelp dataset in terms of sentiment and tense, and the combination of them. Each attribute is paired with two sentences, and we highlight the corresponding salient words in Table 13. We also choose three long controlled text generations from DPrior+c trained on Arxiv dataset in Table 14.

F Human evaluation for controlled text generation

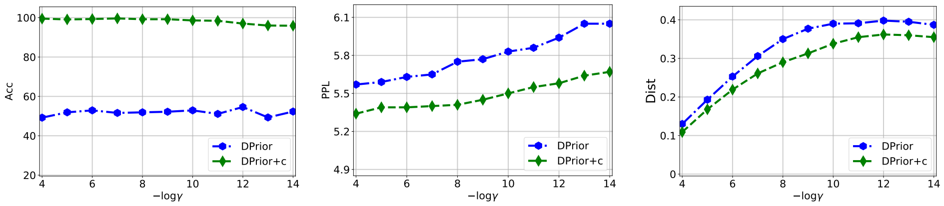
We also conduct human evaluation for the controlled text generation besides automatic evaluation. Due to the limited budgets, here we only compare DPrior+c with Reference, GPT-2, CVAE+c, as shown in Table 5. And we experiment on the Yelp-s and Yelp-t datasets in terms of sentiment and tense attributes. We randomly select 50 samples for each attribute, so there is a total of 200 sentences from each model.

Four annotators with well linguistic background were invited to assess each sentence with desired attributes in a blind manner. The evaluation is on a scale of 1-5 regarding two criteria: accuracy and fluency. Better controlled generation would come with higher accuracy and higher fluency. For example, given a generated sentence *"the price is great and i recommend them!"* with desired *"positive"* sentiment, the accuracy scores [5, 5, 5, 5] were annotated as the sentiment of the sentence could be easily assessed. When it is hard to determine the sentiment of the sentence, annotators might differ their opinions. An example is that [3, 2, 3, 4] were annotated for the sentence *"this was absolutely the first time for me."* with desired *"negative"* sentiment. The fluency scores were assessed in the same manner. Each sentence was reviewed by four judges and the average scores are reported in Table 5. We can see that our DPrior+c achieves the best accuracy, as well as best fluency score except for the Reference. We also set an agreement metric on accuracy and fluency via the percentage of the scale that most annotators agree with. For annotated scores [5, 5, 5, 5] and [3, 2, 3, 4], the agreement would be 100% and 50%, respectively. As seen, humans have a higher agreement when the model performance is high.

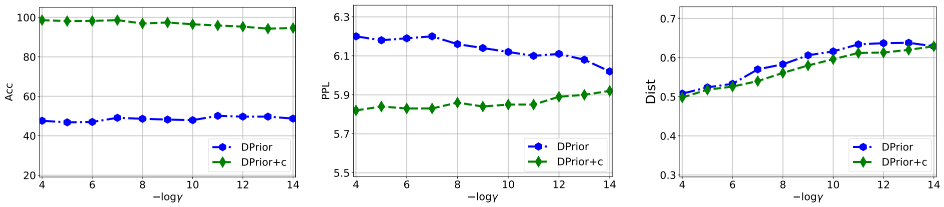
G Influence of Dirichlet Distribution

As γ in Equation 2 determines the density of the Dirichlet distribution which further determines the interpolation coefficients $\boldsymbol{\pi}$, here we analyze its influences on text generation from three aspects, i.e., controllability, fluency, and diversity as in the main results in Section 4.2. We vary $\gamma = 1/2^j, j \in \{4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14\}$, and conduct controlled text generation on the Yelp-s dataset on the transformer-based architecture. We sample 2000 sentences for each γ and employ metrics introduced in Section 4.2 for automatic evaluation. As shown in Figure 4(a), when we set a comparatively large value to γ, the DPrior+c model achieves great performance on controllability, while DPrior gains very poor accuracy, indicating the importance of contrastive learning in our framework. We also take generation fluency into consideration which is measured by GPT-2 PPL score. As in Figure 4(b), the PPL score increases gradually on both models when γ declines, showing larger γ would lead to more fluent generations. Finally, the influence of γ on generation diversity is depicted in Figure 4(c). We can see the two models have similar trends, i.e., the diversity evaluated by Dist increases rapidly when γ decreases from $1/2^4$ to $1/2^{12}$, then diversity has a slight decline. Comprehensively considering the controllability, fluency, and diversity of text generation, we set $\gamma = 1/2^9$ for all experiments on Table 4.

We also analyze the influence of Dirichlet distribution on the OPTIMUS-based architecture that could leverage extra large-scale text corpus. The most salient change is that the diversity measured by Dist significantly increases from 0.1 to 0.5 when γ equals $1/2$, as shown in Figure 4(c) and Figure 4(f), indicating the combination of DPrior and the pre-trained model could generate out-of-domain sentences that exploit more words. In terms of controllability, the OPTIMUS-based architecture exhibits the same trend but slightly lower controllability, as illustrated in Figure 4(a) and Figure 4(d). In terms of fluency, shown in Figure 4(e), OPTIMUS-based architecture presents more similar fluency to the test dataset as reported in Table 4.



(a) γ for controllability (b) γ for fluency (c) γ for diversity



(d) γ for controllability (e) γ for fluency (f) γ for diversity

Figure 4: Influence of Dirichlet distribution on text generation controllability, fluency and diversity. (a) (b) (c) are transformer-based, (d) (e) (f) are OPTIMUS-based.

Attributes	Samples
NLP	[s] the paper studies the use of generative adversarial networks (gans) for natural language parsing applications. upon retrieval of natural text digits, with a gan fixed-sized dictionary and a small set of rules, contextual grammar is generated for a given input group. this contextual grammar offers various incremental mechanism for gans to capture context, including a violation-theoretic scheme for the recognition rate of contextual grammars, exacerbated by accounts of its integration with quantitative metrics such as ver studies or globally-confluent grammars. our approach is primarily agnostic to concepts. furthermore, with real world examples, we show that with just a simple implementation we can expect to improve word parsing performance, carry out a state-of-the-art sequence learning algorithm, and finally generate an effective lexical prop grounding from its trace on the text data. [/s]
CV	[s] the topic of computer vision that attempts to predict gestures (i.e., hands) using probability distributions is rapidly gaining popularity. additionally, binary constraints lead to efficient finite state machine (fsm) composition strategies that tend to preserve image correspondences, since intuitive expressions of the departing fsm mechanisms only require a few trace steps from a given fsm state. we introduce a general cnn architecture that efficiently processes images with probabilistic hand model elements. we present a novel classification setting where the fsm parameters only need to be confirmed at a small level of training and test to improve the classification performance. we perform experiments (toads, limitation, handdisc) on datasets with numbers varying from about 320k samples to a relatively small amount of activity on a held-out dataset of collections of well-known hand gestures. through experiments, we have validated the effectiveness of our architecture; and we discovered that our gated knuckle-less fsm constraints selectively preserve image correspondences. [/s]
AI	[s] one of the problems in real-world monte carlo tree search problems (mcts) is the generation of promising algorithms and performing efficient learning of mcts parameters. parameters distributional constraints induced by a large number of observations are difficult to generate and therefore a way to overcome this issue is posed in this paper. through an empirical analysis of a prototype mct based on the control-box machine learning (cbm) and kleywagatoff-lofert satisfiability problems, we advocate deep belief learning (dl), a procedure with epistemic discretization to kickstart training. dl operates through an abstraction tree which enables better reasoning, language understanding, and preference of trained models. we introduce a number of different psychometric specifications to infer behavioral potentials. as a remedy, we propose an approach that starts with belief processes simultaneously. we present dl mouth-to-teeth behaviors that show considerably better soundness and recall compared to the current state-of-the-art mct based approaches as well as artificial neural networks (anns), and that satisfactorily generates better algorithms. [/s]

Abstract

Neural constituency parsers have reached practical performance on news-domain benchmarks. However, their generalization ability to other domains remains weak. Existing findings on cross-domain constituency parsing are only made on a limited number of domains. Tracking this, we manually annotate a high-quality constituency treebank containing five domains. We analyze challenges to open-domain constituency parsing using a set of linguistic features on various strong constituency parsers. Primarily, we find that 1) BERT significantly increases parsers' cross-domain performance by reducing their sensitivity on the domain-variant features. 2) Compared with single metrics such as unigram distribution and OOV rate, challenges to open-domain constituency parsing arise from combinations of factors, including cross-domain lexical and constituent structure variations.

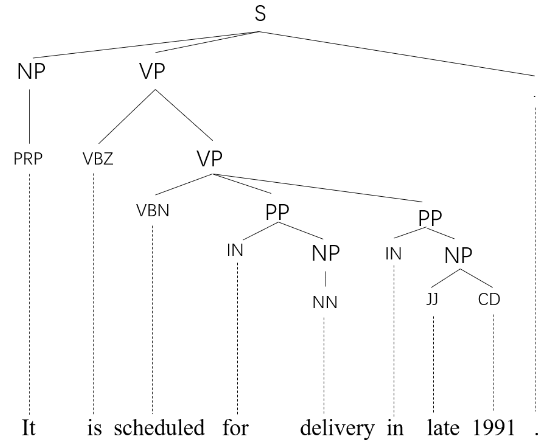

Figure 1: An example of constituency parse tree.

1 Introduction

Constituency parsing is a fundamental task in NLP that has received constant research attention (Cross and Huang, 2016; Liu and Zhang, 2017; Stern et al., 2017; Kitaev and Klein, 2018). As shown in Figure 1, given a sentence, the task is to identify hierarchical phrase structures that reflect its syntax, such as prepositional phrases (PP; e.g., "*in late 1991*"), noun phrases (NP; e.g., "*late 1991*") and verb phrases (VP; e.g., "*scheduled for delivery in late 1991*"). Constituent structures have been shown useful for downstream tasks including machine translation (Wang et al., 2018), natural language inference (Chen et al., 2017), text summarization (Xu and Durrett, 2019). In addition, they can be transformed into dependency tree structures (Zhang and Clark, 2008), which have been shown to be useful for a wide range of NLP tasks.

The dominant approach to constituency parsing employs a neural model with pre-trained token representation (Kitaev et al., 2019), training the network parameters over manually labeled constituent structures from the Penn Treebank (PTB) (Marcus et al., 1993). As labeled constituent trees can be costly to obtain, most work makes use of the PTB data for training, which is financial news. The current state-of-the-art F-scores reach over 95% on the training domain (i.e., newswire) and are around 88% for biomedical and web test data (Tateisi et al., 2005; Silveira et al., 2014). Compared with parser performance decades ago, accuracies around 90% nowadays is much more useful for downstream applications. Fried et al. (2019) showed that pre-training is a key factor that brings consistent cross-domain performance improvements by using BERT (Devlin et al., 2019).

Ideally, a constituency parser should give robust performance *in the open domain*, so that both domain-specific applications (Zhang et al., 2021) and open-domain NLP tasks (Hu et al., 2019) can benefit from syntactic structures. The above observations, however, are made on a rather limited (i.e., 3) number of domains. In addition, there has been relatively little study on the key factors to the performance gap between financial news test and

May 22-27, 2022

test on other domains, when the model is trained on financial news. It remains an interesting research question to understand the performance of constituency parsing with regard to a wider range of domains and text genres in order to understand the boundaries and existing techniques and identify the main challenges for robust open-domain constituent parsing. Such knowledge can be informative for guiding the design of robust open-domain parsers.

To this end, we evaluate three strong constituency parsers on these domains, as well as the existing news, biomedical and web domains. The parsers include the non-neural BLLIP parser (Charniak and Johnson, 2005), the in-order transition-based parser (Liu and Zhang, 2017) and the Berkeley neural chart-based parser (Kitaev and Klein, 2018). For the test domains, we include the vast majority of existing cross-domain test data in the literature, which cover the biomedical, web text, literature fiction and telephone conversations. In addition, given much research interest in NLP for dialogue (Budzianowski et al., 2018), law (Chalkidis et al., 2019) and review (Oved and Levy, 2021) domains, we manually label constituent structures for five typical domains (i.e., dialogue, forum, law, literature, review), resulting in a test set of 1,000 sentences for each domain. Empirically, we aim to answer the following research questions.

First, *what are the parser performances in the open domain, and which domains are the most challenging for constituent parsing?* We find that the parser performance varies from 83% to 93% under different domains, and the most challenging text genres are review, dialogue and literature. The low results on these domains mean that open-domain constituency parsing is still a challenge.

Second, *what are the relative strengths of different parser models, and does BERT give similar improvements for all domains?* We find that the parsers that give stronger results on PTB do not necessarily give stronger results on various other domains, which reflects limitations of evaluating parser performances only on PTB data. Besides, we show that BERT benefits parsers on cross-domain performance by reducing their sensitivity on domain-variant features.

Third, *what are the main challenges for cross-domain parsing?* By analyzing a set of linguistic features, we find that compared with single metrics such as unigram distribution and OOV rate, challenges to cross-domain constituency parsing arise from combinations of factors, including cross-domain lexical and constituent structure variations.

To our knowledge, we are the first to construct constituency parsing test data for the forum and law domains and the first to analyze the factors that make open-domain parsing challenging by extensive empirical evaluation. We release our dataset and results at `https://github.com/RingoS/multi-domain-parsing-analysis`.

2 Related Work

2.1 Cross-domain Treebanks

Penn Treebank (Marcus et al., 1993) was the very first large-scale dataset that enables researchers to implement statistical constituency parsers that achieve high accuracy on phrase structure prediction (Charniak, 1997; Klein and Manning, 2003). Encouraged by the success of PTB, treebanks on other domains have been developed. Brown corpus (Marcus et al., 1993) was created to assess the cross-domain generalization ability of parsers trained on the newswire data of PTB. Switchboard contains transcripts from telephone conversations. BNC (Foster and van Genabith, 2008) consists of 1,000 hand-corrected British National Corpus parse trees. English Web Treebank (EWT) (Silveira et al., 2014) contains phrase structure annotations from five genres of web media: weblogs, newsgroups, emails, reviews, and Yahoo! answers. Genia (Tateisi et al., 2005) is based on biomedical literatures and was created to support the development of NLP for the domain of molecular biology. Our MCTB is constructed to cover a variety of domains for test interest. Some MCTB test domains turn out to be more challenging, as shown in Tables 1 and 3.

2.2 Cross-domain Syntactic Parsing

There has been work considering cross-domain constituent parsing with parser combinations. McClosky et al. (2010) investigated multiple source parser adaptation, which trains several parsers on many different domains. A linear regression model is adopted to predict the combination of these parsers. Their work is different from ours in that: 1) they make use of both PTB and cross-domain training data; In contrast, we consider PTB training to study domain difference in more isolation; 2) Our goal is to systemically compare parser per-

formance for understanding the challenges, and thus we consider more parsers and domains, but no innovative models. Joshi et al. (2018) empirically found that contextualized word representations improves domain adaptation when the target domain is syntactically similar to the source domain. They also proposed to make use of a dozen partial annotations to improve cross-domain performance on syntactically-distant domains. Fried et al. (2019) conducted a systematic analysis on cross-domain parsing. They found that: 1) neural models and non-neural models generalize similarly to new domains; 2) large-scale pretraining improves domain adaptation; 3) structured models (e.g., in-order parser) generalizes better to new domains. Our analysis differs from previous work on the follows: 1) we empirically analysis what factors make cross-domain constituency parsing challenging; 2) we conduct experiments on more domains and datasets, which provide more comprehensive understanding for the open-domain setting.

Cross-domain parsing has also been investigated on other grammar formalisms, in particular dependency syntax. Blodgett et al. (2018) broadened English dependency parsing to handle social media English, especially social media African-American English (AAE). They released a dataset which contains 500 tweets along with their dependency annotations. Li et al. (2019) investigated a semi-supervised approach for domain adaptation in dependency parsing. They combined data from source and target domains using a domain embedding approach. Rotman and Reichart (2019) proposed Deep Contextualized Self-training (DCST), which utilizes representation models trained on sequence labeling tasks that are derived from the parser's output when applied to unlabeled data, and integrates these models with the base parser through a gating mechanism.

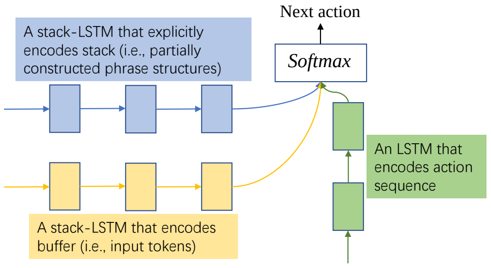
3 Methods and Settings

3.1 Models

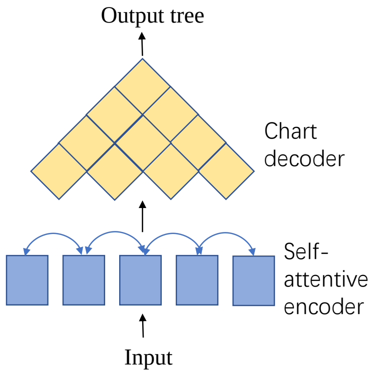
We experiment with a strong non-neural parser and recent SOTA neural parsers. The neural parsers are additionally augmented with pretrained BERT (Devlin et al., 2019).

BLLIP Parser. The BLLIP parser (Charniak and Johnson, 2005) is a statistical parser that includes a generative parser (first-stage) and a maximum entropy based re-ranker (second-stage). It first calculates the n-best (typically n = 50) parses, and then re-ranks all produced parses with weighted-averaged scores that are produced by a set of manually-designed features.

In-order Parser. The in-order parser (Liu and Zhang, 2017) is a transition-based parser that traverses the parse tree in an in-order sequence. As



(a) In-order parser.



(b) Berkeley neural parser.

Figure 2: Structures of the two adopted neural parsers.

shown in Figure 2a, it adopts a stack-LSTM to encode partially constructed tree structures, a stack LSTM to encode input buffer and an LSTM to encode action sequence. In this way, it explicitly models the output phrase structures.

Berkeley Neural Parser. As shown in Figure 2b, Berkeley Neural Parser (Kitaev and Klein, 2018) is a chart-based parser that adopts a self-attentive encoder and a chart-based decoder. Different from in-order parser, it predicts the span labels solely based on local span representations and does not explicitly model the output tree structure.

3.2 Experimental Settings

For BLLIP[1], we adopt their released parser "WSJ-PTB3". For in-order[2], we use their released code, model checkpoints and word embeddings. The embeddings are pretrained on the AFP portion of English Gigaword. The in-order parser requires part-of-speech (POS) tags, for which we adopt a transformer-based tagger trained on the PTB training set. As for the BERT-augmented in-order parser, we adopt the open-sourced code and model checkpoints from Fried et al. (2019)[3]. We train the Berkeley neural parser without and with BERT, respectively, using their released code[4]. The non-BERT Berkeley parser uses randomly initialized embeddings, which differs from the in-order parser. All parsers are trained on standard PTB training set and validated on PTB development set (Marcus et al., 1993).

We evaluate the parsers on 25 test sets, including PTB, Brown (Marcus et al., 1993), Genia (Tateisi et al., 2005), EWT (Silveira et al., 2014), BNC (Foster and van Genabith, 2008), Switchboard and our newly annotated test set. Some of these datasets have multiple subdomains (i.e., Brown and EWT). The domains are shown in Table 1. We call our test set MCTB (Multi-domain constituent Treebank) and provide detailed descriptions in Section 4.

4 Dataset

4.1 Annotation

Our new MCTB testset is composed of texts from 5 genres, including dialogue, forum, law, literature and review. For the dialogue domain, we randomly sample dialogue utterances from Wizard of Wikipedia (Dinan et al., 2019), which is a chit-chat dialogue benchmark produced by humans. For the forum domain, we use users' communication records from Reddit, crawled and released by Völske et al. (2017). For the law domain, we sample text from European Court of Human Rights Database (Stiansen and Voeten, 2019), which includes detailing judicial decision patterns. For the literature domain, we download literary fictions from Project Gutenberg[5]. For the review domain, we use plain text across a variety of product genres, released by SNAP Amazon Review Dataset (He and McAuley, 2016).

We follow PTB's annotation guideline and paradigm (Marcus et al., 1993) to design our annotation guideline, hiring a group of senior undergraduate and master students whose majors are linguistics as our annotators. The annotators are asked to read the guideline, practice and correct the errors of the predicted parse tree, which is produced by a SOTA chart-based parser that is developed based on Berkeley Neural Parser. For annotation clarity, we develop a web-based visualization annotation toolkit, which accepts bracketed format lines and visualizes parse tree structures. The annotation tool

[2] `https://github.com/LeonCrashCode/InOrderParser`

[3] `https://github.com/dpfried/rnng-bert`

[4] `https://github.com/nikitakit/self-attentive-parser`

[5] `https://www.gutenberg.org/`

allows adding/deleting constituents in the tree structure. We release our annotation toolkit at `https://github.com/Nealcly/AnnoCons`.

Annotators are first required to annotate 100 instances from the PTB test set repeatedly, until their labeling is sufficiently accurate to provide useful annotation. To further control annotation quality, the annotators are assigned workloads in batches, with the batch size being 100. For each batch, we randomly select 10 instances (10%), and the main authors check the sampled instances with a side-by-side annotation. If the F-1 scores between the annotator annotated and the inspector annotated for these 10 instance is less than 95%, the corresponding batch will be rejected and assigned to a new annotator. The annotators get their salaries no matter their annotations are rejected or not.

4.2 Data Statistics

We report dataset statistics in Table 1, including the total numbers of instances, of tokens and of constituents, the averaged numbers of tokens within sentences and within constituents and the maximum and minimum numbers of tokens among all sentences. We also report the averaged number of tokens in NP, VP and PP, because they are the most prevalent across all datasets.

From the table, we can see that the dialogue, review and Switchboard domains have the smallest averaged numbers of tokens per sentence, about half of that of PTB. The dialogue, review and Switchboard domains also have the smallest averaged constituent lengths, around 30% shorter than that of PTB. Though the averaged lengths of sentences and of constituents of the literature domain are rather close to those of PTB, the averaged lengths of labeled constituents (especially for NP and PP) are smaller. Among all domains, law shares the most similarities of averaged constituent lengths (both unlabeled and labeled) with PTB. All datasets have similar lengths for shortest sentences, while the literature domain has the largest number of tokens within one sentence.

4.3 Comparison between Features

We report the differences between the PTB training set and various test sets[6] in Table 2, by adopting a list of linguistic features from previous work (Collins and Koo, 2005; Charniak and Johnson, 2005). Each cell in the table represents the Jensen-Shannon divergence between the distribution of a specific feature of the PTB training set and that distribution of a specific test set. Given the distributions P and Q, the Jensen-Shannon divergence is calculated as:

$$JS(P||Q) = \frac{1}{2}(KL(P||M) + KL(Q||M)) \qquad (1)$$

where $KL(P||Q) = \sum_{x \in \mathcal{X}} P(x) \log(\frac{P(x)}{Q(x)})$ is the Kullback-Leibler divergence, and $M = \frac{1}{2}(P+Q)$. Each value ranges from $0 \sim 1$ and a higher value reflects less correlation on that feature between the PTB training set and the corresponding test set.

In the table, the columns Uni, Bi and Tri denotes unigram, bigram, trigram and fourgram tokens and constituent labels, respectively; GR, HGT and GP denotes grammar rule, headed grammar rule and a chain of (grandparent, parent, child) constituents, respectively. We do not calculate token fourgrams because they are sparse and the OOV rate is over 95% on each domain. Constituent n-grams are calculated within each grammar rule. Grammar rules are unbinarized rules, and examples of headed lexicalized grammar rules include VP [eat] –> VB NP and NP [tomato] –> DT ADJ NN. The OOV rates of token ngrams are also shown in Table 2.

From the table, we can see that the biomedical and review domains have the largest token ngram differences from the PTB training data, while the English Web Treebank is lexically the most similar to PTB-train. Compared to lexical patterns, (unlexicalized) grammatical patterns are relatively more consistent across different domains. Among the different domains, switchboard, dialogues and review have the largest difference in grammar rule patterns as compared to PTB, and the Brown-test, EWT-test and law test sets are relatively the closest to the PTB data. Genia-test, forum, law and literature have a similar level of grammar-feature difference from PTB-train, with brown-test being the closest among the four. From the table, we can see that individual statistics vary across domains, which reflects large domain differences.

5 Experiments

5.1 Overall Results

The performances of the parsers on each domain are shown in Table 3. On PTB-test, all the BERT-based parsers achieve labeled bracket F-scores

---

[6] For simplicity, we regard Brown and EWT as two whole test sets, respectively. The feature correlations and parser performances including all 25 test sets and subsets are shown in Appendix A.1.

Literature	70.32	76.44	75.98	84.96 (-36.2%)	86.26 (-42.8%)
Review	74.18	75.91	76.15	83.89 (-33.1%)	84.34 (-34.3%)

Table 3: Results (F1 scores) on various test sets. Δ Err. means error reduction rates when using BERT.

above 95%. In comparison, the performances on Genia, BNC, Brown, Switchboard and EWT fall to a range between 84.42% and 93.68%, with relative error increases of 45% to 258%. According to Table 2, these cross-domain test data are relatively close to the PTB data in the distribution of lexical and syntactic patterns. In contrast, on Switchboard, dialogue, forum, literature and review, the results can drop to 83%, with a relative error increase of over 370% (i.e., 95.65% versus 83.89% F-score). This shows that open-domain constituent parsing is still a challenging task to solve.

Among the domains, we find that the review and switchboard domains are the most difficult, with F-scores of around 84% by the BERT-based parsers. The dialogue, forum and literature domains are relatively easier, with F-scores of around 86%. The law domain is the easiest, where the parsers give F-scores of over 90%. Intuitively, the parser performance differences arise from the differences in the text genre between the test domain and PTB: while the review and switchboard domains can contain a fraction of oral and informal English, the law domain is the closest to the newswire domain in style. We give more detailed feature statistics in Section 5.3.

5.2 Comparison between Different Parsers

Among parsers without making use of BERT, the performance drop of In-order parser is relatively the smallest when comparing PTB-test with the domains. As observed by Fried et al. (2019), the relatively larger cross-domain robustness as compared with Berkeley parser may be attributed to the modeling of output structural dependencies by the shift-reduce parser. BLLIP gives a similar cross-domain performance drop as compared with Berkeley parser, which shows that a discrete parser does not necessarily show weaker cross-domain robustness than a neural parser, which again is consistent with findings of Fried et al. (2019).

BERT improves the performances of all neural parser models, with 48.6% and 38.6% error reduction rates for the In-order and Berkeley parsers on

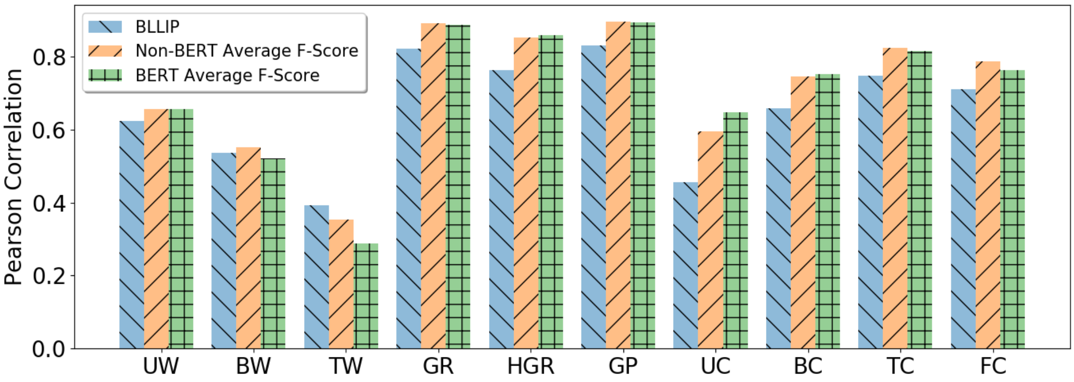

Figure 3: Pearson correlation between feature divergence and parser performance. Because all values are smaller than 0, we simply multiply all values with -1 to make them easier to understand. A higher value represents more reliance on that feature. "Non-BERT Average" refers to the averaged F1 scores of In-order and Berkeley, while "BERT Average" refers to the BERT-augmented version. UW / BW / TW — input token uni- / bi- / tri-gram. GR / HGR / GP — grammar rule / headed grammar rule / grandparent rule. UC / BC / TC / FC — constituent uni- / bi- / tri- / four-gram .

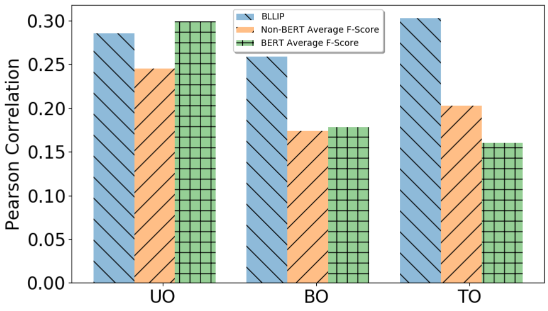

Figure 4: Pearson correlation between OOV rates and parser performance, following the caption of Figure 3. UO / BO / TO — uni- / bi- /tri-gram token OOV.

PTB-test, respectively. For cross-domain test sets, the error reduction rates are 34.3%, 39.4%, 50.2%, 42.8% and 34.3%, respectively for the dialogue, forum, law, literature and review domains with Berkeley neural parser. The reason that a relatively larger error reduction rate is found for the law and literature domains is likely that BERT is trained on Wikipedia and Brown Corpus (i.e., encyclopedia and literature), which has largely similar text genres compared to these datasets. In contrast, the styles of the biomedical (Genia), dialogue and review domains are relatively different from BERT's training data.

5.3 Key Factors to Cross-domain Challenge

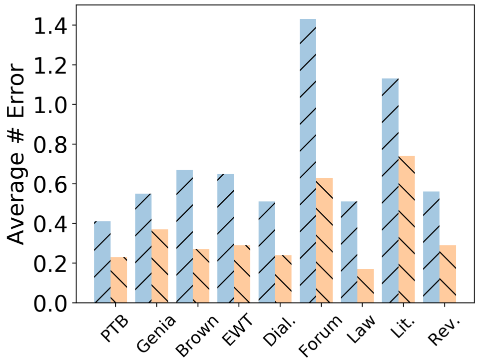
Figure 3 shows the Pearson correlation between parser performances (in Table 3) and feature JS divergences (in Table 2) for all five parsers[7]. In particular, we take the performances of each parser over all the domains in Table 3 (i.e., each column in the table) as a vector, and the JS-divergence values for each feature in Table 2 (i.e. each column in the table) as a vector, calculating the statistical correlation between the two vectors, which reflects the influence of domain shift in each feature on the parser performance. In the figure, each column shows the Pearson correlation of a specific parser with a specific feature, where a longer bar reflects more reliance on the feature.

From Figure 3, we make the following observations. First, overall all the parsers are more influenced by larger grammatical structures such as the whole grammar rule (GR), the grandparent chain (GP) and n-gram sub constituents (BC, TC and FC), while being less influenced by word-level ngram features (BW and TW) and simple constituent label features (UC). This shows that the cross-domain challenge arises mostly from more complex structural variations, instead of cross-domain word and ngram distribution differences.

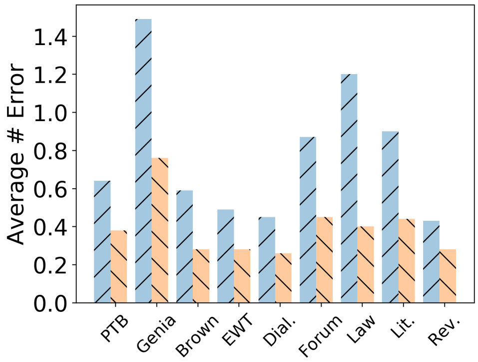
Second, the traditional BLLIP parser is about as sensitive to word and ngram variations as neural parsers, but less sensitive to syntactic pattern variations such as GR and UC. This shows that the strong representation power of neural models allows them to learn more abstract syntactic structure patterns more accurately. Third, after BERT is used,

---

[7] In practice, we use Tables 4 and 5, because the domain differences among the sub-genres of Brown or EWT would be eliminated by only using Tables 2 and 3.



(a) Clause attachment.



(b) PP attachment.

Figure 5: Average number of bracket errors per sentence on each dataset using the parser of Liu and Zhang (2017). The errors are classified with Kummerfeld et al. (2012)'s method. Blue bars with slash "/" are without BERT, while orange bars with backslash "\" are with BERT. "SWB", "Dial. ", "Lit. " and "Rev. " are in short for Switchboard, dialogue, literature and review, respectively.

neural parsers show stronger dependence to UC and BC, and weaker dependence to BW, TW, TC and FC features, compared with randomly initialized versions. In fact, as Table 2 shows, the former features are relatively more stable across domains, with less JS-divergence scores between domain test data and PTB training data. This shows that BERT effectively improves parser domain robustness by providing a level of cross-domain knowledge.

Figure 4 shows the Pearson correlation between OOV rates and cross-domain results. Interestingly, the influence of OOV on all parsers are in the range of 16.0% to 30.3%, which is saliently smaller than that of ngram distributions. This shows that the cross-domain challenge arises not simply from unknown tokens, but is more distribution-sensitive. With regard to different parsers performances, the BLLIP parser shows stronger subjectivity to the influence of OOV as compared with the neural parsers, especially for tri-gram OOV, which demonstrates the advantage of dense word representations over sparse one-hot encoding (Bengio et al., 2013). Finally, by further adding BERT, the relative sensitivity of the neural parsers to OOV uni-grams and bi-grams sees increases, while that to OOV tri-grams decreases. This shows that the effect of BERT on cross-domain parsing is more contextualized, in the sense that simply addressing unknown unigram token representations does not necessarily lead to stronger results, but BERT gives the parsers stronger power in representing context distributions.

5.4 Error Characteristics

Figure 5 shows the error distributions of the in-order parser with and without BERT according to the classification of Kummerfeld et al. (2012). In particular, two error types, clause attachment and PP attachment, are shown in the figure, and the charts for more error types are shown in Appendix A.2. As can be seen from Figure 5, the parser makes different types of error across different domains, which reflects different challenges. In the following, we give an example of MCTB-literature. Due to page limitation, figures of the full parse trees and more case studies are shown in Appendix A.2.

It can be seen from Figures 5a and 5b that the literature domain suffers from clause attachment and PP attachment errors, which may result from the fact that sentence structures of the literature domain are more complicated than the stereotype writing style of the newswire domain and there are many rare words in literary works. For example, given a sentence in literature test set: "*The bulldog growls , his scruff standing , a gobbet of pig 's knuckle between his molars through which rabid scumspittle dribbles .*", the gold bracketed-format annotation is

```
...(NP
    (NP (NP (DT a) (NN gobbet))
        (PP
          (IN of)
          (NP
            (NP (NN pig) (POS 's))
            (NN knuckle))))
    (PP (IN between)
      (NP
        (NP (PRP$ his) (NNS molars))
        (SBAR
          (WHPP (IN through) (WHNP (WDT which)))
          (S
            (NP (JJ rabid) (RB scumspittle))
            (VP (NNS dribbles)))))))...
```

and the predicted bracketed-format tree is

```
...(NP
    (NP (DT a) (NN gobbet))
    (PP
```

```
    (IN of)
    (NP
      (NP (NN pig) (POS 's)) (NN knuckle)))
  (PP
    (IN between)
    (NP (PRP$ his) (NNS molars)))
  (SBAR
    (WHPP (IN through) (WHNP (WDT which)))
    (S
    (NP (JJ rabid) (RB scumspittle))
    (VP (NNS dribbles)))))...
```

The clause phrase "*through which rabid scumspittle dribbles*" is supposed to attach to the noun phrase"*his molars*". However, a clause attachment error is produced by the in-order parser, which assigns the clause phrase to the noun phrase "*a gobbet*". In addition, in the predicted tree structure, the PP phrase "*between his molars ...... dribbles*" shares the same parent node with the noun phrase "*a gobbet*" and with the PP phrase "*pig 's knuckle*", which is incorrect. Instead, the PP phrase "*between his molars ...... dribbles*" should be attached to a higher level. This results in a PP attachment error.

6 Conclusion

We investigated the challenges of cross-domain constituent parsing by making use of a large number of test domains, which include newswire, biomedicine, prose, web-text, conversational speeches, as well as give new test domains including dialogue, forum, law, literature and review, for each of which we construct a test set of 1,000 sentences. Results show that the dominant parsers can achieve 83% to 93% accuracies for different domains, and cross-domain parsing is still a challenge, where different domains exhibit varying types of difficulty. We further find that the difficulty for cross-domain parsing lies more in comprehensive distribution differences involving multiple factors such as grammar rules and patterns, as compared to single factors such as OOV rate and token ngram distribution variations. In addition, BERT helps neural parsers improve cross-domain performance by reducing their sensitivity to domain-variant features. Our results show that toward robust open-domain constituent parsing, more work should be done on addressing out-of-distribution generalization in representation learning.

A Appendix

A.1 Detailed Feature Correlation and Parser Results

Feature correlations and parser performances with all 25 datasets are shown in Tables 4 and 5.

A.2 Error Characteristics

Figure 6 shows nine types of errors made by In-order parser on all test sets. The errors are classified using the method of Kummerfeld et al. (2012). Figures 7 and 8 show the tree structures of the case study in Section 5.4. The tree figures are produced using an open-source visualization toolkit[8].

In Figure 6c, the number of NP internal structure errors of Genia is saliently larger compared to the other domains, which can be because the biomedical domain has a relatively larger amount of special nominal terminologies, which cannot be easily identified using newswire knowledge. Take an instance from Genia test set for example, the gold annotation is

```
...(NP
      (DT a)
      (ADJP
        (NN HLA)
        (NN class)
        (CD II)
        (JJ DR11-restricted))
      (NN fashion))...
```

where "*HLA class II DR11-restricted*" is an adjective phrase modifying the noun "*fashion*". However, the in-order parser prediction is

```
...(NP
      (DT a)
      (NN HLA)
      (NN class)
      (CD II)
      (JJ DR11-restricted)
      (NN fashion))...
```

which does not recognize the sub-structures under the noun phrase "*a HLA class II DR11-restricted fashion*".

Abstract

Sememe knowledge bases (SKBs), which annotate words with the smallest semantic units (i.e., *sememes*), have proven beneficial to many NLP tasks. Building an SKB is very time-consuming and labor-intensive. Therefore, some studies have tried to automate the building process by predicting sememes for the unannotated words. However, all existing sememe prediction studies ignore the hierarchical structures of sememes, which are important in the sememe-based semantic description system. In this work, we tackle the structured sememe prediction problem for the first time, which is aimed at predicting a sememe tree with hierarchical structures rather than a set of sememes. We design a sememe tree generation model based on Transformer with an adjusted attention mechanism, which shows its superiority over the baseline methods in experiments. We also conduct a series of quantitative and qualitative analyses of the effectiveness of our model. All the code and data of this paper are available at `https://github.com/thunlp/STG`.

1 Introduction

A word is the fundamental element of natural languages, but its meaning can be further divided. To explore semantics atomically, linguists define a *sememe* as the minimum semantic unit (Bloomfield, 1926). It is even believed that the meanings of all words in any language can be represented by a limited set of sememes, which is closely related to the idea of semantic primitives (Wierzbicka, 1996).

HowNet (Dong and Dong, 2006) is the most well-known sememe knowledge base (SKB). It comprises more than 100,000 English and Chinese words and phrases manually annotated by about 2,000 sememes that are defined by linguistic experts. Multiple senses of a polysemous word are independently annotated, and the sememes annotated to a sense are hierarchically organized as a sememe tree. Figure 1 illustrates the sememe annotations of two English words in HowNet.

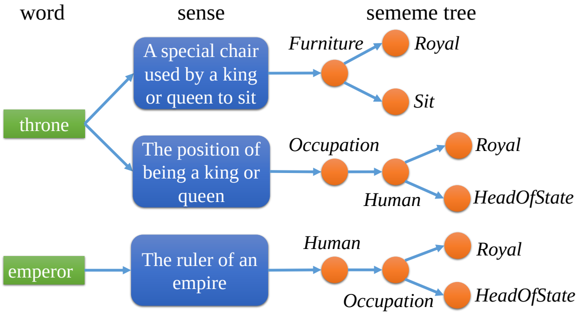

Figure 1: Sememe annotations of the words “throne” and “emperor” in HowNet.

Different from other lexical knowledge bases, SKBs like HowNet define words intensionally with a limited set of semantic units (sememes), thus have some unique strengths. For example, SKBs can be combined with neural network models smoothly by regarding sememes as the external semantic labels of words (Qi et al., 2019; Qin et al., 2020). Moreover, thanks to the limitedness of sememes, SKBs have been proven very useful in the low-data regimes, e.g., improving the representation learning of rare words by transferring knowledge from frequent words via sememes (Niu et al., 2017). As a result, SKBs have been widely utilized in many NLP tasks (Qi et al., 2021b).

However, most languages have no SKBs like HowNet, and it is too expensive to manually build an SKB for a new language from scratch.[1] In addition, even for the languages covered in HowNet (English and Chinese), new words are emerging every day and the meanings of existing words keep changing. It is also costly to expand and update

HowNet. To solve these issues, a series of studies have been conducted, trying to automatically predict sememes for monolingual or cross-lingual words (Xie et al., 2017; Jin et al., 2018; Qi et al., 2018; Du et al., 2020; Lyu et al., 2021). For simplicity, all previous sememe prediction studies ignore the hierarchical structures of sememes. They simplify sememe prediction as a multi-label classification task, and their models output a structureless set of sememes.

However, the structures of sememes are very important. For one thing, the structural information is indispensable in the sememe-based semantic description system, as it carries semantics, and branches of sememe trees stand for the relations of sememes. As shown in Figure 1, the difference in sememe structure results in the different meanings of the second sense of “throne” and “emperor”, although they have four identical sememes. For another, the structures of sememes are necessary for many sememe-based applications (Liu and Li, 2002; Zhu et al., 2019; Liu et al., 2020).

In this paper, we try to tackle structured sememe prediction, which is aimed at predicting sememes together with their hierarchical structures rather than the structureless sememes only. This task is essentially a kind of tree generation task but is more challenging than other tree generation tasks. First, the size of its node type is more than 2,000 (i.e., over 2,000 sememes), which is much larger than that of most tree generation tasks, e.g., less than 100 for code generation and semantic parsing (rab). Second, the structures of sememe trees are extremely diverse — almost any sememe can be the child node of another sememe, and one sememe node can have an arbitrary number of children. Many of the existing tree prediction methods depend on the certain number of children of a node and perform strongly correlated with the number of candidates (Yin and Neubig, 2017), thus are not applicable.

To handle this difficult task, we conduct further formalization. Different from most structureless sememe prediction studies whose input is merely a word, inspired by Du et al. (2020), we regard a sentence of definition as the input, and the task is formalized as a sequence-to-tree task. We do this for two reasons. First, sememe prediction can be conducted at the sense level (one definition corresponds to one sense of a word). Second, definitions can provide more useful information than single words for structured sememe prediction.

Further, we propose a model based on Transformer (Vaswani et al., 2017) especially designed for the task of sememe tree generation (STG). We decompose the attention in Transformer into two parts that capture the semantic similarity and topological relations between sememes, respectively, in order to better represent the characteristics of sememe trees. Experimental results show that our method outperforms baseline methods including the vanilla tree Transformer model. We also conduct quantitative and qualitative analyses of the results of our method.

2 Related Work

2.1 Sememe Knowledge Base

As a kind of special lexical knowledge base, SKBs represented by HowNet have been widely explored in various NLP applications, including word representation learning (Niu et al., 2017), word sense disambiguation (Hou et al., 2020), language modeling (Gu et al., 2018), reverse dictionary (Zhang et al., 2020b), textual adversarial and backdoor attacks (Zang et al., 2020; Qi et al., 2021c), etc.

Meanwhile, some studies focus on automating the process of expanding and constructing SKBs. They propose different methods to automatically predict sememes for words. Xie et al. (2017) present the task of lexical sememe prediction and propose two simple but effective methods that are based on collaborative filtering and matrix factorization, respectively. Jin et al. (2018) and Lyu et al. (2021) utilize the Chinese character and glyph information in lexical sememe prediction and achieve higher performance. Du et al. (2020) introduce dictionary definitions into sememe prediction and find that the abundant semantic information in definitions is very beneficial to sememe prediction. But they do not conduct sense-level sememe prediction. They simply concatenate the definitions of multiple senses of a word and predict the combined sememe set for the word.

The above studies use the sememe annotations of existing words in HowNet to predict sememes for new words, aiming to expand HowNet. Some studies try to construct SKBs for new languages automatically. Qi et al. (2018) present the task of cross-lingual lexical sememe prediction, which predicts sememes for words in a new language by bilingual word embedding alignment of a HowNet-covered language and a new language. Qi et al. (2020) propose to build a multilingual SKB based on BabelNet, a multilingual encyclopedia dictionary (Navigli and Ponzetto, 2012). BabelNet is composed of BabelNet synsets, each of which contains multilingual synonyms, e.g., *hello* (English), 你好 (Chinese) and *bonjour* (French) are included in one BabelNet synset. The multilingual synonyms in a synset convey the same meaning and should have the same sememe annotations. Therefore, they propose the task of sememe prediction for BabelNet synsets, hoping that if all synsets are annotated with sememes, all words in over 200 languages in BabelNet would obtain sememe annotations. Moreover, the sememe annotations are independently annotated to senses, because a synset corresponds to a sense. Following Qi et al. (2020), Qi et al. (2022) further utilize multilingual and multimodal information in BabelNet to improve the performance of sememe prediction for BabelNet synsets.

In addition, Qi et al. (2021a) make an attempt to construct an SKB based on a dictionary fully automatically. They regard the words in the controlled defining vocabulary of a dictionary as sememes rather than use the existing sememe set of HowNet.

Although achieving satisfactory sememe prediction results, all these studies ignore the hierarchical structures of sememes. This work is the first attempt to conduct structured sememe prediction.

2.2 Tree Generation

Structured sememe prediction is a kind of tree generation task. Some tree generation tasks have been widely explored, such as code generation (rab; Yin and Neubig, 2017; Sun et al., 2020; Nguyen et al., 2019), semantic parsing (Shiv and Quirk, 2019; Li et al., 2020) and math word problem solving (Liu et al., 2019; Zhang et al., 2020a; Wu et al., 2021). However, as explained in §1, sememe tree generation is more challenging than these tasks because of its large size of node types and a vast variety of structures.

Quite a few tree generation studies use the sequence modeling models represented by recurrent neural networks, especially LSTM (Hochreiter and Schmidhuber, 1997), and achieve great performance (Zaremba and Sutskever, 2014; Allamanis et al., 2016). Recently, with the widespread use of Transformer in sequence modeling, some studies have shown that Transformer-based models also perform well on tree generation and are more parallelizable to deal a large amount of data (Shiv and Quirk, 2019; Nguyen et al., 2019; Zugner et al., 2021). Therefore, we also design our sememe tree generation model based on Transformer.

3 Methodology

In this section, we first detail two straightforward sememe tree generation (STG) models, which will serve as the baselines. Then, we describe the modification of tree attention and introduce a novel STG model.

3.1 Neighbor-based STG (NSTG)

A sememe tree can be divided into multiple sememe paths from the root node to leaf nodes. Assuming different sememe paths are independent, the probability of generating a sememe tree can be formalized as:

$$P(T|w) = \prod_{S \in T} P(S|w), \tag{1}$$

where T refers to the sememe tree of the synset w, and S denotes a sememe path in T.

Using the multiplicative theorem of probability, the probability of each sememe path is formalized as:

$$P(S|w) = \prod_{i=1}^{N_S} P(s_i|w, S_{0:i-1}), \tag{2}$$

where N_s is the length of S, s_i is the $i-th$ sememe of S, and $S_{0:i-1}$ refers to the previous path from the beginning token `START` to the $(i-1)$-th sememe of S, where `START` is added as the root node of a sememe tree.

With the Markov assumption, we further decompose a sememe path into parent-child sememe pairs. Generating a child sememe based on a father sememe is the atomic step of generating a sememe path:

$$P(S) = \prod_{i=1}^{N_S} P(s_i|w, s_{i-1}), \tag{3}$$

Inspired by Xie et al. (2017), we assume that similar words should share similar sememe tree structures and we can apply collaborative filtering (Xie et al., 2017) to the STG task and propose the Neighbor-based STG (NSTG) model.

Specifically, for each sememe pair $e_i = (s_{i-1}, s_i)$, the non-normalized generation proba-

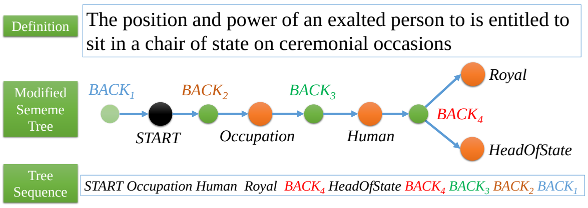

Figure 2: Definition and sememe tree sequence of "bn:00077087n" in BabalNet

bility can be approximated as:

$$\hat{P}(s_i|w, s_{i-1}) = \sum_{w_j} sim(w_j, w) \times M_{j,e_i} \times d^{r_i}, \tag{4}$$

where $sim(w_j, w)$ measures the similarity between two words (senses), based on the embeddings of the two words' definitions from BERT (Devlin et al., 2019). M_{j,e_i} indicates whether the synset w_j possesses the sememe pair e_i. r_j is the descending rank of the similarity. $d \in (0, 1)$ is a hyper-parameter, which can be viewed as the declined confidence factor that helps the model concentrate on the most similar words. We use sigmoid as the normalization strategy.

We also adopt the beam search algorithm to generate sememe paths. The key point in beam search is to design a well-performed generation function at each search step.

3.2 Transformer-based STG (TSTG)

NSTG model is simple and efficient because it does not require extra training. Nevertheless, the generalization ability of NSTG is limited to the representative ability of sentence encoding. And it fails to utilize the sequential information in the generated sememe paths, which are of critical importance in the STG task. To address this issue, we can follow previous tree generation studies and use a Transformer model to learn and decode hierarchical sememe structures. This method is named Transformer-based STG (TSTG).

The normal Transformer architecture accepts sequential inputs. Therefore, we need to convert trees into sequences. We linearize sememe trees by the pre-order depth-first traversal. However, the count of branches of a node is not certain in STG, so we use a special `BACK` token to represent the back and eventually get a one-to-one mapping from sememe tree to sememe tree sequence. An example of the sememe tree sequence is shown in Figure 2.

We decompose the step of STG into repeatedly sememe generation and `BACK` token generation, ending with the depth going back to 0.

3.3 Tree-attention Transformer Model (TaSTG)

The above method enables transformer architecture to generate trees. However, it suffers some problems.

Problems of Attention Computation

Normal attention in Transformer is formalized as:

$$\alpha_{ij} = \frac{\left((\boldsymbol{w}_i + \boldsymbol{p}_i)W^Q\right)\left((\boldsymbol{w}_j + \boldsymbol{p}_j)W^K\right)^T}{\sqrt{d}}, \tag{5}$$

where $\boldsymbol{w}_i, \boldsymbol{w}_j$ refer to node embeddings, and bmp_i, bmp_j refer to positional embeddings. α_{ij} is the attention score of the i-th and j-th nodes.

Absolute positional embedding is tied with node embedding in the normal transformer. However, for the exact position i and j, there is little evidence that the node and where it appears in a sequence has a strong correlation. This randomness may cause noise in attention computation, especially for tree-structured data. One position has two neighbors in a sequence, but it is not true in a tree. As in the example in Figure 2, the topological relations of nodes (Human, Royal) and nodes (Human, HeadOfState) are considered to be the same. However, the distance in the sequence representation of them is 3 and 1, which differs a lot.

To better capture the structure of tree data, we think attention should satisfy the following three requirements: (1) topologically neighbored nodes' attention should be high; (2) semantically similar nodes' attention should be high; (3) some sub-trees of brother nodes can convert symmetrically in STG tasks.

Our Modification

Inspired by Ke et al. (2020), we untie the correlations between positions and words. We divide the computation of attention into two parts: semantic attention and positional attention. (1) **Semantic attention** captures the semantic similarity of twos nodes in the tree, and the computation is the same as normal attention. (2) **Positional attention** is specially designed to capture the topological relations of nodes in the tree.

Correspondingly, we design a new self attention computation method for tree structure as follows:

$$\alpha_{ij} = \frac{\boldsymbol{s}_i \cdot \boldsymbol{s}_j + \boldsymbol{p}_i \cdot \boldsymbol{p}_j}{\sqrt{2d}} + \boldsymbol{b}_{\boldsymbol{i},\boldsymbol{j}}, \tag{6}$$

where $\boldsymbol{s}_i, \boldsymbol{s}_j$ refers to the node encoding, $\boldsymbol{p}_i, \boldsymbol{p}_j$ refers to the positional encoding of i and j, and $\boldsymbol{b}_{i,j}$ refers to the distance encoding of i and j. $\frac{1}{\sqrt{2d}}$ is used to retain the scale of attention score.

For tree position, we define Depth embedding as learnable parameters to capture features of tree input. Simultaneously, we define Distance embedding as learnable parameters as the bias in position attention. Attention is considered to be higher when depths are closer and distance is smaller.

For the multi-head version, Depth embedding and Distance embedding are different in all the heads. And for efficiency, we share the Depth embedding and Distance embedding in all the layers, so we only need to compute position attention in the first layer and reuse it in other layers. The function can be quickly computed by:

$$attn = (\frac{A_Q * A_K^T}{\sqrt{2d}} + \frac{P_Q * P_K^T}{\sqrt{2d}} + B)A_V, \tag{7}$$

where B is formalized as the distance metric of all the nodes in the tree. With the help of `BACK`, we can compute the B in $O(n^2)$ times with a stack-based algorithm.

`BACK` token is special in tree sequence because it has the same number as other nodes and distributes randomly in all the depths. To overcome the imbalance of nodes, we specially add the `BACK` token in odd depth between two sememe nodes, while sememe nodes are in even depth. We will further discuss the efficiency of Tree-attention in §5.1.

The transformer decoder layer is composed of three sub-layers. We adopt Tree-attention in the self-attention sub-layer. For the sub-layer to perform multi-head attention over the output of the encoder stack, we use normal attention because it is hard to capture the attention between tree nodes and sequence reasonably, we leave it for future work.

4 Experiments

4.1 Dataset

HowNet provides no definitions for words, and using an external dictionary requires special efforts to conduct a sense-level alignment with HowNet. In this paper, we resort to the BabelSememe dataset, which is built by Qi et al. (2020). A BabelNet synset corresponds to a sense of a word and includes definitions from other sources like WordNet (Miller, 1998), and some BabelNet synsets are manually aligned with senses of words in HowNet. One example is Figure 2.

Since there is no other attempt aligned with sense-level definitions and sememe trees, we finally use BabelNet as the only dataset. In other words, we try to predict sememes for BabelNet synsets given their definitions. There are 34,964/3,228/3,228 synsets with definitions in the training/validation/test sets.

4.2 Experimental and Parameter Settings

For NSTG, we use sentence-BERT (Reimers et al., 2019) to encode definitions and compute similarity. The embedding dimension is 768. For hyper-parameters, we set the beam size in beam search to 50 and select the top 10 candidates for merging. We set the declined confidence factor base d to 0.9 empirically.

For TSTG and TaSTG, we use the base version of BERT as the encoder, and the dimension of word embeddings is 768. We use sememe embedding pre-trained by SPSE (Xie et al., 2017), and the dimension is 200. We train an 8-layer, 8-head transformer decoder, and the learning rate is set to 10^{-5}. To avoid duplicate prediction, we only choose the valid sememes that have not been predicted. We also use beam search during the prediction.

4.3 Baselines

We use NSTG and TSTG as the baseline. We ablate our TsSTG to understand the efficiency of the modification of the decoder. First, we remove bias and build up the TaSTB-B model, which has almost the same parameters as TaSTG. To understand the compute of depth encoding, we also convert the relative position of tree node i from the depth of i to the traversal order of i, and build up the TaSTB-D model.

4.4 Evaluation Protocol

We use the following metrics for STG:

BLEU Since the generated tree sequence is short, and higher order n-grams may not overlap, we use smoothed BLEU-4 score (Lin and Och, 2004), following Feng et al. (2020).

Strict-F1 To measure the structural similarity of the sememe tree T and predicted tree T', we define the Strict-F1 metric as follows:

Method	BLEU	Strict	Edge	Vertex
NSTG	10.7	25.6	27.5	33.9
TSTG	15.5	35.6	37.2	45.0
TaSTG	**17.0**	**39.7**	**41.2**	**48.2**
TaSTG-D	14.9	37.5	39.0	45.9
TaSTG-B	15.1	39.1	40.5	47.4

Table 1: Result of different models.

1. Start from the roots of T and T' and put them into the current node sets O and O'. The intersection list U is empty.
2. Get the intersections U_i for the children of both O and O' in layer i. Add U_i to U, and then update both O and O' with their children until reaching the deepest leaves.
3. For precision (P), recall (R) and F1 score $F1$, we define $P = \frac{\text{Size}(U)}{\text{Size}(T')}, R = \frac{\text{Size}(U)}{\text{Size}(T)}, F1 = \frac{2 \times P \times R}{P+R}$.

The Strict-F1 metric is challenging because it supposes that if the predicted parent sememe node is incorrect, all its corresponding children sememes are not considered.

Edge, Vertex Inspired by the classical evaluation metrics in structure learning tasks such as taxonomy induction (Bordea et al., 2016), we also use the Edge and Vertex metrics. The former evaluates the precision, recall, and F1-score after breaking down trees into edges, while the latter computes the non-hierarchical prediction result after breaking down trees into nodes.

4.5 Main Results

The experimental results for all the models are shown in Table 1, from which we observe that:

(1) TaSTG model reaches the highest F1 score, which indicates that Tree-attention works more conservatively than the other models. All transformer-based models significantly outperform the NSTG model, which is mainly because NSTG merely makes predictions based on similar synsets and existing sememe pairs, while 11.5% synsets in the test set have unseen sememe pairs, which are hard for NSTG to predict.

(2) Removing the Distance embedding and converting the Depth embedding to Forward embedding both result in a negative impact on the model's performance. This suggests that in tree-structured input, it's more important to focus on topologically similar nodes. And the gain of Depth embedding is much more than that of Distance embedding, which might be because the number of learnable parameters for tree structure in Depth embedding is much more.

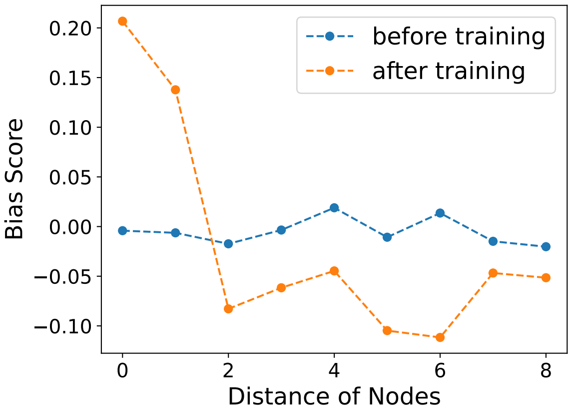

Figure 3: The average score of Distance Embedding of different heads.

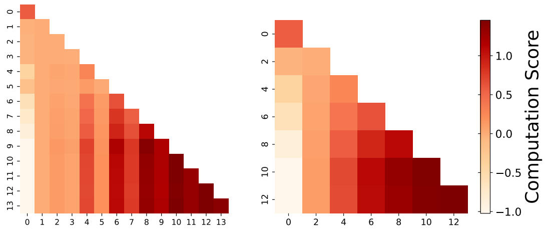


(a) heat with `BACK` token (b) heat without `BACK` token

Figure 4: Visualization of computation results of different Depth embedding.

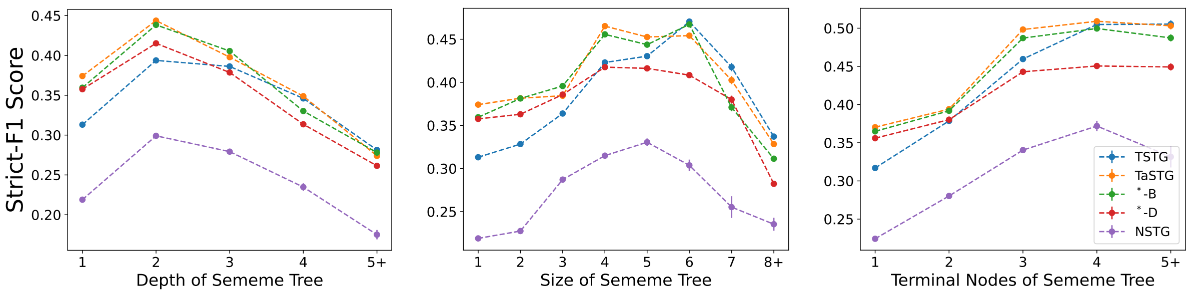
(3) Differences between the BLEU are smaller than those of F1, which indicates that the BLEU score may not capture the hierarchical similarity between the output tree and the answer.

5 Analysis

In this part, we further discussed the efficiency of positional attention and analyzed the performance of our model in different tree complexity, and make a case analysis of our models.

5.1 Hierarchical Feature Capture

In this section, we study whether Tree-attention learns hierarchical structures. And we analyze the performance of Positional attention in structure reconstructing.



(a) change over depth

(b) change over size

(c) change over the number of terminal nodes

Figure 5: Test results over the complexity of trees. Confidence intervals shown in the figures are estimated with a confidence level of 95%.

Visualization of Positional Attention

Considering that the most straightforward way of interpreting the hierarchical features is to visualize the attention scores, we plot the heat-map of our Positional attention result.

The average scores of Distance embedding of different heads are shown in Figure 3. We can explicitly see that when the distance is small, the Positional attention bias is high, which indicates that our Distance embedding mainly focuses on topologically similar nodes. The bias is lower when distance is 2, we guess this is used to eliminate the influence of brother nodes, in which depths are the same and the Depth encoding score is high.

Then we visualize the Depth embedding computation result of different depths, the result is shown in Figure 4. Knowing that we define `BACK` token in odd depth and sememe node in even depth, we plot the score with and without `BACK` token. From the result, we can see that:

(1) The result in the deeper layer tends to be high, which means when generating atomic steps, models focus more on longer tree paths, this may be because different sememe paths indicate different dimensions of senses, and during generating a new path, models need to avoid the existing paths.

(2) In Figure 4(a), scores of depth-0 are much lower than others. It is because depth-0 represents `START`, which is noise when generating other nodes. Likely, `BACK` token in even columns retains a lower score. Our model captures this feature and focuses more on meaningful nodes.

(3) For a row in Figure 4(b) $(i < j)$, the score is higher when the depth is closer; and for a column$(i > j)$, the score is higher when the depth is far, which indicates that during generation, our models focus more on succeeds, and focus more on closer ancestors.

Method	BLEU	Strict	Edge	Vertex
NSTG	23.9	44.3	46.9	65.4
TSTG	**38.2**	69.7	71.9	**82.6**
TaSTG	35.9	**70.3**	**72.5**	82.1
TaSTG-D	32.1	67.6	70.3	81.0
TaSTG-B	33.8	69.5	72.4	82.0

Table 2: The Restricted evaluation result of different models.

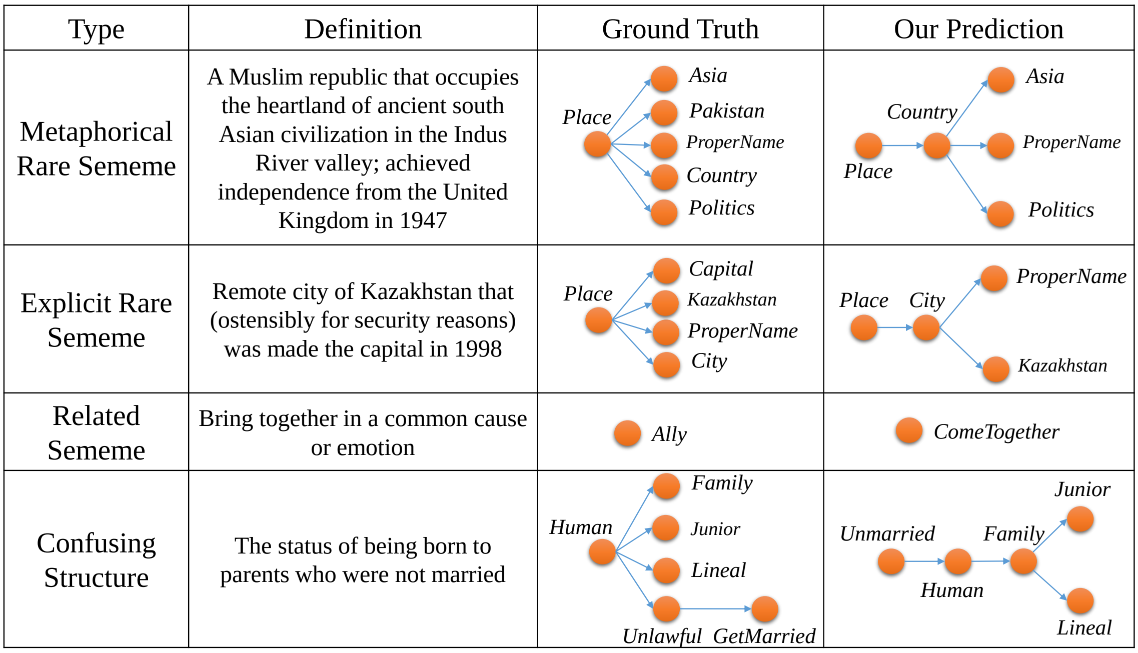
From the visualize, we can directly see that our model successfully captures the hierarchical feature of tree-structured input by using Depth embedding and Distance embedding.

Structure Reconstruction Ability

To better measure the ability of models to capture hierarchical information, we design a Restricted evaluation, during which we provide correct sememes without structures for our models and ask the models to predict structures for the input sememes. This evaluation focuses on evaluating the structure organization ability of our models in STG. Especially, We ignore the synset who have sememe tree of size 1 in Restricted evaluation, because this has no structural information. Results are demonstrated in Table 2, from which we can observe that:

(1) All the models achieve significant improvement over the results in Table 1. It indicates that the major challenge for the STG task comes from selecting appropriate candidate sememes at each level.

(2) NSTG model shares the lowest gain because it tends to give a relatively conservative prediction, resulting in the lowest Recall score (36.6 in the restricted test compared with 53.3 of TaSTG). In



Type	Definition	Ground Truth	Our Prediction
Metaphorical Rare Sememe	A Muslim republic that occupies the heartland of ancient south Asian civilization in the Indus River valley; achieved independence from the United Kingdom in 1947	Place Asia Pakistan ProperName Country Politics	Country Place Asia ProperName Politics
Explicit Rare Sememe	Remote city of Kazakhstan that (ostensibly for security reasons) was made the capital in 1998	Place Capital Kazakhstan ProperName City	Place City ProperName Kazakhstan
Related Sememe	Bring together in a common cause or emotion	Ally	ComeTogether
Confusing Structure	The status of being born to parents who were not married	Human Family Junior Lineal Unlawful GetMarried	Unmarried Human Family Junior Lineal

Figure 6: Some representative cases of STG.

the contrast, the Base transformer model generates big trees (18% larger than TaSTG) and gets a higher Recall score in the restricted test, gaining most improvements in the restricted test, performing similarly with TaSTG.

However, our STG models' performances are far from perfect, which implies that understanding sememe tree structures is still challenging.

5.2 Sememe Tree Complexity (STC) Analysis

In order to further investigate our models under different scenarios and get a deeper understanding of STG tasks, we further conduct three auxiliary experiments over different levels of sememe tree complexity (STC). Here we define the STC as the annotated sememe number of target words, depth of target tree, and number of terminal nodes in a tree. We conduct these experiments with Strict-F1 on Open evaluation due to limited space. We combine results of words that have more than 8 sememes, which is deeper than 6, or which have more than 5 terminal nodes since there are less than 1%. From the result, we can see that:

In Figure 5(a),Figure 5(b), we can see that prediction performance first increases and then drops with the growth of tree size and depth, which indicates that the STG task is difficult both when there are too few or many sememes in synset. This is in compliance with previous work Qi et al. (2020).

Since the big size and high depth of a tree may not absolutely represent high complexity, we also implement the performance of models with the number of terminal nodes, et tree paths, the result are shown in Figure 5(c).

(1) With the help of Depth embedding and Distance embedding, TaSTG reaches the highest score in all the cases. And base transformer model performs worse when there are fewer tree paths.

(2) Due to the number of learnable parameters of structure capture, TaSTG-B performs much better than TaSTG-D. And the gain of Distance embedding and Depth embedding is huge when there are more tree paths. This is because Distance embedding distinguishes nodes from different tree paths.

5.3 Case Study

To show the insights and challenges intuitively, we give some representative cases in Table 6 and make a qualitative case analysis of our model.

(1) Rare Sememe: Some predictions include very rare sememes. This kind of case challenges our model to get the meaning of sememe from a few train data. Our model successfully captures rare information from definition when it appears. For Example, our model learns the connection with sememe "Kazakhstan" and the word "Kazakhstan", because it appears a few times in the train set. However, in some predictions, definitions don't directly imply the meanings of some sememes, and it's difficult for our model to make such predictions without extra training data. For example, our model cannot predict “Pakistan” from the definition. This kind

of case challenges models on learning sememe definitions, but it is not contained in our train set.

(2) Related Sememe: The most common error type is Related Sememes (e.g., predicting "Come-Together" while the correct sememe is "Ally"). It implies that learning BabelNet's annotation preferences to distinguish related sememes that only have minor differences is still challenging for current STG models.

(3) Confusing Structure: Some definitions of synsets have rich meaning. For example, our model predicts correct sememes for “premarital pregnancy” but the incorrect structure, which shows the challenge of predicting correct structures. However, tackling the confusing structure of sememes is a difficult problem even for human experts.

6 Conclusion and Future Work

In this paper, we handle the structured sememe prediction task for the first time. We propose a Transformer-based tree generation model by adapting the attention mechanism to trees. Experimental results show that our model outperforms baselines including the general tree Transformer. We also conduct extensive experiments and detailed analyses to demonstrate the different properties of our models and the challenges of the task.

We will explore the following research directions in the future: (1) We will better measure the semantic similarity of tree nodes. In this paper, the Strict-F1 score only focuses on the structure and ignores the semantic similarity of generated sememe pairs with the answer. (2) We will further explore to import the tree-attention mechanism in all sublayers of the decoder and figure out the influence. (3) We will try to combine our method with other sememe-based applications and further analyze the influence of the structure information of sememes.

Abstract

The table-based fact verification task has recently gained widespread attention and yet remains to be a very challenging problem. It inherently requires informative reasoning over natural language together with different numerical and logical reasoning on tables (e.g., count, superlative, comparative). Considering that, we exploit mixture-of-experts and present in this paper a new method: **S**elf-**a**daptive **M**ixture-**o**f-**E**xperts Network (**SaMoE**). Specifically, we have developed a mixture-of-experts neural network to recognize and execute different types of reasoning—the network is composed of multiple experts, each handling a specific part of the semantics for reasoning, whereas a management module is applied to decide the contribution of each expert network to the verification result. A self-adaptive method is developed to teach the management module combining results of different experts more efficiently without external knowledge. The experimental results illustrate that our framework achieves **85.1%** accuracy on the benchmark dataset TABFACT, comparable with the previous state-of-the-art models. We hope our framework can serve as a new baseline for table-based verification. Our code is available at `https://github.com/THUMLP/SaMoE`.

1 Introduction

Fact Verification, aiming to determine the consistency between a statement and given evidence, has become a crucial part of various applications such as fake news detection, rumor detection (Rashkin et al., 2017; Thorne et al., 2018; Goodrich et al., 2019; Vaibhav et al., 2019; Kryscinski et al., 2020). While most existing research focuses on verification based on unstructured text, a new trend is extending the scope to structured evidence (e.g., tables), which is informative and ubiquitous in our daily lives. Table-based verification faces different challenges than unstructured-text-based due to the complexity of the requirements, including sophisticated textual, numerical, and logical reasoning across evidence tables; even for some statements, multiple types of reasoning are indispensable to complete the verification. An example is presented in Figure 1.

rank	player	country	earnings	wins
1	don january	united states	1338791	21
2	miller barber	united states	1166970	18
3	peter thomson	australia	838535	11
4	gene littler	united states	749216	5
5	lee elder	united states	720164	7

Statement The player with rank 5 have least earnings.
Label ENTAILED

Figure 1: An Example of table-based fact verification.

To tackle the challenges above, previous work established two kinds of methods: (1) *program-enhanced methods* (Chen et al., 2020; Zhong et al., 2020; Shi et al., 2020; Yang et al., 2020) and (2) *table-based pre-trained models* (Eisenschlos et al., 2020; Liu et al., 2021). The program-enhanced methods mainly leverage programs generated by the semantic parser. Specifically, statements are parsed into executable programs to extract the logical/numerical semantics, which is further be leveraged together with contextual semantics learned by a language model (e.g., BERT) in inference. However, the semantic parsers that generate semantic-consistent programs must be trained in a weak supervision setting, which brings difficulties in training. Furthermore, generalizing this method to other datasets is almost impossible without the API set modification according to the reasoning requirements on the new datasets.

The table-based pre-trained models leverage elaborate model structure (Herzig et al., 2020) and pre-training tasks (Eisenschlos et al., 2020; Liu et al., 2021) to enhance the reasoning skills on structured data. Nevertheless, two significant shortcomings remain. Firstly, the process is demanding due

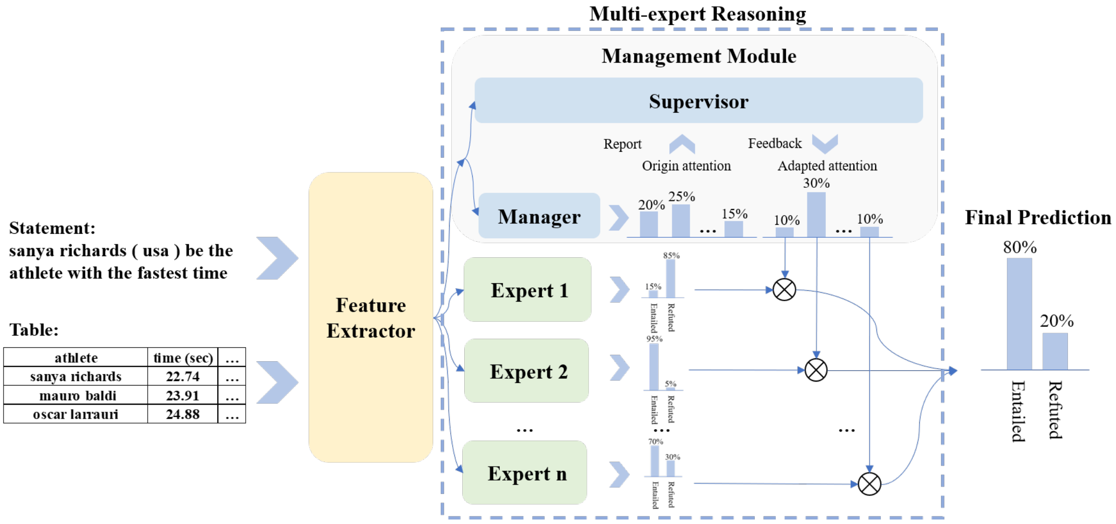

Figure 2: An overview of **S**elf-**a**daptive **M**ixture-**o**f-**E**xperts Network (**SaMoE**) for table-based fact verification.

to the tremendous computing resources required by pre-training. Moreover, the effectiveness of pre-training to its downstream tasks mainly depends on the adaptability between these two tasks. Therefore, implementing pre-training tasks may fail to meet the requirements when facing the unseen reasoning types demanded by new datasets.

In this paper, we introduce an innovative framework, **S**elf-**a**daptive **M**ixture **of** **E**xperts (SaMoE), to address the previously mentioned problems. The entire framework is illustrated in Figure 2. SaMoE consists of 3 components: **feature extractor**, **experts**, and **management module**, which is the combination of **manager** and **supervisor** networks. Each expert initially takes the same feature as input and then learns to deal with different parts of the reasoning types (e.g., contextual/logical/numerical) required by table-based verification. A management module is designed to guide the training of experts and combine experts' verification results effectively. The manager network in this module assigns each expert a unique attention score, allowing each individual to focus on different kinds of reasoning types and summarizes experts' entire outputs as the final verification result. However, managers failed to allocate the highest attention score to the expert who performs best on the current reasoning type in most circumstances. To alleviate this problem, we introduce a supervisor network to adjust the attention score given by the manager. The supervisor network is trained **self-adaptively** (i.e., it learns directly from experts' performance on the train set) without prior knowledge of the task or dataset. Extensive experiments are conducted to show that our proposed framework, implemented with a general pre-trained language model RoBERTa (Liu et al., 2019), outperforms previous state-of-the-art methods, including table-based pre-trained models. The main contributions of this work are as follows:

- We innovatively implement mixture-of-experts for table-based verification, aiming to arrange each expert to different types of reasoning. This method can also be easily generalized to other datasets.
- We investigate a self-adaptive method to adjust suitable attention score to each expert according to its performance on different reasoning types, achieving more efficient cooperation across experts.
- Our framework achieves better performance on the TABFACT dataset without the assistance of table-based pre-trained models.

2 Research Question

The table-based verification task expects one to determine whether a statement S is entailed or refuted by an evidence table T. The process above can be regarded as a binary classification task and thus denoted as $f(S, T) = \hat{y}$, where f is the verification model and $\hat{y} \in \{0, 1\}$ its prediction.

3 Methods

We present the proposed framework (SaMoE), which leverages a set of experts to deal with different parts of the reasoning types involved in table-based verification. This section is organized as follows. Sec.3.1 introduces the feature extractor that extracts the joint semantics of the table-statement pair. Sec.3.2 describes experts that verify the statements separately based on the same extracted semantics. Sec.3.3 describes the management module that guides the experts' training and combines their verification results effectively; two components of this module, the manager and the supervisor, are introduced in this section individually.

3.1 Feature Extractor

Feature extractor parses the statement-table pair and learns the joint table-statement semantics. Tables are initially pruned and serialized into a sequence. Subsequently, the serialized tables are transmitted into the language model together with the statements for joint representation learning. These two processes will be further interpreted in the following subsections.

3.1.1 Table Pre-processing

As for Tables, the pre-processing (pruning and serializing) before the joint representation learning provides convenience for subsequent processing of the existing language model.

Table Pruning Table pruning discards some parts of the table that do not participate in the verification, according to the input size limit of the language model. We take advantage of the table-pruning algorithm proposed in Chen et al. (2020) and further enhance its performance. The original algorithm matches the entities in statements with cells in tables by a heuristic method and selects the columns that include matched cells to form the pruned table. Noticed that the algorithm always fails to select the critical columns of verification while there is still room left for the input sequence of the language model, we further add a greedy strategy on the algorithm that keeps adding columns that are not selected to the pruned table until reaching the maximum input size of the downstream model to make the best use of its capacity.

Table Serializing Tables are further serialized to a 1-D sequence after pruning to be compatible with the input format of the language model. We follow the serializing method used in TABLE-BERT (Chen et al., 2020) that paraphrases tables with a natural language template. Specifically, a table with m rows and n columns is paraphrased as "row 1 is: h_1 is T_{11}; ... ; h_n is T_{1n}. row 2 is: ... row m is: h_1 is T_{m1}; ... ; h_n is T_{mn}.", where h_i refers the i^{th} header and T_{ij} the value in the $(i,j)-th$ cell of table T. We find that such template-serialized tables are more suitable for language models pre-trained on unstructured text to process.

3.1.2 Joint Representation Learning

After the table pre-processing, the serialized table and the statement are further passed to a language model to learn the joint contextual representation of each token. The learned representation vectors are then transmitted to the experts and the management module for inference and management. Specifically, the serialized table and the statement are initially tokenized into two token sequences $\tilde{\mathbf{T}}$ and $\mathbf{S}$. Then the joint token sequence $\mathbf{X}$ is formed as $\mathbf{X} = [\langle s\rangle, \mathbf{S}, \langle/s\rangle, \tilde{\mathbf{T}}, \langle/s\rangle]$, where $\langle s\rangle$ and $\langle/s\rangle$ are the separators that identify the beginning and the end of each token sequence. The token sequence $\mathbf{X}$ will be padded or truncated to fit the maximum input length of the language model. Finally, a transformer model is applied to learn the contextual representation of $\mathbf{X}$:

$$\mathbf{H} = f_{LM}(\mathbf{X}) \tag{1}$$

where $\mathbf{H} \in \mathbb{R}^{n\times d}$ refers to the learned joint representation, n is the maximum input length and d the dimension of the representation vector. f_{LM} denotes the contextual representation learning process of the language model. In this paper, we implement it with *transformer* (Vaswani et al., 2017), the most popular contextual representation model in recent years.

3.2 Experts

A group of experts is applied to verify the statements separately based on the same statement-table joint semantics extracted by the feature extractor module. Experts share the same model structure, while the parameter learning strategy of SaMoE gives expert differentiation. Specifically, each expert is implemented with a stack of transformer encoding layers. An MLP classifier that calculates the probability of the statement is entailed by the evidence table based on the encoded semantics. We implement experts with the same general structure rather than different structures specially designed for certain reasoning types since we anticipate that the proposed framework can be smoothly generalized to other datasets. The process above can be formulated as follows:

$$\mathbf{h}_i = f_{Enc_i}(\mathbf{H}) \tag{2}$$

$$\mathbf{p}_i = softmax(tanh(\mathbf{h}_i \mathbf{W}_1^i)\mathbf{W}_2^i) \tag{3}$$

where $\mathbf{h}_i \in \mathbb{R}^d$ is the token $\langle s \rangle$'s final representation vector encoded by the i^{th} expert's encoder Enc_i. It implies the i^{th} expert's whole understanding to the statement-table pair. $\mathbf{W}_1^i \in \mathbb{R}^{d \times d}$ and $\mathbf{W}_2^i \in \mathbb{R}^{d \times 2}$ are the trainable parameters of i^{th} expert's classifier, which projects $\mathbf{h}_i$ to the probabilities $\mathbf{p}_i \in \mathbb{R}^2$ that the statement is entailed/refuted by the table. $tanh$ and $softmax$ are activation functions. n_e refers to the number of experts.

3.3 Management Module

Learning the joint semantics parsed in Sec.3.1, the management module intends to generate attention scores to bias experts' training and combine experts' results efficiently. The module consists of two components: manager and supervisor, both of them are implemented based on *transformer* model. The manager is mainly designed to guide experts' training, while the supervisor is applied to combine experts' results efficiently.

Manager The manager guides the training of experts and forms a preliminary assumption to the expert combination. It encodes the joint representation matrix and generates attention scores $\mathbf{a}_M$ to guide the experts' training process:

$$\mathbf{h}_M = f_{Enc_M}(\mathbf{H}) \tag{4}$$

$$\mathbf{e}_M = tanh(\mathbf{h}_M \mathbf{W}_1^M)\mathbf{W}_2^M \tag{5}$$

$$\mathbf{a}_M = softmax(\mathbf{e}_M) \tag{6}$$

where Enc_M denotes the manager's encoder, $\mathbf{W}_1^M \in \mathbb{R}^{d \times d}$ and $\mathbf{W}_2^M \in \mathbb{R}^{d \times n_e}$ are trainable parameters. The network structures of the manager and experts are basically the same, only different in the layers of the encoder and the output dimension.

After preceding calculation, the normalized attention scores $\mathbf{a}_M$ are used to guide the training of experts by a specially designed verification loss, which will be introduced in Sec.4.1.1.

Supervisor The supervisor adjusts the attention scores submitted by the manager to improve the cooperative efficiency among experts (i.e. assigning higher weights to experts who perform better on the current input pair). The network predicts the deviation between the preliminary assumption (i.e., the attention) and the ideal combination weights based on the knowledge encoded in the joint representation matrix $\mathbf{H}$:

$$\mathbf{h}_S = f_{Enc_S}(\mathbf{H}) \tag{7}$$

$$\mathbf{e}_S = tanh(\mathbf{h}_S \mathbf{W}_1^S)\mathbf{W}_2^S \tag{8}$$

$$\mathbf{a}_S = softmax(\mathbf{e}_M + \mathbf{e}_S) \tag{9}$$

where $\mathbf{W}_1^S \in \mathbb{R}^{d \times d}$, $\mathbf{W}_2^S \in \mathbb{R}^{d \times n_e}$ are trainable parameters and Enc_S refers to the encoder of the supervisor. Parameters of the supervisor are optimized self-adaptively based on experts' performance on the train set. More details of this learning strategy will be presented in Sec.4.2.

4 Parameter Learning

Parameters in SaMoE are learned in two consecutive stages: 1) Multi-expert training: parameters in the feature extractor, experts and the manager are end-to-end optimized under the supervision of labels; 2) Self-adaptive learning: parameters in the supervisor are self-optimized by observing experts' performance on the train set (other parameters are fixed simultaneously). A weighted sum of two losses is minimized in the first stage to achieve diverse and balanced training of experts. For the second stage, we minimize a self-adaptive loss calculated based on the experts' classification loss. Subsequent sections introduce these two learning stages in detail.

4.1 Multi-expert Training

Multi-expert training guides each expert on dealing with different reasoning types while maintaining balanced training across experts. To achieve the goals above, we develop two loss functions: 1) verification loss $\mathcal{L}_V$ that measures the weighted sum of each expert's classification loss, differentiating experts' learning with different attention scores assigned by the manager; 2) manager assumption loss $\mathcal{L}_M$ that is applied to prevent the occurrence of imbalanced training across experts. The overall loss of this state is calculated by a weighted sum of these two terms: $\mathcal{L}_1 = \mathcal{L}_V + \lambda \mathcal{L}_M$, where λ is a hyperparameter that controls the ratio of $\mathcal{L}_M$. Subsequent sections provide detailed introduction to these two terms.

4.1.1 Verification Loss

The verification loss $\mathcal{L}_V$ is designed based on the loss function proposed in Jacobs et al. (1991). It is calculated by the weighted sum of each expert's cross-entropy:

$$\mathcal{L}_V = \sum_{i=1}^{n_e} (\mathbf{a}_M)_i \cdot CE(\mathbf{p}_i, l) \tag{10}$$

where $(\mathbf{a}_M)_i$ is the i^{th} element of the attention scores $\mathbf{a}_M$, $l \in \{0, 1\}$ is the label of the statement-table pair and $CE(\cdot, \cdot)$ the cross-entropy function. Note that it is necessary to calculate each expert's cross-entropy independently. We want each expert to behave like an independent expert (i.e., complete the verification without the help of other experts). The attention vector $\mathbf{a}_M$ acts as a "training scheduler" in this loss function: experts that are assigned with larger attention scores receive a larger gradient than other experts on the current input, resulting in diverse experts' performance.

4.1.2 Manager Assumption Loss

We have trained the MoE with only the verification loss $\mathcal{L}_V$ and observe a severe "imbalanced experts" phenomenon that only one expert is well-trained (i.e., the expert performance is improved by training) and the manager keeps assigning a close-to-1 attention score to this expert, which is also reported in previous research (Eigen et al., 2013; Shazeer et al., 2017). To avoid this problem, we develop another loss function that forces the manager to assign reasonable attention scores to experts:

$$\mathcal{L}_M = D(\mathbf{a}_P || \mathbf{a}_M) \tag{11}$$

where $D(\cdot||\cdot)$ denotes the Kullback–Leibler divergence and $\mathbf{a}_P$ a prior assumption that is generated with a simple heuristic algorithm (to be introduced in the next paragraph) which requires limited prior knowledge of the reasoning types. By minimizing $\mathcal{L}_M$, the manager learns to assign each expert with a reasonable attention score, resulting in a balanced training across experts.

Prior Assumption Generation The prior assumption $\mathbf{a}_P$ is generated to represent the probabilities that the statement involves different reasoning types that we are interested in. Specifically, we develop a trigger-word-based heuristic algorithm to form the prior assumption for each statement automatically:

1. Initialize the prior assumption with $\mathbf{e}_0 \in \mathbb{R}^{n_e}$, which is empirically set as $(0.1, 0.1, ..., 0.6)^T$. The $(\mathbf{e}_0)_{n_e}$ represents the probability that the statement does not involve any predefined reasoning types and thus is set higher than other values in advance.

2. Traverse the trigger-word set[1] of each reasoning type ($n_e - 1$ types in total). If a trigger word/pattern w that belongs to i^{th} reasoning type is detected in the statement, the trigger's weight s_w (set empirically) is accumulated to the i^{th} dimension of a zero-initialized bias vector $\delta \in \mathbb{R}^{n_e}$: $\delta_i \leftarrow \delta_i + s_w$.

3. Add the bias vector δ to the prior assumption $\mathbf{e}_0$ and normalize to get the prior assumption: $\mathbf{a}_P = softmax(\mathbf{e}_0 + \delta)$.

Figure 3 presents an example of this process. Learning to imitate the prior assumption, the manager guides each expert to focus on different reasoning types and thus achieves diverse experts. We implement a relatively small trigger-word pool in experiments and find the method works effectively, indicating that the method can be smoothly generalized to other datasets with little modification to the predefined reasoning types and trigger-word pool.

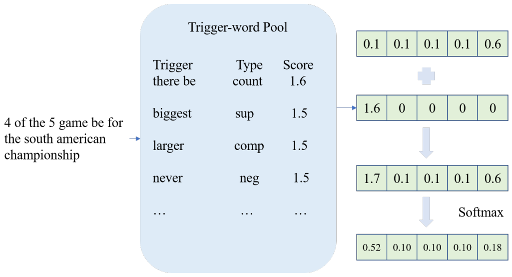

Figure 3: An example of prior assumption generation with $n_e = 5$ and 4 predefined reasoning types.

4.2 Self-adaptive Learning

Self-adaptive learning aims to enhance further the expert combining efficiency with only the knowledge of the expert's performance on the train set. Specifically, an "expert ability" vector $\mathbf{a}_E \in \mathbb{R}^{n_e}$ is calculated based on the "expert loss" vector $\mathbf{m} \in \mathbb{R}^{n_e}$, where $\mathbf{m}_i = CE(\mathbf{p}_i, l)$ is the cross-entropy loss of the i^{th} expert. Note that the cross-entropy of the expert is negatively correlated with its performance. Then the expert ability vector $\mathbf{a}_E$ is calculated as follows:

$$\mathbf{a}_E = softmax(-\alpha \cdot \mathbf{m}) \tag{12}$$

---

[1] a set of words that suggest a specific reasoning type, see Appendix C for more information.

where $\alpha = \sqrt{\beta / Var(\mathbf{m})}$ is a variance-normalizing coefficient and β is a hyperparameter that decides the variance of the expert ability vector before the activation (i.e., $Var(-\alpha \cdot \mathbf{m}) = \beta$). Such normalization is designed based on the observation that **m** tends to have a extreme small variance and $softmax(-\mathbf{m})$ often generates a close-to-uniform distribution. Note that the generated $\mathbf{a}_E$ is positively correlated with the experts' performance (e.g., if the i^{th} expert outperforms the j^{th} expert on the input pair then we have $(\mathbf{a}_E)_i > (\mathbf{a}_E)_j$).

Based on $\mathbf{a}_E$, we develop the loss function that has the same form with $\mathcal{L}_M$ in Sec 4.1.2:

$$\mathcal{L}_S = D(\mathbf{a}_E || \mathbf{a}_S) \tag{13}$$

By minimizing the loss above, the higher attention scores are assigned to the best-performed experts after the supervisor's adjustment, resulting in more efficient cooperation across experts.

5 Experiment Setup

5.1 Data and Metric

We conduct the experiments on TABFACT, a large scale benchmark dataset of the table-based fact verification task[2]. TABFACT contains a total of 117k statements and 16k Wikipedia tables. The test set is further divided into a simple and complex subset based on verification difficulty, for verifying some statements on TABFACT requires more logical/numerical reasoning skills. We choose accuracy as the evaluation metric following the existing work to make our experiment results comparable. More details of TABFACT are presented in Appendix A.

5.2 Implementation Details

Training Details We set $n_e = 5$ expert networks in our implementation of SaMoE. The transformer layers are 12 for encoders in the feature extractor and experts and 2 for encoders in the manager and supervisor. The hidden states' dimension d, the maximum input length n, the λ in Sec.4.1, and the β in Sec.4.2 are set to 1024, 512, 0.1 and 0.1 respectively. We applied RoBERTa-Large (Liu et al., 2019) to initialize the feature extractor and experts in our framework. The details of parameter initialization can be found in Appendix B.

We apply Adam optimizer (Kingma and Ba, 2015) in training with learning rate 2e-5, dropout rate 0.1, warmup step 17,304, and batch size 32. SaMoE is first trained in the Multi-expert training stage for 57,680 steps (20 epochs). Then the supervisor is trained in the self-adaptive learning stage for another 5,000 steps, while the best parameters of other parts in the framework are loaded and fixed. The model is evaluated every 1000 steps, and the model that achieves the highest performance on the development set is saved. All the codes are implemented with Pytorch (Paszke et al., 2019) and the transformers package (Wolf et al., 2020). We train all our models on a single GeForce RTX 3090.

Settings of Prior Assumption We choose the top 4 types of reasoning types that appear most frequently in TABFACT[3] (count, comparative, superlative, negation). We apply a small trigger-word pool containing only 26 trigger words, injecting limited prior knowledge of the dataset. More details of this part are presented in Appendix C.

5.3 Baselines

We compared our proposed framework with different kinds of baselines on TABFACT: (1) Program-enhanced methods: LPA (Chen et al., 2020), LogicalFactChecker (Zhong et al., 2020), HeterTFV (Shi et al., 2020), ProgVGAT (Yang et al., 2020) and Decomp (Yang and Zhu, 2021); (2) Table-based pre-trained models: TAPAS (Eisenschlos et al., 2020) and TAPEX (Liu et al., 2021); (3) Other methods: Table-BERT (Chen et al., 2020) and SAT (Zhang et al., 2020).

6 Results

6.1 Overall Performance

We compare the proposed SaMoE with different kinds of baselines, and the results are listed in Table 1. Baselines are presented with the best performance reported in the corresponding papers. SaMoE obtains an accuracy of **85.1%** on the test set, achieving a new state-of-the-art on the dataset. Results show that our method consistently outperforms all the program-enhanced methods with a significant **2.4%** improvement compared with the Decomp method (the best performed program-enhanced method). Note that SaMoE performs similar with Decomp-LARGE on the simple subset

---

[2] We did not conduct experiments on other datasets such as SEM-TAB-FACTS (Wang et al., 2021) and InfoTabs (Gupta et al., 2020), since there is little work and comparisons have been made on these datasets.

[3] We follow the statistics in Chen et al. (2020) for the frequency of different reasoning types.

Model	Val	Test	Test$_{simple}$	Test$_{complex}$	Small Test
TABLE-BERT	66.1	65.1	79.1	58.2	68.1
LPA	65.1	65.3	78.7	58.5	68.9

Decomp-Large	82.7	82.7	93.6	77.4	84.7
TaPas-Large	81.5	81.2	93.0	75.5	84.1
TaPEx	**84.6**	84.2	**93.9**	79.6	85.9
SaMoE	84.2	**85.1**	93.6	**80.9**	**86.7**
Human Performance	-	-	-	-	92.1

Table 1: Comparative performance (accuracy) on TabFact.

of the test set (93.6% vs. 93.6%) while outperforms Decomp-Large with a remarkable **3.5%** on the complex subset (80.9% vs. 77.4%). Such analysis indicates that the performance improvement is mainly derived from successfully verifying complex statements, which required more sophisticated reasoning than statements in the simple set. SaMoE even shows comparable performance with the previous SOTA TaPEx that is pre-trained to execute SQL queries on tables. Our method outperforms TaPEx with a 0.9% improvement on the test set and a further 1.3% improvement on the complex subset, indicating that SaMoE, based on a **text-based** pre-trained model, performs even better than **table-based** pre-trained models on a variety of complex reasoning types demanded by the table-based verification.

Model	Val	Test
SaMoE	**84.2**	**85.1**
SaMoE w/o Sa	84.0	84.7
SaMoE w/o Sa ($n_e = 1$)	83.6	84.0

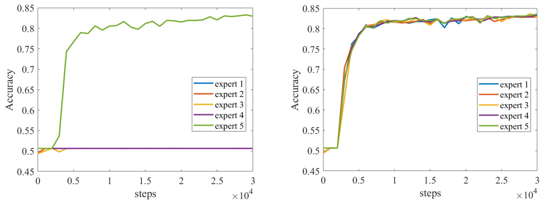
Table 2: Ablation results that shows the effectiveness of the proposed MoE and self-adaptive learning methods. SaMoE w/o Sa denotes that the framework without self-adaptive learning, and $n_e = 1$ denotes that the framework involves only one expert, where the management module does not work in this situation.

6.2 Ablation Study

We further investigate the effectiveness of the MoE structure and self-adaptive learning with an ablation study. We conduct two experiments: one reduces the number of experts to 1 to disable the contribution from the MoE structure (SaMoE w/o Sa ($n_e = 1$)); the other trains the proposed framework with only the Multi-expert training stage (SaMoE w/o Sa). Results are presented in Table 2. The MoE structure achieves a 0.7% improvement on the test set (84.7% vs. 84.0%), and self-adaptive learning further improves the performance slightly (85.1% vs. 84.7%). Note that the slight improvement of self-adaptive learning is expected since the experts and the feature extractor are fixed in this stage. The results demonstrate the effectiveness of both the MoE structure and the self-adaptive learning.

6.3 Effectiveness Analysis

We show in this section that the effectiveness of the proposed framework is derived from two aspects: the **differentiation of experts** (each expert outperforms others on a specific part of reasoning types) and the **effective attention assignment** by the management module (the best-performed experts are assigned with higher attention scores).



(a) Trained with $\mathcal{L}_V$ (b) Trained with $\mathcal{L}_V + \mathcal{L}_M$

Figure 4: Comparison of models trained with/without the manager assumption loss $\mathcal{L}_M$.

6.3.1 Expert Differentiation

We first investigate the proposed manager assumption loss $\mathcal{L}_M$ and find that it achieves balanced training across experts, which is the premise of expert differentiation. Figure 4 compares the two models trained with and without $\mathcal{L}_M$, with the performance curves of different experts on the development set presented in each sub-figure. Once $\mathcal{L}_M$ is applied, four experts that fail to be trained (the performance stays around 50% as training steps increase) achieve comparable performance with the rest expert (expert 5 in sub-figure (a)). The result indicates that the proposed $\mathcal{L}_M$ leads balanced training across experts.

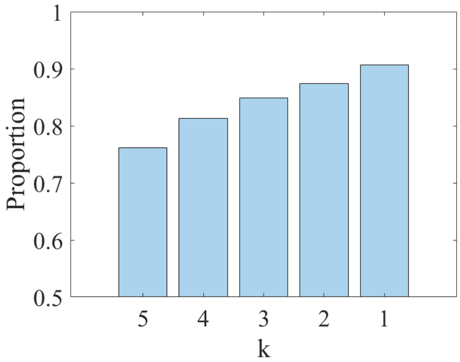


Figure 5: The proportion of statements in the test set that at least k experts verify them correctly ($k \in [1, 5]$).

We further show that the proposed framework achieves differentiation across experts. Figure 5 presents the proportion of statements in the test set that are verified correctly by at least k experts (k varies from 1 to 5). Note that the proportion increases rapidly as k decreases (76.2% to 90.7% for k from 5 to 1), which illustrates that experts behave differently on a large proportion of statements. The results indicate that SaMoE successfully achieves expert differentiation, which expands the original performance upper bound considerably **(90.7%)**.

Model	Accuracy		
	Top 1	Top 2	Top 3
SaMoE	**32.0**	**59.0**	**76.0**
SaMoE w/o Sa	25.4	44.8	67.6

Table 3: The top-k accuracy of the management module that predicts the best-performed experts on the test set.

6.3.2 Effective Attention Assignment

We conduct a detailed analysis to investigate whether the management module assigns higher attention scores to experts with the best performance after self-adaptive learning. To achieve this goal, we regard the management module as a n_e-class classifier and calculate the top-k accuracy of predicting the best-performed expert (the one with the smallest cross-entropy) on the test set where k is chosen in [1, 2, 3]. The results of the analysis are presented in Table 3. The top-k accuracy is improved significantly after self-adaptive learning (**+6.6%, +14.2%, +8.4%** respectively), indicating that the management module successfully assigns higher attention scores to the best-performed experts by self-adaptive learning.

Based on the significant performance upper bound expanded by the expert differentiation, the effective attention assignment achieves more efficient cooperation across these diverse experts, thus improving the verification performance.

7 Related Works

Table-Based Fact Verification Most of the current models utilize programs to improve the model's ability to handle various types of numerical and logical reasoning (Chen et al., 2020; Zhong et al., 2020; Shi et al., 2020; Yang et al., 2020; Yang and Zhu, 2021), while Eisenschlos et al. (2020); Liu et al. (2021) leverage table-based pre-trained models to parse the structural and numerical semantics of tables better. Unlike previous works, we use a novel mixture-of-experts framework to handle different logical and numerical semantics without semantic parsing and table-based pre-training.

Mixture of Experts Mixture of experts is a special model combining method. Jacobs et al. (1991) first introduces this method and proposes a loss that encourages competitive learning across expert models. Afterwards, it is applied in various fields, including dialog system (Le et al., 2016), content recommendation(Ma et al., 2018; Zhu et al., 2020), image classification(Wang et al., 2020; Riquelme et al., 2021), etc. In this paper, we develop a self-adapted mixture-of-experts framework that achieves a more effective combination of experts by learning from the experts' performance on the train set.

8 Conclusion

This paper proposes a new method that exploits the mixture of experts to recognize and execute different types of reasoning required for table-based fact verification. We propose an MoE model guided with limited prior knowledge to handle different parts of the reasoning types required by table-based verification with diverse experts. Moreover, we design a supervisor network to adjust the imprecise attention score and achieve a more efficient combination across experts. A self-adaptive learning strategy is further applied to train the proposed supervisor network without prior knowledge of the task or dataset. The experiments show that the proposed model achieves a new state-of-the-art performance of 85.1% accuracy on the benchmark dataset TABFACT. The ablation studies and analysis further indicate the effectiveness of the proposed MoE structure and self-adaptive learning strategy. We hope our work is helpful for those who aim to further exploit the power of mixture-of-experts on table-based reasoning in the future.

A Statistics of TABFACT

Table 4 shows the basic statistics of TABFACT. As the table shows, the whole dataset is randomly divided into three subsets with the ratio be 8:1:1. The average numbers of rows and columns in tables keep approximately the same across three subsets, which reflects the consistency of data distribution.

Split	#Sentence	#Table	Avg.row	Avg.col
Train	92,283	13,182	14.1	5.5
Dev	12,792	1,696	14.0	5.4
Test	12,779	1,695	14.2	5.4

Table 4: Statistics of TABFACT, including the number of statements, tables, and the average number of rows and columns in tables.

B Parameter Initialization

For parameter initialization, We leverage RoBERTa-Large, a pre-trained language model that has 24 transformer encoding layers. We initial parameters of the feature extractor with the embedding layer and the bottom 12 encoding layers of RoBERTa-Large and each expert with the upper 12 encoding layers of RoBERTa-Large, respectively. We use PyTorch to initialize other parameters randomly.

C Specific Setting of Prior Assumption Generation

We choose four reasoning types that appear most frequently in TABFACT: count, comparative, superlative, and negation. The detailed definitions of four reasoning types chosen in our implementation are listed below:

1. Count: counting the number of specific rows in the table, such as “xxx be listed a total of 3 times", “xxx win only 1 time in ...", etc.
2. Comparative: comparing two values in the statement or cells, such as “xxx play in more than 1 game during ...", “xxx has a larger yyy than zzz", etc.
3. Superlative: finding the highest/lowest value of the specific column, such as “the longest xxx be yyy", “the lowest score at xxx be yyy", etc.
4. Negation: negating the original semantics of the statement, such as “xxx has never lost a game in ...", “xxx never score 0 points", etc.

Type	Trigger	Weight
Count	only+[number]	1.6
Count	[number]+times	2
Count	[number]+of	1.6
Count	there be+[number]	1.6
Negation	no	1.5
Negation	not	1.5
Negation	never	1.5
Negation	didn’t	1.5
Comparative	[JJS] or [RBS]	1.5
Superlative	[JJR] or [RBR]	1.5

Table 5: Some trigger words/patterns applied in the generation of the prior assumption on TABFACT.

A small trigger-word pool that contains only 26 trigger words/patterns is applied for the prior assumption generation: 11 triggers for the "count" type, 15 for "negation"; and for the rest types (i.e., "comparative" and "superlative" types), the NLTK package is employed to recognize the comparative and superlative words automatically. Such a small trigger-word pool injects limit prior knowledge of the dataset, indicating that the proposed method can be generalized to other datasets by simply modifying the pool of trigger words. Table 5 presents some words/patterns in the trigger-word pool applied in our experiments. x+[number] denotes a combination of a word and a number that is served as a trigger (e.g., for the statement “xxx win 3 times in ...", we match the phrase “3 times" with the trigger “[number]+times").

Investigating Data Variance in Evaluations of Automatic Machine Translation Metrics

Abstract

Current practices in metric evaluation focus on one single dataset, *e.g.*, Newstest dataset in each year's WMT Metrics Shared Task. However, in this paper, we qualitatively and quantitatively show that the performances of metrics are sensitive to data. The ranking of metrics varies when the evaluation is conducted on different datasets. Then this paper further investigates two potential hypotheses, *i.e.*, insignificant data points and the deviation of Independent and Identically Distributed (i.i.d) assumption, which may take responsibility for the issue of data variance. In conclusion, our findings suggest that when evaluating automatic translation metrics, researchers should take data variance into account and be cautious to claim the result on a single dataset, because it may leads to inconsistent results with most of other datasets.

1 Introduction

Assessing the quality of machine translation (MT) systems is always crucial to promote MT research (Marie et al., 2021). Since it is costly and time-consuming for human graders to evaluate machine translation (MT) systems, designing automatic metrics for MT has drawn booming attention during the past decades, and many metrics such as BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) have been proposed consequently.

Generally, it is non-trivial to measure automatic metrics. Conference Machine Translation (WMT) (Ma et al., 2019, 2018; Macháček and Bojar, 2013a,b; Bojar et al., 2016) thereby holds the Metric Shared Task to evaluate the performance of automatic metrics. In each year, WMT organizers collect a dataset consisting of many MT outputs annotated with human judgments, and automatic metrics are evaluated on the dataset in terms of their correlations to human judgments. Over the past ten years, the official evaluation reports only independently analyzed the results of that year. To the best of our knowledge, there are no studies to put the evaluation results of ten years together and make a more systematic analysis. Therefore, some key questions remain unknown: are the evaluation results consistent across different years? Are the results on each dataset reliable?

One may simply summarize the existing results from the official evaluation reports of the past years and answer the above questions accordingly. However, the existing results use Pearson's correlation for evaluation which suffers from sensitivity to outlier data points as argued by Mathur et al. (2020). Besides, involved metrics in the evaluation are different year by year, thus it is difficult to directly compare the results among different years. To this end, in this work, we firstly re-evaluate ten popular metrics on all available datasets in the past ten years, with the Error Number evaluation method (Mathur et al., 2020). We then empirically investigate the fluctuation of metric evaluation results. Surprisingly, our experiments show that the evaluation result is sensitive to the choice of datasets, which suggests that the results on some datasets may not be reliable (§3).

Then we investigate two potential hypotheses about the emergence of data variance, i.e., the insignificant data points (§4.1) and deviation of Independent and Identically Distributed (i.i.d) assumption (§4.2). First, we show that the data variance issue is substantially alleviated when the insignificant data points are removed. To further understand the variance that cannot be alleviated by the first hypothesis, we design a simple method to measure the distributional differences between datasets, and hypothesize that the deviation of the i.i.d assumption may contribute to the variance. For future metric evaluation, we recommend WMT community pay attention to the potential issue of data variance

MoverScore	neural representations	micro

Table 2: Features for the metrics we use in the paper. Note that we implement PER by ourselves.

2 Experiment Settings

2.1 Datasets and evaluation metrics

We collect the testing set data and the human assessments of the WMT Metrics Task from 2010 to 2019. In this work, we mainly conduct experiments on the De⇒En task and more details about datasets are shown in Table 1. However, as shown in §3.1, our conclusions are consistent on other translation tasks, such as Ru⇒En.

Since participating metrics in the WMT Metrics Task varied over years, we collect ten most popular metrics and re-evaluate them on all ten datasets to study their performance.These metrics are summarized as follows: BLEU (Papineni et al., 2002), WER (Morris et al., 2004), PER (Tillmann et al., 1997), TER (Snover et al., 2006), chrF (Popović, 2015), chrF+ (Popović, 2017), BEER (Stanojević and Sima'an, 2014), CharacTER (Wang et al., 2016), BERTScore (Zhang et al., 2020), and MoverScore (Zhao et al., 2019). The first 4 metrics are in system-level (i.e., macro) while others are in sentence-level (i.e., micro), as shown in Table 2. Since extending sentence-level metrics to system-level is more natural (Zhang et al., 2020), we only compare them on the system-level.

For each system pair, metrics or humans give a comparison result about whether one system is better than another. Following Graham et al. (2014), we use statistical significance tests to detect if the difference in scores (metrics or humans) between two systems is significant. Specifically, for RR scores, we use the bootstrap method (Koehn, 2004). For DA scores, we apply the Wilcoxon rank-sum test. For macro-average metrics, *i.e.*, BLEU, WER, PER, and TER, we use the bootstrap method (Koehn, 2004). For other micro-average metrics, we use the paired t-test method.

2.2 Measuring Automatic Metrics

The previous WMT Metrics Tasks used Pearson's r to measure the ability of a metric to evaluate MT systems. However, as pointed out by Mathur et al. (2020), Pearson's r is unstable for a small sample size and sensitive to outlier systems. Besides, in practice, metric scores are always used to compare pairs of MT systems[1]. Thus following Mathur et al. (2020), we measure an automatic metric with the number of errors made by the metric when comparing system pairs. Error Number can be considered as an absolute view of measuring a metric.

Error Number Following Mathur et al. (2020), we measure the performance of a metric by its consistency with humans. Specifically, each metric or human can judge whether a system performs better compared to another system (details of system comparison process are presented in the appendix), and the error number is the number of contrary cases between the results of metric and human. As mentioned by Graham and Liu (2016), when the number of compared MT systems are too small on a dataset, differences among different metrics

---

[1] Unless otherwise specified, a system always denotes MT system in our work, rather than an evaluation metric.

Metric	Dataset									
	2010	2011	2012	2013	2014	2015	2016	2017	2018	2019

PER	**10** / 38.6	**9** / 61.7	**10** / 48.0	**10** / 26.9	**5** / 23.8	**7** / 22.8	**10** / 28.2	**8** / 27.6	**9** / 18.4	**9** / 43.5

Table 3: Metric evaluation results on De⇒En datasets from 2010 to 2019. The tuple "**R** / E" shows the performance of a metric, where **R** denotes Significant Ranking (§2.3) among all metrics and E denotes the Error Rate (Error Number divided by the total number of system pairs).

may be insignificant. Thus, the results of the metric evaluation can be highly inconclusive. We indeed observe similar results in our experimental setting. Therefore, we use the hybrid super-sampling method (Graham and Liu, 2016) to create a large number of hybrid system pairs: on each dataset, we synthesize 142 systems in total, which form 10K system pairs. Finally, we calculate the error number of each metric on all 10K system pairs.

2.3 Measuring Data Variance

Significant Ranking Based on the measurement of error number, a qualitative approach to know whether those metrics perform consistently on different datasets is to evaluate the variance of their rankings. To make the ranking more reliable, we propose a *significant ranking* method, which conducts significant test when sorting the error numbers of metrics. For example, in Table 3, the significant ranking of all metrics on 2010 dataset is "1, 6, 2, 3, 3, 3, 8, 7, 9, 10" where chrF, BEER and chrF+ are with the same relative ranking of 3. This is because they are not significantly different, although their absolute error numbers are slightly different. We employ the bootstrap re-sampling method (Koehn, 2004) to test if the number of errors of one metric is significantly less than the others. For the bootstrap method, we repeat resampling 1000 times and set the p-value to 0.05 for all the significance tests.

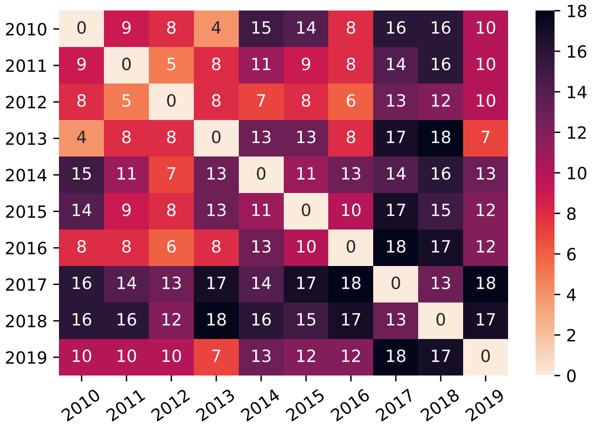

Figure 1: The heatmap for the disagreement numbers between every two datasets on De⇒En task.

Disagreement Number In addition, we also propose a method to quantitatively measure the variance between two datasets $\mathcal{D}$ and D', namely, *disagreement number*. Specifically, we construct a set $\mathcal{S}_D$ by collecting all pairwise metrics that one is significantly better than the other on dataset $\mathcal{D}$. Then to measure the mismatch between $\mathcal{D}$ and $\mathcal{D}'$, we count the **disagreement number** between the pairwise metrics in $\mathcal{S}_{\mathcal{D}}$ and that in $\mathcal{S}_{\mathcal{D}'}$. For example, disagreement number plus one, if BLEU is significantly better than TER on $\mathcal{D}$ and worse than TER on $\mathcal{D}'$. Although this number is linear to Kendall's Tau (Kendall, 1938), it is able to show more informative difference between two overall rankings. For example, two metrics with totally different ranks may just have a slight difference on disagreement number. As a result, we employ disagreement number rather than Kendall's Tau to show the quantitative difference between two overall rankings more intuitively for more detailed analysis. It is worth mentioning that the disagreement number is at most 45 in our setting where there are 10 metrics in total.

3 Data Variance in Metric Evaluations

3.1 Variance of Different Datasets

We conduct experiments on all 10 datasets. We have 10 metrics, which can form 45 metric pairs. On each dataset, for each metric, we calculate its

Metric	Dataset				
	2015	2016	2017	2018	2019
BERTScore	**2** / 18.0	**3** / 16.7	**2** / 32.1	**3** / 24.5	**1** / 35.8
CharacTER	**6** / 20.5	**6** / 19.4	**1** / 30.4	**1** / 22.3	**4** / 37.2
MoverScore	**1** / 14.9	**1** / 15.1	**2** / 31.4	**3** / 24.5	**1** / 36.1
chrF	**3** / 18.7	**2** / 15.7	**2** / 31.9	**2** / 24.0	**4** / 37.1
BEER	**3** / 19.0	**3** / 17.0	**5** / 33.2	**3** / 24.3	**9** / 39.6
chrF+	**5** / 19.7	**5** / 17.6	**5** / 33.3	**3** / 24.5	**4** / 36.9
BLEU	**10** / 27.9	**7** / 21.0	**9** / 34.8	**8** / 25.0	**9** / 39.8
WER	**8** / 23.4	**7** / 21.5	**5** / 33.2	**8** / 25.0	**8** / 37.9
TER	**8** / 23.4	**10** / 23.3	**9** / 34.5	**10** / 25.8	**4** / 36.9
PER	**6** / 21.1	**7** / 21.5	**7** / 34.0	**2** / 23.4	**1** / 35.7

Table 4: Metric evaluation results on Ru⇒En datasets from 2015 - 2019.

error number (described in Section 2.2). In addition, we perform a statistical significance test for each metric pairs in terms of both error numbers, from which we can obtain a ranking result among 10 metrics accordingly.

Table 3 illustrates the error numbers and ranks on 10 datasets. It shows that the ranks are always variant along with different datasets. For example, on the dataset of 2011, the error rate of MoveScore is larger than chrF (39.3 v.s. 37.8), and the former ranks 4 while the latter ranks 1. However, it is opposite on the dataset of 2015, where MoveScore ranks 1 with an error rate of 14.7 while chrF ranks 4 with an error rate of 17.7. As shown in Table 4, we observe a similar trend on the Ru⇒En task.

As shown in Figure 1, there is a high inconsistency between the results of different datasets and none of the dataset pairs achieve zero disagreements. The difference between the datasets in 2010 and 2013 is the smallest (i.e., only 4 disagreed metric pairs). However, most of the disagreement numbers are larger than 10 (the maximum achieves 18). Moreover, datasets from 2017 to 2019 not only have a high disagreement number with datasets of early years, but also have high variances among themselves. This finding is a little surprising, because in our sense the quality of WMT's datasets must be improved year by year.

4 Potential Reasons for Data Variance

Many factors may contribute to the data variance issue, but lots of them are difficult to be evaluated, such as the personal preferences of humans. In this section, we propose to analyze two potential factors that can be quantitatively evaluated.

	2010	2011	2012	2013	2014	2015	2016	2017	2018	2019
2010	0	3	6	1	10	3	4	12	5	2
2011	3	0	3	4	7	1	2	8	2	1
2012	6	3	0	7	6	0	4	7	2	4
2013	1	4	7	0	10	3	5	13	7	2
2014	10	7	6	10	0	2	9	9	6	10
2015	3	1	0	3	2	0	0	6	0	2
2016	4	2	4	5	9	0	0	12	2	3
2017	12	8	7	13	9	6	12	0	4	9
2018	5	2	2	7	6	0	2	4	0	4
2019	2	1	4	2	10	2	3	9	4	0

Figure 2: The heatmap for the disagreement numbers between every two datasets on De⇒En task. Insignificant system pairs according to human assessments are removed.

4.1 Insignificant Data Points

Intuitively, if the translations H_A from system A are much better than those H_B from system B in translation quality according to human evaluation, then it is easy to judge the better system even for a weak automatic metric. In contrast, if H_A is similar to H_B in translation quality, it is typically difficult to judge the better system even for a good metric. This motivates us that such an insignificant data point $\langle H_A, H_B\rangle$ may take responsibility for the data variance issue.

To validate the above intuition, we remove the system pairs that are not significantly different according to human evaluation, and compute the disagreement number between any two datasets again. The experimental results are shown in Figure 2. We can see the disagreement number decreases greatly comparing to the results in Figure 1. In the previous experiment, most of the disagreement numbers are greater than 10, while in the new experiment most of them are less than 5, and some of them even achieve 0, such as the number between 2012 and 2015, which means the ranks of metrics are exactly the same on those datasets. The results indicate that part of the data variance issue can be explained by system pairs that humans think are not significantly different.

However, After the removal of insignificant data points, some disagreement number are still high, e.g., the number between 2013 and 2017 is 13. It demonstrates that there are still some other underlying problems that give rise to the data variance phenomenon. In addition, the datasets for both 2014 and 2017 do not agree well with others. This indicates that we should be cautious to report overall results on some datasets, e.g., 2014 and 2017.

4.2 Deviation of I.I.D Assumption

How to interpret the high variance on datasets, e.g., 2014 and 2017, remains to be an open question. In this section we try to give a hypothesis based on the i.i.d assumption. According to the principle of statistical sampling, if two samples are drawn from the same distribution, then a statement made on one sample is likely to hold on the other sample. Therefore, one hypothesis about the high variance may be that datasets from different years deviate i.i.d assumption. In fact, this may be true in our scenario because each dataset is generated by a set of translation systems but the set of systems is variant each year.

To this end, we design an experiment to measure the extent to which each dataset is drawn from the same distribution during the past ten years. Since the standard method such as Kolmogorov-Smirnov test (Massey Jr, 1951) is difficult to scale with respect to feature dimension, we employ adversarial validation to distinguish the difference between two datasets (Pan et al., 2020). Its basic idea is to formulate the i.i.d test as a classification problem and train a classifier between two datasets. If the classifier can accurately distinguish the data from different datasets, then the distributions of the two datasets are regarded as highly different. Since it is too slow to train classifiers for all pairs of datasets, we conduct experiments on three years from 2017 to 2019. More details are shown in appendix.

The results on two kinds of datasets are shown in Table 5, where higher accuracy indicates clearer distributional differences between two datasets. Note that accuracy scores in main diagonal are got from two subsets of each year via randomly splitting. As shown in Table 5, the distributional differences between MT datasets have been introduced by source sentences. After accompanied with the system outputs, the distributional differences are more severe between different years. This fact shows that some datasets in past ten years deviate the i.i.d assumption, which may be related to the inconsistency of metrics.

4.3 Suggestions

According to those potential factors, we propose some suggestions to alleviate some potential issues for metric evaluation due to data variance in future. First, it would be better if pay more attention to those insignificant data points such that their manual annotations are as good as possible. Since it is costly to hire more annotators for data points, it would be possible to ask more annotators only for those insignificant data points. Second, it would be helpful to construct a dataset with diverse domains and explicitly show the evaluation results for each subset with the same domain rather than a single evaluation result for the entire dataset. Generally, although inconsistent results from different domains are possible, however, the inconsistency in the same domain may be undesirable. Thus, showing the domain information could help researchers to better promote the datasets and metrics.

(b) Src+Output

Table 5: The accuracy of classifiers. The higher value means two datasets deviate i.i.d assumption. We run the model with 5 different random seeds to calculate the average accuracy.

5 Conclusion

Over the past ten years, the official evaluation reports of WMT Metrics Shared Task only independently analyzed the results of that year. In this paper, we re-evaluate ten popular metrics on all available datasets in the past ten years and comparatively analyze the evaluation results among different years together. We show the problem of conducting evaluations with only one dataset. In addition, we analyze its potential reasons that the insignificant data points and deviation of i.i.d assumption may induce the issue of data variance. This fact suggests that future researches on evaluating automatic translation metrics should take data variance into account and be cautious to conclude the result on a single dataset.

A Settings for Adversarial Validation

To train the classifier, we need to construct a binary classification dataset first. Since the difference between distributions may come from both the source sentences and system outputs, we consider two types of classification datasets correspondingly. The first kind of dataset only considers the source information. Supposing that we want to compare the distributions of source sentences of MT datasets from year Y1 and Y2, we follow the three steps below to construct the classification dataset:

1. We label the source sentences from Y1 and Y2 with 0 and 1, respectively;
2. We split the data from Y1 and Y2 to train, dev, and test sets without overlap;
3. We merge the data from Y1 and Y2 according to their split.

For each pairs of MT datasets from year 2010 to 2019, we construct a classification dataset following the steps above. Besides the source information, we also construct another kind of classification datasets that also consider the information of system outputs. The procedure to construct this kind of dataset is almost similar to the previous one, except that we concatenate each system outputs with its source sentences after the Step-2 is finished. In our experiments, we use mBERT (Devlin et al., 2019; Wolf et al., 2020) as the classifier, thus an unified structure can be used for the two kinds of datasets.

Sememe Prediction for BabelNet Synsets using Multilingual and Multimodal Information

Abstract

In linguistics, a sememe is defined as the minimum semantic unit of languages. Sememe knowledge bases (KBs), which are built by manually annotating words with sememes, have been successfully applied to various NLP tasks. However, existing sememe KBs only cover a few languages, which hinders the wide utilization of sememes. To address this issue, the task of sememe prediction for BabelNet synsets (SPBS) is presented, aiming to build a multilingual sememe KB based on BabelNet, a multilingual encyclopedia dictionary. By automatically predicting sememes for a BabelNet synset, the words in many languages in the synset would obtain sememe annotations simultaneously. However, previous SPBS methods have not taken full advantage of the abundant information in BabelNet. In this paper, we utilize the multilingual synonyms, multilingual glosses and images in BabelNet for SPBS. We design a multimodal information fusion model to encode and combine this information for sememe prediction. Experimental results show the substantial outperformance of our model over previous methods (about 10 MAP and F1 scores). All the code and data of this paper can be obtained at `https://github.com/thunlp/MSGI`.

1 Introduction

A word is the smallest unit of language that can stand on its own (O'Grady et al., 1997), but its meaning can be further divided into smaller components. In linguistics, a *sememe* is defined as the minimum semantic unit (Bloomfield, 1926). It is believed by some linguists that the meanings of all the words in any language can be decomposed of a limited set of language-independent sememes, which is equated with the idea of semantic primitives (Wierzbicka, 1996).

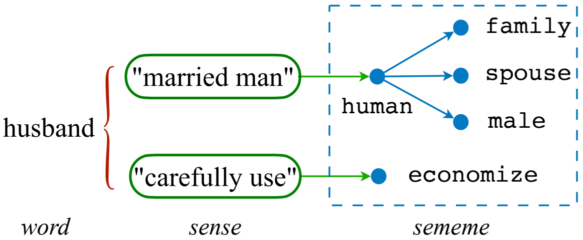

Figure 1: Sememe annotations of the English word "husband" in HowNet. For succinctness, we only show the English notations of sememes, although sememes have both English and Chinese notations in HowNet, e.g., `family|家庭`.

Sememes are implicit in words and hence cannot be utilized in natural language processing (NLP) directly. To tackle this challenge, Dong and Dong (2006) manually defined about $2,000$ sememes and used them to annotate over $100,000$ English and Chinese words, whereupon a sememe knowledge base called HowNet was established. Figure 1 gives an example of sememe annotations in HowNet.

HowNet is a special lexical knowledge base (KB). Different from other lexical KBs like WordNet (Miller, 1998), which explain meanings of words by relations between words, e.g., hyponym and meronym, HowNet provides intensional definitions of words using infra-word sememes. This distinctness gives HowNet unique advantages. First, sememes can be easily incorporated into neural networks as semantic labels (Qi et al., 2019; Qin et al., 2020), which displays the particular suitability of HowNet in knowledge integration into deep learning. Second, the nature that limited sememes can represent meanings of unlimited words endows HowNet with the ability to handle low-data regimes, e.g., sememes can improve the embeddings of rare words (Niu et al., 2017). Because of

Findings of the Association for Computational Linguistics: ACL 2022, pages 158 - 168
May 22-27, 2022

these advantages, HowNet has been successfully utilized in various NLP tasks (Qi et al., 2021b).

HowNet is distinctive and useful, but it covers only two languages (English and Chinese). Plus there are no sememe KBs like HowNet in other languages, which hinders NLP of most languages from benefiting by sememes. Manually building a sememe KB for each language is an obvious solution. But it is not realistic at all because the building process would be extremely time-consuming and labor-intensive — it takes several linguistic experts more than two decades to build HowNet.

To solve this problem, Qi et al. (2020) pioneeringly propose to build a *multilingual* sememe KB based on BabelNet (Navigli and Ponzetto, 2012a), a multilingual encyclopedic dictionary. The entries of BabelNet are synsets composed of synonyms in almost 500 languages, as illustrated in Figure 2. All the multilingual synonyms in a synset have the same meaning and thus should be annotated with the same sememes. Therefore, sememe annotations of words in many languages would be simultaneously obtained by annotating sememes for BabelNet synsets. For example, suppose we annotate four sememes `human`, `family`, `spouse` and `male` to the synset in Figure 2, all the multilingual synonyms in the synset ("husband", "époux", "丈夫", etc.) would be simultaneously annotated with these sememes.[1]

Further, Qi et al. (2020) build a seed dataset by manually annotating sememes for some synsets, and present the task of sememe prediction for BabelNet synsets (SPBS), which is aimed at automatically predicting sememes for the other unannotated synsets. In addition, they put forward two SPBS methods that utilize different information in BabelNet synsets, namely synset-related Wikipedia articles and relations between synsets.

In this paper, we argue that some other information contained in BabelNet can be exploited for SPBS. As shown in Figure 2, in addition to the multilingual synonyms, each BabelNet synset comprises multilingual glosses that are extracted from different sources including WordNet and Wiktionary.[2] Besides, many synsets contain images from Wikipedia and Wikidata (Vrandečić and Krötzsch, 2014). The multilingual synonyms, glosses and images of a synset convey the meaning of the synset, thus naturally helpful in predicting sememes for the synset. Therefore, we propose to utilize all the information in BabelNet synsets for the task of SPBS.

Figure 2: A BabelNet synset that comprises multilingual synonyms and glosses as well as some images.

We design a multimodal information fusion model named MSGI (sememe prediction with Multilingual Synonyms and Glosses as well as Images), which comprises a multilingual text encoder, an image encoder and a multi-label classifier. The text encoder is based on a cross-lingual pre-trained language model that encodes the multilingual synonyms and glosses. To adapt the general pre-trained language model for the task of SPBS, we introduce a new pre-training task named masked contextual sememe prediction to it. The image encoder learns the embeddings of the images, and we adopt the attention-based multi-instance learning mechanism to process multiple images.

In experiments, we find that our MSGI model substantially outperforms previous SPBS methods (by about 10 MAP and F1 scores). We also conduct a series of quantitative and qualitative analyses of the sememe prediction results of MSGI, aiming to explain the effectiveness of MSGI.

---

[1] If a word is polysemous, it would be included in multiple BabelNet synsets and have multiple sets of sememes.

2 Related Work

2.1 Sememe Knowledge Base

HowNet is the most famous sememe KB and has attracted wide attention since it was published (Dong and Dong, 2006). So far it has displayed its effectiveness in various NLP tasks, such as word similarity computation (Liu and Li, 2002), sentiment analysis (Fu et al., 2013), word sense disambiguation (Hou et al., 2020), word representation learning (Niu et al., 2017), language modeling (Gu et al., 2018), relation extraction (Li et al., 2019), reverse dictionary (Zhang et al., 2020), textual adversarial and backdoor attacks (Zang et al., 2020; Qi et al., 2021c), text matching (Lyu et al., 2021b), quote recommendation (Qi et al., 2022), etc.

Besides the application of sememe KBs, another line of research is the automatic expansion and construction of sememe KBs. Among these studies, most of them focus on automatic expansion of existing sememe KBs (Xie et al., 2017b; Jin et al., 2018; Lyu et al., 2021a). They propose different methods to automatically predict sememes for English/Chinese words that are not covered in HowNet, aiming to expand and update HowNet.

Only a few studies try to automatically construct a sememe KB for a new language. Qi et al. (2018) present the task of cross-lingual lexical sememe prediction, aiming to predict sememes for words in a new language based on the sememe annotations of English/Chinese words in HowNet. However, it is not efficient because it can handle only one language at a time. Moreover, it cannot conduct sense-level sememe prediction and thus hardly processes polysemous words. Afterwards, Qi et al. (2020) pioneeringly propose the scheme of the BabelNet-based multilingual sememe KB, which is a more efficient and economical way to build sememe KBs for many languages. They take advantage of the multilingual nature of BabelNet and try to automatically predict sememes for all BabelNet synsets, so that all words in almost 500 languages in BabelNet would obtain sememe annotations. Further, they build a seed dataset by aligning the words in HowNet and BabelNet and propose two methods to automatically predict sememes for synsets. Building on this work, we utilize more information incorporated in BabelNet to predict sememes for BabelNet synsets, achieving much better results.

Moreover, a recent work tries to construct a sememe KB on the basis of a dictionary (Qi et al., 2021a). It does not rely on the existing sememe annotations of HowNet or use the sememe set of HowNet. Instead, it views the words in the controlled defining vocabulary of a dictionary as "sememes", and extracts them directly from dictionary definitions.

2.2 BabelNet

BabelNet (Navigli and Ponzetto, 2012a) is a multilingual encyclopedic dictionary that merges many heterogeneous resources, mainly including WordNet (Miller, 1998), Wikipedia and Wikidata (Vrandečić and Krötzsch, 2014). It has been utilized in multiple NLP tasks (Navigli et al., 2021), especially the cross-lingual or multilingual tasks, such as multilingual word sense disambiguation (Navigli and Ponzetto, 2012b), cross-lingual lexical entailment (Vyas and Carpuat, 2016) and cross-lingual AMR parsing (Blloshmi et al., 2020). Most of these studies regard BabelNet as a large multilingual sense inventory and utilize the multilingual synonyms and glosses in BabelNet synsets, and some studies also use images in it, e.g., Calabrese et al. (2020) learn multimodal sense embeddings with the concepts and images in BabelNet.

Due to the multilingual mapping between different resources, BabelNet has become the hub to ground many linguistic resources, e.g., BabelNet is at the core of a dictionary matrix within the ELEXIS project[3] that aims to interlink different lexicographic resources.

3 Methodology

In this section, we elaborate on our MSGI model. Before that, we first introduce the formalization of the SPBS task. Then we describe the details of MSGI, and finally we present the training strategy of MSGI. Figure 3 illustrates the framework and training strategy of MSGI.

3.1 SPBS Task Formalization

According to Qi et al. (2020), SPBS neglects the hierarchical structures of sememes and regards sememes as discrete semantic labels. Therefore, SPBS is essentially a multi-label classification problem that is aimed at attaching appropriate labels (sememes) to the target BabelNet synset. Formally, suppose $\mathbb{B}$ is the set of all BabelNet synsets and $\mathbb{S}$ is the set of all sememes. For a given target synset $b \in \mathbb{B}$, SPBS is intended to predict its

---

[3] `https://elex.is/`

sememe set $\mathbb{S}_b = \{s_1, \cdots, s_{|\mathbb{S}_b|}\} \subset \mathbb{S}$, where $|\cdot|$ represents the cardinality of a set.

To this end, a prediction score is computed for each sememe. Then the sememes whose prediction scores are higher than a threshold are selected as the prediction results. Formally, the predicted sememe set for the target synset b is

$$\hat{\mathbb{S}}_b = \{s \in \mathbb{S} | P(s|b) > \delta\}, \tag{1}$$

where $P(s|b)$ is the prediction score of a sememe s and δ is the prediction score threshold.

3.2 The MSGI Model

MSGI is a multimodal information fusion model that is composed of a text encoder, an image encoder and a multi-label classifier. Next, we describe the three parts one by one.

Text Encoder

The text encoder is aimed at encoding the semantic information of the multilingual synonyms and glosses of a BabelNet synset. We combine all the multilingual synonyms and glosses into a multilingual text sequence and utilize XLM-R (Conneau et al., 2020) to encode it. XLM-R is a large cross-lingual pre-trained language model, and is pre-trained on a large corpus in many languages using self-supervised training objectives including masked language model (Devlin et al., 2019). Because of the popularity and outstanding performance on multiple cross-lingual NLP tasks, we choose XLM-R as the base text encoder in this paper. But our method also works based on other cross-lingual pre-trained language models.

We construct the multilingual text sequence of a synset in the following way. For a target synset, we first concatenate the synonyms and gloss in the same language. Inspired by Du et al. (2020), we put a special separator token, specifically a colon (:), between the synonyms and gloss to discriminate them. Besides, we use another separator token, namely vertical bar (|), to separate the synonyms. For example, the concatenation of the English synonyms and gloss of the example synset in Figure 2 is { `[/s]` *husband* | *hubby : A woman's partner in marriage* `[/s]` }, where `[/s]` is the language separator token in XLM-R.

After obtaining the monolingual text sequences in many languages, we concatenate them into the final multilingual text sequence. For example, the concatenation of the English and French text sequences is $S_{\{\text{en,fr}\}}$={ `[/s]` *husband* | *hubby : A woman's partner in marriage* `[/s]` `[/s]` *mari* | *époux* | *marié : Partenaire masculin dans un mariage* `[/s]` }, as shown in Figure 3.

Next, we feed the multilingual text sequence into XLM-R and obtain a series of hidden states:

$$\mathbf{h}_{\texttt{[/s]}}, \cdots = \text{XLM-R}(S). \tag{2}$$

We use the first hidden state as the text-based semantic representation of the synset: $\mathbf{b}_t = \mathbf{h}_{\texttt{[/s]}}$.

Image Encoder

The image encoder is used to capture the semantic information contained in the images in a BabelNet synset. Previous studies have shown that images can help learn better semantic representations for concepts and entities (Xie et al., 2017a; Calabrese et al., 2020). We believe that images are also beneficial to SPBS.

We use the popular image classification model ResNet (Deng et al., 2009) as the image encoder to learn image embeddings. Most BabelNet synsets have multiple images, and we need to combine the embeddings of multiple images into one aggregated image-based representation. Simply averaging all image embeddings may suffer from noises and cannot highlight important information. Inspired by Xie et al. (2017a), we utilize the attention-based multi-instance learning mechanism to construct the aggregated image-based representation.

Suppose a BabelNet synset b has m images and the embedding of the j-th image obtained from RestNet is $\mathbf{e}_j$. Based on the text-based representation of the synset $\mathbf{b}_t$, we calculate the attention of each image:

$$\alpha_j = \frac{\exp(\mathbf{b}_t \cdot \mathbf{e}_j)}{\sum_{k=1}^{m} \exp(\mathbf{b}_t \cdot \mathbf{e}_k)}. \tag{3}$$

The aggregated image-based representation is the attention-weighted sum of the image embeddings: $\mathbf{b}_i = \sum_{j=1}^{m} \alpha_j \mathbf{e}_j$.

In experiments, however, we find that images in BabelNet are too diversified, and some are even not related to the corresponding synsets at all.[4] For example, among the displayed four images in the example synset in Figure 2, they vary markedly in styles and semantic descriptive perspectives. Even with the attention mechanism, the model would still be confused if we consider all the images.

---

[4] It is because most images in BabelNet are automatically extracted from Wikipedia and Wikidata without manual examination.

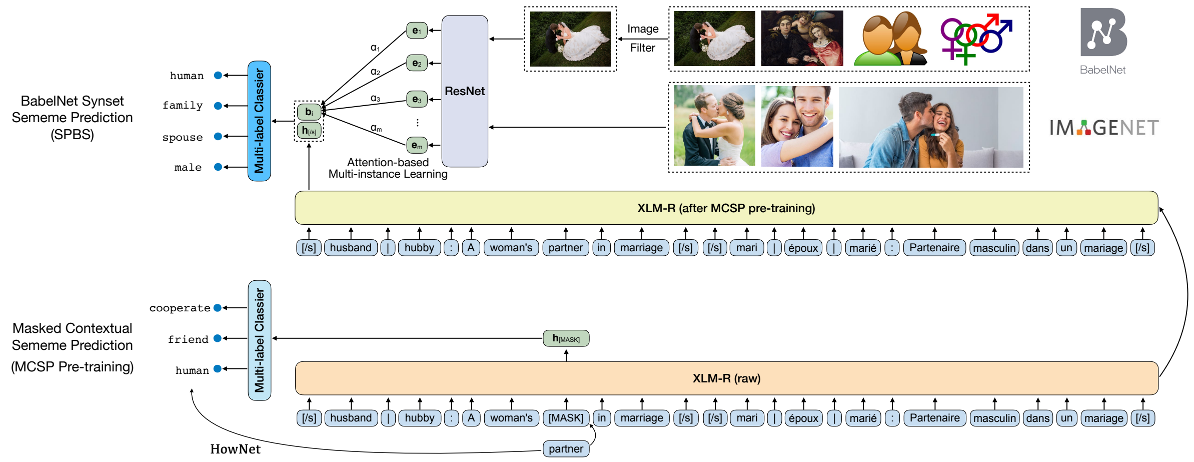

Figure 3: The illustration of the MSGI model. For simplicity, we only show the synonyms and glosses in two languages (English and French) in the multilingual text sequence.

To tackle this issue, we take the following two measures: (1) **Removing Low-quality Images**. We adopt an unsupervised outlier detection algorithm, more specifically One-Class-SVM (Schölkopf et al., 1999), to detect and filter out some low-quality images based on their image embeddings; (2) **Adding High-quality Images**. Since BabelNet synsets are connected with WordNet synsets, we can retrieve more images for some BabelNet synsets from ImageNet (Deng et al., 2009) that is also organized based on WordNet. Images in ImageNet are manually annotated and have much higher quality. After the two measures, we obtain a better image set, and then we adopt the attention-based multi-instance learning mechanism to obtain the final image-based representation $\mathbf{b}_i$.

Multi-label Classifier

We concatenate the text-based and image-based representations of a synset, and pass the concatenation vector into a single-layer perceptron for multi-label classification:

$$\mathbf{p} = \sigma(\mathbf{W}[\mathbf{b}_t; \mathbf{b}_i] + \boldsymbol{\mu}), \tag{4}$$

where $\mathbf{W}$ is a weight matrix, $\boldsymbol{\mu}$ is a bias vector, and σ is the sigmoid function. The obtained $\mathbf{p} \in \mathbb{R}^{|\mathbb{S}|}$ is the sememe prediction score vector whose i-th element is the prediction score of the i-th sememe.

3.3 Training Strategy of MSGI

We can simply train MSGI using the cross-entropy loss, during which the text encoder (XLM-R) is fine-tuned, the multi-label classifier is trained, but the image encoder (ResNet) is frozen.[5] The training loss of a training instance b is

$$\mathcal{L}_b = -\frac{1}{\mathbb{S}}\Big[\sum_{s \in \mathbb{S}_b} \log p_s + \sum_{s \notin \mathbb{S}_b} \log(1 - p_s)\Big], \tag{5}$$

where p_s is the sememe prediction score of s.

Here we directly use the raw XLM-R, which is general and independent on downstream tasks. We argue that it can be enhanced by integrating specific adaptation to the SPBS task. Inspired by the masked language model (Devlin et al., 2019) and sememe-incorporated language model (Gu et al., 2018), we propose the masked contextual sememe prediction (MCSP) pre-training task as the adaptation of XLM-R.

MCSP Pre-training

MCSP is aimed at predicting sememes for a masked word in a sentence by utilizing the contextual information. It is viable for English and Chinese glosses thanks to HowNet that annotates sememes for English and Chinese words. We hope that MCSP pre-training can make the raw XLM-R more familiar with sememes and in turn, perform better in the subsequent training of SPBS.

More specifically, for a multilingual text sequence of a synset, we randomly replace some words in its English and Chinese glosses with a special `[MASK]` token. Then we feed the corrupted text sequence into the raw XLM-R, and pass the hidden states of the `[MASK]` tokens to a multi-label classifier like Equation (4), which serves as the sememe predictor for words. Following previous studies on sememe prediction for words (Xie

---

[5] We find that freezing rather than tuning ResNet can obtain higher performance, presumably because of the limited size of the training set, which is consistent with the findings in previous studies (Xie et al., 2017a).

et al., 2017a; Jin et al., 2018), we neglect the polysemy of the masked words and group sememes of all senses together to form the sememe set of a word.

The training loss for MCSP is also multi-label cross-entropy loss. After the MCSP pre-training, we conduct the training of SPBS as in Equation (5).

4 Experiments

In this section, we evaluate the sememe prediction performance of our MSGI model.

4.1 Experimental Settings

Dataset The evaluation is conducted on BabelSememe, the seed dataset of the multilingual sememe KB based on BabelNet that is built by Qi et al. (2020). Its training/validation/test sets have $12,369/1,546/1,546$ synsets that are manually annotated by a total of $2,106$ sememes.

Baseline Methods We choose the two methods proposed by Qi et al. (2020) as main baselines: (1) **SPBS-SR**, which performs collaborative filtering-based sememe prediction (Xie et al., 2017b) using NASARI embeddings (Camacho-Collados et al., 2016), a set of synset embeddings trained with related Wikipedia articles; (2) **SPBS-RR**, which models SPBS as a relation prediction task in knowledge graph by considering relations between synsets; (3) the **Ensemble** of the above two methods. Besides, we have two naive baselines that are used for comparison in Qi et al. (2020); (4) Logistic regression (**LR**), which directly uses NASARI embeddings for multi-label classification; (5) **TransE** (Bordes et al., 2013), which is a classical relation prediction model and adapted for SPBS in a similar way to SPBS-RR.[6]

Evaluation Metrics Following Qi et al. (2020), we use mean average precision (MAP) and F1 score as the evaluation metrics.

Selection of Languages It is impractical to consider all the 500 languages in BabelNet together. In our experiments, we pick 3 representative languages, namely English, French and Chinese. English and Chinese are the two languages in HowNet and are required for MCSP pre-training. French is a high-resource language and most synsets have French glosses in BabelNet. Besides, these 3 languages have different linguistic distances: English is close to French while Chinese is far from the two. Some synsets have no glosses in French or Chinese, and we remove the whole corresponding monolingual part from the multilingual text sequences.

Implementation Details For the text encoder, we use the pre-trained base version of XLM-R with the help of the Transformers library (Wolf et al., 2020), and the hidden size is 768. For the image encoder, we choose ResNet-152 that contains 152 layers and delivers 1000-dimensional image embeddings, and implement the model with PyTorch.[7] We transform the image embeddings into 768 dimensions with a linear layer in order for attention calculate and concatenation with the text-based representation. For images from BabelNet, we resize them into 256×256. For images from ImageNet, we use the processed version of ImageNet 21K (Ridnik et al., 2021) whose images are resized into 224×224. In BabelSememe, 9,356 synsets have images, among which 2,538 synsets have images from both BabelNet and ImageNet. The average image number of a synset is 45.

We use the Adam (Kingma and Ba, 2015) optimizer in both MCSP pre-training and the final training. The prediction score threshold δ in Equation (1) is continuously tuned on the validation set and set to 0.42 finally. The learning rates for XLM-R and the multi-label classifier are separately tuned in {1e-6, 5e-6, **1e-5**, 5e-5, 1e-4} and {1e-4, 5e-4, **1e-3**, 5e-3, 1e-2}, where the boldfaced ones are final picks based on the validation set performance.

4.2 Main Results

Table 1 shows the SPBS results of different models on the test set. We have the following observations:

(1) The MSGI model achieves consistent and substantial outperformance over previous methods (about 10 for both MAP and F1 score), which demonstrates the usefulness of the multilingual and multimodal information in BabelNet in the SPBS task and the effectiveness of the MSGI model.

(2) Among the four PoS types, MSGI performs best on nominal synsets, which is possibly because nominal synsets have the largest amount and the most abundant information in BabelNet (Navigli and Ponzetto, 2012a).

---

[6] SPBS-SR and LR require NASARI embeddings that only cover nominal synsets. Thus the two methods work on the nominal synsets only.

[7] `https://pytorch.org/hub/pytorch_vision_resnet/`

PoS (#synset)	Noun (10,360)		Verb (2,240)		Adj. (2,419)		Adv. (442)		All (15,461)	
Model	MAP	F1	MAP	F1	MAP	F1	MAP	F1	MAP	F1
LR	54.42	39.81	–	–	–	–	–	–	–	–
TransE	61.05	46.78	34.75	26.76	29.11	22.99	30.05	20.69	51.73	39.73
SPBS-SR	65.16	49.75	–	–	–	–	–	–	–	–
SPBS-RR	62.50	47.92	34.76	25.28	32.68	24.51	30.86	20.07	53.31	40.53
Ensemble	68.85	55.35	34.76	25.28	32.68	24.51	30.86	20.07	57.64	45.61
MSGI (ours)	**71.81**	**64.36**	**59.78**	**47.01**	55.61	41.02	68.52	55.20	**67.23**	**57.68**
-Synonym	67.40	59.07	35.31	24.99	36.33	26.18	48.33	37.45	57.25	48.54
-Gloss	66.90	56.99	54.22	41.54	53.11	39.20	**68.76**	55.14	62.67	52.21
-Image	71.41	61.58	59.70	44.29	**55.86**	**43.15**	63.81	51.63	67.13	56.62
-MCSP	70.58	61.99	57.55	43.27	52.57	40.61	68.49	52.79	65.70	56.05

Table 1: SPBS performance of different models on the test set of BabelSememe. The boldfaced **results** exhibit statistically significant improvement over the other results with $p < 0.1$ according to the paired t-test, and the underlined results indicate no significant difference.

(3) MSGI largely improves the performance on the non-nominal synsets compared with TransE and SPBS-RR. It is because the baselines rely on the relations between synsets, and non-nominal synsets have sparse relations (Qi et al., 2020). In contrast, MSGI utilizes the internal information of BabelNet synsets and is immune to the relation density.

Ablation Study

We conduct a series of ablation studies to show the effectiveness of different parts of the MSGI model. (1) **-Synonym**. We eliminate all the synonyms and separator tokens in the multilingual text sequences, i.e., retain the glosses only. (2) **-Gloss**. We remove all the multilingual glosses and the colon separator tokens, and keep the synonyms together with the vertical bar separator tokens only. (3) **-Image**. We remove the image encoder and use the text encoder together with the multi-label classifier only. (4) **-MCSP**. We skip the MCSP pre-training and directly train the MSGI model on the raw XLM-R.

The results are also shown in Table 1. We can see that the original MSGI model has better overall results than all the above four incomplete models, which proves the effectiveness of the four parts.

4.3 Effectiveness of Image Encoding

According to the ablation study, the benefit of the images seems to be marginal. We conjecture that it is because many synsets (6,105, ~40%) have no available images and the image encoder only plays a limited role. To better demonstrate the effectiveness of image encoding, we conduct experiments on the 9,356 synsets with images, which are randomly split into the training, validation and test sets in the ratio of 8:1:1. In addition, we investigate the effectiveness of the two measures in image encoding, i.e., filtering BabelNet images and adding ImageNet images, on this subset.

Used Images	MAP	F1
No Images	69.40	60.44
All BabelNet Images	70.25	60.99
Filtered BabelNet Images	70.63	61.21
Filtered BabelNet + ImageNet Images	**71.33**	**62.10**

Table 2: SPBS performance of the MSGI model incorporated with different image information.

Table 2 shows the results. We can see that the improvement brought by image encoding is better exhibited (nearly 2 MAP and F1 scores). Further, both the two measures in image encoding are effective and improve the SPBS performance.

4.4 Effectiveness of Multilinguality

In this subsection, we investigate the effectiveness of the multilingual information in the MSGI model. We extract the 8,974 synsets that have synonyms and glosses in all the three languages (English, French and Chinese), and randomly split them into training/validation/test sets in the ratio of 8:1:1. Then we train MSGI with multilingual text sequences in different combinations of languages.

The evaluation results on the test set are shown in Table 3. We observe that considering more languages can bring performance enhancement indeed, which demonstrates the usefulness of the multilin-

Languages	MAP	F1
En	67.22	55.80
Fr	59.87	50.87
Zh	70.87	61.13
En+Fr	68.01	57.48
En+Zh	71.95	61.53
Fr+Zh	71.65	60.45
En+Fr+Zh	**72.98**	**63.46**

Table 3: SPBS performance of the MSGI model with information in different language combinations.

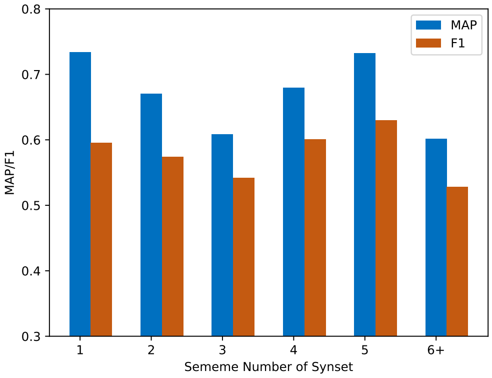

Figure 4: SPBS results of synsets with different numbers of sememes. The numbers of synsets in the six ranges are 422, 422, 287, 208, 119 and 88, respectively.

gual information in the SPBS task. We conjecture the possible reason is that the text sequences in different languages provide semantic information from different perspectives, and combining them can obtain more semantic information to better predict sememes. Besides, En+Zh and Fr+Zh outperform En+Fr, which indicates that the combination of distant languages can produce more benefits, presumably because text sequences in distant languages have more different semantic information.

5 Analysis

In this section, we conduct some quantitative and qualitative analyses of the SPBS results of MSGI. All the experiments are conducted on the validation set of BabelSememe.

5.1 Effect of Synset's Sememe Number

We first investigate how the characteristics of a synset affect its sememe prediction results. The effect of PoS has been studied in §4.2. Here we focus on another quantitative characteristic, namely the number of a synset's annotated sememes. Figure 4 shows the average sememe prediction MAP and F1 scores of the synsets that have different numbers of sememes. We find that the sememe prediction performance of a synset is basically not influenced by its sememe number. In contrast, according to Qi et al. (2020), the baseline methods (SPBS-SR, SPBS-RR and Ensemble) perform badly on the synsets with too few or too many sememes. These results show the higher robustness of our MSGI model to sememe number.

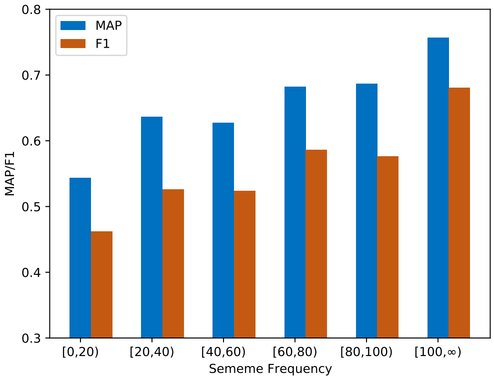

Figure 5: SPBS results of synsets having sememes with different frequencies. The numbers of synsets in the six ranges are 708, 164, 66, 35, 21 and 49, respectively.

5.2 Effect of Sememe Frequency

In this subsection, we explore what sememes are easy or hard to predict. We study the characteristic of sememe frequency, i.e., the number of synsets having a target sememe in the training set, which is the only quantitative feature of sememes. Figure 5 shows the results, where the x-axis denotes the sememe frequency ranges while the y-axis denotes the average sememe prediction performance of the synsets having the sememes within a specific frequency range. We find that the frequent sememes are easier to predict broadly, which is consistent with the findings in previous work (Qi et al., 2020).

5.3 Qualitative Analysis

In this subsection, we conduct qualitative analysis and case studies into the SPBS results of the MSGI model. We randomly select fifty synsets from the validation set, and carry out error analysis one by one. According to their sememe prediction results, we can classify the synsets into four types, namely (1) **Good**: MSGI performs well on these synsets with MAP/F1 score higher than 85; (2) **Fewer**, MSGI predicts fewer sememes for these synsets than the ground truth; (3) **More**, MSGI predicts more sememes for these synsets than the ground

Type	Example Synset		Predicted Sememes	Ground Truth
	Synonym	Gloss		
Good	Egypt	A republic in northeastern Africa	**politics**, **place**, **country**, **ProperName**, **Africa**	politics, place, country, ProperName, Africa
Fewer	anorexia	A psychological disorder characterized by somatic delusions that you are too fat despite being emaciated	**disease**	disease, disgust, eat
More	boiler	A pressurized system in which water is vaporized to steam by heat transferred from a source of higher temperature	StateChange, produce, industrial, **burn**, cook, **WarmUp**, **tool**	burn, WarmUp, tool
Similar	semantic	Of or relating to meaning or the study of meaning	**language**, knowledge	language, information

Table 4: Example synsets of four types classified according to sememe prediction results. We only show one English synonym and gloss for succinctness. The boldfaced **sememes** are the correctly predicted ones.

truth; (4) **Similar**: MSGI predicts some sememes that are different from but similar to the ground-truth sememes. The number of synsets belonging to the four types are 23 (46%), 10 (20%), 3 (6%) and 14 (28%), respectively.

We pick one example synset for each type and show their basic information and sememe prediction results in Table 4. For the synset of "anorexia", the gloss doesn't embody any information about "disgust at eating", thus the MSGI model doesn't predict the two sememes "disgust" and "eat". For the synset of "boiler", the gloss provides much information and the model predicts more sememes than the ground truth, which are basically reasonable. For the synset of "semantic", our model predicts "knowledge" rather than "information", while the two sememes are similar and related.

6 Conclusion and Future Work

In this paper, we propose to utilize the multilingual and multimodal information in BabelNet, i.e., multilingual synonyms, multilingual glosses and images, to predict sememes for BabelNet synsets. We design the MSGI model and it achieves absolute outperformance over previous methods. In the future, we will try to leverage more information in BabelNet, e.g., semantic relations, to better predict sememes. We will also consider expanding BabelSememe with the prediction results of our model after manual examination.

Ethical Statements

In this paper, we use only one dataset, namely BabelSememe, which is completely free and publicly available. The task we tackle, namely SPBS, is only related to NLP research and not for practical application, thus cannot be misused by the ordinary people. To save energy, we use the base version of XLM-R rather than larger cross-lingual pre-trained models, although they may yield higher performance. No demographic or identity characteristics are used in the formation of this paper.

Query and Extract: Refining Event Extraction as Type-oriented Binary Decoding

Abstract

Event extraction is typically modeled as a multi-class classification problem where event types and argument roles are treated as atomic symbols. These approaches are usually limited to a set of pre-defined types. We propose a novel event extraction framework that uses event types and argument roles as natural language queries to extract candidate triggers and arguments from the input text. With the rich semantics in the queries, our framework benefits from the attention mechanisms to better capture the semantic correlation between the event types or argument roles and the input text. Furthermore, the query-and-extract formulation allows our approach to leverage all available event annotations from various ontologies as a unified model. Experiments on ACE and ERE demonstrate that our approach achieves state-of-the-art performance on each dataset and significantly outperforms existing methods on zero-shot event extraction.[1]

1 Introduction

Event extraction (Grishman, 1997; Chinchor and Marsh, 1998; Ahn, 2006) is a task to identify and type event triggers and participants from natural language text. As shown in Figure 1, *married* and *left* are triggers of two event mentions of the *Marry* and *Transport* event types respectively. Two arguments are involved in the *left* event mention: *she* is an *Artifact*, and *Irap* is the *Destination*.

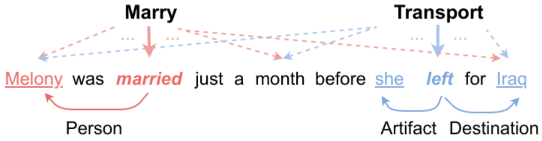

Figure 1: An example of event annotation.

Traditional studies usually model event extraction as a multi-class classification problem (McClosky et al., 2011; Li et al., 2013; Chen et al., 2015; Yang and Mitchell, 2016; Nguyen et al., 2016; Lin et al., 2020), where a set of event types are first defined, and then supervised machine learning approaches will detect and classify each candidate event mention or argument into one of the target types. However, each event type or argument role is treated as an atomic symbol, ignoring their rich semantics in these approaches. Several studies explore the semantics of event types by leveraging the event type structures (Huang et al., 2018), seed event mentions (Bronstein et al., 2015; Lai and Nguyen, 2019), or question answering (QA) (Du and Cardie, 2020; Liu et al., 2020). However, these approaches are still designed for and thus limited to a single target event ontology[2], such as ACE (Consortium, 2005) or ERE (Song et al., 2015).

With the existence of multiple ontologies and the challenge of handling new emerging event types, it is necessary to study event extraction approaches that are generalizable and can use all available training data from distinct event ontologies.[3]

To this end, we propose a new event extraction framework following a query-and-extract paradigm. Our framework represents event types and argument roles as natural language queries with rich semantics. The queries are then used to extract the corresponding event triggers and arguments by leveraging our proposed attention mechanism to capture their interactions with input texts. Specifically, (1) for trigger detection, we formulate each event type as a query based on its type name and a short list of prototype triggers, and make **binary decoding** of each token based on its query-aware

---

[1] Our code is open sourced at `https://github.com/VT-NLP/Event_Query_Extract` for reproduction purpose.

[2] An ontology is defined as a collection of event types and argument roles for a particular domain (Brown et al., 2017; Song et al., 2015).

[3] For argument extraction, the QA-based approaches have certain potential to generalize to new ontologies, but require high-quality template questions. As shown in our experiments, their generalizability is limited compared to ours.

Findings of the Association for Computational Linguistics: ACL 2022, pages 169 - 182
May 22-27, 2022

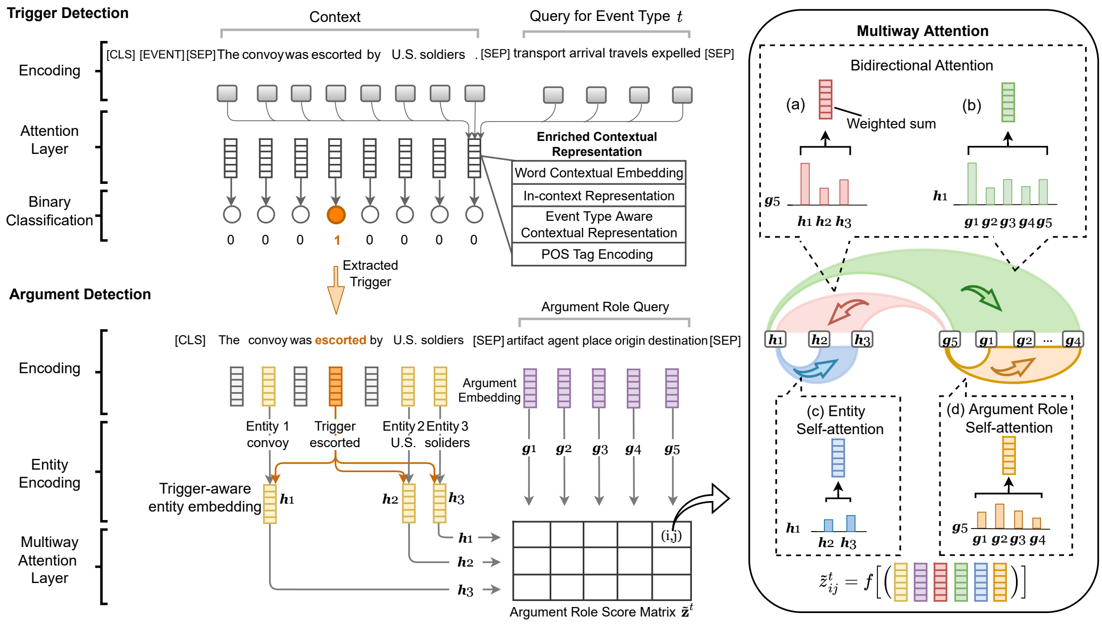

Figure 2: Architecture overview. Each cell in Argument Role Score Matrix indicates the probabilities of an entity being labeled with an argument role. The arrows in Multiway Attention module show four attention mechanisms: (a) entity to argument roles, (b) argument role to entities, (c) entity to entities, (d) argument role to argument roles.

embedding; (2) for argument extraction, we put together all argument roles defined under each event type as a query, followed by a multiway attention mechanism to extract all arguments of each event mention with **one-time encoding**, with each argument predicted as **binary decoding**.

Our approach can naturally handle various ontologies as a unified model – compared to previous studies (Nguyen and Grishman, 2016; Wadden et al., 2019; Lin et al., 2020), our binary decoding mechanism directly works with any event type or argument role represented as natural language queries, thus effectively leveraging cross-ontology event annotations and making zero-shot predictions. Moreover, compared with the QA-based methods (Du and Cardie, 2020; Liu et al., 2020; Li et al., 2020a) that can also conduct zero-shot argument extraction, our approach does not require creating high-quality questions for argument roles or multi-time encoding for different argument roles separately, thus being more accurate and efficient.

We evaluate our approach on two public benchmark datasets, ACE and ERE, and demonstrate state-of-the-art performance in the standard supervised event extraction and the challenging transfer learning settings that generalize to new event types and ontologies. Notably, on zero-shot transfer to new event types, our approach outperforms a strong baseline by 16% on trigger detection and 26% on argument detection. The overall contributions of our work are:

- We refine event extraction as a query-and-extract paradigm, which is more generalizable and efficient than previous top-down classification or QA-based approaches.
- We design a new event extraction model that leverages rich semantics of event types and argument roles, improving accuracy and generalizability.
- We establish new state-of-the-art performance on ACE and ERE in supervised and zero-shot event extraction and demonstrate our framework as an effective unified model for cross ontology transfer.

2 Our Approach

As Figure 2 shows, given an input sentence, we first identify the candidate triggers for each event type by taking it as a query to the sentence. Each event type, such as *Attack*, is represented with a natural language text, including its type name and a shortlist of prototype triggers, such as *invaded* and *airstrikes*, which are selected from the training examples. Then, we concatenate the input sentence with the event type query, encode them with a pre-trained BERT encoder (Devlin et al., 2019), compute the attention distribution over the sequential representation of the event type query for each input token, and finally classify each token into a binary label, indicating it as a trigger candidate of the specific event type or not.

To extract the arguments for each candidate trigger, we follow a similar strategy and take the set of pre-defined argument roles for its corresponding event type as a query to the input sentence. We use another BERT encoder to learn the contextual representations for the input sentence and the query of the argument roles. Then, we take each entity of the input sentence as a candidate argument and compute the semantic correlation between entities and argument roles with multiway attention, and finally classify each entity into a binary label in terms of each argument role.

2.1 Trigger Detection

Event Type Representation A simple and intuitive way of representing an event type is to use the type name. However, the type name itself cannot accurately represent the semantics of the event type due to the ambiguity of the type name and the variety of the event mentions of each type. For example, *Meet* can refer to *an organized event* or an action of *getting together* or *matching*. Inspired by previous studies (Bronstein et al., 2015; Lai and Nguyen, 2019), we use a short list of prototype triggers to enrich the semantics of each event type.

Specifically, for each event type t, we collect a set of annotated triggers from the training examples. For each unique trigger word, we compute its frequency from the whole training dataset as f_o and its frequency of being tagged as an event trigger of type t as f_t, and then obtain a probability f_t/f_o, which will be used to sort all the annotated triggers for event type t. We select the top-K^4 ranked words as prototype triggers $\{\tau_1, \tau_2, \dots, \tau_K\}$.

Finally, each event type will be represented with a natural language sequence of words, consisting of its type name and the list of prototype triggers $T = \{t, \tau_1^t, \tau_2^t, \dots, \tau_K^t\}$. Taking the event type *Attack* as an example, we finally represent it as *Attack invaded airstrikes overthrew ambushed*.

Context Encoding Given an input sentence $W = \{w_1, w_2, \dots, w_N\}$, we take each event type $T = \{t, \tau_1^t, \tau_2^t, \dots, \tau_K^t\}$ as a query to extract the corresponding event triggers. Specifically, we first concatenate them into a sequence as follows:

$$\text{[CLS][EVENT][SEP]}\ w_1\ \dots\ w_N\ \text{[SEP]}$$
$$t\ \tau_1^t\ \dots\ \tau_K^t\ \text{[SEP]}$$

where [SEP] is a separator from the BERT encoder (Devlin et al., 2019). Following (Liu et al., 2020), we use a special symbol [EVENT] to emphasis the trigger detection task.

Then we use a pre-trained BERT encoder to encode the whole sequence and get contextual representations for the input sentence $\boldsymbol{W} = \{\boldsymbol{w}_0, \boldsymbol{w}_2, ..., \boldsymbol{w}_N\}$ as well as the event type $\boldsymbol{T} = \{\boldsymbol{t}, \boldsymbol{\tau}_0^t, \boldsymbol{\tau}_1^t, ..., \boldsymbol{\tau}_K^t\}$.[5]

Enriched Contextual Representation Given a query of each event type, we aim to automatically extract corresponding event triggers from the input sentence. To achieve this goal, we need to capture the semantic correlation of each input token to the event type. Thus we apply attention mechanism to learn a weight distribution over the sequence of contextual representations of the event type query and get an event type aware contextual representation for each token:

$$\boldsymbol{A}_i^T = \frac{1}{T}\sum_{j=1}^{|T|} \alpha_{ij} \cdot \boldsymbol{T}_j \ ,$$

$$\alpha_{ij} = \cos(\boldsymbol{w}_i,\ \boldsymbol{T}_j) \ ,$$

where $\boldsymbol{T}_j$ is the contextual representation of the j-th token in the sequence $T = \{t, \tau_1^t, \tau_2^t, \dots, \tau_K^t\}$. $\cos(\cdot)$ is the cosine similarity function between two vectors. $\boldsymbol{A}_i^T$ denotes the event type t aware contextual representation of token w_i.

In addition, the prediction of event triggers also depends on the occurrence of a particular context. For example, according to ACE event annotation guidelines (Consortium, 2005), to qualify as a *Meet* event, the meeting must be known to be "*face-to-face and physically located somewhere*". To capture such context information, we further apply in-context attention to capture the meaningful contextual words for each input token:

$$\boldsymbol{A}_i^W = \frac{1}{N}\sum_{j=1}^{N} \tilde{\alpha}_{ij} \cdot \boldsymbol{w}_j \ ,$$

$$\tilde{\alpha}_{ij} = \rho(\boldsymbol{w}_i,\ \boldsymbol{w}_j) \ ,$$

where $\rho(.)$ is the attention function and is computed as the average of the self-attention weights from the last m layers of BERT.[6]

---

[4] In our experiments, we set $K = 4$.

[5] We use bold symbols to denote vectors.

[6] We set m as 3 as it achieved the best performance.

Event Trigger Detection With the event type oriented attention and in-context attention mechanisms, each token w_i from the input sentence will obtain two enriched contextual representations $\boldsymbol{A}_i^W$ and $\boldsymbol{A}_i^T$. We concatenate them with the original contextual representation $\boldsymbol{w}_i$ from the BERT encoder, and classify it into a binary label, indicating it as a candidate trigger of event type t or not:

$$\tilde{\boldsymbol{y}}_i^t = \boldsymbol{U}_o \cdot ([\boldsymbol{w}_i;\ \boldsymbol{A}_i^W;\ \boldsymbol{A}_i^T; \boldsymbol{P}_i]) \ ,$$

where $[;]$ denotes concatenation operation, $\boldsymbol{U}_o$ is a learnable parameter matrix for event trigger detection, and $\boldsymbol{P}_i$ is the one-hot part-of-speech (POS) encoding of word w_i. We optimize the following objective for event trigger detection

$$\mathcal{L}_1 = -\frac{1}{|\mathcal{T}||\mathcal{N}|} \sum_{t \in \mathcal{T}} \sum_{i=1}^{|\mathcal{N}|} \boldsymbol{y}_i^t \cdot \log \tilde{\boldsymbol{y}}_i^t \ ,$$

where $\mathcal{T}$ is the set of target event types and $\mathcal{N}$ is the set of tokens from the training dataset. $\boldsymbol{y}_i^t$ denotes the groundtruth label vector.

2.2 Event Argument Extraction

After detecting event triggers for each event type, we further extract their arguments based on the pre-defined argument roles of each event type.

Context Encoding Given a candidate trigger r from the sentence $W = \{w_1, w_2, \ldots, w_N\}$ and its event type t, we first obtain the set of pre-defined argument roles for event type t as $G^t = \{g_1^t, g_2^t, ..., g_D^t\}$. To extract the corresponding arguments for r, similar as event trigger detection, we take all argument roles G^t as a query and concatenate them with the original input sentence

$$\text{[CLS]}\ w_1\ w_2\ ...\ w_N\ \text{[SEP]}\ g_1^t\ g_2^t\ ...\ g_D^t\ \text{[SEP]}$$

where we use the last [SEP] separator to denote *Other* category, indicating the entity is not an argument. Then, we encode the whole sequence with another pre-trained BERT encoder (Devlin et al., 2019) to get the contextual representations of the sentence $\tilde{\boldsymbol{W}} = \{\tilde{\boldsymbol{w}}_0, \tilde{\boldsymbol{w}}_2, ..., \tilde{\boldsymbol{w}}_N\}$, and the argument roles $\boldsymbol{G}^t = \{\boldsymbol{g}_0^t, \boldsymbol{g}_1^t, ..., \boldsymbol{g}_D^t, \boldsymbol{g}_{\text{[Other]}}^t\}$.

As the candidate trigger r may span multiple tokens within the sentence, we obtain its contextual representation $\boldsymbol{r}$ as the average of the contextual representations of all tokens within r. In addition, as the arguments are usually detected from the entities of sentence W, we apply a BERT-CRF model, which is optimized on the same training set as event extraction to identify the entities $E = \{e_1, e_2, ..., e_M\}$. As each entity may also span multiple tokens, following the same strategy, we average the contextual representations of all tokens within each entity and obtain the entity contextual representations as $\boldsymbol{E} = \{\boldsymbol{e}_1, \boldsymbol{e}_2, ..., \boldsymbol{e}_M\}$.

Multiway Attention Given a candidate trigger r of type t and an entity e_i, for each argument role g_j^t, we need to determine whether the underlying relation between r and e_i corresponds to g_j^t or not, namely, whether e_i plays the argument role of g_j^t in event mention r. To do this, for each e_i, we first obtain a trigger-aware entity representation as

$$\boldsymbol{h}_i = \boldsymbol{U}_h \cdot ([\boldsymbol{e}_i;\ \boldsymbol{r};\ \boldsymbol{e}_i \circ \boldsymbol{r}]) \ ,$$

where $\circ$ denotes element-wise multiplication operation. $\boldsymbol{U}_h$ is a learnable parameter matrix.

In order to determine the semantic correlation between each argument role and each entity, we first compute a similarity matrix $\boldsymbol{S}$ between the trigger-aware entity representations $\{\boldsymbol{h}_1, \boldsymbol{h}_2, ..., \boldsymbol{h}_M\}$ and the argument role representations $\{\boldsymbol{g}_0^t, \boldsymbol{g}_1^t, ..., \boldsymbol{g}_D^t\}$

$$S_{ij} = \frac{1}{\sqrt{d}} \sigma(\boldsymbol{h}_i,\ \boldsymbol{g}_j^t) \ ,$$

where σ denotes dot product operator, d denotes embedding dimension of $\boldsymbol{g}^t$, and S_{ij} indicates the semantic correlation of entity e_i to a particular argument role g_j^t given the candidate trigger r.

Based on the correlation matrix $\boldsymbol{S}$, we further apply a bidirectional attention mechanism to get an argument role aware contextual representation for each entity and an entity-aware contextual representation for each argument role as follows:

$$\boldsymbol{A}_i^{e2g} = \sum_{j=1}^{D} \boldsymbol{S}_{ij} \cdot \boldsymbol{g}_j^t \ ,$$

$$\boldsymbol{A}_j^{g2e} = \sum_{i=1}^{M} \boldsymbol{S}_{ij} \cdot \boldsymbol{h}_i \ .$$

In addition, previous studies (Hong et al., 2011; Li et al., 2013; Lin et al., 2020) have revealed that the underlying relations among entities or argument roles are also important to extract the arguments. For example, if entity e_1 is predicted as *Attacker* of an *Attack* event and e_1 is *located in* another entity e_2, it's very likely that e_2 plays an argument role of *Place* for the *Attack* event. To capture the underlying relations among the entities, we further compute the self-attention among them

$$\mu_{ij} = \frac{1}{\sqrt{d}}\sigma(\boldsymbol{h}_i,\, \boldsymbol{h}_j) \ , \quad \tilde{\boldsymbol{\mu}}_i = \text{Softmax}(\boldsymbol{\mu}_i) \ ,$$

$$\boldsymbol{A}_i^{e2e} = \sum_{j=1}^{M} \tilde{\mu}_{ij} \cdot \boldsymbol{h}_j \ .$$

Similarly, to capture the underlying relations among argument roles, we also compute the self-attention among them

$$v_{jk} = \frac{1}{\sqrt{d}}\sigma(\boldsymbol{g}_j^t,\, \boldsymbol{g}_k^t) \ , \quad \tilde{\boldsymbol{v}}_j = \text{Softmax}(\boldsymbol{v}_j) \ ,$$

$$\boldsymbol{A}_j^{g2g} = \sum_{k=1}^{D} \tilde{v}_{jk} \cdot \boldsymbol{g}_k^t \ .$$

Event Argument Predication Finally, for each candidate event trigger r, we determine whether an entity e_i plays an argument role of g_j^t in the event mention by classifying it into a binary class:

$$\tilde{\boldsymbol{z}}_{ij}^t = \boldsymbol{U}_a \cdot ([\boldsymbol{h}_i;\, \boldsymbol{g}_j^t;\, \boldsymbol{A}_i^{e2g};\, \boldsymbol{A}_j^{g2e};\, \boldsymbol{A}_i^{e2e};\, \boldsymbol{A}_j^{g2g}]),$$

where $\boldsymbol{U}_a$ is a learnable parameter matrix for argument extraction. And $\tilde{z}^t$ is argument role score matrix for event type t. The training objective is to minimize the following loss function:

$$\mathcal{L}_2 = -\frac{1}{|\mathcal{A}||\mathcal{E}|}\sum_{j=1}^{|\mathcal{A}|}\sum_{i=1}^{|\mathcal{E}|} \boldsymbol{z}_{ij} \log \tilde{\boldsymbol{z}}_{ij} \ ,$$

where $\mathcal{A}$ denotes the collection of possible argument roles, and $\mathcal{E}$ is the set of entities we need to consider for argument extraction. $\boldsymbol{z}_{ij}$ denotes the ground truth label vector. During test, an entity will be labeled as a non-argument if the prediction for *Other* category is 1. Otherwise, it can be labeled with multiple argument roles.

3 Experiments

3.1 Experimental Setup

We perform experiments on two public benchmarks, ACE05-E^{+}[7] and ERE-EN (Song et al., 2015)[8]. ACE defines 33 event types while ERE includes 38 types, among which there are 31 overlapped event types. We use the same data split of ACE and ERE as (Wadden et al., 2019; Lin et al., 2020; Du and Cardie, 2020) for supervised event extraction. For zero-shot event extraction, we use the top-10 most popular event types in ACE as seen types for training and treat the remaining 23 event types as unseen for testing, following Huang et al. (2018). In our experiments, we use random seeds and report averaged scores of each setting. More details regarding the data statistics and evaluation are shown in Appendix A.

We further design two more challenging and practical settings to evaluate how well the approach could leverage resources from different ontologies: (1) *cross-ontology direct transfer*, where we only use the annotations from ACE or ERE for training and directly test the model on another event ontology. This corresponds to the *domain adaptation setting* in transfer learning literature; (2) *joint-ontology enhancement*, where we take the annotations from both ACE and ERE as the training set and test the approaches on ACE or ERE ontology separately. This corresponds to the *multi-domain learning setting* in transfer learning literature. Intuitively, an approach with good transferability should benefit more from the enhanced training data from other ontologies. We follow the same train/dev/test splits of ACE and ERE as supervised event extraction.

3.2 Supervised Event Extraction

Table 1 shows the supervised event extraction results of various approaches on ACE and ERE datasets. Though studies (Yang and Mitchell, 2016; Liu et al., 2020, 2018; Sha et al., 2018; Lai et al., 2020; Veyseh et al., 2020) have been conducted on the ACE dataset, they follow different settings[9], especially regarding whether the Time and Value arguments are considered and whether all Time-related argument roles are viewed as a single role. Following several recent state-of-the-art studies (Wadden et al., 2019; Lin et al., 2020; Du and Cardie, 2020), we do not consider Time and Value arguments. Our approach significantly outperforms most of the previous comparable baseline methods, especially on the ERE dataset[10]. Next, we take BERT_QA_Arg, a QA_based method, as the main baseline as it shares similar ideas to our approach to compare their performance.

---

[7] `https://catalog.ldc.upenn.edu/LDC2006T06`

[8] Following Lin et al. (2020), we merge LDC2015E29, LDC2015E68, and LDC2015E78 as the ERE dataset.

[9] Many studies did not describe their argument extraction setting in detail.

[10] Appendix E describes several remaining challenges identified from the prediction errors on ACE05 dataset.

Model	ACE05-E$^+$		ERE-EN	
	Trigger Ext.	Argument Ext.	Trigger Ext.	Argument Ext.
DYGIE++ (Wadden et al., 2019)	67.3*	42.7*	-	-
BERT_QA_Arg (Du and Cardie, 2020)	70.6*	48.3*	57.0	39.2
OneIE (Lin et al., 2020)	72.8	54.8	57.0	46.5
Text2Event (Lu et al., 2021)	71.8	54.4	59.4	48.3
FourIE (Nguyen et al., 2021)	73.3	**57.5**	57.9	48.6
Our Approach	**73.6** (0.2)	55.1 (0.5)	**60.4** (0.3)	**50.4** (0.3)

Table 1: Event extraction results on ACE05-E$^+$ and ERE-EN datasets (F-score, %). * indicates scores obtained from their released codes. The performance of BERT_QA_Arg is lower than that reported in (Du and Cardie, 2020) as they only consider single-token event triggers. Each score of our approach is the mean of three runs and the variance is shown in parenthesis.

Specifically, for trigger detection, all the baseline methods treat the event types as symbols and classify each input token into one of the target types or *Other*. So they heavily rely on human annotations and do not perform well when the annotations are not enough. For example, there are only 31 annotated event mentions for *End_Org* in the ACE05 training dataset, so BERT_QA_Arg only achieves 35.3% F-score. In comparison, our approach leverages the semantic interaction between the input tokens and the event types. Therefore it still performs well when the annotations are limited, e.g., it achieves 66.7% F-score for *End_Org*. In addition, by leveraging the rich semantics of event types, our approach also successfully detects event triggers that are rarely seen in the training dataset, e.g., *ousting* and *purge* of *End-Position*, while BERT_QA_Arg misses all these triggers. A more detailed discussion about the impact of seed triggers is in Appendix B.

For argument extraction, our approach shows more consistent results than baseline methods. For example, in the sentence "*Shalom was to fly on to London for talks with British Prime Minister Tony Blair and Foreign Secretary Jack Straw*", the BERT_QA_Arg method correctly predicts *Tony Blair* and *Jack Straw* as *Entity* arguments of the *Meet* event triggered by *talks*, but misses *Shalom*. However, by employing multiway attention, especially the self-attention among all the entities, our approach can capture their underlying semantic relations, e.g., *Shalom* and *Tony Blair* are two persons to talk, so that it successfully predicts all the three *Entity* arguments for the *Meet* event.

3.3 Zero-Shot Event Extraction

As there are no fully comparable baseline methods for zero-shot event extraction, we adapt one of the most recent states of the arts, BERT_QA_Arg (Du and Cardie, 2020), which is expected to have specific transferability due to its QA formulation. However, the original BERT_QA_Arg utilizes a generic query, e.g., "*trigger*" or "*verb*", to classify each input token into one of the target event types or *Other*, thus is not capable of detecting event mentions for any new event types during the test. We adapt the BERT_QA_Arg framework by taking each event type instead of the generic words as a query for event detection. Note that our approach utilizes the event types as queries without prototype triggers for zero-shot event extraction.

Model	Trigger Ext.	Arg Ext. (GT)
BERT_QA_Arg†	31.6	17.0
Our Approach	**47.8**	**43.0**

Table 2: Zero-shot F-scores on 23 unseen event types. †: adapted implementation from (Du and Cardie, 2020). GT indicates using gold-standard triggers as input.

As Table 2 shows, our approach significantly outperforms BERT_QA_Arg under zero-shot event extraction, with over 16% F-score gain on trigger detection and 26% F-score gain on argument extraction. Comparing with BERT_QA_Arg, which only relies on the self-attention from the BERT encoder to learn the correlation between the input tokens and the event types or argument roles, our approach further applies multiple carefully designed attention mechanisms over BERT contextual representations to better capture the semantic interaction between event types or argument roles and input tokens, yielding much better accuracy and generalizability.

We further pick 13 unseen event types and analyze our approach's zero-shot event extraction performance on each of them. As shown in Figure 3, our approach performs exceptionally well on

ACE+ERE	ACE	70.1	47.0	71.3	49.8	74.4	56.2
ACE	ERE	47.2 (47.2)	18.0 (18.0)	47.2 (45.0)	17.9 (17.1)	55.9 (46.3)	31.9 (26.0)
ERE	ERE	57.0	39.2	56.7	42.9	60.4	50.4
ACE+ERE	ERE	57.0	38.6	54.6	37.1	63.0	52.3

Table 3: Cross ontology transfer between ACE and ERE datasets (F-score %). The scores in parenthesis indicate the performance on the ACE and ERE shared event types.

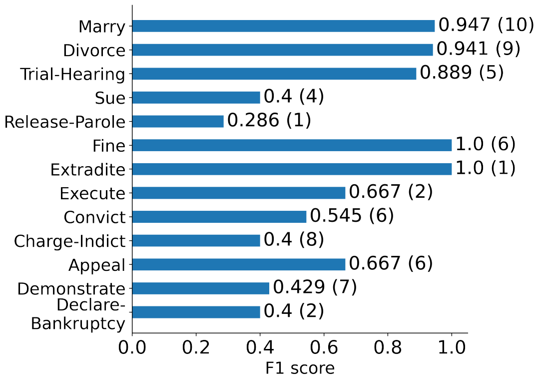

Figure 3: Zero-shot event extraction on each unseen event type. The number in parenthesis indicates # gold event mentions of each unseen type in the test set.

Marry, *Divorce*, *Trial-Hearing*, and *Fine*, but worse on *Sue*, *Release-Parole*, *Charge-Indict*, *Demonstrate*, and *Declare-Bankruptcy*, with two possible reasons: first, the semantics of event types, such as *Marry*, *Divorce*, is more straightforward and explicit than other types, such as *Charge-Indict*, *Declare-Bankruptcy*. Thus our approach can better interpret these types. Second, the diversity of the event triggers for some types, e.g., *Divorce*, is much lower than other types, e.g., *Demonstrate*. For example, among the 9 *Divorce* event triggers, there are only 2 unique strings, i.e., *divorce* and *breakdowns*, while there are 6 unique strings among the 7 event mentions of *Demonstrate*.

3.4 Cross Ontology Transfer

For cross-ontology transfer, we develop two variations of BERT_QA_Arg as baseline methods: (1) BERT_QA_Arg$_{\text{multi}}$, which is the same as the original implementation and use multi-classification to detect event triggers. (2) BERT_QA_Arg$_{\text{binary}}$, for which we apply the same query adaptation as Section 3.3 and use multiple binary-classification for event detection. For *joint-ontology enhancement*, we combine the training datasets of ACE and ERE and optimize the models from scratch.[11]

Table 3 shows the cross-ontology transfer results in both *direct transfer* and *enhancement* settings. Our approach significantly outperforms the baseline methods under all the settings. Notably, for *direct transfer*, e.g., from ERE to ACE, by comparing the F-scores on the whole test set with the performance on the ACE and ERE shared event types (F-scores shown in parenthesis), our approach not only achieves better performance on the shared event types but also extracts event triggers and arguments for the new event types in ACE. In contrast, the baseline methods hardly extract any events or arguments for the new event types. Moreover, by combining the training datasets of ACE and ERE for *joint-ontology enhancement*, our approach's performance can be further boosted compared with using the annotations of the target event ontology only, demonstrating the superior transfer capability across different ontologies. For example, ACE includes a *Transport* event type while ERE defines two more fine-grained types *Transport-Person* and *Transport-Artifact*. By adding the annotations of *Transport-Person* and *Transport-Artifact* from ERE into ACE, our approach can capture the underlying semantic interaction between *Transport*-related event type queries and the corresponding input tokens and thus yield 1.5% F-score gain on the *Transport* event type of ACE test set. In contrast, both baseline methods fail to be enhanced with additional annotations from a slightly different event ontology without explicitly capturing semantic interaction between event types and input tokens. Appendix C provides a more in-depth comparison between our approach and the baseline approaches.

---

[11] Another intuitive training strategy is to train the model on the source and target ontologies sequentially. Our pilot study shows that this strategy performs slightly worse.

3.5 Ablation Study

We further evaluate the impact of each attention mechanism on event trigger detection and argument extraction. As Table 4 shows, all the attention mechanisms show significant benefit to trigger or argument extraction, especially on the ERE dataset. The Event Type Attention and Multiway Attention show the most effects to trigger and argument extraction, which is understandable as they are designed to capture the correlation between the input texts and the event type or argument role-based queries. We also notice that, without taking entities detected by the BERT-CRF name tagging model as input, but instead considering all the tokens as candidate arguments[12], our approach still shows competitive performance for argument extraction compared with the strong baselines. More ablation studies are discussed in Appendix D.

	Model	ACE	ERE
Trigger	Our Approach	73.6	60.4
	w/o Seed Trigger	72.2	58.2
	w/o In-Context Attention	72.3	57.9
	w/o Event Type Attention	71.1	56.9
Arg.	Our Approach	55.1	50.4
	w/o Entity Detection	53.0	47.6
	w/o Multiway Attention	53.4	42.8
	w/o Entity Self-attention	53.7	48.3
	w/o Arg Role Self-attention	54.1	47.7

Table 4: Results of various ablation studies. Each score is the average of three runs for each experiment.

3.6 Pros and Cons of Type-oriented Decoding

The advantages of our type-oriented binary decoding include: (1) it allows the model to better leverage the semantics of event types which have been proved effective for both supervised and zero-shot event extraction; (2) it allows the approach to leverage all available event annotations from distinct ontologies, which is demonstrated in zero-shot event extraction and cross-ontology transfer; (3) in practice, new event types and annotations could emerge incessantly, and it is not possible to always train a model for all the event types. Our approach has the potential to be continuously updated and extract events for any desired event types.

We also admit that binary decoding usually increases the computation cost. We design two strategies to mitigate this issue: (1) More than 69% of the sentences in the training dataset do not contain any event triggers, so we randomly sample 20% of them for training. (2) Our one-time argument encoding and decoding strategies extract all arguments of each event trigger at once. It is more efficient than the previous QA-based approaches, which only extract arguments for one argument role at once. With these strategies, for trigger detection, our approach takes 80% more time for training and 19% less for inference compared with BERT_QA_Arg which relies on multi-class classification, while for argument extraction, our approach takes 36% less time for training and inference than BERT_QA_Arg. Even on a more fine-grained event ontology MAVEN (Wang et al., 2020), which consists of 168 event types, for trigger extraction, our approach roughly takes 20% more time for training and twice the time for inference compared with BERT_QA_Arg, with slightly better performance than the state of the art (Wang et al., 2021)[13].

4 Related Work

Traditional event extraction studies (McClosky et al., 2011; Li et al., 2013; Chen et al., 2015; Cao et al., 2015; Feng et al., 2016; Yang and Mitchell, 2016; Nguyen et al., 2016; Zhang et al., 2017; Wadden et al., 2019; Lin et al., 2020; Wang et al., 2021) usually detect event triggers and arguments with multi-class classifiers. Unlike all these methods that treat event types and argument roles as symbols, our approach considers them queries with rich semantics and leverages the semantic interaction between input tokens and each event type or argument role.

Several studies have explored the semantics of event types based on seed event triggers (Bronstein et al., 2015; Lai and Nguyen, 2019; Zhang et al., 2021), event type structures (Huang et al., 2016, 2018), definitions (Chen et al., 2019) and latent representations (Huang and Ji, 2020). However, they can hardly be generalized to argument extraction. Question answering based event extraction (Du and Cardie, 2020; Liu et al., 2020; Li et al., 2020a; Lyu et al., 2021) can take advantage of the semantics of event types and the large-scale question answering datasets. Compared with these methods, there are three different vital designs, making our approach perform and be generalized better than these

---

[12] We take consecutive tokens predicted with the same argument role as a single argument span.

[13] Our approach achieves 68.8% F-score on MAVEN. We do not discuss more as MAVEN only contains trigger annotations.

QA-based approaches: (1) our approach directly takes event types and argument roles as queries. In contrast, previous QA-based approaches rely on templates or generative modules to create natural language questions. However, it is difficult to find the optimal format of questions for each event type, and many studies (Du and Cardie, 2020; Li et al., 2020b) have shown that MRC or QA models are sensitive to the subtle change of the questions. (2) QA-based approaches can only detect arguments for one argument role at once, while our approach extracts all arguments of an event trigger with one-time encoding and decoding, which is more efficient and leverages the implicit relations among the candidate arguments or argument roles. (3) QA-based approaches rely on span prediction to extract arguments without requiring entity extraction, which could result in more entity boundary errors. Thus we choose to pre-train a name tagging model and use binary decoding over system detected entities.Moreover, it is pretty challenging to fully adapt the event extraction task to the span-based Question Answering. The main reason is that each sentence may contain multiple triggers for a particular event type. Even if we can formalize a question, e.g., "what is the trigger for Attack?" it is difficult for the model to return all the spans of event triggers correctly.

5 Conclusion and Future Work

We refine event extraction with a query-and-extract paradigm and design a new framework that leverages rich semantics of event types and argument roles and captures their interactions with input texts using attention mechanisms to extract event triggers and arguments. Experimental results demonstrate that our approach achieves state-of-the-art performance on supervised event extraction and shows prominent accuracy and generalizability to new event types and across ontologies. In the future, we will explore better representations of event types and argument roles and combine them prompt tuning approach further to improve the accuracy and generalizability of event extraction.

A Data Statistics and Implementation Details

Table 5 shows the detailed data statics of the training, development and test sets of the ACE05-E+ and ERE datasets. The statistics for the ERE dataset is slightly different from previous work (Lin et al., 2020; Lu et al., 2021) as we consider the event triggers that are annotated with multiple types as different instances while the previous studies just keep one annotated type for each trigger span. For example, in the ERE-EN dataset, a token *"succeeded"* in the sentence *"Chun ruled until 1988 , when he was succeeded by Roh Tae - woo , his partner in the 1979 coup ."* triggers a *End-Position* event of *Chun* and a *Start-Position* of *Roh*. Previous classification based approaches did not predict multiple types for each candidate trigger.

Dataset	Split	# Events	# Arguments
ACE05-E+	Train	4419	6605
	Dev	468	757
	Test	424	689
ERE-EN	Train	7394	11576
	Dev	632	979
	Test	669	1078

Table 5: Data statistics for ACE2005 and ERE datasets.

Zero-Shot Event Extraction To evaluate the transfer capability of our approach, we use the top-10 most popular event types in ACE05 as seen types for training and treat the remaining 23 event types as unseen for testing, following Huang et al. (2018). The top-10 training event types include *Attack*, *Transport*, *Die*, *Meet*, *Sentence*, *Arrest-Jail*, *Transfer-Money*, *Elect*, *Transfer-Ownership*, *End-Position*. We use the same data split as supervised event extraction but only keep the event annotations of the 10 seen types for training and development sets and sample 150 sentences with 120 annotated event mentions for the 23 unseen types from the test set for evaluation.

Implementation For fair comparison with previous baseline approaches, we use the same pretrained `bert-large-uncased` model for fine-tuning and optimize our model with BertAdam. We optimize the parameters with grid search: training epoch 10, learning rate $\in [3e\text{-}6, 1e\text{-}4]$, training batch size $\in \{8, 12, 16, 24, 32\}$, dropout rate $\in \{0.4, 0.5, 0.6\}$. Our experiments run on one Quadro RTX 8000. For trigger detection, the average runtime is 3.0 hours. For argument detection, the average runtime is 1.3 hours. We use Spacy to generate POS tags.

Evaluation Criteria For evaluation of supervised event extraction, we use the same criteria as (Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016; Lin et al., 2020) as follows:

- **Trigger**: A trigger mention is correct if its span and event type matches a reference trigger. Each candidate may act as triggers for multiple event occurrences.
- **Argument**: An argument prediction is correct only if the event trigger is correctly detected. Meanwhile, its span and argument role need to match a reference argument. An argument candidate can be involved in multiple events as different roles. Furthermore, within a single event extent, an argument candidate may play multiple roles.

B Impact of Seed Triggers

To investigate the impact of seed triggers on event trigger extraction, we take the supervised event extraction ACE dataset as a case study, where we divide the triggers in the evaluation dataset into two groups: overlapped triggers with the seeds or non-overlapped ones with the seeds. Then, we compare the performance of our approach with and without using seed triggers as part of the event type representations. As Table 6 shows, by incorporating the seed triggers as part of the event type representations, our approach achieves better performance on both overlapped and non-overlapped triggers, demonstrating the benefit of seed triggers on representing event types. As the total number of overlapped triggers (34) is much lower than that of non-overlapped triggers (390), we view the impact of seed triggers on overlapped and non-overlapped triggers as comparable. On the other hand, by comparing our approach without using seed triggers with the BERT_QA_Arg baseline, our approach also achieves much better performance which is mostly due to the attention mechanism we used which can better capture the semantic consistency between the input tokens and the event type query which just consists of the event type name.

C In-depth Comparison for Cross Ontology Transfer

To deeply investigate the reason that our approach performs better than QA-based baselines from cross ontology transfer, we conducted ablation study by removing the seed triggers from the event type queries of our approach, as shown in Table 7. The BERT_QA_Arg$_{\text{multi}}$ utilizes a generic query, e.g., *what's the trigger*, and classify each input token into one of the target types. It's essentially a multiclass classifier but just taking a query as the prompt. The BERT_QA_Arg$_{\text{binary}}$ utilizes each event type as the query to extract the corresponding event mentions. Comparing the two baseline methods, BERT_QA_Arg$_{\text{binary}}$ works slightly better than BERT_QA_Arg$_{\text{multi}}$, especially on ACE, demonstrating the benefit of type-oriented binary decoding mechanism. The only difference between BERT_QA_Arg$_{\text{binary}}$ and our approach without seed triggers is the learning of enriched contextual representations. The comparison of their scores demonstrates the effectiveness of the attention mechanisms designed for trigger extraction. Finally, by incorporating the seed triggers into event type representations, our approach is further improved significantly for all the settings. These in-depth comparisons demonstrate the effectiveness of both seed triggers and the attention mechanisms in our approach for transferring annotations from old types to the new types.

	Overlapped Triggers	**Non-overlapped Triggers**
OneIE (Lin et al., 2020)	88.2	71.0
BERT_QA_Arg (Du and Cardie, 2020)	72.2	70.9
Our Approach w/o Seed Triggers	88.9	70.8
Out Approach w/ Seed Triggers	97.2	71.3

Table 6: Impact of seed triggers on supervised trigger extraction on ACE (F-score, %)

Source	Target	BERT_QA_Arg$_{\text{multi}}$ †	BERT_QA_Arg$_{\text{binary}}$ †	**Our Approach** w/o Seed Triggers	**Our Approach** w/ Seed Triggers
ERE	ACE	48.9	50.8	53.8	53.9
ACE	ACE	70.6	72.2	72.2	73.6
ACE+ERE	ACE	70.1	71.3	72.2	74.4
ACE	ERE	47.2	47.2	48.7	55.9
ERE	ERE	57.0	56.7	58.2	60.4
ACE+ERE	ERE	57.0	54.6	56.2	63.0

Table 7: Cross ontology transfer results for queries without seed triggers, between ACE and ERE datasets (F-score %)

D More Ablation Studies of Supervised Event Extraction

The entity recognition model is based on a pre-trained BERT (Devlin et al., 2019) encoder with a CRF (Lafferty et al., 2001; Passos et al., 2014) based prediction network. It's trained on the same training dataset from ACE05 before event extraction, and the predictions are taken as input to argument extraction to indicate the candidate argument spans. Table 8 shows the comparison of the entity extraction performance between our BERT-CRF approach and the baselines.

Model	F1
OneIE	89.6
FourIE	91.1
BERT+CRF	89.3

Table 8: Performance of Entity Extraction (F-score, %)

To understand the factors that affect argument extraction and decompose the errors propagated along the learning process (from predicted triggers or predicted entities), we conduct experiments that condition on given ground truth labels for those factors. Specifically, we investigate three settings: 1) given gold entity, 2) given gold event trigger, and 3) given both gold entity and event trigger. The experimental results is shown in Table 9.

Given Information	ACE	ERE
None	55.1	50.2
GE	59.7 (+4.6)	59.5 (+9.3)
GT	68.7 (+13.6)	67.2 (+17.0)
GT & GE	74.2 (+19.1)	72.2 (+22.0)

Table 9: Performance of argument extraction conditioning on various input information: gold trigger (GT), and gold entities (GE). (F-score, %)

E Remaining Challenges for Supervised Event Extraction

We sample 200 supervised trigger detection and argument extraction errors from the ACE test dataset and identify the remaining challenges.

Lack of Background Knowledge Background knowledge, as well as human commonsense knowledge, sometimes is essential to event extraction. For example, from the sentence "*since the intifada exploded in September 2000, the source said*", without knowing that *intifada* refers to a resistance movement, our approach failed to detect it as an *Attack* event mention.

Pronoun Resolution Extracting arguments by resolving coreference between entities and pronouns is still challenging. For example, in the following sentence "*Attempts by Laleh and Ladan to have their operation elsewhere in the world were rejected, with doctors in Germany saying one or both of them could die*", without pronoun resolution, our approach mistakenly extracted *one*, *both* and *them* as *Victims* of the *Die* event triggered by *die*, while the actual *Victims* are *Ladan* and *Laleh*.

Ambiguous Context The ACE annotation guidelines (Consortium, 2005) provide detailed rules and constraints for annotating events of all event types. For example, a *Meet* event must be specified by the context as *face-to-face and physically located somewhere*. Though we carefully designed several attention mechanisms, it is difficult for the machines to capture such context features accurately. For example, from the sentence "*The admission came during three-day talks in Beijing which concluded Friday, the first meeting between US and North Korean officials since the nuclear crisis erupted six months ago.*", our approach failed to capture the context features that *the talks is not an explicit face-to-face meet event*, and thus mistakenly identified it as a *Meet* event mention.

LEVEN: A Large-Scale Chinese Legal Event Detection Dataset

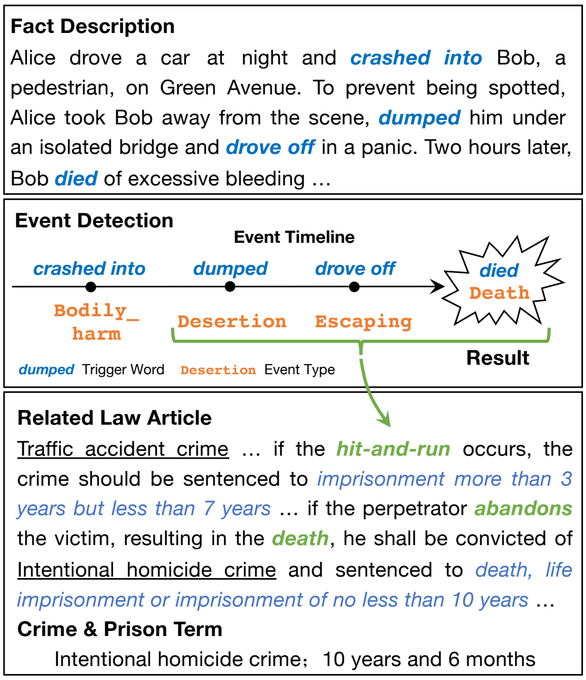
Abstract

Recognizing facts is the most fundamental step in making judgments, hence detecting events in the legal documents is important to legal case analysis tasks. However, existing Legal Event Detection (LED) datasets only concern incomprehensive event types and have limited annotated data, which restricts the development of LED methods and their downstream applications. To alleviate these issues, we present LEVEN, a large-scale Chinese LEgal eVENt detection dataset, with 8,116 legal documents and 150,977 human-annotated event mentions in 108 event types. Not only charge-related events, LEVEN also covers general events, which are critical for legal case understanding but neglected in existing LED datasets. To our knowledge, LEVEN is the largest LED dataset and has dozens of times the data scale of others, which shall significantly promote the training and evaluation of LED methods. The results of extensive experiments indicate that LED is challenging and needs further effort. Moreover, we simply utilize legal events as side information to promote downstream applications. The method achieves improvements of average 2.2 points precision in low-resource judgment prediction, and 1.5 points mean average precision in unsupervised case retrieval, which suggests the fundamentality of LED. The source code and dataset can be obtained from `https://github.com/thunlp/LEVEN`.



Fact Description

Alice drove a car at night and *crashed into* Bob, a pedestrian, on Green Avenue. To prevent being spotted, Alice took Bob away from the scene, *dumped* him under an isolated bridge and *drove off* in a panic. Two hours later, Bob *died* of excessive bleeding …

Related Law Article

Traffic accident crime … if the *hit-and-run* occurs, the crime should be sentenced to *imprisonment more than 3 years but less than 7 years* … if the perpetrator *abandons* the victim, resulting in the *death*, he shall be convicted of Intentional homicide crime and sentenced to *death, life imprisonment or imprisonment of no less than 10 years* …

Crime & Prison Term

Intentional homicide crime；10 years and 6 months

Figure 1: An example legal document describing the fact with the annotated event triggers, the corresponding event types, the related law article, and penalties.

1 Introduction

Finding out the occurred events and causal relations between them is fundamental to analyzing legal cases and making judgments. Legal event detection (LED) aims to automatically extract the event triggers from legal cases and then classify their corresponding event types, which will naturally benefit many legal artificial intelligence applications, such as Legal Judgment Prediction (LJP) and Similar Case Retrieval (SCR) (Zhong et al., 2020a). For instance, Figure 1 shows a case with the trigger words highlighted in the plain text and the corresponding event types. Based on the detected events, we can observe that Alice causes a traffic accident, and the subsequent `Desertion` and `Escaping` events jointly result in the `Death` event, which changes Alice's charge from traffic accident crime to intentional homicide crime and increases the expected penalties.

Findings of the Association for Computational Linguistics: ACL 2022, pages 183 - 201
May 22-27, 2022 ©2022 Association for Computational Linguistics

Inspired by the previous success for general-domain event detection (Ji and Grishman, 2008; Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016; Feng et al., 2016; Yan et al., 2019; Wang et al., 2020), some works attempt to build LED systems with hand-crafted features (Lagos et al., 2010; Bertoldi et al., 2014), or neural networks (Li et al., 2019, 2020a; Shen et al., 2020). However, two major challenges of existing LED resources seriously restrict the development of LED methods:

(1) **Limited Data.** Existing LED datasets (Shen et al., 2020; Li et al., 2020a) only contain thousands of event mention annotations, which can not provide sufficient training signals and reliable evaluation results. To promote the progress of legal information extraction and legal document analysis, it is an urgent need to develop a large-scale and high-quality dataset for the LED task. (2) **Incomprehensive Event Schema.** Existing LED works merely concern a dozen of charge-oriented event types, which are either the judicial event types defined in general-domain datasets (Maxwell et al., 2009) or some newly-defined charge-oriented event types to meet specific downstream requirements (Li et al., 2019, 2020a; Shen et al., 2020). Their event schemata only cover a narrow scope of charges. Besides, existing datasets focus on charge-oriented events and ignore the general events in the cases, such as `Desertion` and `Escaping` in Figure 1, which are also critical for analyzing legal cases.

To alleviate the above issues and provide a solid foundation for LED, we present LEVEN, a large-scale Chinese legal event detection dataset, based on the cases published by the Chinese government[1]. We highlight LEVEN with the following merits:

(1) **Large scale**. LEVEN contains $8,116$ legal documents covering 118 criminal charges and has $150,977$ human-annotated event mentions, which is dozens of times larger than previous LED datasets. To the best of our knowledge, LEVEN is also the largest Chinese event detection dataset. Based on the scale, we believe LEVEN can well train and reliably benchmark data-driven LED methods, which shall promote this field. (2) **High coverage**. LEVEN contains 108 event types in total, including 64 charge-oriented events and 44 general events. The LEVEN event schema has a sophisticated hierarchical structure, which is shown in appendix E. To build the schema, we conduct a two-stage event schema construction process. We first summarize the critical charge-oriented event types based on law articles and then simplify and supplement the event schema based on the events in sample cases. The two-stage process ensures the high coverage of LEVEN schema.

To explore the challenges of LEVEN, we implement some state-of-the-art models and evaluate them on our dataset. The results show that though existing models can achieve better performance on legal documents than in the general domain, it still needs future efforts to reach a practical level.

Moreover, we demonstrate the fundamentality of LED for downstream Legal AI applications. Specifically, we train an LED model on LEVEN and use it to detect events for unlabeled legal documents. We then use the auto-detected events as side information to handle LJP and SCR. Experiments show that the performance of these two tasks can be substantially improved in this simple way, indicating that LED can provide helpful fine-grained information and thus serve as a fundamental process in Legal AI. Hence we advocate more research attention to LED.

2 Related Work

2.1 Event Detection

Event detection (ED) is an important information extraction task and many efforts have been devoted to (Ji and Grishman, 2008; Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016; Liu and Zhao, 2017; Zhao et al., 2018; Yan et al., 2019; Wang et al., 2021b). The majority of existing ED datasets are developed for the general domain (Christopher et al., 2006; Song et al., 2015; Wang et al., 2020) and mostly for English. Besides, some datasets are also developed for specific domains (Thompson et al., 2009; Kim et al., 2008; Ritter et al., 2012; Yang et al., 2018; Zheng et al., 2019) and Chinese (Li et al., 2020b). Considering the rapid growth of Chinese legal artificial intelligence (Zhong et al., 2020a), we believe constructing Chinese LED datasets is helpful and necessary. In the context of LED, some works define specific legal event types to analyze for legal documents (Maxwell et al., 2009; Lagos et al., 2010; Li et al., 2019; Shen et al., 2020; Li et al., 2020a), but these constructed datasets are typically small-scale and cannot well train and evaluate practical LED systems. Hence we construct LEVEN, which is the largest LED dataset and also the largest Chinese event detection dataset to our knowledge.

2.2 Legal Artificial Intelligence

Thanks to the rapid progress of natural language processing and the openness of legal documents, legal artificial intelligence (LegalAI) has drawn increasing attention from both AI researchers and legal professionals in recent years (Bommarito II et al., 2021; Ye et al., 2018; Chalkidis et al., 2021; Zhong et al., 2020a; Tsarapatsanis and Aletras, 2021; Wang et al., 2021a). LegalAI can not only provide handy references for people who are not familiar with legal knowledge, but also reduce the redundant paperwork for legal practitioners. Many efforts have been devoted to a variety of LegalAI tasks, including legal judgment prediction (Zhong et al., 2018; Chalkidis et al., 2019; Yang et al., 2019), legal question answering (Ravichander et al., 2019; Zhong et al., 2020b; Kien et al., 2020), contract review (Hendrycks et al., 2021; Zhang et al., 2021; Koreeda and Manning, 2021), legal case retrieval (Ma et al., 2021; Shao et al., 2021), and legal pre-trained models (Chalkidis et al., 2020; Xiao et al., 2021). Most existing works focus on the application in LegalAI while ignoring the basic key event information in the legal documents. Some works attempt to extract events from the legal documents (Li et al., 2019; Shen et al., 2020; Li et al., 2020a). But these works are limited to the event coverage and the number of annotation instances. We argue that our proposed large-scale and comprehensive dataset, LEVEN, can promote the development of legal event detection and thus benefit downstream legal artificial intelligence tasks.

3 Data Collection

Our ultimate goal is to construct a large-scale legal event detection dataset with a high-coverage event type schema and sufficient event instances, which is scarce in existing LED datasets. Therefore, we need to redefine a new event schema, select the trigger candidates, and annotate the corresponding event types. As criminal cases usually involve principal rights and complex facts, we focus on criminal legal events in this paper. In the following sections, we first introduce the construction of event schema and then describe the process of annotation of candidates and related event types.

3.1 Event Schema Construction

To construct an event schema with high coverage, we need to consider events for both judicial behaviors and general behaviors. Therefore, we follow a two-stage process to define our new event schema: 1) We first collect charge-oriented events based on the law articles and legal textbooks. 2) We then collect general events from the sampled case documents. The two-stage process enables LEVEN to cover essential events recorded in legal documents.

Inspired by previous works (Li et al., 2020a; Shen et al., 2020), in the first stage, we use law articles and a classical legal textbook, *Specific Theory of Criminal Law*, as our references to summarize the charge-oriented events. *Criminal Law* provides the definition of each criminal charge and a hierarchical structure for these charges. We first collect 459 criminal charges, which are then divided into 61 types based on the targets and measures of criminal behaviors. Considering that some criminal charges are too abstract to be specific event types (e.g., `dereliction`), we manually filter out them. Besides, as there are some similar charges involving the same event types (e.g., `intentional_homicide` and `involuntary_homicide`), we merge them. After the first stage, we obtain 198 event types highly correlating to the criminal charges.

As the charge-oriented event schema is constructed from legal professional references, there are two main issues: 1) The charge-oriented event schema mainly focuses on illegal behaviors, while ignoring important general behaviors. 2) There are some event types that infrequently or never occur in real-world cases. To address these issues, we further modify the event schema based on the summarization of real-world cases. Specifically, we sample 20 case documents for each criminal charge, which can ensure good coverage. And then we invite a legal expert to manually extract and summarize the event mentions occurring in sampled cases. Based on the extracted events, we further filter out the abstract event types and merge some detailed event types in the schema. We finally get 108 event types to annotate, with both charge-oriented events and general events.

According to the criminal theory, the key elements of the crime include the act, the harmful results, and the causal relation between them. Therefore, we organize the event types in a hierarchical structure, with three categories representing behavior and a category representing results. During the annotation process, the annotators are required to label the most fine-grained types. Please refer to Appendix E for details of the event schema.

Dataset	#Documents	#Tokens	#Sentences	#Event Types	#Event Mentions	Language	Domain
MAVEN	4,480	1,276k	49,873	168	118,732	English	General
ACE2005-zh	633	185k	7,955	33	4,090	Chinese	General
DuEE	11,224	530k	16,900	65	19,640	Chinese	General
DivorceEE*	3,100	–	–	13	–	Chinese	Legal
CLEE*	3,000	–	6,538	5	6,538	Chinese	Legal
DyHiLED*	–	–	–	11	2,380	Chinese	Legal
LEVEN	8,116	2,241k	63,616	108	150,977	Chinese	Legal

Table 1: The statistics of widely-adopted event detection datasets. For Chinese datasets, we adopt JIEBA toolkit to perform tokenization. Datasets denoted with * are not publicly available, and – means the value is not accessible.

3.2 Document Selection

To support the manual annotation, we adopt cases collected from the government website as our data source. Following Xiao et al. (2018), we only keep the criminal judgment documents for annotation.

We first extract the related charges with regular expression from the documents and divide each document into several parts based on the content, where only the fact description is maintained. Moreover, to ensure the dataset quality, we filter out the documents with less than 50 characters and more than $2,500$ characters in fact description. Notably, though we get 198 charges in the first stage of event schema construction, there are some charges where no cases are published due to the privacy and secrecy involved. Therefore, we get case documents with only 107 charges. We randomly sample 200 documents for charges with high frequency and maintain all cases for charges with low frequency. Finally, we select $8,288$ documents for annotation. After discarding the low-quality documents labeled by annotators, we finally retain $8,166$ documents.

3.3 Candidate Selection

The annotation of LED dataset requires the annotators to find the triggers from the documents and label the corresponding event types within 108 options. Following Wang et al. (2020), we adopt heuristic methods to automatically select the trigger candidates and narrow down the event type options for each trigger candidate.

Candidate trigger selection. Inspired by Chen et al. (2017), which utilizes the lexical unit in FrameNet (Baker et al., 1998) to select trigger words, we require a legal expert to collect semantic-related words for each event type in our schema. And we obtain a semantic vocabulary consisting of $1,013$ words with their corresponding event types. Then we apply tokenization and POS tagging with JIEBA toolkit[2], and all the content words, including nouns and verbs, are selected as trigger candidates. Besides, the words in the collected vocabulary are also selected as trigger candidates.

Candidate event type selection. Further, we recommend 30 event types for each trigger candidate, which can provide references for annotators. We first calculate the cosine similarity between the representations of trigger candidates and event types. And then we rank the event types by the calculated similarity and retrieve the top 30 ones as the recommended candidates. Here, we utilize the representations calculated by SBERT (Reimers and Gurevych, 2019), which can generate semantic meaningful embeddings.

The automatic candidate selection mechanism aims to provide a good reference for the annotators. Notably, considering that not all triggers and event types can be automatically selected, we also require the annotators to label the words and event types that are not in the recommended list. The final annotation results show that 95.6% trigger words and 92.8% event types are recommended, and the rest are supplemented by annotators manually. The results demonstrate that the automatic candidate selection is helpful to improve the annotation efficiency, and the annotators can also label the trigger words and event types that are not recommended.

3.4 Human Annotation

The final process is to annotate the triggers from documents manually. We write a 59-page annotation guideline in Chinese to help the annotators better understand the annotation task. We also embed the guideline in the annotation platform so that the annotators can easily refer to it. A simplified version in English is provided in Appendix F.

Following previous works (Christopher et al., 2006; Wang et al., 2020), we adopt a two-stage

---

Top-level Event Type	Category	#Type	#Mention	Percentage	Sub-type Examples
`General_behaviors`	Behavior	40	68,616	45.4%	`Selling`, `Employing`, `Manufacturing`
`Prohibited_acts`	Behavior	40	43,021	28.5%	`Killing`, `Blackmail`, `Theft`, `Destroying`
`Judicature_related`	Behavior	13	29,709	19.7%	`Arrest`, `Surrendering`
`Consequences`	Result	7	6,832	4.5%	`Death`, `Injury`, `Being_trapped`
`Accident`	Result	4	2,742	1.8%	`Traffic_accident`, `Fire_accident`
`Natural_disaster`	Majeure	4	57	0.03%	`Drought`, `Flood_and_waterlogging`

Table 2: Data distribution over the top-level event types and the corresponding categories and samples.

annotation process. In the first stage, we invite crowd-source annotators to choose the correct answers from case documents when given the candidate triggers and corresponding event types. Each document is annotated independently twice. The annotators first went through several hours of training for labeling, so as to ensure the annotation quality. Besides, for each labeled document, we discard the annotation results and require another two annotators to annotate it, if the inter-annotator agreement of the document is lower than 0.2. In the second stage, we invite experienced annotators to choose final event types given the results of the first-stage annotation. Only the results labeled differently in the first stage are required to be labeled again in the second stage.

We measure the data quality via inter-annotator agreements between two annotators, i.e., Cohen's Kappa (Cohen, 1960). The Kappa coefficient for the first stage is 0.609. To evaluate the data quality in the second stage, we randomly sample 5% documents to be labeled twice independently. The Kappa coefficient for the second stage is 0.875. The satisfactory Kappa coefficient demonstrates that LEVEN is a high-quality manually annotated LED dataset, and we hope the dataset can accelerate the development of LED and legal case analysis.

4 Data Analysis

In this section, we conduct analysis from various aspects to provide a deep understanding of LEVEN.

4.1 Data Size

The detailed statistics of LEVEN and some widely-used event detection datasets are shown in Table 1. We compare LEVEN with two types of datasets: (1) **General-domain ED datasets.** ACE2005 (Christopher et al., 2006) is the most popular multi-lingual event extraction dataset and here we compare with its Chinese subset (denoted as ACE2005-zh). MAVEN (Wang et al., 2020) is the largest general-domain event detection dataset, with 168 event types and hundreds of thousands of event instances. DuEE (Li et al., 2020b) is the largest Chinese ED dataset, which is collected from Chinese news articles. (2) **LED datasets.** DivorceEE (Li et al., 2019) focuses on event extraction in divorce cases. CLEE (Li et al., 2020a) is for larceny cases. DyHiLED (Shen et al., 2020) is a LED dataset with a hierarchical event schema.

From the comparisons, we can observe that LEVEN is the largest LED dataset with dozens of the scale of previous LED datasets and is also the largest Chinese event detection dataset. LEVEN's scale is even comparable to the previous largest general-domain event detection dataset MAVEN. Moreover, LEVEN contains the most event types among the Chinese event detection datasets. These suggest that LEVEN may help LED, Chinese ED, and general ED at the same time.

	#Doc.	#Sentences	#Event	#Negative.
Training	5,301	41,238	98,410	297,252
Validation	1,230	9,788	22,885	69,645
Test	1,585	12,590	29,682	90,512

Table 3: The detailed statistics of subsets of LEVEN.

4.2 Data Distribution

Event Types. As mentioned before, our event schema contains three event categories representing behavior, two event categories representing results, and one event category representing force majeure. The instance distribution over these top-level event types is shown in Table 2. There are 45.4% events belonging to general behavior, which is ignored in the previous LED dataset. It demonstrates that modeling the general events in LED is necessary. Besides, LEVEN meets long-tail distribution, which raises a challenge for future research.

Number of Instances. LEVEN is a large-scale dataset, where 89.6% event types contains more than 100 event mentions, and 43.4% event types contains more than 1,000 event mentions. Therefore, LEVEN can provide sufficient training signals and reliable evaluation results for LED.

Model		Micro			Macro	
	Precision	Recall	F1	Precision	Recall	F1
DMCNN	**85.88** ± 0.70	79.70 ± 0.59	82.67 ± 0.08	80.55 ±0.49	73.31 ± 3.88	75.03 ± 0.40
BiLSTM	83.09 ± 0.89	85.16 ± 0.95	84.11 ± 0.24	78.70 ± 0.92	76.67 ± 2.23	76.65 ± 1.42
BiLSTM+CRF	84.74 ± 0.55	83.33 ± 0.49	84.03 ± 0.05	78.56 ± 1.31	72.60 ± 1.11	74.49 ± 0.77
BERT	84.19 ± 0.39	84.31 ± 0.34	84.25 ± 0.18	79.61 ± 0.91	76.76 ± 1.79	77.33 ± 1.30
BERT+CRF	83.82 ± 0.48	84.56 ± 0.52	84.19 ± 0.09	79.77 ± 1.10	77.65 ± 2.20	77.84 ± 1.58
DMBERT	84.77 ± 0.91	**86.22** ± 0.77	**85.48** ± 0.18	**81.57** ± 1.04	**80.90** ± 1.38	**80.34** ± 0.74

Table 4: The test performances of ED baselines on LEVEN. Refer to Appendix A.1 for validation performances.

5 Experiments

5.1 Benchmark Settings

We randomly split the dataset into training set, validation set, and test set according to the ratio, $0.65 : 0.15 : 0.2$. Following Wang et al. (2020), we provide official negative samples for a fair comparison between different methods. As stated in Section 3.3, we first employ Chinese word segmentation and POS-tagging to the documents, and then select the content words (verbs and nouns) or words in the human-collected semantic vocabulary as the trigger candidates. The detailed statistics of the data splits are listed in Table 3. As the dataset is unbalanced, we adopt both the micro-averaged and macro-averaged precision, recall, and F1 score as the evaluation metrics for the experiments.

5.2 Baseline Models

Event detection has been explored for decades. In this section, we evaluate several competitive baseline models, which are widely used in the general domain event detection task, on LEVEN, including (1) Token classification. We first encode the given sentences with deep neural networks, including **BiLSTM** (Hochreiter and Schmidhuber, 1997) and **BERT** (Devlin et al., 2019), and then use the hidden representations of the candidate triggers to classify their corresponding event types. (2) Dynamic max-pooling. These models adopt convolutional neural network (**DMCNN**, Chen et al. (2015)) or pre-trained language model, BERT (**DMBERT**, Wang et al. (2019)), to extract the sequence features, and employ dynamic pooling layers to obtain trigger-specific representation for each candidate. (3) Sequence labeling. Different from previous models, we adopt sequence labelling models (**BiLSTM+CRF**, **BERT+CRF**) to capture the correlations between different events. The implementation details can be found in Appendix A.1. We run each experiment 5 times, and the averages and standard deviations of the results are reported.

5.3 Overall Performance Comparison

The baseline results are shown in Table 4. And we can observe that (1) DMBERT can outperform other baselines significantly, with the micro-F1 score of 85.48%, which is still not satisfactory for real-world applications. (2) The standard deviations on the micro-metrics are relatively small, indicating that LEVEN contains sufficient data in the test set and can provide stable evaluation results. (3) From the comparison between BiLSTM-based and BERT-based models, we find that BERT-based models cannot achieve significant improvement on LEVEN. It suggests that designing event-oriented pre-trained models is necessary for LED, which we leave for future work. (4) CRF-based models perform slightly worse than their corresponding token classification models. We attempt to employ CRF to capture the dependencies of multiple events as suggested by Wang et al. (2020), while the result is inconsistent with the expectation. Therefore, it still needs exploration to model the correlations between multiple events in a single sentence.

Notably, as the legal documents are well-written and the used language is more standardized than the general domain, the event detection models can achieve better performance on LEVEN than on the general domain dataset (DMBERT can only achieve 67.1% micro-F1 score on MAVEN (Wang et al., 2020), while 85.5% on LEVEN.) Therefore, we can apply existing LED models to promote the downstream tasks (Section 5.5). However, the performance is still unsatisfactory and needs future research (Section 5.4).

5.4 Error Analysis

To analyze the defect of existing models and point out the future directions for LED, we conduct error analysis on the prediction errors of the model with the best performance. We categorize the prediction errors into several types and find some challenges which require future efforts.

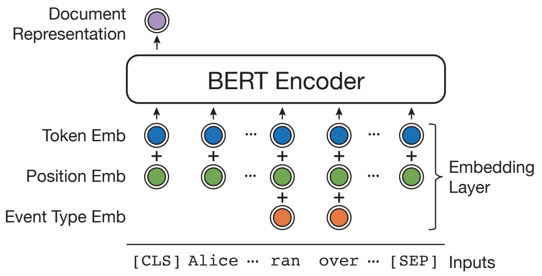

Figure 2: The framework for downstream tasks.

Model	Charge			Law			Term
	P	R	F1	P	R	F1	Dis ↓
50-shot							
BERT	76.6	**77.0**	76.8	73.6	**76.8**	75.2	2.398
+ event	**79.2**	76.2	**77.7**	**75.4**	75.6	**75.5**	**2.364**
full							
BERT	88.2	89.4	88.8	83.7	86.8	85.2	1.895
+ event	**88.2**	**89.7**	**88.9**	**83.8**	**87.7**	**85.7**	**1.878**

Table 5: The results for legal judgment prediction. Here P, R, and F1 indicate precision, recall, and F1 scores, respectively.

(1) **Long-tail Problem**. Though LEVEN contains hundreds of thousands of event mentions, there are some event types with limited instances inevitably. We compute the performance on low-frequency event types, where the micro-F1 score is 65.97% for event types with less than 50 instances and 72.24% for event types with less than 100 instances. There is still a large gap between the performance of the low-frequency types and the overall average performance. More discussion can be found in Appendix.

(2) **Context-aware Prediction**. Many triggers require the model to integrate the information of the complex context from argument entities or other sentences to predict corresponding event types. For instance, in the sentence *Bob rushed to call **ENT** to inform the situation*, if ***ENT*** is *the police* or *110*, the event type for trigger *call* is `Reporting_to_police`, while if ***ENT*** is other people, the event type is `Reporting`. Sometimes, the essential information comes from other sentences, which require the model to capture cross sentence dependency. We randomly sample 100 cases and ask another annotator to count the number of errors that need context-aware prediction. From the statistics, 36.98% errors are caused by incorrectly capturing contextual information, which still needs further effort.

(3) **Identification Mistakes**. Similar to Wang et al. (2020), the most common mistake is confusing the negative samples and positive samples, i.e., the false positive and false negative. The results show that 48.99% and 34.41% errors are false positive and false negative, respectively. Therefore, how to identify the event semantic is a challenge.

5.5 Applications of Legal Event Detection

Furthermore, in order to provide a perspective of how to use LEVEN for other Legal AI tasks and to verify the effectiveness of LED for legal documents analysis, we utilize legal events as side information in two typical downstream tasks in legal artificial intelligence, including Legal Judgment Prediction (LJP) and Similar Case Retrieval (SCR).

In the following sections, we will first introduce the encoder architecture and applications of LED in legal judgment prediction and similar case retrieval. We compare the performance of the original BERT model and BERT model with event features to show the effectiveness of LED. Notably, the event features can either be used independently or fed into other models to further promote the performance. The details about model implementation and dataset statistics can be found in Appendix A.2.

Encoder Architecture

As pre-trained language models have achieved promising results in many legal tasks (Chalkidis et al., 2020; Xiao et al., 2021), we adopt the BERT as our basic encoder. To verify the effectiveness of event detection in LegalAI, we only make minor changes in the embedding layer to integrate the event information. Figure 2 illustrates the encoder architecture. Given the input document, to highlight the event information, we first employ the **BERT+CRF** model to detect the trigger words and their event types from the case documents[3]. And then we utilize the event information in the BERT model by adding the event type embedding in the input embedding layer. The event type embedding is randomly initialized and updated during the training process. Specifically, for non-trigger tokens, we feed the sum of the token embeddings and position embeddings into the encoder. For trigger tokens, we also define an event type embedding for each event type and add the corresponding event type embeddings to the inputs.

---

[3] Notably, due to the high computational complexity of DMBERT, we use BERT+CRF here, which also achieve comparable results with DMBERT.

Model	MAP	NDCG@10	NDCG@20	NDCG@30	P@5	P@10
BM25	48.40	73.10	79.70	88.80	40.60	38.10
TFIDF	45.70	79.50	83.20	84.80	30.40	26.10
LMIR	49.50	76.90	81.80	90.00	43.60	40.60
Bag-of-Event	50.94	78.37	83.66	90.32	44.11	42.62

Table 6: The experiment results under both unsupervised and supervised settings for similar case retrieval.

Legal Judgment Prediction

Legal judgment prediction (LJP) aims to predict the judgment results, including related laws, charges, and prison terms, based on the textual fact description, and LJP is an essential task for LegalAI (Zhong et al., 2018; Chalkidis et al., 2019; Yang et al., 2019). LJP requires the model to capture the key event information and mine the causal relationship between behaviors and consequences.

Therefore, in this section, we attempt to investigate the effect of LED for judgment prediction. We adopt the CAIL2018 (Xiao et al., 2018) as the evaluation benchmark, which is the largest LJP dataset. Following Zhong et al. (2020a), we formalize LJP as a multi-task learning problem. Specifically, we formalize law article prediction and charge prediction as multi-label classification tasks, and adopt binary cross-entropy function as the loss. We formalize prison term prediction as a regression task and adopt the log distance function as the loss. As for the output layer, we feed the document representation into three linear layers for the prediction of three tasks, respectively. In addition to training the model with the full dataset, we also explore the effectiveness of legal events under a low-resource setting. We only sample 50 cases for each charge and law article to train the model.

The results are shown in Table 5. We can observe that LED can promote the performance of LJP, especially under low-resource settings, which proves the effectiveness of LED. Besides, LED can only achieve slight improvement on charge prediction and law prediction under with full training dataset, while can achieve consistent improvement on prison term prediction. That is because prison term prediction is more complex and requires the model to capture both the criminal behaviors and severity-level of the consequences. Legal events can provide fine-grained information for predicting prison terms, and thus promote the performance under both low-resource and full dataset settings.

Similar Case Retrieval

Similar case retrieval (SCR) aims to retrieve supporting cases given a query case, which is a widely-applied task with high practical value (Kano et al., 2018; Shao et al., 2021). SCR requires the leverage of fine-grained information from multiple perspectives, including element-level, event-level, and law-level. In this paper, we adopt LeCaRD (Ma et al., 2021) as the evaluation benchmark, which contains 107 queries and $43,000$ candidates. We adopt 5-fold cross-validation for evaluation, and employ the top-k Normalized Discounted Cumulative Gain (NDCG@k), Precision (P@k), and Mean Average Precision (MAP) as evaluation metrics.

We verify the effectiveness of utilizing event features for similar case retrieval task under both unsupervised and supervised settings. In the unsupervised setting, we adopt "Bag-of-Event", i.e., the frequency of each event, as the representation of each legal document, and use cosine similarity to compute the similarity scores between two different legal documents. Further, considering the fact that the events occurring in the legal cases are not equally important, we compute the inverse document frequencies for different event types in the TF-IDF fashion, which are used as the weights of different event types. We denote the weighted representation as Bag-of-Event$_w$. In the supervised setting, we train the BERT model in a sentence-pair classification paradigm. We concatenate the query case and candidate case as the input sequence, and require the model to classify whether the two cases are relevant or not.

The results are shown in Table 6. From the results, we can observe that both Bag-of-Event and Bag-of-Event$_w$ are powerful representation methods for similar case retrieval and can achieve superior performance than other unsupervised models. Besides, the event information can facilitate the performance of BERT model, which further proves that event information is crucial for case retrieval.

6 Conclusion and Future Work

In this paper, we construct the largest legal event detection dataset, LEVEN, which contains a comprehensive legal event schema and hundreds of thousands of event mentions. We evaluate several competitive baseline models and conduct error analysis for these models on LEVEN. The experimental results prove that it still needs future efforts to promote the development of LED. Furthermore, we employ LED for downstream legal document analysis, including legal judgment prediction and similar case retrieval. It indicates that LED can provide fine-grained information and serve as a fundamental process for legal artificial intelligence. In the future, we will explore to conduct more analysis on large-scale legal documents based on the event information, and annotate LEVEN with event relations and event arguments.

Ethical Considerations

LEVEN focuses on detecting events from the fact and does not involve any value judgment. LED aims to transform the unstructured legal text into structured event information, which is helpful to further processing. Therefore, our work can help reduce the workload for legal professionals and improve their work efficiency. Considering the fact that, like any other legal AI application, LED models would inevitably make mistakes and have negative influences, we argue that LED can only serve as an auxiliary tool for legal work and the final decision on a specific legal issue has to be ensured by legal professionals. In such case, we could exploit the advantage of legal AI and avoid the potential risk.

The corpus we use is released by the Chinese government and has been anonymized wherever necessary. Therefore, our dataset does not involve any personal privacy. In terms of human annotation, we first annotate a few examples on our own to approximate the workload and then determine the wages for annotators according to local standards.

Acknowledgement

We are grateful to Meng Zhang and Danyang Guo from School of Law, Tsinghua University for their professional legal support. This work is supported by the National Key R&D Program of China (No. 2018YFC0831900, No. 2020AAA0106502), Institute for Guo Qiang at Tsinghua University, Beijing Academy of Artificial Intelligence (BAAI), and International Innovation Center of Tsinghua University, Shanghai, China.

Feng Yao, Chaojun Xiao, and Xiaozhi Wang designed the annotation schema. Feng Yao, Chaojun Xiao, and Xiaozhi Wang designed and conducted the experiments. Chaojun Xiao, Xiaozhi Wang, Feng Yao, and Zhiyuan Liu wrote the paper. Lei Hou, Cunchao Tu, Juanzi Li, Yun Liu, Weixing Shen, and Maosong Sun provided valuable advice to the research.

A Implementation Details

In this section, we introduce the hyper-parameters of the baseline models, models for legal judgment prediction, and models for similar case retrieval.

A.1 Baseline Models

For all baseline models, we run the model 5 times to get stable results, and the average performance is reported. For each model, we choose the checkpoint with the best performance on the validation set to evaluate on the test set. We train these models on GeForce RTX 2080Ti GPUs, and use Adam to optimize the models. The validation performances are shown in Table 7.

Model	Micro			Macro		
	P	R	F1	P	R	F1
DMCNN	86.15	79.27	82.57	79.42	69.77	73.00
BiLSTM	83.01	84.30	83.65	78.45	73.39	74.27
BiLSTM+CRF	84.63	83.10	83.86	80.99	73.39	75.73
BERT	84.35	83.80	84.07	80.21	76.08	77.38
BERT+CRF	83.72	84.13	83.93	78.38	75.39	76.01
DMBERT	83.40	86.76	85.05	79.18	79.28	78.42

Table 7: Validation Performances of ED baselines.

For **DMCNN**, the hyper-parameters are the same as Chen et al. (2015), excluding the unmentioned dimension of word embedding and learning rate. We use JIEBA toolkit[4] to perform the Chinese word segmentation, and use the pre-trained word vectors released in Li et al. (2018). Specifically, the word embedding is the one trained by the Wikipedia-zh corpus with word, character, and N-gram context. The training parameters are shown in Table 8.

Batch Size	170
Dropout Rate	0.5
Learning Rate	1×10^{-3}
Kernel Size	3
Hidden Size	200
Dimension of PF	5
Dimension of Word Embedding	300

Table 8: Hyper-parameters for DMCNN.

For **BiLSTM-based models**, we also use JIEBA to perform word segmentation, and adopt the same pre-trained Chinese word vectors used in DMCNN. The detailed training hyper-parameters are shown in Table 9.

Batch Size	200
Dropout Rate	0.5
Learning Rate	1×10^{-3}
Kernel Size	3
Hidden Size	256
Dimension of Word Embedding	300

Table 9: Hyper-parameters for BiLSTM-based models.

For **BERT-based models**, we adopt BERT-base as the basic encoder with the bert-base-chinese checkpoint[5]. For BERT, BERT-CRF and DMBERT, the training hyper-parameters are shared and the training hardwares are 4× RTX 2080TI. The detailed hyper-parameters are shown in Table 10.

Batch Size	64
Dropout Rate	0.5
Adam ϵ	1×10^{-8}
Learning Rate	5×10^{-5}
Validation Steps During Training	500

Table 10: Hyper-parameters for BERT-based models.

For **CRF-based models**, we use BIO tagging schema for training and evaluation.

A.2 Downstream Applications

For all downstream application experiments, we first adopt the **BERT+CRF** model to detect the trigger words in the original downstream datasets. We add an extra **Event Type Embedding Layer** to incorporate the event information, where the embedding matrix with the shape of 109×768 is randomly initialized and updated during training.

For **Legal Judgment Prediction (LJP)** task, we adopt the dataset released in the first stage of CAIL2018[6] as the benchmark. We evaluate the LJP task with the detected events under both full data and low-resource settings. The data size is shown in Table 11. The training data for the low-resource setting is obtained by randomly selecting 50 samples for each label and the corresponding data we used is also released in the github repository. The experiments are based on the source code released in Zhong et al. (2020a).

[5] `https://huggingface.co/bert-base-chinese`

[6] `https://github.com/china-ai-law-challenge/CAIL2018`

Setting	Training	Validation	Test
Full-data	154,592	17,131	32,508
Low-resource	12,702		

Table 11: Statistics of Data for LJP Experiments.

For **Similar Case Retrieval (SCR)**, we use LeCaRD[7] as benchmark and implement the models based on the code released in Xiao et al. (2021). As the documents in LeCaRD are usually longer than 512, we truncate the text to feed into the encoder. Specifically, the maximum lengths we use for the query and candidates are 100 and 409, respectively. We also conduct experiments in the unsupervised setting, where we use a 108-dimension vector as the representation of a document and each entry of the vector is the number of the detected events.

B Performance on Different Top-level Types

Top-level Event Type	precision	recall	F1
`General_behaviors`	83.71	85.67	84.86
`Prohibited_acts`	83.01	82.93	82.97
`Judicature_related`	94.17	91.89	93.01
`Consequences`	84.54	82.92	83.73
`Accident`	86.04	84.40	85.21
`Natural_disaster`	77.78	63.64	70.00

Table 12: Performance of DMBERT on different top-level event types.

In this section, we further analyze the performance of DMBERT on different top-level types to explore the fine-grained performance on LEVEN. From the results, we can observe that as the `Judicature_related` events are usually described in legal terminologies, thus the models can easily identify trigger words correctly by memorizing a set of specific words. As the `Natural_disaster` only contains tens of event instances, the model cannot be well-trained for these event types.

C Performance on Long-tail Event Types

In this section, we further analyze the performance on long-tail event types in detail. From Table 13, we can observe that overall, the model performance decreases as the number of training instances decreases. But there are some exceptions. Some event types only contain limited instances while the model can achieve high F1-scores on these types. For instances, `Suicide` only contains 55 event mentions, but the model can achieve 95.65% F1-score due to its non-diverse expression. Though some long-tail event types can be predicted accurately, there are 9 long-tail event types that can only reach F1-scores lower than 0.6. Therefore, we argue that detecting the event types accurately with limited instances needs future efforts.

F1-score	[0,0.4)	[0.4,0.6)	[0.6,0.8)	[0.8,0.9)	[0.9,1.0]	sum
#low-freq.	5	4	4	4	4	21
#mid-freq.	0	0	9	13	6	28
#high-freq.	0	0	14	23	22	59

Table 13: Distribution of event types by their performance on the test set. Here, low-freq and high-freq represent the number of event types that have less than 150 event mentions and more than 500 event mentions. And mid-freq denotes the number of event types containing between 150 and 500 event mentions.

D Data Distribution

To help the following researchers to better understand the features and details of LEVEN, we present more data analysis in this section regarding multiple events in one sentence and the sentence length distribution.

Number of Events in One Sentence. Legal cases usually involve complicated facts, and it is common in LEVEN that there are multiple events mentioned in one sentence. Table 14 shows the percentage of sentences containing different numbers of events.

#Event/Sent.	0	1	[2,5)	[5,10)	[10,100)
Percentage (%)	12.8	26.7	47.9	11.6	1.0

Table 14: The percentage of sentences containing different numbers of sentences.

Length&Number of Sentences. LEVEN is constructed based on real-world corpus, which makes it a perfect resource for developing practical applications. Figure 3 and 4 exhibit a comparison between the sentence length and number distributions of LEVEN and CAIL2018(Xiao et al., 2018), which is the largest legal judgment prediction dataset with over 1.7 million criminal judgment documents and can serve as a good real-world reference, indicating that LEVEN is consistent with the reality.

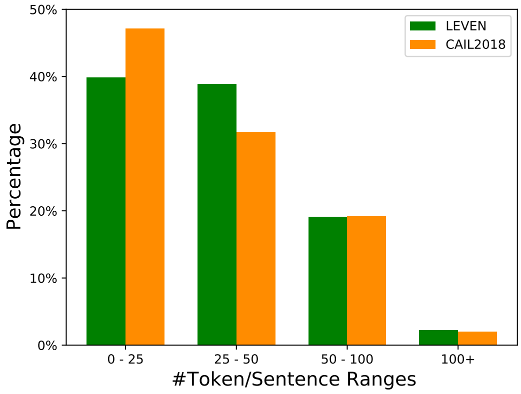

Figure 3: Sentence length distributions of LEVEN and CAIL2018.

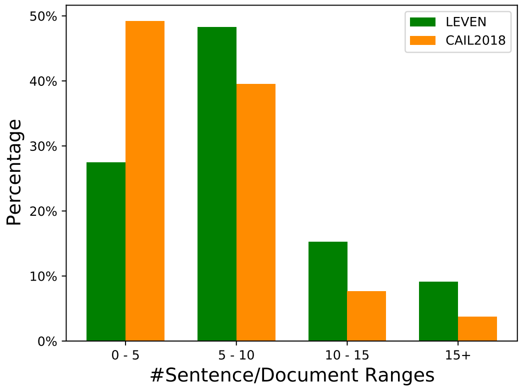

Figure 4: Sentence number distributions of LEVEN and CAIL2018.

E Event Type Schema and Description

To promote future research, we provide the hierarchical event schema in Figure 5, and the list of event types, including the event names and the corresponded descriptions, in Table 15, 16, 17, and 18.

F Annotation Guidelines

The annotation guidelines can be obtained from `https://github.com/thunlp/LEVEN`.

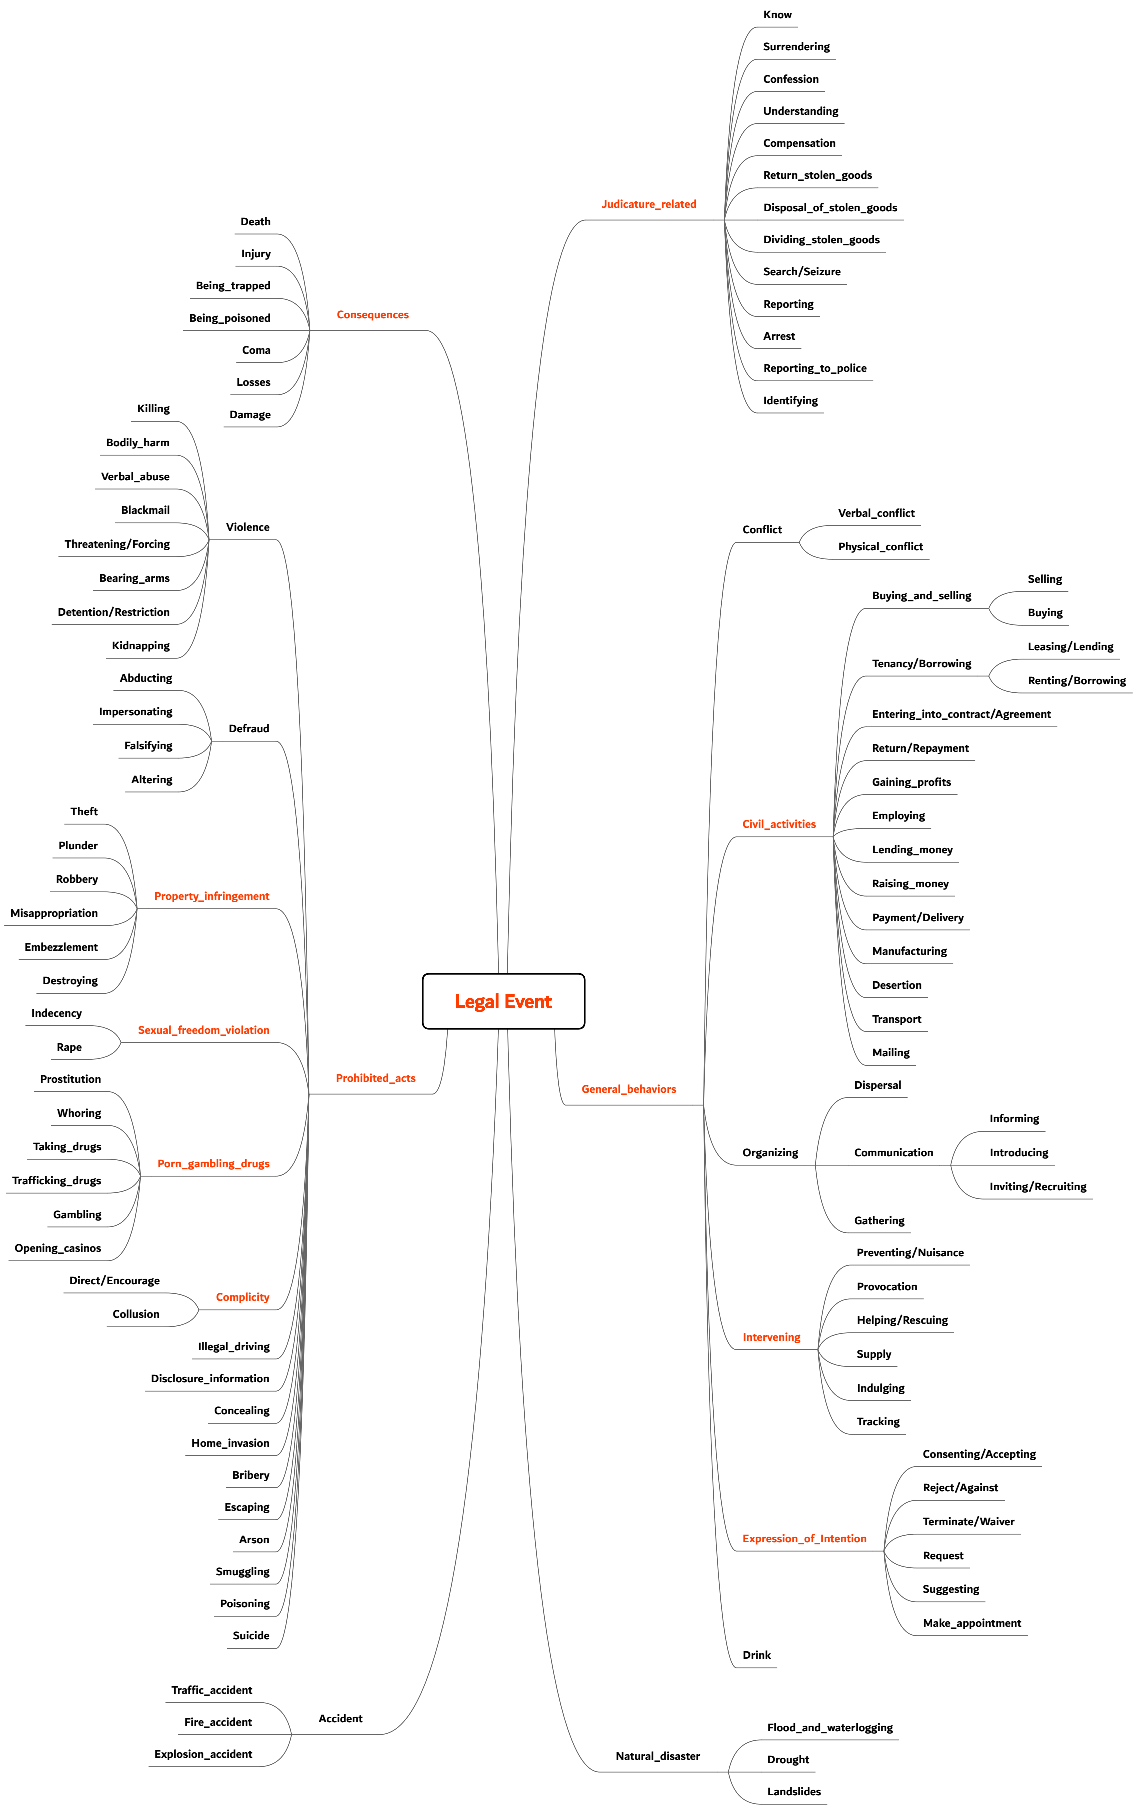

Figure 5: The detailed event schema of our proposed LEVEN.

Event Type Name	Descriptions
Judicature Related Events	
Judicature_related	JUDICATURE_RELATED events mainly refer to the activities of judicial organs or some legal penalty circumstances.
Know	A KNOW event means the doer ought to know the fact or understand the fact clearly.
Surrendering	A SURRENDERING event refers to the doer voluntarily surrendering after committing a crime.
Confession	A CONFESSION event refers to the suspect or defendant telling the facts to the police.
Understanding	AN UNDERSTANDING event refers to the forgiveness from the victim or victim's families to the criminal.
Compensation	A COMPENSATION event refers to the act of compensating the victim for his loss, damage, or injury.
Return_stolen_goods	A TERURN_STOLEN_GOODS event refers to the act of returning the stolen money or stolen goods to the victim or government.
Disposal_of_stolen_goods	A DISPOSAL_OF_STOLEN_GOODS event refers to the act of destroying stolen goods, selling stolen goods, or squandering stolen money, that is, the stolen goods/money have been disposed of.
Dividing_stolen_goods	A DICIDING_STOLEN_GOODS event refers to the act of sharing stolen goods or money.
Search/Seizure	A SEARCH/SEIZURE event mainly refers to the search and inspection of the suspect's body, articles, residence, or other space by the reconnaissance personnel, or the seizure of contraband, including the seizure of real estate. However, illegal search or seizure by non-reconnaissance personnel can also mark this event.
Reporting	A REPORTING event refers to the act of reporting bad people or bad things to relevant units.
Arrest	AN ARREST event refers to the act of detaining or arresting suspects.
Reporting_to_police	A REPORTING_TO_POLICE event refers to the act of calling the police to ask for help or reporting a case to the police.
Identifying	AN IDENTIFYING event refers to a kind of behavior in which the investigation organ appoints or hires people with expertise to make a scientific judgment and draw professional conclusions on the specialized problems in criminal cases in order to solve the specialized problems in criminal cases.
Accident Events	
Accident	AN ACCIDENT event refers to accidental loss or disaster.
Traffic_accident	A TRAFFIC_ACCIDENT event occurs when a traffic accident happens, which usually causes personal injury, death or property loss.
Fire_accident	A FIRE_ACCIDENT event refers to the disaster caused by uncontrolled combustion.
Explosion_accident	AN EXPLOSION_ACCIDENT event refers to the disaster caused by a sudden release of a large amount of energy, which leads to property losses and personal casualties.
Natural Disaster Events	
Natural_disaster	NATURAL_DISASTER events refer to Natural phenomena or man-made influences that endanger human survival or damage the human living environment.
Flood_and_waterlogging	A FLOOD_AND_WATERLOGGING event occurs where a large amount of water covers an area that is usually dry.
Drought	A DROUGHT event occurs when there is little or no rain during a long period of time.
Landslides	A LANDSLIDES event refers to a geographic disaster caused by a mass of earth or rock falling down the slope of a mountain.
Consequence Events	
Consequence	CONSEQUENCE events contain the fact of damage to the object caused by harmful acts.
Death	A DEATH event refers to the state of a human being dead.
Injury	AN INJURY event refers to the fact of personal injury.
Being_trapped	A BEING_TRAPPED event means the state in which people are physically in trouble and can't get out.
Being_poisoned	A BEING_POISONED event refers to one's discomfort caused by toxic effects, emphasizing the state of one's being poisoned.
Coma	A COMA event refers to the state of one's unconsciousness.
Losses	A LOSSES event refers to the fact of property loss.
Damage	A DAMAGE event refers to the fact that the property has been damaged.
General Behavior Events (I)	
General_behavior	GENERAL_BEHAVIOR events contain common behaviors in daily life, which usually do not violate laws.
Conflict	A CONFLICT event refers to two or more parties having verbal, physical, or other conflicts, disputes, or contradictions.

Table 15: Event type list (I), including the event type names and the corresponded descriptions.

Event Type Name	Descriptions
General Behavior Events (II)	
Verbal_conflict	A VERBAL_CONFLICT event refers to oral conflicts happen between two or more people without physical contact.
Physical_conflict	A PHYSICAL_CONFLICT event refers to a physical clash that happens between two or more people, including fighting. This event emphasizes the mutual behavior of both parties, pay attention to distinguish this event from a BODILY_HARM event, which emphasizes that one hurts another.
Civil_activities	CIVIL_ACTIVITIES events contain typical activities in civil and commercial areas.
Buying_and_selling	A BUYING_AND_SELLING event refers to the act of transacting within or between groups, including the exchange of goods and online transactions.
Selling	A SELLING event refers to one's act of selling something for a profit.
Buying	A BUYING event refers to one's act of buying or consuming something.
Tenancy/Borrowing	A TENANCY/BORROWING event refers to the relationship between two groups/persons to lease or rent something.
Leasing/Lending	A LEASING/LENDING event refers to the act of renting or lending something to others.
Renting/Borrowing	A RENTING/BORROWING event refers to the act of renting or borrowing something from others.
Return/Repayment	A RETURN/REPAYMENT refers to the act of returning something to its original place or owner.
Gaining_profits	A GAINING_PROFITS event refers to one obtaining money or other benefits through a certain act or activity.
Employing	AN EMPLOYING event refers to the act of giving others a job to do for payment.
Lending_money	A LENDING_MONEY event refers to specialized institutions or people making loans to earn profits, including bank loans and individual loans.
Raising_money	A RAISING_MONEY event refers to the act of raising money from unspecified majority people.
Payment/Delivery	A PAYMENT/DELIVERY event refers to the act of giving money or other things to others.
Entering_into_contract/agreement	AN ENTERING_INTO_CONTRACT/AGREEMENT event refers to the act of two or more person/groups signing contracts, including written contracts, written agreements, oral agreements, etc.
Manufacturing	A MANUFACTURING event refers to producing, manufacturing, or making tangible objects, emphasizing from scratch, excluding "noise", "explosion" or other intangible objects.
Desertion	A DESERTION event refers to one's act of actively abandoning or discarding something or someone.
Transport	A TRANSPORT event refers to one's act of transporting someone or something from one place to another.
Mailing	A MAILING event refers to delivering documents or articles through the post office or third-party postal service.
Organizing	AN ORGANIZING event refers to the act of arranging scattered people or things to serve a common goal.
Dispersal	A DISPERSAL event refers to the act of spreading information, data, rumors to the unspecified majority of people on the Internet or in public.
Communication	A COMMUNICATION event generally refers to the connection between two or more people, such as making a phone call.
Informing	AN INFORMING event refers to one's act of telling others information or reminding others of certain information, or the notified one should not have known the information.
Introducing	AN INTRODUCING refers to one's behavior to make other people or groups know each other or have a connection, excluding product instructions (because the introduction here does not mean "intermediary", but just a kind of teaching).
Inviting/Recruiting	AN INVITING/RECRUITING event refers to the acts of recruiting, inviting others to a place, or inviting others to do something or participate in an activity.
Gathering	A GATHERING event refers to the act of gathering a group of people together.
Intervening	AN INTERVENING event refers to one's act of intervening in an ongoing event.
Preventing/Nuisance	A PREVENTING/NUISANCE event refers to one's act of preventing things from going smoothly or hindering others from doing something by words or actions.
Provocation	A PROVOCATION event refers to one attempting to trigger off conflicts with others, or trigger off conflicts between other two groups.

Table 16: Event type list (II), including the event type names and the corresponded descriptions.

Event Type Name	Descriptions
General Behavior Events (III)	
Helping/Rescuing	A HELPING/RESCUING event refers to one's act of helping others to do something in the process of life, work or crime, it is limited to behavioral help, excluding providing materials, suggestions, etc. A HELPING/RESCUING event also refers to one's act of saving, rescuing, or assisting others who are injured or in trouble.
Supply	A SUPPLY event refers to one providing materials, conditions, intelligence information, or other specific things to others, excluding abstract things such as "providing help" or "providing advice".
Indulging	AN INDULGING event refers to one's act of allowing bad things to develop without any interference.
Tracking	A TRACKING event refers to one's act of following others quietly without being detected.
Expression_of_Intention	EXPRESSION_OF_INTENTION events contain the acts of one expressing a certain intention in a verbal way.
Consenting/Accepting	A CONSENTING/ACCEPTING event refers to one agreeing with the opinions of others, accepting others' asks, or accepting the property given by others.
Reject/Against	A REJECT/AGAINST event refers to one rejecting others' asks or the property given by others.
Terminate/Waiver	A TERMINATE/WAIVER event refers to one stopping doing something, giving up the original persistence, or giving up a right.
Request	A REQUEST event refers to one putting forward specific matters or wishes, hoping or requiring others to realize them.
Suggesting	A SUGGESTING event refers to one putting forward a plan or idea to others.
Make_appointment	A MAKE_APPOINTMENT event refers to the act of two or more people discussing and determining something.
Drink	A DRINK event refers to one's act of drinking alcohol, usually accompanied by other behaviors, such as driving, etc.
Prohibited Acts Events (I)	
Prohibited_acts	PROHIBITED_ACTS events contain behaviors prohibited by law, including not only typical criminal behaviors, but also behaviors that are not up to the degree of crime but prohibited by law. Therefore, events in this part are events that should be given negative evaluation, which is opposite to general behaviors.
Violence	VIOLENCE events contain violent behaviors that are intended to hurt others' mental or physical health, including physical force as well as language.
Killing	A KILLING event refers to one's act of killing others in order to make others die.
Bodily_harm	A BODILY_HARM event refers to the act of harming the physical health of others, usually manifested in beating.
Verbal_abuse	A VERBAL_ABUSE event refers to the act of insulting, attacking or hurting others through language. Pay attention to distinguishing this event from a VERBAL_CONFLICT event, which emphasizes mutual abuse.
Blackmail	A BLACKMAIL event refers to the act of demanding money from others by threatening or deceiving them.
Threatening/Forcing	A THREATENING/FORCING event refers to the act of forcing others to do or not do something through violence or power, mostly referring to the use of force to make others obey.
Bearing_arms	A BEARING_ARMS event refers to one's holding or carrying sticks, props, guns, or other instruments.
Detention/restriction	A DETENTION/RESTRICTION event refers to the act of depriving or restricting the freedom of others, such as binding or detaining people in specific places.
Kidnapping	A KIDNAPPING event refers to the act of taking hostages by violent means in exchange for interests, emphasizing that the object must be people.
Defraud	A DEFRAUD event refers to the act of covering up the real situation with false words or actions to deceive others.
Abducting	AN ABDUCTING event refers to one's act of cheating someone away by luring, cheating, or other means.
Impersonating	AN IMPERSONATING event refers to the act of disguising a real thing with a false thing or one's act of pretending to be somebody in order to trick people.
Falsifying	A FALSIFYING event refers to the act of making fake goods or false news.
Altering	AN ALTERING event refers to the act of modifying real basis A without authorization to make it have another illusion B.
Property Infringement	PROPERTY INFRINGEMENT events contain acts of infringing upon others' property rights and interests of others.
Theft	A THEFT event refers to one's act of stealing others' property by secret.
Plunder	A PLUNDER event refers to one's act of seizing property blatantly in front of the victims and taking them away, including seizing guns or knives, excluding competing for customers or land rights. The object of robbery must be tangible things.

Table 17: Event type list (III), including the event type names and the corresponded descriptions.

Event Type Name	Descriptions
	Prohibited Acts Events (II)
Robbery	A ROBBERY event refers to one's act of using violent means to rob others' property, such as robbery with a knife. The establishment of this event is strict. If it is impossible to judge whether it is a ROBBERY event, then PLUNDER may be marked.
Misappropriation	A MISAPPROPRIATION event refers to the act of changing the original use of the property to another without authorization.
Embezzlement	AN EMBEZZLEMENT event refers to one's act of taking others' property illegally, including real estate, emphasizing the state of possession.
Destroying	A DESTROYING event refers to one's act of destroying property, this event has a subject, which is the main difference against A DAMAGE event.
Sexual_freedom_violation	SEXUAL_FREEDOM_VIOLATION events contain acts of making others unable to freely dispose of their sexual rights by means of inducement, deception, coercion, etc.
Indecency	AN INDECENCY event refers to one's act of forcibly sexually harassing others by touching private parts or other acts other than adultery.
Rape	A RAPE event refers to one's act of forcing women to have sex when they do not want to.
Porn_gambling_drugs	PORN_GAMBLING_DRUGS events contain illegal or criminal phenomena involving pornography, gambling, and drugs.
Prostitution	A PROSTITUTION event refers to women providing paid sexual services to others.
Whoring	A WHORING event refers to one purchasing sexual service with money.
Taking_drugs	A TAKING_DRUGS event refers to one's act of taking drugs.
Trafficking_drugs	A TRAFFICKING_DRUGS event refers to one's act of peddling drugs.
Gambling	A GAMBLING event refers to one's act of gambling.
Opening_casinos	AN OPENING_CASINOS event refers to one's act of opening casinos for multiple plays to gamble on.
Complicity	COMPLICITY events occur when intentional contacts happen between two or more criminals.
Direct/Encourage	A DIRECT/ENCOURAGE refer to one's act of letting others commit crimes by means of command, inspiration, or temptation. Specifically, a DIRECT event refers to the act of summoning others to commit criminal acts or other negative acts according to the instigator's intention. AN ENCOURAGE event refers to one's act of making people who do not have criminal intention have the intention of committing a crime.
Collusion	A COLLUSION event refers to the act of two or more people scheming a crime plan together.
Illegal_driving	AN ILLEGAL_DRIVING event refers to one's act of driving a car illegally.
Disclosure_information	A DISCLOSURE_INFORMATION event refers to one's act of disclosing information that should be kept secret.
Concealing	A CONCEALING event refers to one's act of hiding something from discovery.
Home Invasion	A HOME INVASION event refers to one's act of invading or sneaking into other people's private space without the permission of others. This event is usually the pre-act of another criminal act (such as theft or rape).
Bribery	A BRIBERY event refers to one's act of bribing others with property to seek illegitimate interests or accepting others' property to seek illegitimate interests for others.
Escaping	AN ESCAPING event means one's escaping and hiding in order to avoid capture.
Arson	AN ARSON event refers to one's act of setting on fire.
Smuggling	A SMUGGLING event refers to the act of one's illegally transporting goods into or out of the country in violation of customs regulations.
Poisoning	A POISONING event refers to one putting poison in containers or a specific environment in order to kill people, animals, or plants.
Suicide	A SUICIDE event refers to the act of one's killing himself.

Analyzing Dynamic Adversarial Training Data in the Limit

Abstract

To create models that are robust across a wide range of test inputs, training datasets should include diverse examples that span numerous phenomena. Dynamic adversarial data collection (DADC), where annotators craft examples that challenge continually improving models, holds promise as an approach for generating such diverse training sets. Prior work has shown that running DADC over 1–3 rounds can help models fix some error types, but it does not necessarily lead to better generalization beyond adversarial test data. We argue that running DADC over *many* rounds maximizes its training-time benefits, as the different rounds can together cover many of the task-relevant phenomena. We present the first study of longer-term DADC, where we collect 20 rounds of NLI examples for a small set of premise paragraphs, with both adversarial and non-adversarial approaches. Models trained on DADC examples make 26% fewer errors on our expert-curated test set compared to models trained on non-adversarial data. Our analysis shows that DADC yields examples that are more difficult, more lexically and syntactically diverse, and contain fewer annotation artifacts compared to non-adversarial examples.

1 Introduction

Traditional crowdsourcing methods often yield datasets that lack diversity, contain spurious correlations, and are easy for existing models (Gururangan et al., 2018; Poliak et al., 2018; Geva et al., 2019; Ko et al., 2020; Potts et al., 2021). Training on such examples can lead to models that reach deceptively high accuracy on in-distribution test data, yet fail on challenge sets (Naik et al., 2018; Glockner et al., 2018; Gardner et al., 2020), input perturbations (Wallace et al., 2019; Kaushik et al., 2020), and distribution shifts (Talmor and Berant, 2019; Hendrycks et al., 2020).

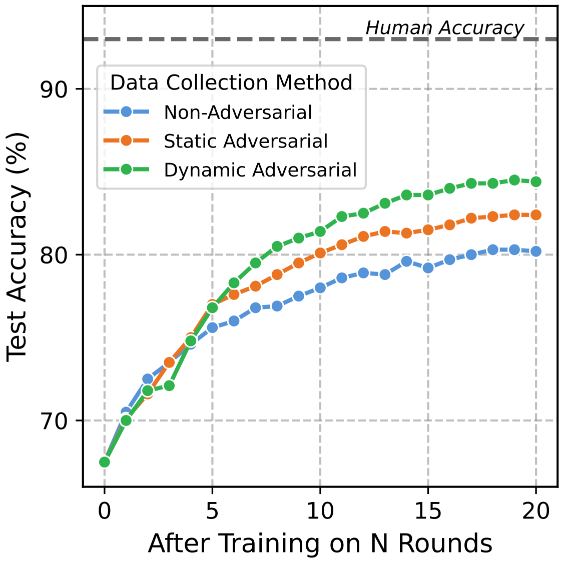

Figure 1: *Model accuracy on our expert-curated test set* when training on data collected from three different methods. Standard non-adversarial data collection is more effective than adversarial data collection in the short-term. However, in the long term, adversarial data collection statistically significantly outperforms standard data, especially when the data is collected using a dynamic model that is updated after each round.

Dynamic adversarial data collection (DADC) holds promise as an approach to mitigate these training set problems. In DADC, humans are tasked with creating examples that fool state-of-the-art models but are answerable by humans. Crucially, DADC is dynamic in that data collection is repeated over many rounds with a stream of ever-improving models-in-the-loop. As models improve, annotators are incentivized to craft new types of examples that challenge the latest models. In the limit, this process would ideally cover most task-relevant phenomena, leading to more robust models.

Whether DADC actually leads to diverse, high-coverage training data, however, has remained unclear. It could cause annotators to write unnatural examples or to focus on a narrow subset of unusual

May 22-27, 2022

examples that models find difficult to learn, thus decreasing data diversity (Bowman and Dahl, 2021). Some prior work has shown that a few rounds of DADC can indeed improve robustness to adversarial inputs (Dinan et al., 2019; Nie et al., 2020a), however, there are mixed results on improving accuracy on other distributions (Kaushik et al., 2021). To date, no study has analyzed how DADC evolves over *many* rounds. Thus, the long-term benefits or drawbacks of adopting it as a core dataset creation paradigm remain poorly understood.

In this work, we conduct the first study of DADC's effects in the long term, where we conduct many rounds and rapidly update models. We focus on the task of natural language inference (NLI), which serves as a crucial benchmark for research on language understanding (Bowman et al., 2015; Williams et al., 2018a). To make our study feasible, we conduct intensive data collection on a small set of context passages that span different genres and exhibit numerous natural language phenomena. By using a small set of contexts, we create a scenario in which models can improve quickly from round to round, thus approximating the dynamics of running DADC at a larger scale. We compare three approaches for collecting training data—no model, static model-in-the-loop, and dynamic model-in-the-loop—in a controlled setting for 20 rounds.

To evaluate the different methods, we collect expert-curated non-adversarial test examples for each context that span numerous NLI phenomena which humans can handle correctly. On this test set, DADC outperforms the alternative approaches after many rounds of data collection (e.g., Figure 1). Standard non-adversarial data collection causes model accuracy to climb quickly for a short period of time, but accuracy quickly plateaus after more examples are collected. On the other hand, DADC examples yield larger improvements for later rounds. To understand these results, we show that DADC examples are overall more diverse in lexical and syntactic patterns, contain fewer artifacts, and become more difficult over each round. Overall, our results show that building large adversarial training sets may be more useful than standard model-agnostic collection in the long term.

2 Background

Collecting Data with Crowdsourcing. Most large-scale supervised datasets are collected using crowd workers (Bowman et al., 2015; Rajpurkar et al., 2016; Kočiský et al., 2018). Compared to experts, crowd workers often produce lower quality data as they are not necessarily well-trained for one's task and can be apathetic to the goals of the research (Snow et al., 2008; Gadiraju et al., 2017). These data quality issues are exacerbated for language tasks because crowd workers also need to *write* inputs, e.g., writing hypothesis sentences for natural language inference tasks. These manually-written inputs often follow a very narrow distribution: they lack diversity over lexical items, syntactic patterns, domains, example difficulties, reasoning types, and more (Yang et al., 2018; Gururangan et al., 2018; Geva et al., 2019; Min et al., 2019; Kiela et al., 2021).

Dynamic Adversarial Data Collection. In DADC, workers are tasked with writing examples that are answerable by humans but fool existing models (Wallace et al., 2019; Nie et al., 2020a; Kiela et al., 2021). Concretely, workers are presented with a user interface where they can observe model predictions and interactively build data that exposes model failures. Multiple *rounds* may also be conducted, where the model is updated on the adversarial data collected thus far and redeployed; the goal of this is to encourage workers to write increasingly more difficult examples. Adversarial data collection has been widely adopted in recent work, especially for building *evaluation* datasets (Dua et al., 2019; Nie et al., 2020a; Dinan et al., 2019; Bartolo et al., 2020; Potts et al., 2021; Liu et al., 2021; Kaushik et al., 2021; Xu et al., 2020, 2021). Our focus is instead on *training*, where past work has shown that after a few rounds of adversarial data, a model noticeably improves on its errors, yet many problems still remain (Nie et al., 2020a; Bartolo et al., 2020; Kaushik et al., 2021; Zellers et al., 2019). Moreover, it remains unclear whether collecting adversarial or non-adversarial data leads to generally more robust models in the long term (Kaushik et al., 2021).

3 Dynamic Data Collection in the Limit

The paradigm of DADC raises a natural but unanswered question: what would happen if we kept going? If we ran DADC for many years, how robust would the resulting models be? Would models improve more quickly than if we had collected training data without a model-in-the-loop?

Answering these forward-looking questions is key to understanding whether researchers and prac-

Premise	Model	Rd	Hypotheses	Label	Error

Table 1: Examples from the training sets that are generated by crowd workers, with *No*, *Static*, or *Dynamic* models in the loop. The error column shows whether the worker successfully fooled the model in the loop when submitting the example in the user interface. See Table 5 for the full premise paragraphs.

titioners should continue to collect data in an adversarial fashion. Of course, we cannot practically run many years of data collection at once due to cost and time constraints. Our key idea is to instead answer these questions for a more manageable test bed that still retains many of the key challenges associated with language understanding tasks. In particular, we scale down the natural language inference (NLI) task to a small number of paragraph-length premises. In this setting, many rounds of smaller-scale data collection can tell us whether DADC or non-adversarial data collection leads to more robust model accuracy on test hypotheses for these same contexts. If DADC is indeed superior, this suggests that DADC can collect data that more effectively covers the challenging phenomena required for NLI, and therefore scaling it up to (many) more contexts could yield models that are similarly robust for more general NLI.

3.1 Task and Context Paragraphs

We choose to focus on NLI, a canonical and well-studied natural language understanding task (Dagan et al., 2005; Bos and Markert, 2005; Giampiccolo et al., 2007; MacCartney and Manning, 2009). NLI training datasets are notorious for being rife with artifacts and biases (Poliak et al., 2018; Gururangan et al., 2018; Tsuchiya, 2018; McCoy et al., 2019), which makes NLI a suitable test bed for studying questions surrounding training dataset quality. Using NLI also enables us to write a rich and diverse test set with a small number of contexts because each premise admits many possible hypotheses. We focus on *binary* NLI—definitely entailing or not entailing—to minimize labeling disagreements stemming from the distinction between neutral and contradiction in three-way NLI (Pavlick and Kwiatkowski, 2019; Nie et al., 2020b).

We use ten diverse paragraphs from Project Gutenberg[1] as the premises—each one is chosen to elicit many possible hypotheses. We choose these paragraphs to span a range of genres (scientific, biographical, historical, narrative) and present a different set of challenges. For instance, some passages describe physical objects in detail, requiring commonsense understanding of the physical world (e.g., *"…Phonny had not measured his wires in respect to length, but had cut them off of various lengths, taking care however not to have any of them too short. The result was that the ends of the wires projected to various distances above the board…"*). Other passages describe reasoning about uncertainty (e.g., *"…this negative result might be because these animals are not susceptible to the disease…"*) or hypothetical events (e.g., *"…If there should be even partial cooperation between the Austrian leaders, he must retreat…"*). See Appendix A for the full premise paragraphs. We minimally edit each paragraph so that they can be read standalone, e.g., we resolve coreferences.

3.2 Data Collection Procedure

We collect data over many rounds, where each round comprises three steps. First, crowdworkers write hypothesis sentences that are either entailed or not entailed by one of our premises while interacting with the current model-in-the-loop. Second, other crowdworkers relabel these examples and help filter out spam and other malformed examples. Finally, we update the model-in-the-loop by finetuning on all collected data, including data from the newest round. We use Amazon Mechanical

---

[1] https://www.gutenberg.org/

Turk (AMT) for data collection.

Hypothesis Generation. To generate hypotheses, we run AMT tasks where a worker is randomly provided one of the premises and is asked to write ten different hypotheses. After writing each hypothesis, they are shown the predictions of a live model in the loop. To encourage workers to write model-fooling examples, they are given a bonus every time one of their examples fools the model and passes the later label verification step. We ask workers to write ten hypotheses for a single premise, as this allows them to better understand the model's behavior and empirically leads to more-difficult examples (Section 4). The worker can generate hypotheses for either of the binary labels, but we encourage them to generate balanced examples in the onboarding instructions. The user interface is shown in Appendix B.

Label Verification. To ensure the generated hypotheses are labeled correctly, we run a separate AMT task where workers are asked to label each example without being shown the original label. Each example is labeled by at least three workers. If all three agree, that example is saved. If there is a disagreement, we ask two additional workers and keep the example if four out of five agree on the label. We also provide an option to flag a hypothesis as "bad", e.g., it is very ungrammatical or clearly spam. If more than one worker flags an example as bad, we remove it. We do not allow workers to participate in both the labeling and validation AMT tasks, as we do not want workers to be influenced by one another's hypotheses.

Updating the Model. For the initial round of data collection, we use as our starting point a RoBERTa-large model (Liu et al., 2019) that has been finetuned on SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018a), and FEVER-NLI (Nie et al., 2019).We use this training data as it provides us with an accurate initial model, and note that we collapse the neutral and contradiction labels during training as we focus on binary NLI. To update the model after each round, we continue finetuning it on all of the data collected thus far and then deploy it for the next round. Our finetuning hyperparameters follow the recommendations of Mosbach et al. (2021): we use a learning rate of 2×10^{-5}, a learning rate warmup over the first 10% of steps, bias-corrected Adam, and 15 epochs of training. We early stop using held-out validation data (see Section 3.3). We refer to this setting, where crowdworkers interact with a model-in-the-loop that is updated after each round, as the **Dynamic Model** setting.

Baselines. In addition to the above, we also collect data with two baseline approaches:

- **No Model.** This is the typical procedure for collecting training data where workers do not interact with a model.
- **Static Model.** We provide a model in the loop to the workers but the model is kept fixed across all the rounds. We use the same model that the Dynamic Model setting uses in its first round.

No data is mixed between methods and workers can not participate in multiple methods.

3.3 Dataset Details

Our codebase is built on top of the Dynabench platform (Kiela et al., 2021), we deploy tasks using the Mephisto library,[2] and we serve models using Dynalab (Ma et al., 2021). We restrict our AMT workers to those that speak English, have completed at least 100 tasks on AMT, and have an approval rating of at least 97%. To qualify for the task, a worker must also pass an onboarding procedure where they are tasked with correctly labeling five NLI examples in a row.

For each data collection method, we run 20 rounds of data collection. We stop at 20 rounds as model performance on our validation sets begins to saturate. We collect 550 examples per round before label verification, with an equal distribution over the ten premises. All the data collection methods are run in parallel at the same time of day to control for the effects of time on data quality (Karpinska et al., 2021). At this scale, we are able to complete each round of data collection for all three methods in approximately 24 hours. We hold out 50 examples from each round to use for early stopping and for reporting validation metrics.

Table 2 shows overall statistics of our final datasets. These statistics are similar across the three datasets, including the label balance, the rate at which examples are discarded, and the number of AMT workers. However, the datasets differ in the rate at which workers fooled the models in the loop; Figure 2 shows that the fooling rate is relatively constant for the static model but goes down for the dynamic model as the model is updated.

# Verified Hypo.	7,684	7,102	6,911
# Workers	115	104	121
% Contradiction	58.5	56.3	54.6

Table 2: *Statistics of our datasets.* For each method, we independently run 20 rounds of data collection with 550 hypotheses per round. We verify the labels of each hypothesis using additional crowd workers and discard any low-agreement examples; the adversarial data is discarded slightly more often. The datasets are roughly balanced between entailment and contradiction.

Table 1 shows qualitative examples of training hypotheses from each method. We will release our data and models publicly.

3.4 Expert-Curated Test Set

Kaushik et al. (2021) compared standard data collection to a single round of adversarial data collection, finding that adversarial training data improves accuracy only on adversarially-constructed test datasets but not on others. We hypothesize that running DADC for many rounds can overcome this limitation and improve generalization to independent, non-adversarial test data. To test this, we built an expert-curated test set for our ten premise paragraphs that is intended to be challenging but not necessarily adversarial to models. We (three of the authors) wrote 680 NLI examples, and we recruited five researchers who have published in NLI and spurious correlations to write an additional 320 examples. The test set spans different challenges, syntactic patterns, and reasoning types, loosely inspired by the categorizations from Williams et al. 2020. The examples are not written with a model in the loop, they are balanced across the labels, and they are equally distributed over the premises. Examples are shown in Table 3.

We also collect crowd worker labels for our test set to ensure that the labels are unambiguous and to measure human accuracy. First, we collect 15 labels for each example. We remove any example from the test set where 9 or fewer workers chose the correct label; this removed 21 examples. Second, we collect an additional 5 labels to use for estimating human accuracy. The average accuracy is **93.2%** when using each label individually.

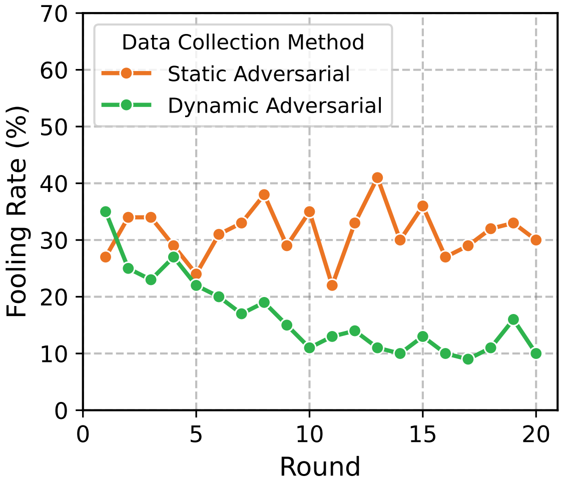

Figure 2: *Model fooling rates.* We show how often crowd workers write examples that are successfully answered by humans but fool the model they interact with. For the static model, the fooling rate is relatively constant as the model is kept fixed (the variance across rounds is due to different crowd workers having different fooling rates). For the dynamic model, the fooling rate goes down over time as the model is updated.

4 Dynamic Adversarial Data Outperforms Non-Adversarial Data

Here, we show that DADC outperforms both standard and static adversarial data collection in the long term. In particular, we train various models using the three different datasets and compare them on the validation and expert-curated test sets.

4.1 Training Final Models

For each dataset, we train 20 models—one for each round—on all of the training data up to and including a given round. All models start with the same RoBERTa-large model that was used for round one of adversarial data collection. We then continue finetuning this model on the associated training data using the hyperparameters from Section 3.2. Moreover, to measure possible variance across different finetuning runs, we train each model with five different random seeds.

4.2 Main Results

Figure 1 shows our models' accuracy on the expert test set described in Section 3.4. In the short term, standard non-adversarial data collection performs best—it has the highest accuracy after the first four rounds. However, in the long term, adversarial data collection, especially when done dynamically, leads to the highest accuracy by a noticeable margin. We run McNemar's statistical test to compute

Premise	Hypotheses	Label
Sound	The head of a drum and the strings of a piano are similar in that they both vibrate.	Entailment
	A piano produces sound because the keys vibrate when they are struck by the pianist.	Contradiction
Yellow	The speaker only ran one experiment of injecting yellow fever blood into animals.	Contradiction
	Dr. Daniel Cruz took blood from a sick patient to run his experiment.	Entailment
Faraday	Michael Faraday's wife was named Margaret Hastwell.	Contradiction
	Yorkshire is a less populous locality to be from then Manchester Square.	Entailment

Table 3: Examples from our expert-curated test set. See Table 5 for the premise paragraphs.

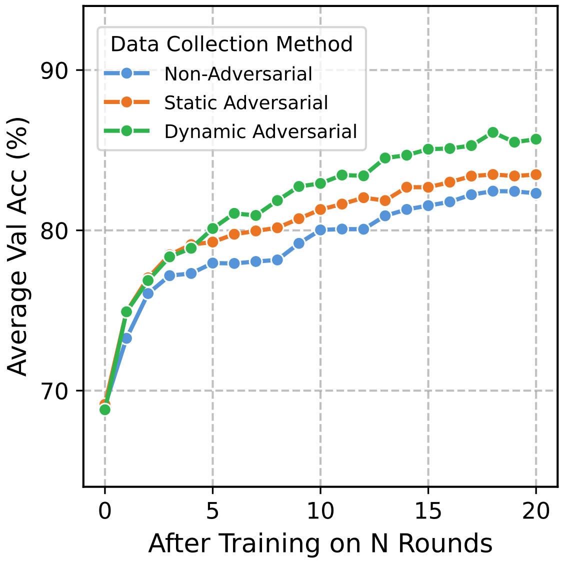

Figure 3: *Combined validation accuracy*. We create a validation set by pooling together validation data from each data collection method. We find the same trend as the expert-curated test set—dynamic adversarial data performs best in the long term.

whether the results are significantly different for the final round 20 models: the DADC model outperforms the static adversarial model with $p < 0.05$ and the non-adversarial model with $p < 0.01$; the static adversarial model outperforms the non-adversarial model with $p < 0.05$.

We also evaluate models on validation data that is split off from each round of each data collection method. Figure 3 shows results on a validation set that is created by pooling validation data from all three collection methods; we observe the same trends as our test set, although the accuracies are slightly higher on average.

Overall, these results show that when building training sets in our setting, adversarial data is not necessarily preferred when the number of examples is small. On the contrary, when the number of training examples and rounds is large, using DADC leads to more robust, broader coverage models.

Costs of DADC. DADC examples are more expensive to collect as it takes crowd workers longer on average to write and verify them. However, DADC examples provide more "bang for your buck"—it is more cost-effective to collect few DADC examples compared to many regular examples. This can be seen from Figure 1 while accounting for DADC being approximately two times more expensive per example than non-adversarial data.

Comparison to Humans. Even though the round 20 models have approximately 700 training examples for each premise, they are still noticeably worse than human accuracy. In particular, the best DADC model reaches 84.4% accuracy, whereas human accuracy is 93.2%. This shows that while DADC does lead to better models, we are still far from creating NLP systems that perform robust NLI on our premise paragraphs.

Generalization of DADC Data Across Models. One possible concern with adversarially-collected data is that it could be too model-specific, similar to datasets built with active learning (Lowell et al., 2019). To test whether the DADC data can generalize to other (newer) models, we train an ALBERT XXLarge-v2 model (Lan et al., 2020) on SNLI, MNLI, and FeverNLI. We then finetune the model on the data from all 20 rounds for each of our three datasets. The model has an accuracy of 69.1% before updating on our collected data, and it reaches an accuracy of 83.1%, 84.6%, and 85.8% on the no model, static model, and dynamic model datasets, respectively. This shows that our DADC data does generalize to better models—it leads to the highest accuracy among the three datasets—but the gap from DADC to static adversarial data is smaller than one from our RoBERTa model.

Generalization Beyond Our Premises. Since the DADC data is more difficult than typical crowdsourced data, it may promote models to learn more robust NLI features. To evaluate this, we test our round 20 models on out-of-distribution datasets, including HANS (McCoy et al., 2019) and the MNLI mismatched test set (Williams et al., 2018b). We convert both test sets to binary classification by collapsing the neutral and contradiction labels. We found that the round 20 models from all three settings, as well as our initial model trained on SNLI, MNLI, and FEVER-NLI, reached comparable accuracies on these test sets. This shows that while the DADC data does lead to improved in-distribution test performance, it does not necessarily lead to better performance under distribution shift.

5 Analyzing Adversarial Data

Why is dynamic adversarial data superior to standard data in the long term? In Table 4, we report summary statistics about our three collected datasets. We find that dynamic adversarial data is more diverse, has higher complexity, and contains fewer artifacts than non-adversarial data. These findings agree with our intuition surrounding adversarial datasets: small adversarial training sets that contain diverse and challenging examples may be hard for models to learn from. However, larger datasets of this type will ultimately lead to more accurate and robust models in the long term. We describe our analyses in detail below.[3]

Diversity. DADC data is more diverse at both the lexical (unigram and bigram) and example levels (Table 4, top). To measure lexical diversity, we count the number of unique unigrams and bigrams in the dataset. To measure example-level diversity, we iterate through each training example and find the most similar other training sample according to BLEU score (Papineni et al., 2002). We then report the average of these BLEU scores similarities; the dynamic adversarial examples are the least similar to one another.[4] The difference in inter-example similarity between the DADC data and the static adversarial data is significant with $p < 0.01$ according to a t-test.

Syntax and Sentence Complexity. The dynamic adversarial data is more complex (Table 4, middle). For each hypothesis, we measure its length in words, its Flesch-Kincaid readability (Flesch, 1948), and its syntactic complexity using Yngve scores (Yngve, 1960; Roark et al., 2007). Yngve scores roughly measure the deviation of a parse tree from a purely right-branching tree—it is the average number of left branches on the path from the root node to each word. To compute Yngve scores, we parse sentences using the Benepar parser (Kitaev and Klein, 2018) based on T5 small (Raffel et al., 2020). In all three metrics, the dynamic adversarial data scores highest, and it is statistically significantly higher than the static model data based on a t-test with $p < 0.05$. We also show how the syntactic complexity evolves over the rounds in Figure 4. For the non-adversarial and static adversarial data, the syntactic complexity is relatively constant while the DADC examples become increasingly more complex.

	No Model	Static Model	Dynamic Model
Diversity			
Unique Unigrams	4.0k	4.2k	**4.3k**
Unique Bigrams	23.3k	24.8k	**25.6k**
Inter-example Sim.	41.2	41.9	**39.5**
Complexity			
Syntax	2.0	2.1	**2.3**
Reading Level	4.9	5.4	**5.9**
Length	10.1	10.9	**12.1**
Artifacts			
Hypo-only Acc %	75.4	**69.3**	69.7
Overlap Entail %	54.2	49.2	**47.3**

Table 4: *Dataset analysis.* The hypotheses generated by DADC are more diverse based on the number of lexical items and inter-example similarity. The hypotheses are also more complex, as shown by their increased syntactic complexity, reading level, and lengths. Finally, adversarial data contains fewer instances of known artifacts. We bold the best result—lower is better for inter-example similarity and the artifact analyses.

Fewer Artifacts. NLI training datasets are known to suffer from spurious correlations. The DADC examples contain fewer instances of two known artifacts: hypothesis-only information (Poliak et al., 2018; Gururangan et al., 2018; Tsuchiya, 2018) and high-overlap entailment examples (McCoy et al., 2019). To measure such artifacts, we first train a hypothesis-only model on the training set for each dataset using RoBERTa large. We test

---

[3] Note that when computing each metric, we use a version of the No Model and Static Model datasets that are randomly downsampled to be the same size as the dynamic model data (6,911 examples). This controls for any effect that dataset size would have on our analyses.

[4] Note that this diversity metric is effective because we collect hundreds of examples for a single context paragraph; otherwise, we would need to measure similarity between hypotheses for different premises, a more complicated problem. We also experimented with BERTScore (Zhang et al., 2019) and found similar trends as BLEU score.

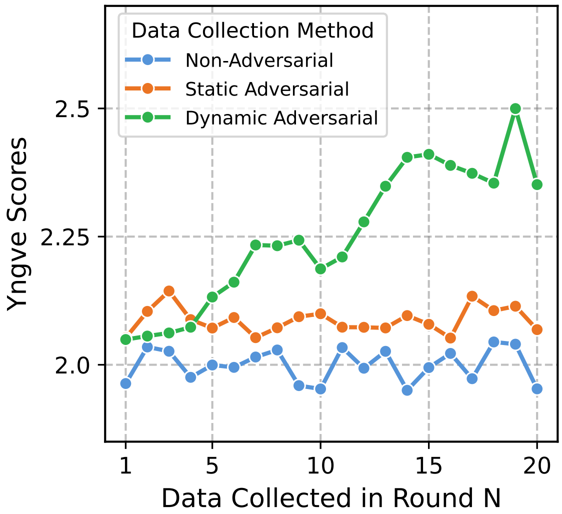

Figure 4: *Complexity of syntax over time.* We show how the average syntactic complexity changes over each round. For the non-adversarial and static adversarial data, the syntactic complexity is relatively constant across rounds. On the other hand, the DADC examples become increasingly more complex as annotators are faced with ever-improving models in the loop.

on validation data split off from each respective training set, which allows us to measure how much hypothesis-only information is present within each dataset. The static adversarial and dynamic adversarial datasets have the lowest hypothesis-only accuracy. To measure high-overlap entailment instances, we find examples where the hypothesis has high (>90%) word overlap with the premise and compute how often the label is entailment. Such examples appear less frequently in DADC data.

6 Related Work

Post-hoc Adversarial Filtering. In adversarial filtering (Le Bras et al., 2020; Zellers et al., 2018), one takes an existing dataset and trains a model on the most difficult subportion of the data. Adversarial filtering shares motivations with adversarial data collection—difficult examples are more informative for learning—but it is focused on post-hoc data filtering rather than collection of new data.

Adversarial Training. Rather than having humans craft adversarial inputs, past work automatically generates adversarial examples and trains on them (Goodfellow et al., 2014; Ribeiro et al., 2018; Ebrahimi et al., 2018). The main downside of such approaches is their limited diversity—they focus on specific aspects like paraphrase (Ribeiro et al., 2018) or syntax (Iyyer et al., 2018) whereas DADC examples are only limited by human creativity.

Active Learning. Active learning (Lewis and Gale, 1994), especially when performed using an uncertainty-based acquisition function, is also closely related to DADC. The key differences are in the setup: active learning assumes access to unlabeled inputs, whereas in our setting we are interested in building datasets from scratch.

Other Data Quality Improvements. Aside from adversarial data collection, researchers have explored numerous methods for improving data quality when using crowdsourcing. This includes feedback from experts (Parrish et al., 2021; Nangia et al., 2021), gamifying the data collection process (Yang et al., 2018; Eisenschlos et al., 2021), encouraging counterfactual examples (Kaushik et al., 2020; Gardner et al., 2020), or providing prompts that workers can edit (Bowman et al., 2020; Vania et al., 2020). Many of the ideas from these methods can be combined with adversarial data collection.

7 Conclusion and Future Work

We investigated dynamic adversarial data collection in the limit—over a large number of rounds until model performance starts plateauing—and demonstrated that data collected via this method is more valuable for training than alternatives, both on validation data and an expert-curated test set. We analyzed the collected data, showing that DADC yields examples that are more diverse, more complex, and contain fewer annotation artifacts compared to non-adversarial examples. Our results show that when building large training sets for training NLP models, data collected in an adversarial fashion with a continually updating model-in-the-loop can be more useful than standard model-agnostic collection in the long term.

In future work, it is vital to conduct similar experiments on different tasks, e.g., question answering and sentiment analysis, as well as on a larger number of contexts for NLI. Such experiments can provide insight into the generalizability of our findings. Moreover, given that a core benefit of DADC is promoting diversity and complexity of examples, one could explore other diversity-promoting methods of data collection. Lastly, our DADC setup is relatively simplistic in that we use a single target model and provide no other guides to the annotator; it would be interesting to provide generative models, model interpretations, or other methods to potentially further improve our DADC results.

Addressing Possible Ethical Concerns

The premises that we use are sourced from publicly available sources and were vetted to ensure they contained no overtly offensive content. As described in main text, we designed our incentive structure to ensure that crowdworkers were well compensated (i.e., paid over minimum wage in the U.S.). Our datasets focus on the English language as it is spoken in the United States. They are not collected for the purpose of designing NLP applications but to conduct a scientific study into collecting data for training machine learning models. We share our datasets to allow the community to replicate our findings and do not foresee any risks associated with the free use of this data.

Acknowledgements

We thank Max Bartolo, Yixin Nie, Tristan Thrush, Pedro Rodriguez, and the other members of the Dynabench team for their valuable feedback on our crowdsourcing platform and paper. We also thank Alicia Parrish, Max Bartolo, Jessy Lin, and Nelson Liu for help annotating our test set.

A Dataset Examples

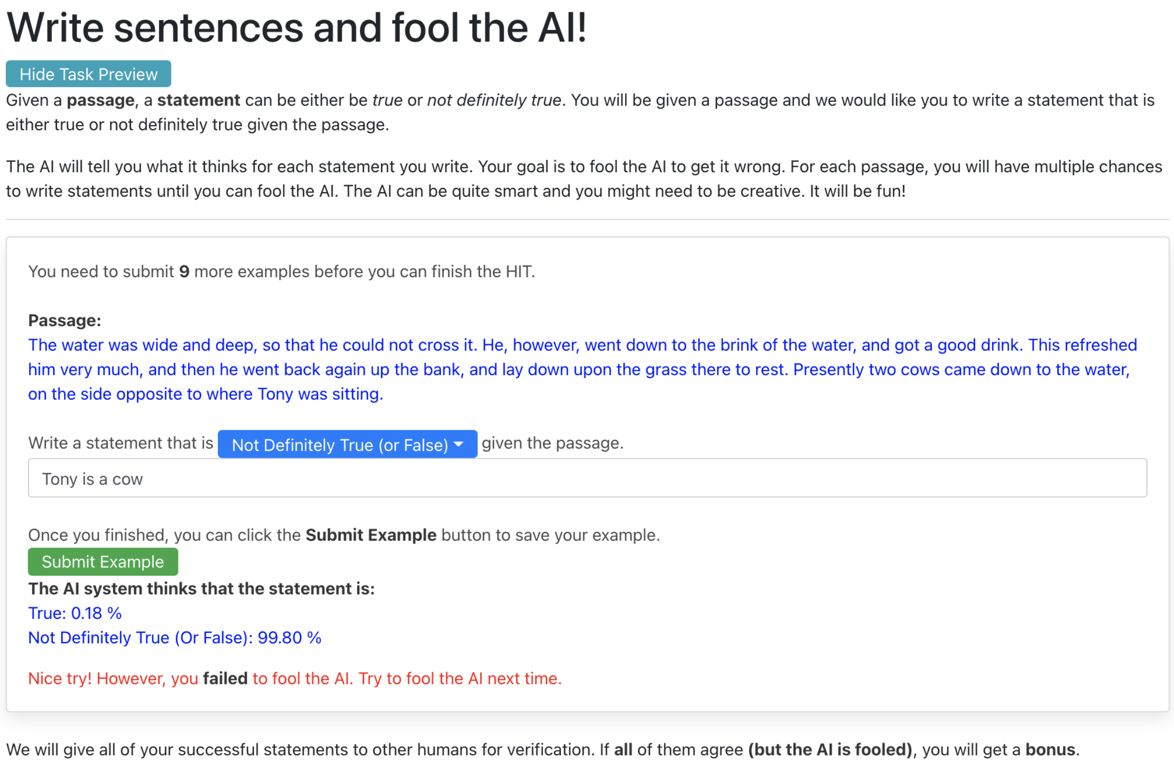
Table 5 shows the ten paragraphs that are used as the premises in our experiments.

B Mechanical Turk Interface

Figure 5 shows our Amazon Mechanical Turk interface for the model-in-the-loop setting.

Premises
Sound is due to the vibrations of objects. A piano string produces sound because of its vibration when struck, or pulled to one side and then released. This vibration sets the air in rapid motion, and the result is the recording of the sound on our ear-drums. In old telephones, this recording corresponds to a film of sheepskin or bladder drawn over a hollow cup or cylinder. When the head of a drum is struck with a small stick it vibrates. In this case the vibrations are set in motion by the blow, while in the telephone a similar phenomenon is the result of vibratory waves falling from the voice on the thin membrane, or disk of metal, in the transmitter. When these vibrations reach the ear-drumm the nervous system, corresponding to electricity in the mechanical telephone, carries this sound to our brains where it is recorded and understood. In the telephone the wire, charged with electricity, carries the sound from one place to another.
Michael Faraday was born at Newington, Surrey, on September 22, 1791, and was the third of four children. His father, James Faraday, was the son of Robert and Elizabeth Faraday, of Clapham Wood Hall, in the north-west of Yorkshire, and was brought up as a blacksmith. He was the third of ten children, and, in 1786, married Margaret Hastwell, a farmer's daughter. Soon after his marriage he came to London, where Michael was born. In 1796 James Faraday, with his family, moved from Newington, and took rooms over a coach-house in Jacob's Well Mews, Charles Street, Manchester Square. In looking at this humble abode one can scarcely help thinking that the Yorkshire blacksmith and his little family would have been far happier in a country house than in their new crowded London one, however, had he remained in the countryside, it is difficult to see how the genius of young Michael could have met with the requisites for its development.
I had demonstrated by repeated experiments that inoculations of yellow fever blood into animals–dogs, rabbits, guinea pigs–gives a negative result. However, this negative result might be because these animals are not susceptible to the disease. In the civil hospital in Vera Cruz in 1887, Dr. Daniel Ruiz ran a single inoculation experiment on a man. But, this experiment was inconclusive because the patient from whom the blood was obtained was in the eighth day of the disease, and it was quite possible that the specific germ was destoyed at that point. These were the facts surrounding yellow fever when Dr. Reed and his associates commenced their investigations in Cuba during the summer of 1900. In a preliminary note read at the meeting of the American Public Health Association, October 22, 1900, the board gave a report of three cases of yellow fever which they believed to be direct results of mosquito inoculations.
There are other signs of a coming change in the weather known less generally. When birds of long flight, such as swallows and others, hang about home and fly low—rain or wind may be expected. Also when animals seek sheltered places, instead of spreading over their usual range: when pigs carry straw to their sties; and when smoke from chimneys does not ascend readily, an unfavourable change may be looked for. Dew, on the other hand, is an indication of fine weather. So is fog. Neither of of these two formations occurs under an overcast sky, or when there is much wind.
A fierce onslaught was made against Alvinczy's position by Massena's corps. It was entirely unsuccessful, and the French were repulsed with the serious loss of three thousand men. Bonaparte's position was now even more critical than it had been at Castiglione; he had to contend with two new Austrian armies, one on each flank, and Wurmser with a third stood ready to sally out of Mantua in his rear. If there should be even partial cooeperation between the Austrian leaders, he must retreat. But he felt sure there would be no cooeperation whatsoever.
The pendulum had swung—it was no longer the Federalist merchants of New England who were discontent with the policies of the governement, but the planters of the South and particularly of South Carolina. New England was now in favor of a protective tariff. Webster, New England's foremost man at Washington, had voted against the tariff of 1816, but had changed his mind and supported a higher tariff in 1824, and a still higher in 1828. The planters of the South had not found it easy to manufacture goods. They had little or nothing, therefore, to protect against the products of European countries. On the contrary, they exported much to England, and imported from England and other countries many of the things they consumed. Accordingly, they were opposed to the whole system of tariff taxation and desired free trade.
The water was wide and deep, so that he could not cross it. He, however, went down to the brink of the water, and got a good drink. This refreshed him very much, and then he went back again up the bank, and lay down upon the grass there to rest. Presently two cows came down to the water, on the side opposite to where Tony was sitting.
The death of Socrates was brought under three of his enemies—Lycon, Meletus, and Anytus, the last a man of high rank and reputation in the state. Socrates was accused by them of despising the ancient gods of the state, introducing new divinities and corrupting the youth of Athens. He was charged with having taught his followers, young men of the first Athenian families, to despise the established government, to be turbulent and seditious, and his accusors pointed to Alcibiades and Critias, notorious for their lawlessness, as examples of the fruits of his teaching.
In some places the wires came very near together, and in others the spaces between them were so wide, that Wallace thought that the squirrel, if by any chance he should ever get put into the cage, would be very likely to squeeze his way out. Then, besides, Phonny had not measured his wires in respect to length, but had cut them off of various lengths, taking care however not to have any of them too short. The result was that the ends of the wires projected to various distances above the board, presenting a ragged and unworkmanlike appearance.
Garrity was the most sinister figure in organized baseball. Once a newspaper reporter, he had somehow obtained control of the Rockets by chicanery and fraud. Sympathy and gratitude were sentiments unknown to him. He would work a winning pitcher to death, and then send the man shooting down to the minors the moment he showed the slightest symptom of weakness. He scoffed at regulations and bylaws; he defied restraint and control; he was in a constant wrangle with other owners and managers; and as a creator of discord and dissension he held the belt.

Table 5: The ten paragraphs we use as premises in our experiments. We refer to these contexts as Sound, Faraday, Yellow, Weather, Battle, Tariff, Water, Socrates, Wires, and Garrity, respectively.



Write sentences and fool the AI!

Given a **passage**, a **statement** can be either be *true* or *not definitely true*. You will be given a passage and we would like you to write a statement that is either true or not definitely true given the passage.

The AI will tell you what it thinks for each statement you write. Your goal is to fool the AI to get it wrong. For each passage, you will have multiple chances to write statements until you can fool the AI. The AI can be quite smart and you might need to be creative. It will be fun!

You need to submit **9** more examples before you can finish the HIT.

Passage:
The water was wide and deep, so that he could not cross it. He, however, went down to the brink of the water, and got a good drink. This refreshed him very much, and then he went back again up the bank, and lay down upon the grass there to rest. Presently two cows came down to the water, on the side opposite to where Tony was sitting.

Write a statement that is Not Definitely True (or False) given the passage.

Tony is a cow

Once you finished, you can click the **Submit Example** button to save your example.

The AI system thinks that the statement is:
True: 0.18 %
Not Definitely True (Or False): 99.80 %

Nice try! However, you **failed** to fool the AI. Try to fool the AI next time.

We will give all of your successful statements to other humans for verification. If **all** of them agree **(but the AI is fooled)**, you will get a **bonus**.

AbductionRules: Training Transformers to Explain Unexpected Inputs

Nathan Young, Qiming Bao, Joshua Bensemann, Michael Witbrock

Abstract

Transformers have recently been shown to be capable of reliably performing logical reasoning over facts and rules expressed in natural language, but abductive reasoning - inference to the best explanation of an unexpected observation - has been underexplored despite significant applications to scientific discovery, common-sense reasoning, and model interpretability.

We present AbductionRules, a group of natural language datasets designed to train and test generalisable abduction over natural-language knowledge bases. We use these datasets to finetune pretrained Transformers and discuss their performance, finding that our models learned generalisable abductive techniques but also learned to exploit the structure of our data. Finally, we discuss the viability of this approach to abductive reasoning and ways in which it may be improved in future work.

1 Introduction

Since its introduction, models based on the Transformer (Vaswani et al., 2017) have, due to their learning ability and Turing-completeness (Bhattamishra et al., 2020), sparked research into their use in many applications beyond their original purpose of natural language processing (NLP), including image processing and generation (Parmar et al., 2018; Chen et al., 2020), theorem proving (Polu and Sutskever, 2020; Welleck et al., 2021), and chess (Noever et al., 2020).

One such task is logical inference - reasoning over first-order logic (FOL) knowledge bases (collections of facts and rules). Given a knowledge base, one may attempt to find logical implications (deduction), discover rules that extrapolate patterns in known facts (induction), or infer facts that would explain surprising observations (abduction). More specifically, if a newly observed fact p cannot be deduced from an existing knowledge base, abduction is the process of finding one or more facts that, if added to the knowledge base, would allow p to be deduced from existing rules. Figure 1 demonstrates the difference between these three kinds of inference.

Traditionally, FOL is represented using a formal mathematical syntax, with facts resembling $\textsc{Human}(\textsc{Socrates})$ and rules resembling $\forall X : \textsc{Human}(X) \implies \textsc{Mortal}(X)$. Clark et al. (2020) recently pioneered an alternative approach we call *natural-language logic*, which might represent these as "Socrates is human" and "Humans are mortal". This approach, properly followed, retains the precision of the mathematical syntax while also taking advantage of Transformers' NLP aptitude and pretraining. This approach also allows reasoning over texts not written in formal representations.

Clark et al. (2020) examined their models' potential for deduction only. Tafjord et al. (2021) extended this work to explore abduction but retained a focus on deduction.

Our goal is to train Transformers to perform abductive reasoning with the following properties:

- **Natural**: Operate over natural language.
- **Generalisable**: Be able to apply techniques outside domains in which they were learned.
- **Generative**: Produce explanations rather than labelling them as sufficient or insufficient.
- **Single-hop**: Produce direct explanations. Instead of "plants are green because chlorophyll is green because green light is not used in photosynthesis", prefer "plants are green because chlorophyll is green". If further explanation is desired, abduction can be applied again.
- **Discerning**: Prefer simpler explanations.
- **Explicit**: Use given knowledge bases rather than relying on pretraining.

Findings of the Association for Computational Linguistics: ACL 2022, pages 218 - 227

Deduction:	Socrates is human	→	Humans are mortal	→	?
Induction:	Socrates is human	→	?	→	Socrates is mortal
Abduction:	?	→	Humans are mortal	→	Socrates is mortal

Figure 1: A comparison of deduction, induction, and abduction, as attempts to reconstruct different parts of the same line of FOL reasoning. Note that only deduction is fully reliable, induction may go in either direction in this case, and only abduction produces new knowledge.

Our efforts to train abduction in this way are motivated by multiple potential applications.

- Ray (2007) describes the use of automated abduction in scientific discovery. Since much scientific knowledge exists in the form of natural language rather than formal representations, advances in natural-language abduction would greatly assist in automating the scientific method by helping to explain experimental observations.
- Ignatiev et al. (2019) describe the use of abduction to interpret deep learning models similar to Transformers, which are infamously difficult to interpret.
- Abduction may also help solve the longstanding problem of automating common-sense reasoning. Transformers excel at memorising common knowledge but routinely fail to capture any underlying reasoning. Training these models to explain their own outputs may remedy this problem by providing a way to integrate this fractured knowledge into a more connected model of reality.

We present the following contributions:

- A collection of datasets for training and testing natural-language abduction.
- A method of synthetically generating more realistic natural-language logic datasets.
- Experimental results showing that Transformers can perform abductive reasoning without additional architecture.

2 Related Work

2.1 Natural-language logic

Our work builds on the RuleTaker line of research on natural-language logic. This line began with Clark et al. (2020), who developed RuleTakers to reason deductively over FOL knowledge bases expressed in natural language, judging given facts to be true or false. These achieved promising results but failed to accurately explain their reasoning or generalise to inferences requiring more steps than were seen at training time. PRover (Saha et al., 2020) achieved greater explainability by generating proofs of its answers. Similarly, the Iterative variant of ProofWriter (Tafjord et al., 2021) chained single-hop deductions rather than reasoning through multi-hop deductions all at once, making its reasoning transparent and easily generalisable to unseen depths. multiPRover (Saha et al., 2021) also made use of this iterative approach. The generalisability and interpretability of iterative single-hop reasoning are why we seek to train single-hop abduction.

Tafjord et al. (2021) also adapted their deduction-based datasets to train abductive reasoning, achieving success but training multi-hop abduction only, and also requiring models to output every possible explanation. By contrast, we seek to train models to discern between simpler and more complex explanations - for example, to prefer explanations requiring fewer unknown facts.

2.2 Other adjacent work

Bhagavatula et al. (2019) presented two more abduction-based datasets: α-NLI, which tests models' ability to choose which of two hypotheses better explains an observation, and α-NLG, a generative version of the same dataset. These datasets do not give supporting knowledge bases - all background information must come from pretraining. While this is a valuable approach, we seek to investigate how well Transformers can reason over given knowledge bases to incorporate explicit background knowledge.

Gontier et al. (2020) investigated Transformers' ability to perform inductive reasoning in natural language, finding them able to extrapolate patterns in given proofs but again unable to generalise to more complex proofs.

Saparov and Mitchell (2021) developed an alternative approach to classifying the ProofWriter datasets that does not reason over natural language, instead using a symbolic, Bayesian approach and using abductive reasoning to satisfy constraints. Their models' superior performance demonstrates that while Transformers are effective at logical reasoning, they may benefit from more specialised architecture.

3 Methodology

Prior to our work, there existed no dataset capable of training or testing the kind of abductive reasoning we seek. We therefore present **AbductionRules**, a natural-language logic dataset designed for this task, and use it to train and test several models based on a pretrained Text-to-Text Transfer Transformer, or T5 (Raffel et al., 2020).

3.1 Datasets

AbductionRules has three main predecessors.

3.1.1 Rule Reasoning

The Rule Reasoning dataset developed by Clark et al. (2020) was, to our knowledge, the first natural-language logic dataset.

To create this dataset, FOL predicates (e.g. $\textsc{Big}(\textsc{Lion})$) were procedurally generated, entities ($\textsc{Lion}$) and attributes ($\textsc{Big}(X)$) were extracted, and templates ("The {entity} is {attribute}") were used to create natural-language logic translations ("The lion is big"). Rules were created similarly (e.g. $\forall X : \textsc{Big}(X) \implies \textsc{Blue}(X)$ became "If something is big then it is blue"). Facts and rules were grouped into knowledge bases, each with several questions; the model's task is to label each question true or false.

The Rule Reasoning dataset includes knowledge bases in several domains; those in the *animal-domain* use animals as entities while those in the *person-domain* use peoples' names. All subsequent datasets similarly use these two domains. The animal-domain includes *multi-entity* facts ($\textsc{Chases}(\textsc{Lion}, \textsc{Mouse})$, or "the lion chases the mouse"). For our purposes, we consider the lion to be the main entity and "chases the mouse" to be an attribute of the lion.

3.1.2 ParaRules

Recognising that their translations of mathematical syntax into natural language were strict and unrealistic (e.g. "Charlie is green. Charlie is rough."), Clark et al. (2020) also produced ParaRules, which contained knowledge bases and questions similar to those in the Rule Reasoning dataset, but were paraphrased into more colloquial language (e.g. "Charlie has green teeth and rough skin."). This approach much better prepares Transformers to reason logically over naturally-occurring texts but requires large amounts of human labour to produce. For this reason, ParaRules is much smaller than the Rule Reasoning dataset.

3.1.3 PARARULE Plus

Seeing the value in RuleTaker's size and ease of production as well as the greater utility of ParaRules, Bao (2021) produced PARARULE Plus, a compromise between the Rule Reasoning dataset and ParaRules that procedurally rephrases all rules during generation by using various templates. PARARULE Plus also avoids eschewingz word associations entirely by grouping related attributes (such as "big", "strong", "high" and "huge") and only giving entities attributes from one group. While PARARULE Plus falls short of ParaRules' variety, its greater collection of rephrased rules is highly valuable.

3.1.4 AbductionRules

We adapt the open-source code used to generate PARARULE Plus to create AbductionRules[1], making the following changes:

- Instead of labelling questions (for our purposes, "observations") with "true" or "false", we use the lone fact (or "explanation") that would prove or disprove it.
- We ensure that no two knowledge bases in the same dataset give the same attributes to the same entities to avoid repeats. This reduces the size of the datasets; to compensate, we increase the number of entities.
- While each rule has a single condition in PARARULE Plus ("If something is cute, then..."), we give three ("If something is cute, funny, and adorable, then..."), with an entity that satisfies exactly two conditions; the model must identify the third.

After making these changes, we produce datasets with increasing levels of complexity.

- The first complexity level contains no further changes from PARARULE Plus and yields the dataset **Abduction-Animal-0.1**.

---

[1] AbductionRules can be found and downloaded at `https://github.com/Strong-AI-Lab/AbductionRules/tree/main/datasets/`.

Context(Facts+Rules):
Facts: **The squirrel is quiet.** The leopard is slow. The dog is adorable. The crocodile is heavy. The leopard is boring. The leopard is angry. The crocodile is awful. The leopard attacks the squirrel. The dog is small. The dog is cute. The squirrel is nice. The crocodile likes the dog. **The squirrel is kind.**
Rules: If something is cute, is adorable, and is furry, then it is also lovely. All animals that are obese, are awful, and are heavy, are big. If an animal is fierce, sees the squirrel, and likes the dog, it is tired. **Things that are smart, are kind, and are quiet, are also round.** If an animal chases the dog, is boring, and attacks the squirrel, then it is also strong. All things that are slow, are sleepy, and are angry, are rough.
Observation: The squirrel is round.
Explanation: The squirrel is smart.

Figure 2: An example observation, explanation, and corresponding context from Abduction-Animal-Simple. The model must output the explanation given the context and observation as input. Facts and rules used to explain the observation are bolded while relevant attributes are highlighted.

- At the second complexity level, we shuffle all knowledge bases to prevent models from exploiting the constant position of all sentences and attributes. This yields the dataset **Abduction-Animal-0.2**.

- At the third complexity level, we procedurally rephrase rules with random variations instead of using the same templates as PARARULE Plus. For example, the animal-domain FOL rule $\forall X : (\textsc{Big}(X) \land \textsc{Heavy}(X) \land \textsc{Fierce}(X)) \implies \textsc{Strong}(X)$ might be rephrased as "All animals that are big, are heavy, and are fierce, are also strong" or "If something is heavy, is fierce, and is big, it is strong", among many other similar variations. Notably, this rephrasing process involves reordering all attributes so that attributes contained in correct abductions might be first, second, or third. This yields the datasets **Abduction-Animal-Simple** and **Abduction-Person-Simple.**
  Figure 2 contains an example item from Animal-Simple.[2]
  This method of procedural rule rephrasing represents a useful iteration on the natural-language logic approach and leaves room for further improvement. Concentrated work in this line of research may produce synthetic natural-language logic datasets that are larger yet exhibit much wider variety, making this approach more powerful and robust.

- At the fourth and final complexity level, we add extraneous confounding rules to knowledge bases. While lower complexity levels only ever have one rule that could explain a given observation, here we create two variations of every (single-entity) rule; one replaces a satisfied condition with an unsatisfied condition, while the other replaces all three conditions. All replacements come from different pools. This yields the datasets **Abduction-Animal** and **Abduction-Person**.

Figure 3 contains simplified examples of data from each complexity level.

We intend each successive complexity level to remove additional idiosyncrasies that might be exploited in lieu of using abduction (i.e. used to "cheat"), so that this exploitation can be detected. We also intend the fourth to train models to favour simpler explanations when strictly more complex explanations are available.

3.2 Experiments

We use AbductionRules to train 8 models based on the pretrained T5 implementation from the HuggingFace Transformers library (Wolf et al., 2020).[3]

We first use each training set to train 1 model, yielding 6 models trained at 4 complexity levels across 2 domains. To compare domains and complexity levels, we test all models on all test sets, giving us intra-domain results (isolating the effect of the complexity), and inter-domain results (some isolating the effect of the domain). We expect each successive complexity level to train a better-quality model and the two domains to be mostly comparable with some variation attributable to the animal-domain's multi-entity facts.

If our approach were adapted to models extensively trained to reason on many domains, we expect that teaching abduction in every domain would

---

[2] For brevity, we omit the "Abduction-" prefix when discussing the AbductionRules datasets within this paper.

[3] All code used for experiments in this paper can be found at `https://github.com/Strong-AI-Lab/AbductionRules/`.

Figure 3: A diagram demonstrating the successive changes we make to the AbductionRules knowledge bases.

be prohibitively expensive. Therefore, we seek to investigate Transformers' ability to transfer abductive reasoning techniques to domains where these techniques have not been taught but are nonetheless familiar to the Transformer. To this end, we train two more multi-domain models.

- We train one model on our simplest dataset and our most complex dataset in another domain, i.e. Animal-0.1 and Person. We name this model *Person+Animal-0.1*.
- We train another model on the simplest person-domain dataset and the most complex animal-domain dataset, i.e. Person-Simple and Animal, to compare the two domains. We name this model *Animal+Person-Simple*.

While we are interested in these multi-domain models' performance on all datasets, we are particularly interested in their results on the most complex dataset on which they were not trained (Abduction-Animal and Abduction-Person, respectively). We treat performance on these datasets as a proxy for Transformers' ability to apply abductive reasoning outside the domains in which it was trained.

Finally, we use the existing pretrained T5 model with no additional training as our baseline model.

4 Results

Table 1 contains our results, showing the percentage of abductions correctly performed by each model on each test set. [4]

Note that no model ever gave a correct answer in a domain on which it was not trained. On the surface, this would suggest that our models were unable to generalise to new domains. However, inspection of inter-domain results shows that this is not entirely accurate; many explanations contain errors but nonetheless identify the ground-truth explanation. For example, the animal models commonly appended "The" to correct explanations, as in "The Bob is small"; while this is incorrect, it nonetheless indicates the correct explanation in a way that suggests the model still performed the correct abduction. We distinguish between two kinds of errors in correct-yet-useful explanations: *lossless errors* and *lossy errors*.

4.1 Lossless errors

Explanations with lossless errors failed to match the correct explanation character-for-character but allowed it to be reliably identified.

We found several ways in which recognisably correct explanations differed from the ground-truth, such as extra words ("The Bob is small", "The lion is attacks the mouse"), looping ("The dog is is is is is small"), and incorrect grammar ("The anne is wealthy"). While these errors point towards flaws in training, it is a strength of natural-language logic and soft reasoners that they can cope with minor grammar mistakes as long as meaning is preserved.

Table 2 contains our results after correcting for these errors. Note that animal-domain models achieved performance comparable to the person-domain models on novel datasets in their own domain, while person-domain models saw minimal inter-domain improvement. multi-domain models also saw almost no improvement, suggesting that having seen correct explanations in both domains eliminated this kind of formatting error.

4.2 Lossy errors

The most important aspect of abduction in our datasets is identification of the correct attribute.

Table 2: Improvement of all models on all test sets after allowing lossless errors.

The entity at the beginning of the explanation always matches that at the beginning of the observation; therefore, if the correct attribute is identified, the correct explanation can be reconstructed.

Table 3 contains our results after correcting for these errors. Note that every model achieved some useful results on every test set. Most inter-domain results improved to rival intra-domain results, although the Abduction-Person model continued to struggle. Intra-domain results saw minimal improvement, with none seeing a >2% point increase. The multi-domain models again saw no visible improvement, further suggesting that these inferior results were avoidable from seeing facts, rules, and explanations in different formats at training time.

5 Discussion

Our results show that models trained on our simplest datasets struggle to generalise to new complexity levels and domains, while those trained on our more complex datasets are better able to generalise but still perform suboptimally. Meanwhile, those trained on combined multi-domain datasets achieve performance superior to the sum of models trained on their parts and easily apply skills outside domains in which they were learned. It is also clear that models trained in the animal-domain achieve better intra-domain and inter-domain performance than person-domain models.

The untrained T5 model performs abysmally and merits little discussion, indicating that this abduction task is non-trivial (at least in the way we present it here).

5.1 Animal-0.1 and Animal-0.2

Unsurprisingly, the models trained on our simplest datasets fare the worst of our trained models. Our Animal-0.1 and -0.2 models perform similarly poorly, suggesting that Animal-0.2's additional complexity from randomised sentence orderings was of minimal importance. In fact, the Animal-0.2 model's performance on more complex datasets is worse than its simpler counterpart; examination of its results reveals a tendency to loop on unfamiliar inputs. Given the Animal-0.1 model's 99.3% correct (100% allowing lossy errors) performance on Animal-0.2, we treat these complexity levels as equivalent and the Animal-0.1 model as definitive.

The Animal-0.1 model is approximately 1/3 as accurate on the person-domain when allowing lossless errors but only loses approximately 6% points when allowing lossy errors, suggesting that it fails to adapt to new formats but is mostly able to use the same techniques as in the animal-domain.

These models' significant performance hit on higher complexity levels clearly indicates that they exploit the structure of their training set. However,

Model \ Test set	Animal-0.1	Animal-0.2	Animal-Simple	Animal	Person-Simple	Person
Untrained	0.0%	0.2%	0.1%	0.0%	0.0%	0.0%
Abduction-Animal-0.1	**100.0% (-)**	100.0% (+0.7%)	48.4% (+0.4%)	29.1% (+0.3%)	41.9% (+28.8%)	23.5% (+13.4%)
Abduction-Animal-0.2	100.0% (-)	**100.0% (-)**	39.4% (+0.8%)	24.5% (+0.9%)	29.4% (+19.8%)	14.3% (+8.6%)
Abduction-Animal-Simple	100.0% (-)	100.0% (-)	**100.0% (-)**	50.1% (-)	66.4% (+32.0%)	14.9% (+7.9%)
Abduction-Animal	92.6% (-)	93.5% (-)	94.2% (-)	**100.0% (-)**	39.1% (+14.1%)	62.7% (+26.2%)
Abduction-Person-Simple	39.8% (+38.4%)	42.8% (+41.5%)	39.6% (+38.7%)	11.5% (+11.2%)	**100.0% (-)**	25.6% (-)
Abduction-Person	5.2% (+5.2%)	5.0% (+5.0%)	4.9% (+4.9%)	15.8% (+15.8%)	26.8% (-)	**100.0% (-)**
Person+Animal-0.1	**100.0% (-)**	100.0% (-)	76.7% (-)	85.6% (+0.0%)	92.9% (-)	**100.0% (-)**
Animal+Person-Simple	99.1% (-)	99.1% (-)	99.4% (-)	**100.0% (-)**	**100.0% (-)**	99.8% (-)

Table 3: Improvement of all models on all test sets after allowing lossy errors.

it should be noted that the Animal-0.1 model drops each time by approximately a factor of 2. If this model only chose the penultimate attribute in a sentence containing the attribute in the question, its accuracy would drop by a factor of 3 with procedural rephrasing and again with confounding rules. Therefore, both models utilise some level of generalised abductive reasoning.

5.2 Animal-Simple and Person-Simple

The Animal-Simple model significantly outperforms our simpler models; this makes sense since Animal-0.1 and -0.2 can be thought of as special, unshuffled cases of Animal-Simple.[5] Similarly to the Animal-0.1 model, the Animal-Simple model performs about half as well on Animal as on Animal-Simple. This model also performs worse on Person-Simple than Animal when allowing lossless errors but better when allowing lossy errors, implying that it exploits the structure of Animal-Simple to some degree to identify correct attributes. Its performance drop from Person-Simple to Person is greater than from Animal-Simple to Animal, suggesting that changes in domain and complexity are more difficult to generalise when compounded.

Our Person-Simple model also performs well but fails to generalise to higher complexity; this can be partially explained by the multi-entity facts in the animal-domain, as rules using these facts are not used to create confounding rules. This model gives almost no correct inter-domain explanations unless lossy errors are allowed, in which case it achieves similar inter-domain performance to the animal-domain models. Its performance drop on Animal can be compared to that of the Animal-Simple model from Person-Simple to Person, exacerbated by the person-domain models' poorer performance in general.

5.3 Abduction-Animal and Abduction-Person

The Animal model performs the best of all single-domain models, achieving >60% performance on all datasets except Person-Simple when allowing lossy errors. The drop from Person to Person-Simple is evidence of cheating, but its generalisability is superior to all other models and demonstrates some abductive ability. Surprisingly, it achieves worse intra-domain results on lower complexity levels than the Animal-Simple model, again indicating that some of its performance is dependent on Animal's rule structure. Still, this performance drop is relatively small (being <10% in all cases), further reinforcing that while this model utilises some degree of both cheating and abduction (like all our models), its abductive capabilities generalise to a promising extent.

By contrast, the Person model achieves the worst performance of any model, performing as well on Person-Simple as that dataset's model does on Person and achieving abysmal inter-domain performance, even on Animal. This model is the clearest indication that (our instantiations of) the two domains are not equivalent; the animal-domain's models are much better able to generalise.The multi-entity rules again offer some explanatory power - the Animal model demonstrates some overtraining on the confounding rules and so performs more poorly in their absence, but still learned to explain observations using multi-entity rules that lacked confounding equivalents, making it robust to extraneous rules but not reliant on them. If this were a major determining factor, we would expect models trained on both maximally and minimally complex datasets to be even more robust and generalised.

5.4 Multi-domain models

Our multi-domain models are our best-performing models by far, achieving superior performance on unseen datasets than the sum of models trained on

---

[5] Because of this and their failure to train generalisable abduction, we do not include either Animal-0.1 or -0.2 in the public release of AbductionRules. The code we used for our experiments can be used to regenerate them if desired.

their combined training sets' parts.

The Person+Animal-0.1 model, being trained on our simplest dataset and having its most complex training set come from the worse of our two training domains, is the worse of our two multi-domain models. Nonetheless, it reaches a remarkable level of performance, explaining >76% of all observations correctly on all test sets. Its performance in the face of unconfounded rephrased rules (something unprecedented in its training) is dependent on the domain. In the person-domain (i.e. on Person-Simple), where it received its most complex training, it achieves its best result on a dataset it was not trained on (excepting Animal-0.2), while in the animal-domain (i.e. on Animal-Simple) it achieves its worst result, having not seen any rephrased animal rules at training time. Still, it demonstrates a greater ability than any single-domain model to generalise to these unfamiliar rule structures. It can also apply its training on confounded rules outside the domain in which it was learned, achieving far greater performance on Animal than any other dataset that it was not trained on.

The Animal+Person-Simple model is our best and most promising, achieving >99% performance on every dataset and consistently adapting to all complexity levels in every domain. Like Person+Animal-0.1, it encounters unprecedented rule structures (singular single-entity animal rules, confounded person rules) and generalises almost perfectly to each. While our datasets remain somewhat limited in scope, we believe that this result demonstrates that Transformers can generalise abductive techniques beyond the domains in which those techniques were trained, provided the domain itself is not entirely novel.

Extrapolating these multi-domain results, it seems likely that finetuning Transformers that have received extensive pretraining (such as GPT-3 (Brown et al., 2020)) on datasets covering more varied and complex examples of abduction would make these models capable of much more generalised natural-language abductive reasoning.

6 Conclusion

We have presented the AbductionRules datasets and shown that pretrained T5 models finetuned on them exhibit generalised abductive reasoning. Our more complex datasets train abduction more generally and reliably than our less complex datasets. Further, training in multiple domains is superior to training in only one domain, and we have clear evidence of generalisation of techniques from one domain to another.

We have presented an innovation in natural-language logic dataset generation, presenting a new middle-ground between the template-based PARARULE Plus (Bao, 2021) and the manually rephrased Pararules (Clark et al., 2020). We believe our results are promising and demonstrate the viability of Transformer-based abduction (and logical reasoning in general), but also indicate opportunities for improvement.

6.1 Future Work

Future work in this area might explore:

- Examining skill transfer between different kinds of logical reasoning.
- Applying abductive techniques in real-world, as opposed to artificial, domains.
- Generating probability distributions over multiple possible explanations.
- Testing explanations by verifying that they allow the original observation to be deduced.
- Explanations that include not only missing premises but the relevant rule(s) they satisfy.

Appendices

A Rephrasing method

Table 4 demonstrates the method we used to rephrase rules in our more complex datasets. Our method made several binary phrasing choices to decide between 16 possible templates, providing more internal variety than PARARULE Plus but less than ParaRules. As well as this random variation, all 3 conditions were shuffled, giving 6 possible orderings and 96 total possible rephrasings.

B Lossless errors

The following encompass all errors we considered lossless - i.e. close enough to the ground truth answer to be reasonably counted as correct.

- Unnecessary inclusion of 'the', as in "The Bob is small."
- Omission of 'the', as in "Cat is smart."
- Unnecessary inclusion of 'is', as in "The lion is attacks the mouse."
- Omission of 'is', as in "The squirrel funny."
- Inclusion of words that are never included in our answers, specifically 'and', 'are', and 'a'.

Plural?	Specific?	Also?	Then/All?	Example rephrasing
×	×	×	×	If something is big, is heavy, and is fierce, it is strong.
×	×	×	✓	If something is big, is heavy, and is fierce, then it is strong.
×	×	✓	×	If something is big, is heavy, and is fierce, it is also strong.
×	×	✓	✓	If something is big, is heavy, and is fierce, then it is also strong.
×	✓	×	×	If an animal is big, is heavy, and is fierce, it is strong.
×	✓	×	✓	If an animal is big, is heavy, and is fierce, then it is strong.
×	✓	✓	×	If an animal is big, is heavy, and is fierce, it is also strong.
×	✓	✓	✓	If an animal is big, is heavy, and is fierce, then it is also strong.
✓	×	×	×	Things that are big, are heavy, and are fierce, are strong.
✓	×	×	✓	All things that are big, are heavy, and are fierce, are strong.
✓	×	✓	×	Things that are big, are heavy, and are fierce, are also strong.
✓	×	✓	✓	All things that are big, are heavy, and are fierce, are also strong.
✓	✓	×	×	Animals that are big, are heavy, and are fierce, are strong.
✓	✓	×	✓	All animals that are big, are heavy, and are fierce, are strong.
✓	✓	✓	×	Animals that are big, is heavy, and is fierce, are also strong.
✓	✓	✓	✓	All animals that are big, are heavy, and are fierce, are also strong.

Table 4: A diagram demonstrating the successive changes we make to the AbductionRules knowledge bases.

- Renaming the entity to better resemble training examples; for example, person-domain models sometimes replaced ’the crocodile’ with ’Cro’ while animal-domain models replaced ’Bob’ with ’the bobster’.
- Looping the correct answer or some part thereof, as in "The dog is is is is is small." or "The rabbit is rabbit is adorable."
- Incorrect capitalisation, as in "The anne is wealthy."
- Omission of spaces, as in "Thebob is small."

C Abduction-Person-Simple example

Figure 4 contains an example item from Abduction-Person-Simple, similarly to Figure 2’s example from Abduction-Animal-Simple.

Context(Facts+Rules):
Facts: Anne is dull. Dave is nice. Erin is tiny. **Fiona is high. Fiona is strong.** Erin is small. Dave is clever. Fiona is heavy. Anne is sad. Anne is rough. Erin is thin.
Rules: **All things that are big, are high, and are strong, are also huge.** If something is poor, is small, and is nice, it is also huge. All things that are high, are rough, and are little, are also smart. All things that are clever, are quiet, and are dull, are smart. People that are big, are dull, and are clever, are also short. If a person is thin, is small, and is little, that person is short. If a person is thin, is strong, and is quiet, that person is imperfect. Things that are little, are small, and are nice, are short. If a person is high, is poor, and is rough, then that person is also imperfect. All things that are thin, are big, and are strong, are also huge. If something is clever, is nice, and is quiet, then it is smart. If a person is poor, is rough, and is dull, then that person is imperfect.
Question: Fiona is huge.
Label: Fiona is big.

Figure 4: An example observation, explanation, and corresponding context from Abduction-Person-Simple. The model must output the explanation given the context and observation as input. Facts and rules used to explain the observation are bolded while relevant attributes are highlighted.

On the Importance of Data Size in Probing Fine-tuned Models

Abstract

Several studies have investigated the reasons behind the effectiveness of fine-tuning, usually through the lens of probing. However, these studies often neglect the role of the size of the dataset on which the model is fine-tuned. In this paper, we highlight the importance of this factor and its undeniable role in probing performance. We show that the extent of encoded linguistic knowledge depends on the number of fine-tuning samples. The analysis also reveals that larger training data mainly affects higher layers, and that the extent of this change is a factor of the number of iterations updating the model during fine-tuning rather than the diversity of the training samples. Finally, we show through a set of experiments that fine-tuning data size affects the recoverability of the changes made to the model's linguistic knowledge.[1]

1 Introduction

The outstanding performance of pre-trained language models (LMs) on many NLP benchmarks has provoked curiosity about the reasons behind their effectiveness. To this end, several probes have been proposed to explore their capacity (Tenney et al., 2019b; Hewitt and Manning, 2019; Wu et al., 2020). The investigations have clearly highlighted the ability of LMs in capturing various types of linguistic knowledge (Liu et al., 2019; Clark et al., 2019; Michael et al., 2020; Klafka and Ettinger, 2020; Tenney et al., 2019a).

However, to take full advantage of the encoded knowledge of pre-trained models in specific target tasks, it is usually required to perform a further fine-tuning (Devlin et al., 2019). The broad application of fine-tuning has garnered the attention of many researchers to explore its peculiarities. Trying to understand the fine-tuning procedure, recent analyses have shown that most of the pre-trained linguistic knowledge is preserved after fine-tuning (Tenney et al., 2019b). Furthermore, by encoding the essential linguistic knowledge in the lower layers, this procedure makes the higher layers task-specific (Durrani et al., 2021). However, Mosbach et al. (2020) argued that the changes in the probing performance can not be attributed entirely to the modifications a model undergoes with respect to its linguistic knowledge after fine-tuning.

While the previous studies focused on the role of the target task as a factor that affects the probing performance of fine-tuned models, we present another important factor in interpreting probing results for such models. Our investigations reveal that the conclusions drawn by previous probing studies that investigate the impact of fine-tuning on acquiring or forgetting knowledge might not be entirely reliable unless the size of the fine-tuning dataset is also taken into account. Through several experiments, we show that the encoded linguistic knowledge can highly depend on the size of target tasks' datasets. Specifically, the larger the task data, the more the probing performance deviates from the pre-trained model, irrespective of the fine-tuning tasks.

To address the overlooked role of data size, we run several experiments by limiting training samples and probing the fine-tuned models. Our results indicate that models fine-tuned on large training datasets witness more change in their encoded linguistic knowledge compared to pre-trained BERT. However, by reducing fine-tuning training data size (e.g., from 393k in MNLI to 7k), the gap between probing scores becomes smaller. Moreover, we expand our analysis and evaluate the extent to which large training datasets affect the captured knowledge across layers. The layer-wise results show that the effect of data size is more notable on higher

Findings of the Association for Computational Linguistics: ACL 2022, pages 228 - 238
May 22-27, 2022

layers, particularly for models trained on larger datasets. We take our analysis a step further and show that the difference in probing performance among different data sizes is due to the total number of optimization steps rather than the diversity of training samples. Finally, through a set of experiments, we show that the changes made to the probing performance by a fine-tuning task can be recovered if the model is re-fine-tuned on a task with comparable data size.

The findings of this paper can be summarized as follows:

- Data size is a factor that highly impacts a fine-tuned model's probing performance.
- The size of the dataset mainly affects the probing performance of the higher layers.
- The number of training steps is what makes larger datasets have higher impacts on the model's linguistic knowledge (rather than the diversity in training samples).
- Fine-tuning data size affects the extent to which the modifications made to a model's linguistic knowledge are recoverable.

2 Related Work

Recently, many studies have shown that pre-trained language models, such as BERT (Devlin et al., 2019), encode certain linguistic knowledge in their internal representations (Tenney et al., 2019b). For instance, Hewitt and Manning (2019) found that syntactic dependencies can be obtained from BERT's token embeddings, suggesting that BERT encodes syntactic knowledge in its representations. Nevertheless, not all layers behave similarly in capturing linguistic features: lower layers tend to encode surface-level knowledge, middle layers seem to be responsible for syntactic information, and higher layers capture semantic knowledge in their representations (Jawahar et al., 2019).

While models such as BERT capture considerable amounts of linguistic features, one still requires to fine-tune them to take full advantage of their potential in specific downstream tasks (Wang et al., 2018). Fine-tuning affects BERT in various ways; for instance, Hao et al. (2020) found that fine-tuning mainly affects the attention mode of the higher layers and alters the feature extraction mode of the middle and last layers. In addition, fine-tuning BERT on a negation scope task improves the model's attention sensitivity to negation (Zhao and Bethard, 2020).

Apart from the changes made to BERT's attention, recent work has studied how fine-tuning affects BERT's representations and, as a result, its linguistic knowledge. Merchant et al. (2020) found that fine-tuning primarily affects the representations in higher layers, and depending on the downstream task, the changes made to lower layers could be either deep or shallow. Moreover, on only a small number of downstream tasks, fine-tuning seems to have a positive impact on the probing accuracy (Mosbach et al., 2020). Given the fact that fine-tuning mostly affects higher layers, Durrani et al. (2021) showed that after fine-tuning, most of the model's linguistic knowledge is transferred to lower layers to reserve the capacity in the higher layers for task-specific knowledge.

Studies so far have relied on probing accuracy to explain how fine-tuning affects a model's linguistic knowledge (Mosbach et al., 2020; Durrani et al., 2021; Merchant et al., 2020). However, given the fact that fine-tuning tasks do not share the same number of samples, concluding to what extent target tasks contribute to the model's linguistic knowledge is not fully reliable. To the best of our knowledge, none of the previous studies have considered the role of data size in fine-tuned models' linguistic knowledge. In this work, we show that the size of the dataset plays a crucial role in the amount of knowledge captured during fine-tuning. By designing different experiments, we analyze the effect of the size of the dataset in-depth.

3 Experimental Setup

We have carried out over 600 experiments to study the linguistic features captured during fine-tuning. This allows us to examine how much different factors impact performance on various probing tasks. Moreover, varying the sample size lets us understand its importance in analyzing fine-tuned models. In this section, we provide more details on setups, downstream tasks, and probing tasks.

3.1 Fine-tuning

For our analyses, we concentrate on the BERT-base model, which is arguably the most popular pre-trained model. We fine-tuned the 12-layer BERT on a set of tasks from the GLUE Benchmark (Wang et al., 2018) for five epochs and saved the best checkpoint based on performance on the validation

	Full	7k	2.5k	1k
CoLA	57.55	56.87	46.68	42.72
SST-2	92.78	91.28	89.79	86.81
MNLI	83.19	73.73	68.63	60.16
QQP	90.63	82.37	79.93	76.93
MRPC	86.43	-	81.78	77.82

Table 1: The performance of fine-tuned BERT on five tasks from GLUE (dev set) after fine-tuning on training data of varying size. The numbers are reported based on accuracy for SST, MNLI, QQP, MRPC, and Matthew's correlation for CoLA.

set. We used the [CLS] token for classification and set the learning rate as $5e^{-5}$. We have chosen the following target tasks:

CoLA. The Corpus of Linguistic Acceptability is a binary classification task in which **8.5k** training samples are labeled based on their grammatical correctness (Warstadt et al., 2019).

MRPC. The Microsoft Research Paraphrase Corpus includes **3.6k** training sentence pairs in which the semantic equivalence of two sentences is determined (Dolan and Brockett, 2005).

SST-2. The Stanford Sentiment Treebank is a sentiment classification task containing **67k** training sentences (Socher et al., 2013).

QQP. With **364k** question pairs, the goal of the Quora Question Pairs dataset is to determine whether two questions in a pair are semantically similar.

MNLI. The Multi-Genre Natural Language Inference is a Natural Language Inference (NLI) task with about **393k** records in its training set (Williams et al., 2018).

3.2 Fine-tuning performance

The performance of the fine-tuned models on these tasks is presented in Table 1. We report the results on different training data sizes[2] to highlight the extent to which reducing training data affects a model's performance on the corresponding tasks. It is worth mentioning that even though the performance of target tasks decreases by reducing their training data, it is still far better than the pre-trained version. Therefore, the models have learned the corresponding target tasks to some extent.

3.3 Probing tasks

We probe the pre-trained and fine-tuned BERT models by training a linear classifier on top while the weights of the encoders are frozen. Keeping the probing classifier simple allows us to scrutinize the linguistic knowledge by eliminating the possibility of the classifier learning such knowledge. All probes are trained with a batch size of 32, a learning rate of $3e^{-4}$, a linear scheduler for adjusting the learning rate with 10% warm-up steps, and for ten epochs. We also used Adam as the optimizer. Due to limited computational resources, we were not able to run all the experiments multiple times with different random seeds. However, to ensure the reliability of our results, we repeated several randomly chosen experiments three times (with different random seeds). The probing accuracy remained stable, ranging within ± 1.0. Finally, we report the evaluation scores on test sets for the models with the highest validation accuracy on the validation set.

We opted for four syntactic and semantic probing tasks from the SentEval benchmark (Conneau and Kiela, 2018) to study the linguistic knowledge encoded in the models[3]. The binary classification tasks are as follows:

Bigram Shift is a task that aims to test the model's ability to predict whether two successive random tokens in the same sentence have been inverted.

Object Number focuses on the model's ability to determine the singularity or plurality of the main clause's direct object.

Coordination Inversion examines the model's ability to distinguish between original sentences and sentences where the order of two coordinated clausal conjoints have been inverted.

Semantic Odd Man Out is a task that tests the model's ability to predict if a sentence is original or whether a random word has been replaced with another word from the same part of speech.

---

[2] Since MRPC only has 3.6k training samples, we do not report any 7k results for this dataset.

[3] We also repeat our experiments on the structural probe of Hewitt and Manning (2019). This probe investigates how well syntactic dependency trees are encoded within a model's representations. We report the UUAS score for the distance between word pairs in the parse tree. The results are reported in Appendix A. We choose this probe because it is different from SentEval's probes in terms of training objective to show our statement still stands.

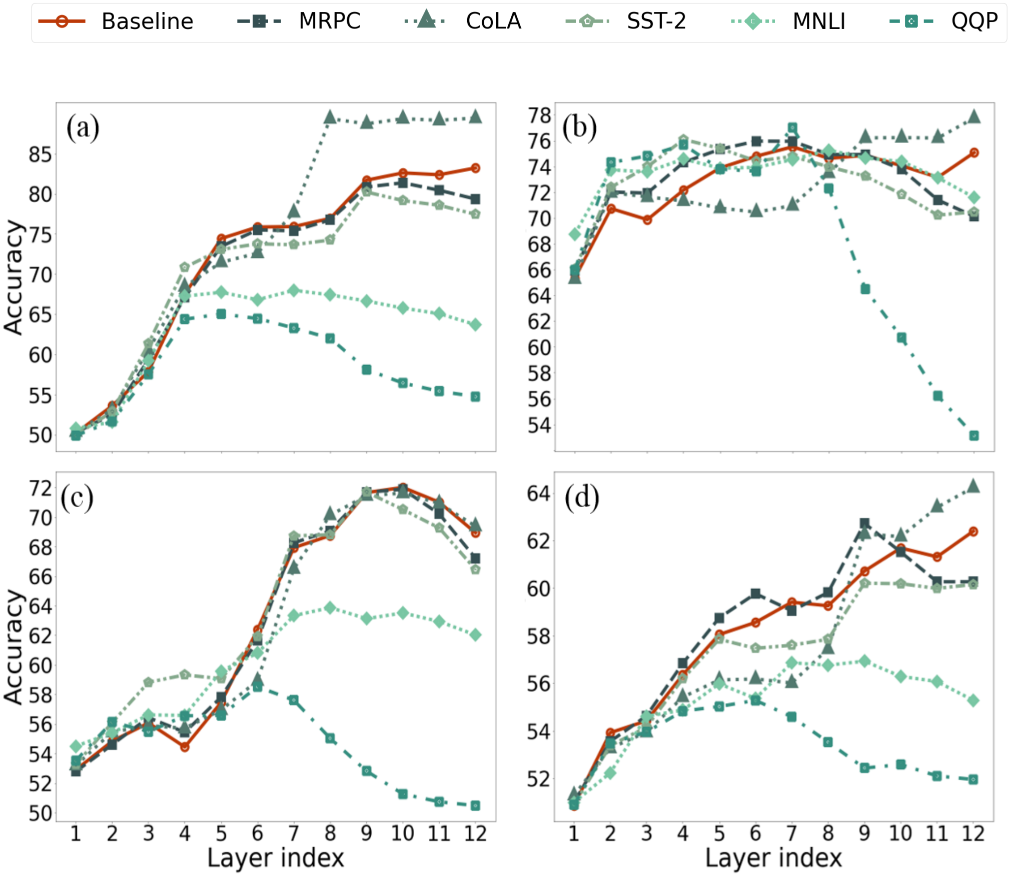

Figure 1: Probing accuracy on all the layers of fine-tuned models on (a) Bigram Shift (b) Object Number (c) Coordination Inversion (d) Semantic Odd Man Out. As shown, there is a large accuracy gap between models fine-tuned on larger data sizes (e.g., MNLI and QQP) and the baseline.

4 Data Size Analysis

In this section, we first provide insight on the role of target tasks in capturing or forgetting different types of knowledge (e.g., syntactic and semantic) during fine-tuning. Then, we investigate the role of datasets' size on linguistic knowledge.

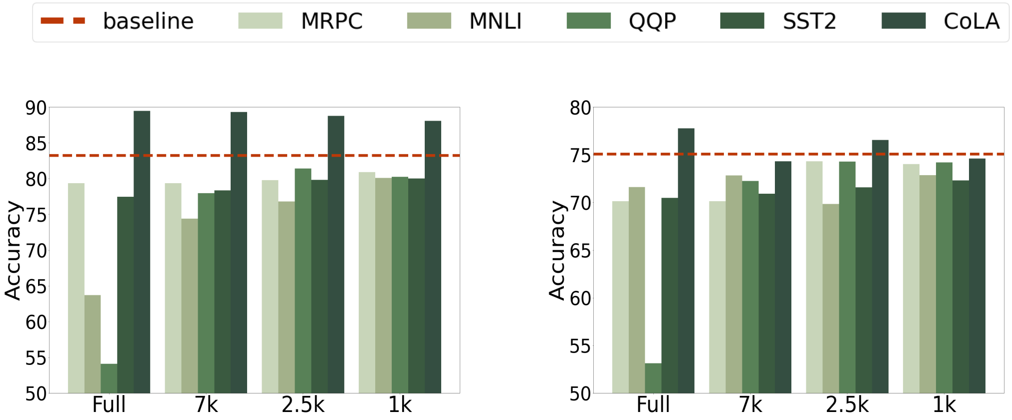
4.1 Probing Linguistic Knowledge

We empirically evaluate the linguistic knowledge captured by several fine-tuned models through the lens of probing performance. Figure 1 illustrates the layer-wise probing performance of fine-tuned models, considering pre-trained BERT as our baseline. As can be observed, different models carry similar linguistic knowledge up to the middle layers, and the difference gradually increases as we move up to the higher layers. This observation is consistent with the reported results by Merchant et al. (2020). Their experimental analysis indicates that fine-tuning mostly changes the higher layers while having a smaller impact on the lower layers. Durrani et al. (2021) also reported a similar behavior in other LMs through different probing tasks.

The results illustrated in Figure 1 clearly highlight the impact of data size on probing accuracy. We can observe that the probing performance of the baseline and models fine-tuned on smaller datasets (e.g., MRPC, SST-2, and CoLA) are comparable, whereas fine-tuning on larger data sizes (e.g., QQP and MNLI) seems to have impacted probing performance by a significant margin. In what follows, we carry out experiments to better understand the reasons behind this observation.

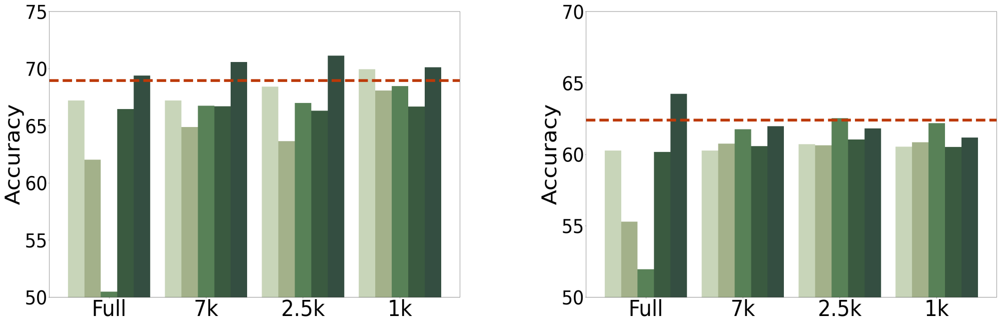
4.2 The Impact of Data Size

One of the popular studies in probing is investigating the changes made to a model's linguistic knowledge after fine-tuning. The changes brought about in the model upon fine-tuning are taken as a means to explain the nature of the corresponding task on which fine-tuning has been carried out (Durrani et al., 2021). Existing studies usually consider several tasks, many of which do not have datasets of



(a) Bigram Shift

(b) Object Number



(c) Coordination Inversion

(d) Semantic Odd Man Out

Figure 2: An illustration of the probing performance of models fine-tuned on fixed-size training sets of five different tasks. The pre-trained BERT's performance on each of the four probing tasks has been shown by the dashed red line. The figures suggest that different fine-tuned models, irrespective of the fine-tuning task, almost encode similar linguistic knowledge when trained on equal-sized data.

comparable size. For instance, in the GLUE benchmark, MNLI is 46 times larger than CoLA. These studies usually focus on the type of downstream tasks only, overlooking the size of their datasets.

Based on our observations in Section 4.1, we hypothesize that, in addition to the type of the downstream task, the size of its corresponding dataset can play an important role in improving or impairing the linguistic knowledge encoded in the model. We examined our hypothesis by fine-tuning pre-trained BERT on the selected downstream tasks with different sets of samples. Specifically, taking the pre-trained BERT as the baseline, we analyze the effect of the training set size on the encoded linguistic knowledge by limiting the number of samples to 7k, 2.5k, and 1k. Figure 2 shows the results of this experiment. In general, the results confirm our hypothesis that data size plays a significant role in probing accuracy. In what follows, we further discuss our observations from this experiment.

4.3 Discussion

The effect of data size on both syntactic and semantic probing tasks is notable, denoted by the large gaps between the probing results of the models fine-tuned on larger data sizes and the baseline (see Figure 1). We observe that as the number of samples increases, the gap between fine-tuned models and the pre-trained BERT (baseline) becomes more apparent. For instance, probing the model fine-tuned on QQP's full training set demonstrates that it has far less linguistic knowledge than the baseline. However, after fine-tuning the model on QQP with fewer training samples (7k, 2.5, and 1k), not much change is observed across the results. This shows that fine-tuning data size indeed affects the linguistic knowledge encoded by the model.

Overall, we can conclude that the amount of linguistic knowledge through fine-tuning is highly affected by data size. This suggests that data size

should be taken into account when analyzing fine-tuned models.

5 Layer-wise Analysis

Given our observations on the role of data size, we were curious to see how it affects the encoded knowledge in specific layers. As noted by Jawahar et al. (2019), BERT's layers can be divided into three classes in terms of the linguistic knowledge they capture. To this end, we carry out experiments by probing layers 2, 7, and 11-12 to cover all the three categories.

Table 2 shows our results obtained from this experiment, which are compared with BERT-base. Due to our limited resources and the excessive number of experiments, we omitted probing tasks that did not show any distinguishable patterns (Figures 1 and 2), i.e., Coordination Inversion and Object Number. The results follow a similar trend to the ones depicted in Figure 2. As we decrease the number of training samples, the probing performance on the fine-tuned models gets closer to the baseline across all layers. MNLI and QQP's behaviors are compelling evidence of the effectiveness of data size across layers. Such models fine-tuned on larger datasets undergo more considerable changes than those with smaller data sizes.

Regardless of data size, we can also observe that fine-tuning mainly affects higher layers. Our finding is aligned with Merchant et al. (2020) that fine-tuning has a more significant impact on higher layers and negligible effects on lower layers. There is also an interesting pattern concerning CoLA's performance. Despite a drop in performance of around 15% from the full to 1k version (Table 1), the linguistic knowledge has been marginally affected by data size. We leave further investigations on this to future work.

6 Fixed Iteration Analysis

Given the observations from Section 5, we have realized that by training BERT on larger datasets, the model's performance deviates substantially from the baseline. However, by reducing the size of training data, the gap between the fine-tuned models and the baseline decreases. This behavior can be either attributed to the diversity of training samples or to the larger number of iterations through which the model is updated.

To address this, we repeated the same experiments carried out in Section 5 but with fixing the number of iterations on all data sizes. This allows the model to be fine-tuned for an equal number of iterations across different data sizes of a specific task. Note that we fine-tuned the full models for just one epoch to avoid a large number of iterations for the 7k and 2.5k models. Since SST-2, CoLA, and MRPC have much smaller datasets, and

		Full	7k	2.5k

	Layer 11	57.27	2.10	1.17
	Layer 12	56.77	2.43	1.22

Table 3: The performance of models trained with fixed and equal number of iterations across different sizes on each downstream task. Every cell demonstrates the difference (delta) between the full and the fixed-sized models. With an equal number of iterations, in each layer, fine-tuned models have a similar performance.

the number of iterations does not substantially differ across the full, 7k, and 2.5k models, we have dropped them from this scenario.

Table 3 summarizes our results. The first interesting pattern is that fine-tuning for more epochs significantly impairs the captured linguistic knowledge. For instance, we can observe the impact of longer training by comparing Bigram Shift performance on QQP across Tables 2 (54.11) and 3 (73.25)[4]. As Table 3 suggests, fixing the number of iterations reduces the gap across different data sizes, making the 7k and 2.5k models behave almost similarly to the full models. For instance, in Table 2, there is a gap of 24% in the last layer's performance between the full and the 7k QQP on Bigram Shift, which has been reduced to approximately -0.1 with equal training steps (Table 2).

This finding is interesting because, firstly, it indicates that the high variance between baselines and full models is mainly due to the number of times their weights are updated during fine-tuning rather than the diversity of the training samples. Secondly, with equal data sizes, the role of target tasks becomes less influential in the linguistic knowledge introduced into the model by fine-tuning, reinforcing the conclusions from Section 5.

7 Linguistic Knowledge Recoverability

Fine-tuning procedure modifies the encoded linguistic knowledge in the pre-trained model. In this section, we aim at verifying the extent to which these modifications are recoverable. To this end, taking a fine-tuned model on a specific task as our baseline, we further fine-tune the model on another task. We then compare the probing performance of the resulting models with their corresponding baselines. High similarity in probing performance indicates the recoverability of the modifications.

We opt for CoLA and SST-2 as a pair of tasks with different linguistic objectives but with comparable data sizes. Also, we experiment with MRPC and QQP, which are similar tasks but with significantly different data sizes (the former's data size is a hundred times larger than the latter's). For instance, considering CoLA and SST-2 as our fine-tuning task pair, *SST-2 → CoLA → SST-2* stands for a setting where we have consecutively fine-tuned the model on SST-2, CoLA, and SST-2. Following our previous experiments, we report the probing results for the Bigram Shift and Semantic Odd Man Out tasks.[5]

The results are presented in Figure 3. The three-quarters of a circle in the figures represent the maximum value in the corresponding probing task. As shown in the figures, the linguistic knowledge is recoverable through re-fine-tuning on a set of pairs with comparable data sizes. In the previous sections, we observed that CoLA and SST-2 have notably different performances on Bigram Shift and Semantic Odd Man Out. Nevertheless, after re-fine-tuning, both target tasks can recover the knowledge modified by the previous fine-tuning step.

On the other hand, for the QQP and MRPC pair, we observe a different behavior in which the data size of QQP highly limits the extent of knowledge recoverability. Considering Bigram Shift, we observe that the final MRPC fine-tuning in the *QQP → MRPC* and *MRPC → QQP → MRPC* settings can not recover the modification introduced by QQP (the probing results remain similar to QQP's). In the reverse setting (*MRPC → QQP* and *QQP → MRPC → QQP*), the probing performance is negligently affected by MRPC data size, leading to

---

[4] As mentioned in Section 3.1, the models in Table 2 were fine-tuned for five epochs.

[5] More results for the Object Number and Coordination Inversion tasks can be found in Appendix B.

Figure 3: The performance of the models after being sequentially fine-tuned on different tasks. Three-quarters of a circle represents the maximum value and the outer circle is the baseline. The figures demonstrate that the modified knowledge recoverability depends on the fine-tuning data size.

a performance fairly similar to QQP's.[6]

Our results suggest that the extent of knowledge recoverability is bound to the fine-tuning data size. More specifically, further fine-tuning a fine-tuned model with a comparable data size (e.g., *SST-2 → CoLA* and *CoLA → SST-2 → CoLA* introduces the same modifications as fine-tuning a pre-trained model (e.g., CoLA). However, increasing the data size in one of these tasks decreases the extent of recoverability by the other task.

8 Conclusion

In this paper, we carried out a set of experiments to determine the effect of training data size on the probing performance of fine-tuned models. To begin with, by individually probing all layers, we found out that models fine-tuned on larger datasets deviate more from the base model in terms of their encoded linguistic knowledge. Therefore, we argue that comparing the linguistic knowledge of fine-tuned models is valid only if they are trained on datasets of comparable sizes. Through layer-wise probing analysis, we realized that the number of training samples mainly affects the probing results for the higher layers, while the results remain similar in the lower layers across different target tasks. Furthermore, we investigated why data size affects the probing performance of fine-tuned models through training the models with limited training data for the same number of iterations as we trained the full models. We showed that the gap in probing performance between models fine-tuned on different data sizes is due to the number of iterations for which the model is updated during fine-tuning rather than the diversity of the training set. Finally, in our last experiment, we showed that the size of a target task's dataset affects the extent to which it can recover the linguistic knowledge previously changed by a different task.

We argue that probing accuracy cannot fully represent the linguistic knowledge captured by fine-tuned models, given that factors, such as the size of the dataset, can highly affect probing accuracy and should be ruled out in any such study. As future work, we plan to evaluate the reliability of existing accuracy and loss-based probes and design more robust metrics for investigating the encoded knowledge in the existing language models.

A Structural Probe Analysis

We have also repeated our data size analysis experiment on the structural probe to show that our findings stand for different probes. Figure 4 confirms our conclusions drawn from Section 4, which denotes that data size affects the probing performance of fine-tuned models.

B Linguistic Knowledge Recoverability

Abstract

We present RuCCoN, a new dataset for clinical concept normalization in Russian manually annotated by medical professionals. It contains over 16,028 entity mentions manually linked to over 2,409 unique concepts from the Russian language part of the UMLS ontology. We provide train/test splits for different settings (stratified, zero-shot, and CUI-less) and present strong baselines obtained with state-of-the-art models such as SapBERT. At present, Russian medical NLP is lacking in both datasets and trained models, and we view this work as an important step towards filling this gap. Our dataset and annotation guidelines are available at `https://github.com/sberbank-ai-lab/RuCCoN`.

1 Introduction

Electronic health records and other clinical texts contain patient histories through the progression of diseases and represent a treasure trove of information for medical specialists. This information is often unstructured, concealed in free-form text, which leads to the need for natural language processing on medical texts. Mentions of diseases, symptoms, drugs, and other concepts are highly variable, and since the medical vocabulary is very large, entity linking and concept normalization become hard and important problems. State-of-the-art models are increasingly successful in high-resource languages such as English or Spanish, where labeled datasets include ShARe/CLEF eHealth 2013 Task 1 (Suominen et al., 2013), SemEval-2014 Task 7 (Pradhan et al., 2014), SemEval-2015 Task 14 (Elhadad et al., 2015), MCN (Luo et al., 2019), CANTEMIST (Miranda-Escalada et al., 2020a), CodiEsp (Miranda-Escalada et al., 2020b), and others. However, little has been done for medical entity linking in many languages that are high-resource in other regards. One example is Russian: it is among top 10 languages in the world and has many NLP datasets and resources, but the medical part of Russian NLP is underdeveloped. The Russian UMLS includes translations of Medical Dictionary for Regulatory Activities (MedDRA) (Brown et al., 1999), Logical Observation Identifiers Names and Codes (LOINC) (Forrey et al., 1996), and Medical Subject Headings (MeSH) (Coletti and Bleich, 2001), but it still only amounts to 1.8% of the English UMLS in vocabulary and 1.36% in source counts (NIH 2021, a).

In this work, we present RuCCoN (**Ru**ssian **C**linical **Co**ncept **N**ormalization), a new labeled dataset for clinical concept normalization in Russian. We have employed medical professionals to label the dataset based on concepts from the Russian UMLS (Section 2). Moreover, we present several types of test sets for various settings, including stratified, zero-shot, and CUI-less settings (Section 2.4). We evaluate several state-of-the-art models on RuCCoN, including various fine-tuning variations, and check whether labeled data in Russian is necessary (spoiler alert: it is) by testing cross-lingual concept normalization from English (Section 3). Our results can serve as baselines for RuCCoN and cross-lingual concept normalization.

2 RuCCoN Dataset

2.1 Basic Dataset with NER Labeling

We supplement with entity linking labeling the only large-scale available dataset of clinical free-text notes in Russian with named entity recognition (NER) labeling (Shelmanov et al., 2015), created by researchers and practitioners from the Scientific Center of Children Health (SCCH). The corpus is based on medical histories of over 60 SCCH patients with allergic and pulmonary disorders and diseases. It contains discharge summaries, radiology, echocardiography, and ultrasound diagnostic reports, recommendations, and other records from a number of different physicians. Documents in the corpus are deidentified: all names are removed, dates are altered. The corpus, freely available for research purposes[1], contains 160 fully annotated texts with nearly 250,000 tokens. It has over 18,200 annotated entities, over 7,400 attributes and 3,500 relations with 7 types of entities: “Disease”, “Symptom”, “Drug”, “Treatment”, “Body location”, “Severity”, “Course”. The nearest counterparts for English are the corpus of the Shared Annotated Resources (ShARe) initiative (Pradhan et al., 2015) and the corpus of Strategic Health IT Advanced Research Project: Area 4 (SHARPn) (Rea et al., 2012).

2.2 Annotation Process and Principles

Annotators mapped each mention to a concept unique identifier (CUI) from the Unified Medical Language System (UMLS) ontology (Bodenreider, 2004). The goal of entity normalization is to assign the same identifier to different synonyms of a given medical concept; e.g., “anemic heart infarction” and “myocardial infarction” refer to the same concept with CUI C0027051. Annotation was carried out in *Brat* (Stenetorp et al., 2012) with UMLS 2020 AB release. To speed up labeling, each text fragment was linked to CUI from UMLS automatically with the *tf-idf* baseline method. Annotators were allowed to use web search and the *UMLS Metathesaurus Browser* (NIH 2021, b) for meta-information. Each entity was independently annotated by three annotators. Following (Luo et al., 2019), we calculate Inter-Annotator Agreement (IAA) as the accuracy of the markups matched by at least two annotators over all annotated mentions. At least two annotators linked an entity to the same concept from the ontology in 13,125 cases and annotated 1032 entities as CUI-less; IAA was 78.37%. In 3900 cases when all annotators disagreed, the expert annotator with Ph.D. in medicine (the first author of the paper) was asked to decide whether the CUI selected by one of the annotators was in fact correct. After this procedure we obtained a corpora with 16,028 entities linked to 2,409 concepts and 1,293 entities linked with no concept (CUI-less). Table 1 shows the basic statistics of the dataset; percentages are obtained by greedily choosing the first relevant semantic type for a given CUI. Semantic types best represented in our annotation are *Disease or Syndrome* ($\approx$ 22%), *Body Part, Organ, or Organ Component* (17%), *Organic Chemical* (14.5%), *Finding* (7%), *Sign or Symptom* (6.5%), and *Pathologic Function* (4%). Annotation guidelines were created by an expert with Ph.D. in medicine. The dataset was labeled by three annotators with higher education in different fields of medicine, two of them with Ph.D. in medicine. Each annotator was paid an hourly wage of $55 for about 80 hours of labeling, so each annotator was paid $4400; the minimal monthly wage in Russia for full-time employment is under $200.

Semantic Type	Train		Test	
	#	%	#	%
Disease or Syndrome	2032	18.11	848	17.62
Body Part, Organ, etc.	1670	14.88	699	14.52
Organic Chemical	1502	13.38	694	14.42
Finding	896	7.98	373	7.75
Sign or Symptom	677	6.03	254	5.27
Therapeutic or Preventive Proc.	542	4.83	202	4.19
Pathologic Function	449	4	188	3.9
Am. Acid, Peptide, or Protein	358	3.19	160	3.31
Organ or Tissue Function	339	3.02	136	2.81
Body System	150	1.33	73	1.5

Table 1: Top 10 semantic types counts in RuCCoN.

2.3 Annotation Design and Challenges

During the annotation process, we have encountered a number of challenges that are specific to Russian and other low-resource languages.

Lack of Russian translation for UMLS concepts. Many terms have not been translated from English into Russian. This often holds for terms that characterize the severity of symptoms, morphological characteristics of anatomical formations, and body locations; examples include “regular shape” (“форма правильная”) or “patent lumen”(“просвет свободен”). In these cases, we obtain NER labeling for general entity types such as “Disease” or “Body

---

[1] `http://nlp.isa.ru/datasets/clinical`

location", but there are no CUIs that annotators could link in Russian.

Combining many related concepts into one NER fragment. Many phrases annotated in NER labeling as a single entity could be split into several separate and/or nested entities. These cases most often found in morphological descriptions of anatomical formations (e.g., "average size (left lobe = 44mm, 1-st segment 11, right lobe = 93mm), smooth contour, homogeneous parenchymatous tissue, average chogenicity") and cases where adjectives characterizing a concept are combined into a single fragment; e.g., "mild repolarization disorders" ("легкие нарушения процесса реполяризации") could be labeled as a single entity but here the adjective "mild" ("легкие") might also be separated from the main concept "repolarization disorders" ("нарушения процесса реполяризации"). This happens since NER labeling is usually done for "flat" NER rather than nested; nested NER would allow for multiple embedded entities but is much harder for manual labeling, and has not been done in this case. In our dataset, annotators were instructed to link several CUIs to a single text fragment in these cases.

Redundancy of the UMLS vocabulary. Some UMLS concepts in Russian have different CUIs even though they are phrased in exactly the same way, and the CUIs have different semantic types; for example, "amyloidosis" ("амилоидоз") appears for both C0002726 (type: Disease or Syndrome) and C0268381 (type: Neoplastic Process). Also, some concepts have different CUIs while they are synonymous in their meaning; for example, "acholic stool" ("ахоличный стул") has a code C2675627 and "pale stool" ("светлый стул") has a code C0232720. In such cases, annotators were advised to choose a more appropriate CUI based on its meta-information provided in the UMLS.

Complex rephrasing. In entity linking, annotators have to change the wording to establish correspondences between mentions and concepts, relying on their domain knowledge and comprehensive search for synonyms. In Russian, this is complicated by minor inconsistencies in the UMLS translation itself: several different CUIs may either have minor semantic differences that cannot be distinguished or overlap significantly in their meaning. E.g., "adenoid hypertrophy" ("гипертрофия аденоидов") may be annotated as "nasopharyngeal tonsil hypertrophy (adenoids)" ("гипертрофия глоточных миндалин (аденоиды)") or "hypertrophy of adenoids exclusively" ("гипертрофия исключительно аденоидов"), two different CUIs. This effect often leads to inconsistencies between annotators.

MCN	13609	5979	3792

Table 2: Dataset statistics.

2.4 Train/test Splits

We release the full annotated corpus along with three test sets, setting aside 30% of the corpus and then applying different filtering strategies. Table 2 shows the statistics for each split.

Stratified. In this case, we filter the test set so that each UMLS concept appears in the test set appears at least once in the training set, but not this specific mention from the test set (Miftahutdinov and Tutubalina, 2019). Thus, 100% of concepts in this test set are covered in the training set, but no mentions in the training set are literally the same as mentions in the test set.

Zero-shot. In this case, we filter the test set to contain only novel concepts that do not appear in the training set at all. In other words, the *Stratified* split is designed to ensure that the model encounters the same concepts in the training, development, and test sets, but with different surface forms, while the *Zero-Shot* split instead exposes models to unseen terms and concepts in the development and testing sets, making it the harder setting of the two.

CUI-less. In this case, we supplement the random train/test split with 30% of the cases where there is no CUI associated with an entity. This set is intended to test whether a linking system is able to refrain from linking to a concept when there is no suitable concept in the vocabulary ("CUI-less" category in CLEF/SemEval challenges). We call the "full test set" and "full train set" the subsets with this addition of CUI-less cases, and use "in-KB" for subsets without CUI-less mentions. Stratified and zero-shot settings are commonly used in general domain entity linking, but the CUI-less setting is specific for medical data.

Table 3: Evaluation results with test set filtering.

ing sets. In our basic evaluation setting, we use only our own labeled dataset for training and testing. However, we could also supplement the training set with other resources. First, the XL-BEL cross-lingual biomedical entity linking benchmark maps entity mentions from *Wikipedia* to UMLS in a number of languages, including Russian (Liu et al., 2021b). Second, we have applied the following linking procedure to the medical part of *RuWordNet* (RWN) (Loukachevitch et al., 2016): found all lemmas of RWN synsets from the medical domain, intersected these synsets with lemmatized Russian UMLS terms, composed the vocabulary of synsets that have at least one lemma in UMLS, and filtered out exact matches with UMLS, resulting in a set of senses not contained in UMLS but from synsets with another sense contained in both UMLS and RuWordNet. We note that both RWN and XL-BEL have small intersection of 13 and 9 CUIs with zero-shot RuCCoN test set, respectively.

Third, we also test cross-lingual entity linking with models trained on the MCN (Medical Concept Normalization) dataset (Luo et al., 2019), a large-scale manually annotated corpus in English for clinical concept normalization produced from a corpus released for the 4th i2b2/VA shared task (Uzuner et al., 2011). Statistics for all supplementary datasets are also shown in Table 2.

3 Evaluation

For entity linking, we use ranking based on embeddings of a mention and a possible concept. Each entity mention and concept name are first passed through a model that produces their embeddings and then through a pooling layer that yields a fixed-sized vector. The inference task is then reduced to finding the closest concept name representation to the entity mention representation in a common embedding space, where the Euclidean distance can be used as the metric. Nearest concept names are chosen as top-k concepts for entities. For ranking, we use the publicly available code[2] from (Tutubalina et al., 2020).

We compare ranking models based on several different embeddings:

1. *Tf-idf*: standard sparse *tf-idf* representations constructed on character-level unigrams and bigrams;
2. *BERT*: multilingual BERT embeddings with no fine-tuning (Devlin et al., 2019); this is a cross-lingual baseline that has not been trained on biomedical texts;
3. *RuBERT*: Russian BERT embeddings (Kuratov and Arkhipov, 2019) trained on the Russian part of Wikipedia and news data;
4. *SapBERT*: a BERT-based metric learning framework that generates hard triplets based on the UMLS for large-scale pre-training (Liu et al., 2021a) and also allows for a cross-lingual variant trained on XL-BEL (Liu et al., 2021b).

Additionally, we compare several variations of fine-tuning on datasets with training sets via synonym marginalization as suggested by the authors of *BioSyn* (Sung et al., 2020):

1. *SapBERT+RuCCoN*, with fine-tuning on our target train set of EHRs;
2. *SapBERT+MCN*, with tuning on the MCN set;
3. *SapBERT+WRN*, on the dataset extracted from the medical part of the RuWordNet thesaurus;

---

[2] `https://github.com/insilicomedicine/Fair-Evaluation-BERT`

4. *SapBERT+XL-BEL*, on the the Russian part of XL-BEL;

5. *SapBERT+RuCCoN+RWMXL-BEL*, on the combination of all three sets.

For training, we have used the publicly available code provided by the authors at `https://github.com/dmis-lab/BioSyn` with the following parameters: the number of top candidates k is 20, the mini-batch size is 16, the learning rate is 1e-5, the dense ratio for candidate retrieval is 0.5, the number of epochs is 5. To deal with *nil* prediction, we apply the strategy from (Miftahutdinov et al., 2021); a mention is out of KB if the nearest candidate is further than a threshold in terms of weighted average of two distances: minimum distance of false positives and maximum distance of true positives, as computed on the train set.

Following previous works on entity linking (Suominen et al., 2013; Pradhan et al., 2014; Wright et al., 2019; Phan et al., 2019; Sung et al., 2020; Miftahutdinov et al., 2021; Tutubalina et al., 2020), we use top-k accuracy as the evaluation metric: $\mathrm{Acc@k} = 1$ if the correct CUI is retrieved at rank $\leq k$, otherwise $\mathrm{Acc@k} = 0$. Table 3 shows the Acc@1 and Acc@5 metrics for our test sets. We see that SapBERT significantly outperforms other models, and steadily improves the results as more datasets are added for fine-tuning. Note how SapBERT trained on RuCCoN is much better on the full test set that SapBERT trained on other data, but the difference almost disappears on the zero-shot test, suggesting that it was almost entirely due to specific entities labeled in the training set. This confirms the need to label additional data to further improve the results of even the best state-of-the-art entity linking models, which is what RuCCoN itself provides for the Russian language. Another result is that fine-tuning on additional medical data is generally beneficial; e.g., we have found that SapBERT fine-tuned on English clinical notes outperforms basic SapBERT consistently across all datasets in our study.

4 Error Analysis

To better understand the quality of our best model, we analyzed its erroneous predictions. For analysis, we randomly selected 100 erroneous predictions, which were then analyzed by an expert annotator with Ph.D. in medicine. As can be seen from Table 4, most of the errors are related to the lexical similarity of incorrectly predicted entities (for example, the text “concor” was incorrectly associated with the entity C0009738 “Congo” due to the similarity of spelling; for the same reason, the text “decrease in EF” was incorrectly associated with the entity C0520837 “decrease in FEV”). An interesting fact is that in second place in the frequency of errors are predictions close in meaning to the source text. For example, the source text “bilateral acute maxilloethmoidal sinusitis” was associated with the entity C0155806 “acute ethmoiditis”. This entity is not a complete synonym of the source text, but it is very close to its meaning. It should be noted that the errors described in the last two rows of the table are not inherently errors. Some of the errors are related to the complete synonymy of ground truth and model prediction. For example, the text “biliary tract dysfunction” was annotated as C0005395 “pathology of the biliary tract”, while the model predicted the entity C0005424 “biliary tract disease”, which in its meaning is a complete synonym, but does not coincide with the golden truth according to CUI.

Cause of error	**Number of mentions**
No obvious reason	18
Lexical similarity	38
Nested entity	11
Semantic similarity	19
Complete synonymy	9
Annotation error	5

Table 4: Manual evaluation of incorrect predictions of the SapBERT+RuCCoN model on 100 randomly selected mentions from the in-KB test set.

5 Conclusion

In this work, we have presented RuCCoN, a new clinical concept normalization dataset in Russian, labeled by medical professionals and accompanied with several train/test splits for fair evaluation in various settings. We make RuCCoN publicly available for research purposes, and we hope that future works will make use of RuCCoN as a training and evaluation resource.

Abstract

Contrastive learning has shown great potential in unsupervised sentence embedding tasks, e.g., SimCSE (Gao et al., 2021). However, We find that these existing solutions are heavily affected by superficial features like the length of sentences or syntactic structures. In this paper, we propose a semantics-aware contrastive learning framework for sentence embeddings, termed Pseudo-Token BERT (PT-BERT), which is able to exploit the pseudo-token space (i.e., latent semantic space) representation of a sentence while eliminating the impact of superficial features such as sentence length and syntax. Specifically, we introduce an additional pseudo token embedding layer independent of the BERT encoder to map each sentence into a sequence of pseudo tokens in a fixed length. Leveraging these pseudo sequences, we are able to construct same-length positive and negative pairs based on the attention mechanism to perform contrastive learning. In addition, we utilize both the gradient-updating and momentum-updating encoders to encode instances while dynamically maintaining an additional queue to store the representation of sentence embeddings, enhancing the encoder's learning performance for negative examples. Experiments show that our model outperforms the state-of-the-art baselines on six standard semantic textual similarity (STS) tasks. Furthermore, experiments on alignments and uniformity losses, as well as hard examples with different sentence lengths and syntax, consistently verify the effectiveness of our method.

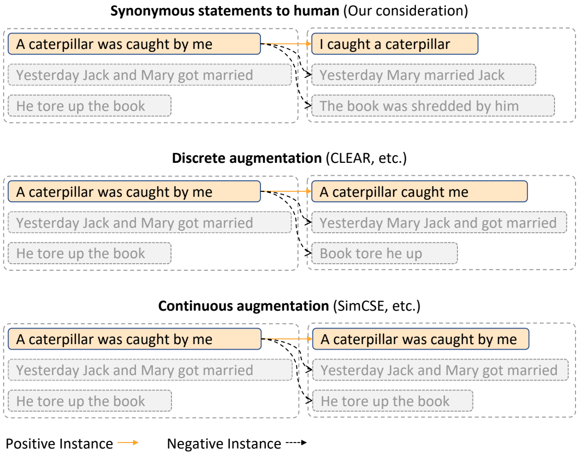

Figure 1: A realistic scenario is described at the top, negative examples have the same length and structure, while positive examples act in the opposite way. In comparison, discrete augmentation obtains positive instances with word deletion or reordering (Wu et al., 2020; Meng et al., 2021), which may misinterpret the meaning. The continuous method treats embeddings of the same original sentence as positive examples and augments sentences with the different encoding functions (Carlsson et al., 2021; Gao et al., 2021).

1 Introduction

Sentence embedding serves as an essential technique in a wide range of applications, including semantic search, text clustering, text classification, etc. (Kiros et al., 2015; Logeswaran and Lee, 2018; Conneau et al., 2017; Cer et al., 2018; Reimers and Gurevych, 2019; Gao et al., 2021). Contrastive learning works on learning representations such that similar examples stay close whereas dissimilar ones are far apart, and thus is suitable for sentence embeddings due to its natural availability of similar examples. Incorporating contrastive learning in sentence embeddings improves the efficiency of semantic information learning in an unsupervised manner (He et al., 2020; Chen et al., 2020) and has been shown to be effective on a variety of tasks (Reimers and Gurevych, 2019; Gao et al., 2021; Zhang et al., 2020).

In contrastive learning for sentence embeddings, a key challenge is constructing positive instances. Both discrete and continuous augmentation methods have been studied recently. Methods in Wu et al. (2018); Meng et al. (2021) perform discrete operations directly on the original sentences, such

May 22-27, 2022 ©2022 Association for Computational Linguistics

as word deletion and sentence shuffling, to get positive samples. However, these methods may lead to unacceptable semantic distortions or even complete misinterpretations of the original statement. In contrast, the SimCSE method (Gao et al., 2021) obtains two different embeddings in the continuous embedding space as a positive pair for one sentence through different *dropout masks* (Srivastava et al., 2014) in the neural network for representation learning. Nonetheless, this method overly relies on superficial features existing in the dataset like sentence lengths and syntactic structures and may pay less reflection on meaningful semantic information. As an illustrative example, the sentence-pair in Fig. 1 "A caterpillar was caught by me." and "I caught a caterpillar." appear to organize differently in expression but convey exactly the same semantics.

To overcome these drawbacks, in this paper, we propose a semantic-aware contrastive learning framework for sentence embeddings, termed Pseudo-Token BERT (PT-BERT), that is able to capture the pseudo-token space (i.e., latent semantic space) representation while ignoring effects of superficial features like sentence lengths and syntactic structures. Inspired by previous works on prompt learning and sentence selection (Li and Liang, 2021; Liu et al., 2021; Humeau et al., 2020), which create a pseudo-sequence and have it serve the downstream tasks, we present PT-BERT to train pseudo token representations and then to map sentences into pseudo token spaces based on an attention mechanism.

In particular, we train additional 128 pseudo token embeddings, together with sentence embeddings extracted from the BERT model (i.e., gradient-encoder), and then use the attention mechanism (Vaswani et al., 2017) to map the sentence embedding to the pseudo token space (i.e., semantic space). We use another BERT model (i.e., momentum-encoder (He et al., 2020)) to encode the original sentence, adopt a similar attention mechanism with the pseudo token embeddings, and finally output a continuously augmented version of the sentence embedding. We treat the representations of the original sentence encoded by the gradient-encoder and the momentum-encoder as a positive pair. In addition, the momentum-encoder also generates negative examples, dynamically maintains a queue to store these negative examples, and updates them over time. By projecting all sentences onto the same pseudo sentence, the model greatly reduces the dependence on sentence length and syntax when making judgments and makes the model more focused on the semantic level information.

In our experiments, we compare our results with the previous state-of-the-art work. We train PT-BERT on 10^6 randomly sampled sentences from English Wikipedia and evaluate on seven standard semantic textual similarity (STS) tasks (Agirre et al., 2012, 2013, 2014, 2015, 2016) (Marelli et al., 2014). Besides, we also compare our approach with a framework based on an advanced discrete augmentation we proposed. We obtain a new state-of-the-art on standard semantic textual similarity tasks with our PT-BERT, which achieves 77.74% of Spearman's correlation. To show the effectiveness of pseudo tokens, we calculate the align-loss and uniformity loss (Wang and Isola, 2020) and verify our approach on a sub-dataset with hard examples sampled from STS-(2012-2016). We have released our source code[1] to facilitate future work.

2 Related Work

In this section, we discuss related studies with repect to the contrastive learning framework and sentence embedding.

2.1 Contrastive Learning for Sentence Embedding

Contrastive learning. Contrastive learning (Hadsell et al., 2006) has been used with much success in both natural language processing and computer vision (Yang et al., 2019; Klein and Nabi, 2020; Chen et al., 2020; He et al., 2020; Gao et al., 2021). In contrast to generative learning, contrastive learning requires learning to distinguish and match data at the abstract semantic level of the feature space. It focuses on learning common features between similar examples and distinguishing differences between non-similar examples. In order to compare the instances with more negative examples and less computation, memory bank (Wu et al., 2018) is proposed to enhance the performance under the contrastive learning framework. While with a large capacity to store more samples, the memory bank is not consistent enough, which could not update the negative examples during comparison. Momentum-Contrast (MoCo) (He et al., 2020) uses a queue to maintain the dictionary of samples

---

[1] `https://github.com/Namco0816/PT-BERT`

which allows the model to compare the query with more keys for each step and ensure the consistency of the framework. It updates the parameter of the dictionary in a momentum way.

Discrete and continuous augmentation. By equipping discrete augmentation that modifies sentences directly on token level with contrastive learning, significant success has been achieved in obtaining sentence embeddings. Such methods include word omission (Yang et al., 2019), entity replacement (Xiong et al., 2020), trigger words (Klein and Nabi, 2020) and traditional augmentations such as deletion, reorder and substitution (Wu et al., 2020; Meng et al., 2021). Examples with diverse expressions can be learned during training, making the model more robust to expressions of different sentence lengths and styles. However, these approaches are limited because there are huge difficulties in augmenting sentences precisely since a few changes can make the meaning completely different or even opposite.

Researchers have also explored the possibility of building sentences continuously, which instead applies operation in embedding space. CT-BERT (Carlsson et al., 2021) encodes the same sentence with two different encoders. Unsup-SimCSE (Gao et al., 2021) compares the representations of the same sentence with different dropout masks among the mini-batch. These approaches continuously augment sentences while retaining the original meaning. However, positive pairs seen by SimCSE always have the same length and structure, whereas negative samples are likely to act oppositely. As a result, sentence length and structure are highly correlated to the similarity score of examples. During training, the model has never seen positive samples with diverse expressions, so that in real test scenarios, the model would be more inclined to classify the synonymous pairs with different expressions as negatives, and those sentences with the same length and structures are more likely to be grouped as positive pairs. This may cause a biased encoder.

2.2 Pseudo Tokens

In the domain of prompt learning (Liu et al., 2021; Jiang et al., 2020; Li and Liang, 2021; Gao et al., 2020), the way to create prompt can be divided into two types, namely discrete and continuous ways. Discrete methods usually search the natural language template as the prompt (Davison et al., 2019; Petroni et al., 2019), while the continuous way always directly works on the embedding space with "pseudo tokens" (Liu et al., 2021; Li and Liang, 2021). In retrieval and dialogue tasks, the current approach adopts "pseudo tokens", namely "poly codes" (Humeau et al., 2020), to jointly encode the query and response precisely and ensure the inference time when compared with the Cross-Encoders and Bi-Encoders (Wolf et al., 2019; Mazaré et al., 2018; Dinan et al., 2019). The essence of these methods is to create a pseudo-sequence and have it serve the downstream tasks without the need for humans to understand the exact meaning. The parameters of these pseudo tokens are independent of the natural language embeddings, and can be tuned based on a specific downstream task. In the following sections, we will show the idea to weaken the model's consideration of sentence length and structures by introducing additional pseudo token embeddings on top of the BERT encoder.

	Sub-dataset	**original**

3 Methods

In this section, we introduce PT-BERT, which provides novel contributions on combining advantages of both discrete and continuous augmentations to advance the state-of-art of sentence embeddings. We first present the setup of problems with a thorough analysis on the bias introduced by the textual similarity theoretically and experimentally. Then we show the details of Pseudo-Token representation and our model's architecture.

3.1 Preliminary

Consider a sentence s, we say that the augmentation is continuous if s is augmented by different encoding functions, $f(\cdot)$ and $f'(\cdot)$. Sentence em-

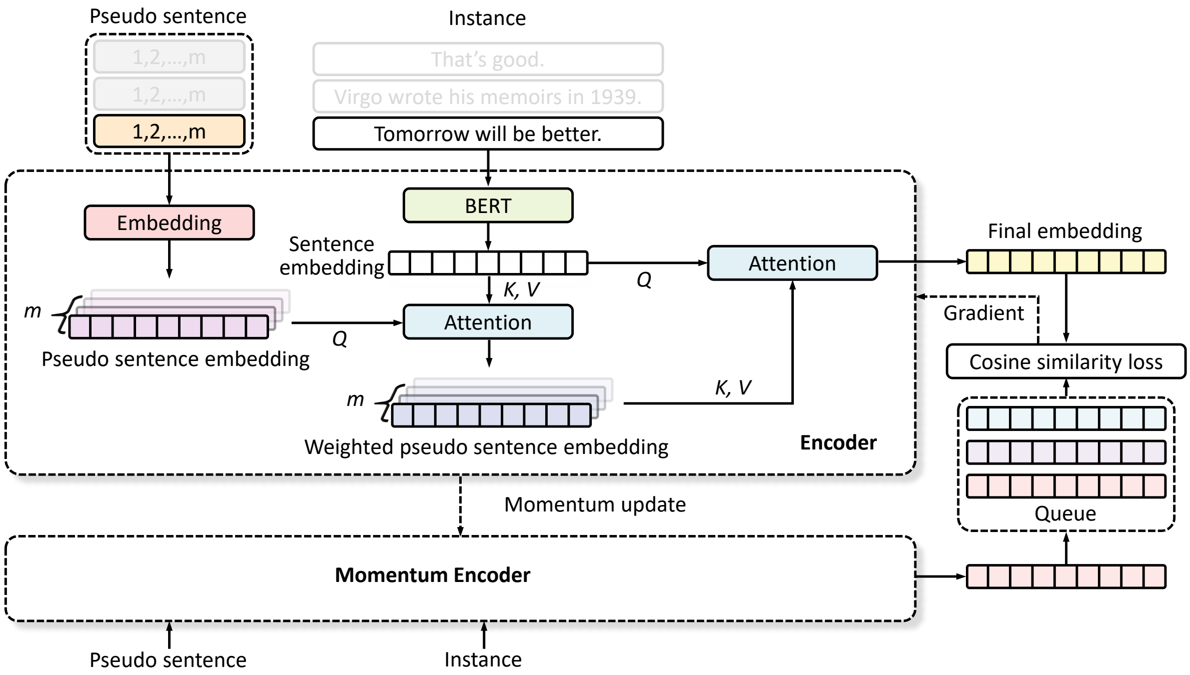

Figure 2: The model is divided into two parts, the upper part (Encoder) updates the learnable parameters with gradient, while the bottom (Momentum Encoder) inherits parameters from the upper part with momentum-updating. We repeatedly input the same sequence of pseudo tokens while processing the original sentences. An additional BERT attention mapping the pooler-output of BERT to pseudo sequence representation, extending the sentence embedding to a fixed length and mapping the syntactic structure to the style of the pseudo sentence. The two attentions in the figure are the same and with identical parameters.

beddings $\mathbf{h} = f(s)$ and $\mathbf{h}' = f'(s)$ are obtained by these two functions. With a slight change of the encoding function (e.g., encoders with different *dropout* masks), $\mathbf{h}'$ can be seen as a more precisely augmented version of $\mathbf{h}$ compared with the discrete augmentation. Semantic information of $\mathbf{h}'$ should be the same as $\mathbf{h}$. Therefore, $\mathbf{h}$ and $\mathbf{h}'$ are a pair of positive examples and we could randomly sample a sentence to construct negative example pairs.

Previous state-of-the-art models (Gao et al., 2021) adopt the continuous strategy that augments sentences with *dropout* (Srivastava et al., 2014). It is obvious that all the positive examples in SimCSE have the same length and structure while negative examples act oppositely. In this way, SimCSE will inevitably take these two factors as hints during test. To further verify this conjecture, we sort out the positive pairs with a length difference of more than five words and negative pairs of less than two words from STS-(2012-2016).

Table 1 shows that the performance of SimCSE plummets on this dataset. Besides, we also find that SimCSE truncates all training corpus into 32 tokens, which shortens the discrepancy of the sentence's length. After we scale the max length that SimCSE could accept from 32 to 64 and 128, the performance degrades significantly during the test even though the model is supposed to learn more from the complete version of sentences(See Table 2). The reason for this result may lie in the fact that, without truncation, all positive pairs still have the same length, whereas the difference in length between the negative and positive ones is enlarged. Therefore, the encoder will rely more on sentence length and make the wrong decision.

3.2 Pseudo-Token BERT

We realize it is vital to train an unbiased encoder that captures the semantics and also would not introduce intermediate errors. This motivates us to propose the PT-BERT, as evidence shows that the encoder may fail to make predictions when trained on a biased dataset with same-length positive pairs, by learning the spurious correlations that work only well on the training dataset (Arjovsky et al., 2019; Nam et al., 2020).

Pseudo-Token representations. The idea of PT-BERT is to reduce the model's excessive dependence on textual similarity when making predictions. Discrete augmentation achieves this goal by providing both positive and negative examples with diverse expressions. Therefore the model does not jump to conclusions based on sentence length and syntactic structure during the test.

Note that we achieve this same purpose in a seemingly opposite way: *mapping the representations of both positive and negative examples to a pseudo sentence with the same length and structure.* We take an additional embedding layer outside the BERT encoder to represent a pseudo sentence $\{0, 1, ..., m\}$ with fixed length m and syntax. This embedding layer is fully independent of the BERT encoder, including the parameters and corresponding vocabulary. Random initialization is applied to this layer, and each parameter will be updated during training. The size of this layer depends on the vocabulary of pseudo tokens(length of pseudo sentences). Besides, adopting the attention mechanism (Vaswani et al., 2017; Bahdanau et al., 2015; Gehring et al., 2017), we take the pseudo sentence embeddings as the query states of cross attention while key and value states are the sentence embeddings obtained from the BERT encoder. This allows the pseudo sentence to attend to the core part and ignore the redundant part of original sentence while keeping the fixed length and structure.

Fig. 2 illustrates the framework of PT-BERT. Denoting the pseudo sentence embedding as **P** and the sentence embedding encoded by BERT as **Y**, we obtain the weighted pseudo sentence embedding of each sentence by mapping the sentence embedding to the pseudo tokens with attention:

$$\mathbf{Z_i'} = \text{Attention}(\mathbf{PW^Q}, \mathbf{Y_iW^K}, \mathbf{Y_iW^V}) \quad (1)$$

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\frac{\mathbf{QK^T}}{\sqrt{\mathrm{d_k}}})\mathbf{V}, \quad (2)$$

where d_k is the dimension of the model, $\mathbf{W^Q}$, $\mathbf{W^K}$, $\mathbf{W^V}$ are the learnable parameters with $\mathbb{R}^{d_k \times d_k}$, i denotes the i-th sentence in the dataset. Then we obtain the final embedding $\mathbf{h_i}$ with the same attention layer by mapping pseudo sentences back to original sentence embeddings:

$$\mathbf{h_i} = \text{Attention}(\mathbf{Y_iW^Q}, \mathbf{Z_i'W^K}, \mathbf{Z_i'W^V}). \quad (3)$$

Finally, we compare the cosine similarities between the obtained embeddings of $\mathbf{h}$ and $\mathbf{h}'$ using Eq. 4 , where $\mathbf{h}'$ are the samples encoded by the momentum-encoder and stored in a queue.

Model architecture. Instead of inputting the same sentence twice to the same encoder, we follow the architecture proposed in Momentum-Contrast (MoCo) (He et al., 2020) such that PT-BERT can efficiently learn from more negative examples. Samples in PT-BERT are encoded into vectors with two encoders: gradient-update encoder (the upper encoder in Fig. 2) and momentum-update encoder (the momentum encoder in Fig. 2). We dynamically maintain a queue to store the sentence representations from momentum-update encoder.

This mechanism allows us to store as much negative samples as possible without re-computation. Once the queue is full, we replace the "oldest" negative sample with a "fresh" one encoded by the momentum-encoder.

Similar to the works based on continuous augmentation, at the very beginning of the framework, PT-BERT takes input sentence s and obtains $\mathbf{h_i}$ and $\mathbf{h_i'}$ with two different encoder functions. We measure the loss function with:

$$\ell_i = -\log \frac{e^{sim(\mathbf{h_i}, \mathbf{h_i'})/\tau}}{\sum_{j=1}^{M} e^{sim(\mathbf{h_i}, \mathbf{h_{j'}})/\tau}}, \quad (4)$$

where $\mathbf{h_i}$ denotes the representations extracted from the gradient-update encoder, $\mathbf{h_i'}$ represents the sentence embedding in the queue, and M is the queue size. Our gradient-update and momentum-update encoder are based on the pre-trained language model with the same structure and dimensions as BERT-base-uncased (Devlin et al., 2019). The momentum encoder will update its parameters similar to MoCo:

$$\theta_k \leftarrow \lambda\theta_k + (1-\lambda)\theta_q, \quad (5)$$

where θ_k is the parameter of the momentum-contrast encoder that maintains the dictionary, θ_q is the query encoder that updates the parameters with gradients, and λ is a hyperparameter used to control the updating process.

Relationship with prompt learning. Rather than directly perform soft prompting in the embedding space (Li and Liang, 2021; Qin and Eisner, 2021; Liu et al., 2021) of the model, our method follows the "plug and play" fashion that project the representations to pseudo sentences only during the period of training. During inference time, PT-BERT predicts the results only with its BERT backbone. Our original intention of designing this procedure is to make the model predict sentence

embedding precisely without adding extra computation. In some tasks, fixed-LM tuning (Li and Liang, 2021) in soft prompting becomes competitive only when the language models been scaled to big enough (Lester et al., 2021). While the prompt+LM (Ben-David et al., 2021; Liu et al., 2021) tuning adds more burdens for both the period of training and inference. Both prompt+LM and fixed-LM prompt tuning require storing separate copies of soft prompts for different tasks, while our approach only saves the trained BERT model, which draws on some ideas in prompt learning and makes our considerations in computational and memory efficiency and generality.

4 Experiments

In this section, we perform the standard semantic textual similarity (STS) (Agirre et al., 2012, 2013, 2014, 2015, 2016) tasks to test our model. For all tasks, we measure the Spearman's correlation to compare our performance with the previous state-of-the-art SimCSE (Gao et al., 2021). In the following, we will describe the training procedure in detail.

4.1 Training Data and Settings

Datasets. Following SimCSE, We train our model on 1-million sentences randomly sampled from English Wikipedia, and evaluate the model every 125 steps to find the best checkpoints. Note that we do not fine-tune our model on any dataset, which indicates that our method is completely unsupervised.

Hardware and schedule. We train our model on the machine with one NVIDIA V100s GPU. Following the settings of SimCSE (Gao et al., 2021), it takes 50 minutes to run an epoch.

4.2 Implementations

We implement PT-BERT based on Huggingface transformers (Wolf et al., 2020) and initialize it with the released BERT$_{base}$ (Devlin et al., 2019). We initialize a new embedding for pseudo tokens with 128×768. During training, we create a pseudo sentence $\{0, 1, 2, ..., 127\}$ for every input and map the original sentence to this pseudo sentence by attention. With batches of 64 sentences and an additional dynamically maintained queue of 256 sentences, each sentence has one positive sample and 255 negative samples. Adam (Kingma and Ba,

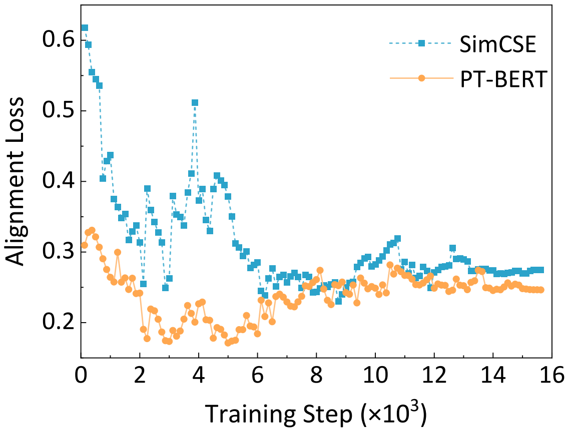
2014) optimizer is used to update the model parameters. We also take the original dropout strategy of BERT with rate $p = 0.1$. We set the momentum for the momentum-encoder with $\lambda = 0.885$.

4.3 Evaluation Setup

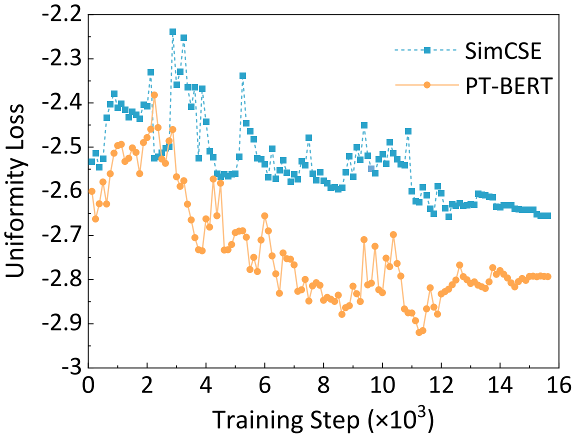
We evaluate the fine-tuned BERT encoder on STS-B development sets every 125 steps to select the best checkpoints. We report all the checkpoints based on the evaluation results reported in Table 4. The training process is fully unsupervised since no training corpus from STS is used. During the evaluation, we also calculate the trends of alignment-loss and uniformity-loss. Losses were compared with SimCSE (Gao et al., 2021) under the same experimental settings. After training and evaluation, we test models on 7 STS tasks: STS 2012-2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), STS Benchmark (Cer et al., 2017) and SICK-Relatedness (Marelli et al., 2014). We report the result of Spearman's correlation for all the experiments.

4.4 Main Results and Analysis

We first compare PT-BERT with our baseline: MoCo framework + BERT encoder (MoCo-BERT). MoCo-BERT could be seen as a version of PT-BERT without pseudo token embeddings. Then we apply traditional discrete augmentations such as reorder, duplication, and deletion on this framework. We also compare our work with CLEAR (Wu et al., 2020) that substitutes and deletes the token spans. Besides, we argue that the performance of these methods is too weak. We additionally propose an advanced discrete augmentation approach that produces positive examples with the guidance of Semantic Role Labeling (SRL) (Gildea and Jurafsky, 2002; Palmer et al., 2010) information, instead of random deletion and reordering. SRL-guided augmentation could compensate the errors caused by these factors, acting as a combination of deletion, duplication, and reordering with better accuracy. SRL is broadly used to identify the predicate-argument structures of a sentence, it detects the arguments associated with the predicate or verb of a sentence and could indicate the main semantic information of *who* did *what* to *whom*. For the sentences with multiple predicates, we keep all the sets with order [ARG0, PRED, ARGM − NEG, ARG1] and concatenate them into a new sequence. For the sentences without recognized predicate-argument sets, we keep the original sentence as positive examples. In addition to the work based on discrete approaches, we also compare with SimCSE (Gao et al., 2021) which continuously augment sentences with *dropout*. In Table 3, PT-BERT with 128 pseudo tokens further pushed the state-of-the-art results to 77.74% and significantly outperformed SimCSE over six datasets.



(a) Alignment loss comparison on STS-B



(b) Uniformity loss comparison on STS-B

Figure 3: Alignment and uniformity loss plot for PT-BERT and SimCSE. We visualize the checkpoints every 125 training steps. For both measurements, lower numbers are better.

In Fig 3, we observe that PT-BERT also achieves better alignment and uniformity against SimCSE, which indicates that pseudo tokens really help the learning of sentence representations. In detail, alignment and uniformity are proposed by (Wang and Isola, 2020) to evaluate the quality of representations in contrastive learning. The calculation of these two metrics are shown in the following formulas:

$$L_{alignment} = \underset{(x,x^+)\sim p_{pos}}{E} ||f(x) - f(x^+)||^2, \quad (6)$$

(c) Evaluations on hard sentence pairs with different length								
SimCSE	66.54	78.50	68.76	70.27	71.31	-	-	71.08
PT-BERT	**72.02**	**80.24**	**72.92**	**74.50**	**72.50**	-	-	**74.44**

Table 5: Evaluation results of ablation studies and hard sentence pairs.

$$L_{uniformity} = \log \underset{(x,y)\sim p_{data}}{E} e^{-2||f(x)-f(y)||^2}, \tag{7}$$

where (x, x^+) is the positive pair, (x, y) is the pair consisting of any two different sentences in the whole sentence set, $f(x)$ is the normalized representation of x. We employ the final embedding $\mathbf{h}$ to calculate these scores.

According to the above formulas, lower alignment loss means a shorter distance between the positive samples, and low uniformity loss implies the diversity of embeddings of all sentences. Both are our expectations for the representations based on contrastive learning. To evaluate our model's performance on alignment and uniformity, we compare it with SimCSE on the STS-benchmark dataset (Cer et al., 2017), and the result is shown in Figure 3. The result demonstrates that PT-BERT outperforms SimCSE on these two metrics: our model has a lower alignment and uniformity than SimCSE in almost all the training steps, which indicates that the representations produced by our model are more in line with the goal of the contrastive learning.

5 Analysis

5.1 Ablation Studies

In this section, we first investigate the impact of different sizes of pseudo token embeddings. Then we would like to report the performance difference caused by queue size under the MoCo framework.

Pseudo Sentence Length Different lengths of pseudo tokens can affect the ability of the model to express the sentence representations. By mapping the original sentences to various lengths of pseudo tokens, the performance of PT-BERT could be different. In this section, we keep all the parts except the pseudo tokens and their embeddings unchanged. We scale the pseudo sequence length from 64 to 360. Table 5(a) shows a comparison between different lengths of pseudo sequence in PT-BERT. We find that during training, PT-BERT performs better when attending to pseudo sequences with 128 tokens. Too few pseudo tokens do not fully explain the semantics of the original sentence, while too many pseudo tokens increase the number of parameters and over-express the sentence.

Queue Size The introduction of more negative samples would make the model's training more reliable. By training with different queue sizes, we report the result of PT-BERT with different performances due to the number of negative samples. In Table 5(b), queue size $q = 4$ performs best. However, the difference in performance between the three sets of experiments is not large, suggesting that the model can learn well as long as it can see enough negative samples.

5.2 Exploration on Hard Examples with Different Length

To prove the effectiveness of PT-BERT that could weaken the hints caused by textual similarity, we further test PT-BERT on the sub-dataset introduced in Sec. 3.1. We sorted out the positive pairs with a length difference of more than five words and negative pairs of less than two words from STS-(2012-2016). PT-BERT significantly outperforms SimCSE with 3.36% Spearman's correlation, indicating that PT-BERT could handle these hard examples better than SimCSE. This further proves that PT-BERT could debias the spurious correlation introduced by sentence length and syntax, and focus more on the semantics.

6 Conclusion

In this paper, we propose a semantic-aware contrastive learning framework for sentence embeddings, termed PT-BERT. Our proposed PT-BERT approach is able to weaken textual similarity information, such as sentence length and syntactic structures, by mapping the original sentence to a fixed pseudo sentence embedding. We provide analysis of these factors on methods based on continuous and discrete augmentation, showing that PT-BERT augments sentences more accurately than discrete methods while considering more semantics instead of textual similarity than continuous approaches. Lower uniformity loss and alignment loss prove the effectiveness of PT-BERT and further experiments also show that PT-BERT could handle hard examples better than existing approaches.

Providing a new perspective to the continuous data augmentation in sentence embeddings, we believe our proposed PT-BERT has great potential to be applied in broader downstream applications, such as text classification, text clustering, and sentiment analysis.

Abstract

Document-level relation extraction (DocRE) aims to extract semantic relations among entity pairs in a document. Typical DocRE methods blindly take the full document as input, while a subset of the sentences in the document, noted as the evidence, are often sufficient for humans to predict the relation of an entity pair. In this paper, we propose an evidence-enhanced framework, EIDER, that empowers DocRE by efficiently extracting evidence and effectively fusing the extracted evidence in inference.[1] We first jointly train an RE model with a lightweight evidence extraction model, which is efficient in both memory and runtime. Empirically, even training the evidence model on silver labels constructed by our heuristic rules can lead to better RE performance. We further design a simple yet effective inference process that makes RE predictions on both extracted evidence and the full document, then fuses the predictions through a blending layer. This allows EIDER to focus on important sentences while still having access to the complete information in the document. Extensive experiments show that EIDER outperforms state-of-the-art methods on three benchmark datasets (e.g., by 1.37/1.26 Ign F1/F1 on DocRED).

1 Introduction

Relation extraction (RE) is the task of extracting semantic relations among entities within a given text, which has abundant applications such as knowledge graph construction, question answering, and biomedical text analysis (Yu et al., 2017; Shi et al., 2019; Trisedya et al., 2019). Prior studies mostly focus on predicting the relation between two entity mentions in a single sentence. However, in reality, an entity may have multiple mentions throughout a document. It is also common that a relation can only be inferred given multiple sentences as the context. As a result, recent studies have been moving towards the more realistic setting of document-level relation extraction (DocRE) (Peng et al., 2017; Yao et al., 2019; Zeng et al., 2020).

Head:Hero of the Day Tail:the United States Rel:[country of origin]
GT evidence sentences: [1,10] Extracted evidence: [1,10]

Original document as input: [1] Load is the sixth studio album by the American heavy metal band Metallica, released on June 4, 1996 by Elektra Records in **the United States** … [9] It was certified 5×platinum … for shipping five million copies in **the United States**. [10] Four singles—"**Hero of the Day**", "Until It Sleeps", "Mama Said", and "King Nothing" — were released as part of the marketing campaign for the album.
Prediction scores: NA: 17.63 **country of origin**: 14.79

Extracted evidence as input: [1] Load is the sixth studio album … released … in **the United States** … [10] Four singles — "**Hero of the Day**", … were released … for the album.
Prediction scores: **country of origin**: 18.31 NA: 13.45

Final prediction of our model: **country of origin** (✓)

Figure 1: A test sample in the DocRED dataset (Yao et al., 2019), where the i^{th} sentence in the document is marked with [i] at the start. Our model correctly predicts [1,10] as evidence, and if we only use the extracted evidence as input, the model can predict the relation "country of origin" correctly.

Unlike typical DocRE models that blindly take the whole document as input, a human may only need a few sentences to infer the relation of an entity pair. For each entity pair, we define the minimal set of sentences required by human annotators to infer their relation as their *evidence sentences*. As shown in Figure 1, to predict the relation between *"Hero of the Day"* and *"the United States"*, it is sufficient to know that *Load (the album)* was released in *the United States* from the 1^{st} sentence, and *"Hero of the Day"* is a single of *Load* from the 10^{th} sentence. In other words, the 1^{st} and 10^{th} sentences serve as the evidence to infer this relation. Although the 9^{th} sentence also mentions *"the United States"*, it is irrelevant to this specific relation. Including such irrelevant sentences in input might sometimes introduce noise to the model and be more detrimental than beneficial.

Findings of the Association for Computational Linguistics: ACL 2022, pages 257 - 268
May 22-27, 2022 ©2022 Association for Computational Linguistics

Despite the usefulness of evidence, few prior studies leverage it in a proper way (Huang et al., 2021a,b). In particular, Huang et al. (2021a) extracts the evidence sentences together with RE but does not utilize them after extraction. Besides, it requires human-annotated evidence for training, and also suffers from massive memory usage and training time. Another work (Huang et al., 2021b) trains an RE model solely on evidence sentences, which misses important information in the original document and fails to show improvements when paired up with pre-trained language models.

In this paper, we propose an **evid**ence-**e**nhanced Doc**RE** framework EIDER, which efficiently extracts evidence and effectively leverages the extracted evidence to improve DocRE. During training, we enhance DocRE by jointly extracting relations and evidence using multi-task learning, which allows the two tasks to benefit from providing additional training signals for each other. There are two major challenges regarding evidence extraction. The first challenge is the memory and runtime overhead due to training an additional task. For example, a prior multi-task method (Huang et al., 2021a) needs over 14h and three consumer GPUs to train, while the individual RE model only takes around 90min on one GPU. In comparison, EIDER uses a simpler evidence extraction model, which can fit into a single GPU and only requires 95min runtime. The second challenge is that human-annotated evidence sentences are costly and heavily relying on them limits model applicability. Therefore, we design several heuristic rules to construct silver labels in case the evidence annotation is unavailable. We observe that EIDER still improves RE performance when trained with our silver labels, and sometimes even performs on par with using gold labels.

With the evidence extracted, either by our rules or evidence extraction model, we propose to further enhance DocRE by utilizing the evidence in inference. In the extreme case, if there is only one sentence related to the relation, one can make predictions solely based on this sentence and reduce the problem to sentence-level relation extraction. One naive approach is thus to directly replace the original document with the extracted evidence (Huang et al., 2021b). However, since no systems can extract evidence perfectly, solely relying on extracted sentences may miss important information and harm model performance in certain cases (see Table 5). To avoid information loss, we fuse the prediction results of the original document and extracted evidence through a blending layer (Wolpert, 1992). In this way, EIDER pays more attention to the extracted important sentences, while still having access to all the information in the document. Empirical analysis demonstrates that removing either source would lead to degenerate performance.

We conduct extensive experiments on three widely-adopted DocRE benchmarks: DocRED (Yao et al., 2019), CDR (Li et al., 2016) and GDA (Wu et al., 2019). Experiment results show that EIDER achieves state-of-the-art performance on all the datasets. Performance analysis further shows that the improvement of EIDER is most significant on inter-sentence entity pairs, suggesting that leveraging evidence is especially effective in reasoning over multiple sentences. In particular, EIDER significantly improves the performance on entity pairs that require co-reference/multi-hop reasoning by 1.98/2.08 F1 on DocRED, respectively.

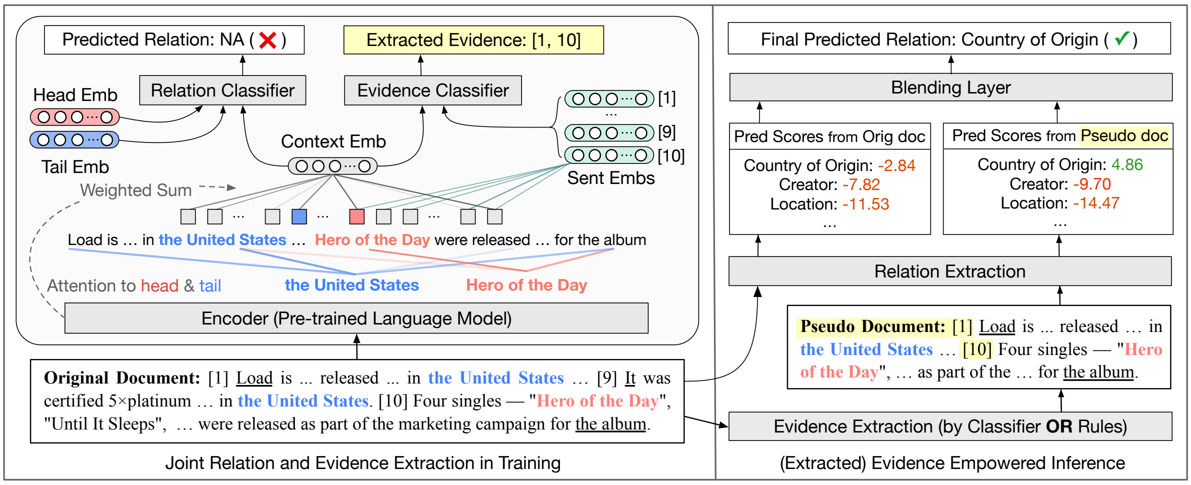
Contributions. (1) We propose an efficient joint relation and evidence extraction model that allows the two tasks to mutually enhance each other without heavily relying on evidence annotation. (2) We design a simple and effective DocRE inference process enhanced by the extracted evidence, enabling more focus on the important sentences with no information loss. (3) We demonstrate that our evidence-enhanced framework outperforms state-of-the-art methods on three DocRE datasets.

2 Problem Formulation

Given a document d comprised of N sentences $\{s_n\}_{n=1}^{N}$, L tokens $\{h_l\}_{l=1}^{L}$, E named entities $\{e_i\}_{i=1}^{E}$ and all the proper-noun mentions of each entity, $\{m_j^i\}$, the task of document-level relation extraction (DocRE) is to predict the set of all possible relations between all entity pairs (e_h, e_t) from a pre-defined relation set $\mathcal{R} \bigcup \{\text{NA}\}$. We refer to e_h and e_t as the head entity and tail entity, respectively. A relation r belongs to the positive class $\mathcal{P}_{h,t}^{T}$ if it exists between (e_h, e_t) and otherwise the negative class $\mathcal{N}_{h,t}^{T}$. For each entity pair (e_h, e_t) that possesses a non-NA relation, we define its *evidence*[2] $V_{h,t} = \{s_{v_k}\}_{k=1}^{K}$ as the subset of sentences in the document that are sufficient for human annotators to infer the relation. Human annotation of evidence may or may not be given in training, depending on the datasets, but is not available in inference.

---

[2] We use "*evidence sentence*" and "*evidence*" interchangeably throughout the paper.



Original Document: [1] Load is ... released ... in the United States ... [9] It was certified 5×platinum ... in the United States. [10] Four singles — "Hero of the Day", "Until It Sleeps", ... were released as part of the marketing campaign for the album.

Pseudo Document: [1] Load is ... released ... in the United States ... [10] Four singles — "Hero of the Day", ... as part of the ... for the album.

Figure 2: The overall architecture of EIDER. The left part illustrates the training stage and the right shows the inference stages of EIDER. We highlight head entities, tail entities and extracted evidences.

3 Methodology

An illustration of the framework of EIDER is shown in Figure 2. In training, we jointly extract relation and evidence using multi-task learning, where the two tasks have their own classifier and share the base encoder (Sec. 3.1). In inference, we fuse the predictions on the original document and the extracted evidence using a blending layer (Sec. 3.2). In case the evidence annotation is not available, we also provide several heuristic rules to construct silver evidence labels as an alternative (Sec. 3.3).

3.1 Joint Relation and Evidence Extraction

In our framework, we jointly train the relation extraction model with an evidence extraction model using multi-task learning. As shown in Figure 2, the two tasks have their own classifier but share the base encoder. Intuitively, tokens relevant to predicting the relation are essential in both models. By sharing the base encoder, the two tasks can provide additional training signals for each other and hence mutually enhance each other (Ruder, 2017).

Base Encoder. We leverage pre-trained language models (Devlin et al., 2019) to encode the semantic meanings of each token in the document. Specifically, given a document $d = [h_l]_{l=1}^{L}$, we insert a special token "*" before and after each entity mention $\{m_j^i\}$ and leverage the encoder to obtain the s-dim token embeddings $\boldsymbol{H} = [\mathbf{h}_1, ..., \mathbf{h}_L], \mathbf{h}_l \in \mathbb{R}^s$ and the cross token attention $\boldsymbol{A} \in \mathbb{R}^{L \times L}$:

$$\boldsymbol{H}, \boldsymbol{A} = \text{Encoder}([h_1, ..., h_L]), \quad (1)$$

where $\boldsymbol{A}$ is the average of the attention heads in the last transformer layer (Vaswani et al., 2017). For each mention of an entity e_i, we use the embedding of the start symbol "*" as its mention embedding $\mathbf{m_j^i}$. Then, we obtain the embedding of entity e_i by adopting LogSumExp pooling (Jia et al., 2019; Zhou et al., 2021) over the embeddings of all its mentions: $\mathbf{e}_i = \log \sum_j \exp(\mathbf{m_j^i})$.

To predict the relation of different entity pairs, a model may need to focus on different parts of the context. To capture the context relevant to each entity pair (e_h, e_t), we compute its context embedding $\mathbf{c}_{h,t} \in \mathbb{R}^s$ based on the attention matrix $\boldsymbol{A}$ from the pre-trained encoder (Zhou et al., 2021):

$$\mathbf{c}_{h,t} = \boldsymbol{H}^T \frac{\boldsymbol{A}_h \circ \boldsymbol{A}_t}{\boldsymbol{A}_h^T \boldsymbol{A}_t}, \quad (2)$$

where $\circ$ is the Hadamard product and $\boldsymbol{A}_h \in \mathbb{R}^L$ is e_h's attention to all the tokens in the document, obtained by averaging e_h's mention-level attention. Similarly for $\boldsymbol{A}_t$. The intuition is that tokens with high attention towards both e_h and e_t are important to both entities. Hence, these tokens are likely to be essential to the relation and should contribute more to the context embedding.

Relation Classifier. To predict the relation between an entity pair (e_h, e_t), we first compute their context-aware representations $(\mathbf{z_h}, \mathbf{z_t})$ by combining their entity embeddings $(\mathbf{e}_h, \mathbf{e}_t)$ with their context embedding $\mathbf{c}_{h,t}$ and then utilize a bilinear function to calculate the logit of how likely a relation $r \in \mathcal{R}$ exists between e_h and e_t:

$$\begin{aligned} \boldsymbol{z}_h &= \tanh\left(\boldsymbol{W}_h \mathbf{e}_h + \boldsymbol{W}_{c_h} \mathbf{c}_{h,t}\right), \\ \boldsymbol{z}_t &= \tanh\left(\boldsymbol{W}_t \mathbf{e}_t + \boldsymbol{W}_{c_t} \mathbf{c}_{h,t}\right), \\ \mathbf{y}_r &= \boldsymbol{z}_h \boldsymbol{W}_r \boldsymbol{z}_t + \boldsymbol{b}_r, \end{aligned} \quad (3)$$

where $\boldsymbol{W}_h, \boldsymbol{W}_t, \boldsymbol{W}_{c_h}, \boldsymbol{W}_{c_t}, \boldsymbol{W}_r$ and $\boldsymbol{b}_r$ are learnable parameters. As the model may have different confidence for different entity pairs, we apply the adaptive-thresholding loss (Zhou et al., 2021), which learns a dummy relation class TH that serves as the dynamic threshold for each entity pair:

$$\mathbf{y}_{\text{TH}} = \boldsymbol{z}_h \boldsymbol{W}_{\text{TH}} \boldsymbol{z}_t + \boldsymbol{b}_r. \quad (4)$$

During inference, for each tuple $(e_h, e_t, r), r \in \mathcal{R}$, we obtain the prediction score: $S^{(O)}_{h,t,r} = \mathbf{y}_r - \mathbf{y}_{TH}$. Finally, we define our training objective for relation extraction as follows:

$$\mathcal{L}_{RE} = -\sum_{h \neq t} \sum_{r \in \mathcal{P}^T_{h,t}} \log \left(\frac{\exp(\mathbf{y}_r)}{\sum_{r' \in \mathcal{P}^T_{h,t} \cup \{\text{TH}\}} \exp(\mathbf{y}_{r'})} \right) - \log \left(\frac{\exp(\mathbf{y}_{\text{TH}})}{\sum_{r' \in \mathcal{N}^T_{h,t} \cup \{\text{TH}\}} \exp(\mathbf{y}_{r'})} \right). \quad (5)$$

Evidence Classifier. In addition to the relation, we also predict whether each sentence s_n is an evidence sentence of entity pair (e_h, e_t). Similar to entity embeddings, to obtain sentence embedding $\mathbf{s}_n$, we apply a LogSumExp pooling over all the tokens in s_n: $\mathbf{s}_n = \log \sum_{h_l \in s_n} \exp(\mathbf{h}_l)$. Intuitively, if s_n is an evidence sentence of (e_h, e_t), the tokens in s_n would be relevant to the relation prediction, and should contribute more to $\mathbf{c}_{h,t}$. Hence, we use a bilinear function between context embedding $\mathbf{c}_{h,t}$ and sentence embedding $\mathbf{s}_n$ to measure the importance of sentence s_n to entity pair (e_h, e_t):

$$\mathrm{P}(s_n | e_h, e_t) = \sigma(\mathbf{s}_n \boldsymbol{W}_v \mathbf{c}_{h,t} + \boldsymbol{b}_v), \quad (6)$$

where $\boldsymbol{W}_v$ and $\boldsymbol{b}_v$ are learnable parameters.

As an entity pair may have more than one evidence sentence, we use the binary cross entropy as the objective to train the evidence extraction model.

$$\mathcal{L}_{Evi} = -\sum_{h \neq t, \text{NA} \notin \mathcal{P}^T_{h,t}} \sum_{s_n \in \mathcal{D}} y_n \cdot \mathrm{P}(s_n | e_h, e_t) + (1 - y_n) \cdot \log(1 - \mathrm{P}(s_n | e_h, e_t)), \quad (7)$$

where the evidence label y_n is 1 when $s_n \in V_{h,t}$ and otherwise 0. If golden labels are not provided, we use several heuristic rules to construct silver labels instead. Details are introduced in Sec 3.3.

Finally, we optimize our model by the combination of the relation extraction loss $\mathcal{L}_{RE}$ and evidence extraction loss $\mathcal{L}_{Evi}$:

$$\mathcal{L} = \mathcal{L}_{RE} + \mathcal{L}_{Evi}. \quad (8)$$

Efficiency Considerations. Compared to a previous method E2GRE (Huang et al., 2021a) that also extracts the evidence, EIDER is significantly more efficient in both memory and training time for two reasons. First, E2GRE learns $|\mathcal{R}|$ representations for each sentence. Namely, it makes evidence prediction for every (entity, entity, sentence, relation) tuple, which requires expensive computation especially when $|\mathcal{R}|$ is large (e.g., $|\mathcal{R}| = 96$ in DocRED). In contrast, we observe that most entity pairs only have one set of evidence across relations and thus predict only one set of evidence for each entity pair.

Second, E2GRE regards the evidence label of entity pairs with $r = \text{NA}$ as an empty set. However, these entity pairs may still involve some relation beyond the pre-defined relation set $\mathcal{R}$, which also have their evidence sentences. Hence, we train the evidence extraction model only on entity pairs with at least one non-NA relation, which accounts for a small subset (e.g., 2.97% in DocRED) of all the entity pairs. Experiments show that EIDER achieves better performances than E2GRE in both RE and evidence extraction while requiring only 30% of its memory usage and 11% of its runtime.

Furthermore, E2GRE does not utilize the evidence after extraction and relies heavily on the human annotation of evidence, which we will address in the following sections.

3.2 Fusion of Evidence in Inference

Suppose the extracted evidence sentences already contain all the information relevant to the relation, then there is no need to use the whole document for relation extraction. However, no system can perfectly extract the evidence without missing any sentences. Solely relying on the extracted evidence may miss important information in the document and lead to sub-optimal performance. Therefore, we combine the prediction results on both the original document and the extracted evidence, which can either be learned by our evidence classifier (Sec. 3.1) or constructed by our heuristic rules (Sec. 3.3) if evidence annotation is unavailable. Even without joint training, one may directly improve general (trained) DocRE models by applying our proposed inference process (noted as EIDER (Rule)-Nojoint in Table 5).

Specifically, as shown in Figure 2, we first obtain a set of relation prediction scores $S^{(O)}_{h,t,r}$ from the original documents. Then we construct a pseudo document $d'_{h,t}$ for each entity pair by concatenating the extracted evidence sentences $V'_{h,t}$ in the order they present in the original document. The prediction score of the RE model on the pseudo document is noted as $S^{(E)}_{h,t,r}$. Finally, we fuse the results by aggregating the two sets of prediction sores through a blending layer (Wolpert, 1992):

$$\mathrm{P}_{Fuse}\left(r|e_h, e_t\right) = \sigma(S^{(O)}_{h,t,r} + S^{(E)}_{h,t,r} - \tau). \quad (9)$$

We choose this design because it is simple and only includes one learnable parameter, τ, alleviating over-fitting in the development set. We optimize the parameter τ on the development set as follows:

$$\mathcal{L}_{Fuse} = -\sum_{d \in \mathcal{D}} \sum_{h \neq t} \sum_{r \in \mathcal{R}} y_r \cdot \mathrm{P}_{Fuse}\left(r|e_h, e_t\right) + \\ (1 - y_r) \cdot \log(1 - \mathrm{P}_{Fuse}\left(r|e_h, e_t\right)), \quad (10)$$

where $y_r = 1$ if relation r holds between (e_h, e_t) and $y_r = 0$ otherwise. Empirically, using other loss functions does not affect the performance much.

3.3 Heuristic Evidence Label Construction

In case that human annotation of evidence is not available, we design a set of heuristic rules to automatically construct silver labels for evidence extraction. Then we train our joint model on the silver labels and directly use the silver labels as pseudo documents in inference. The percentage of test samples covered by each rule is shown in Table 6.

Co-occur. If the head and tail entities co-occur in the same sentence (e.g., "Load" and "the United States" co-occur in the 1^{st} sentence in Figure 2), we use all the sentences they co-occur as evidence.

Coref. If the proper-noun mentions of the head and tail entity do not co-occur, but their coreferential mentions co-occur (e.g., "Hero of the Day" and "the album", the co-reference of "Load" co-occur in the 10^{th} sentence in Figure 2), we use all the sentences where their coreferential mentions co-occur as evidence. In practice, we directly apply a pre-trained coreference resolution model, HOI (Xu and Choi, 2020), without fine-tuning on our dataset.

Bridge. If the first two conditions are not met, but there exists a third bridge entity whose coreferential mention co-occurs with both head and tail (e.g., "Load" or its coreferential mention "the album" co-occurs with both "the United States" and "Hero of the Day" in Figure 2), we take all the sentences where the bridge co-occurs with head or tail as the evidence. If there are more than one bridge entities, we choose the one with the highest frequency. While this rule can be easily extended to multiple bridges, we empirically observe that capturing one bridge already leads to satisfying results.

4 Experiments

4.1 Experiment Setup

Datasets. We evaluate the effectiveness of EIDER on three datasets: DocRED (Yao et al., 2019), CDR (Li et al., 2016) and GDA (Wu et al., 2019), where DocRED is the only dataset that provides evidence labels as part of the annotation. The details of the datasets are listed in Appendix A.1.

Implementation Details. Our model is implemented based on PyTorch and Huggingface's Transformers (Wolf et al., 2019). We use cased-$\mathrm{BERT_{base}}$ (Devlin et al., 2019) and $\mathrm{RoBERTa_{large}}$ as the base encoders and optimize our model using AdamW with learning rate 5e-5 for the encoder and $1e-4$ for other parameters. We adopt a linear warmup for the first 6% steps. The batch size (number of documents per batch) is set to 4 and the ratio between relation extraction and evidence extraction losses is set to 0.1. We perform early stopping based on the F1 score on the development set, with a maximum of 30 epochs. Our $\mathrm{BERT_{base}}$ models are trained with one GTX 1080 Ti GPU and $\mathrm{RoBERTa_{large}}$ models with one RTX A6000 GPU.

Evaluation Metrics. Following prior studies (Yao et al., 2019), we use **F1** and **Ign F1** as the main evaluation metrics for relation extraction, where **Ign F1** measures the F1 score excluding the relations shared by the training and development/test set. We also report **Intra F1** and **Inter F1**, where the former measures the performance on the co-occurred (intra-sentence) entity pairs and the latter evaluates the inter-sentence entity pairs where none of their proper-noun mentions co-occurs. For evidence extraction, we compute the F1 score (denoted as **Evi F1**) and further introduce **PosEvi F1**, which measures the F1 score of evidence only on positive entity pairs (i.e., those with non-NA relations).

4.2 Main Results

We compare our methods with both *Graph-based methods* and *transformer-based methods*. Graph-based methods explicitly perform inference on document-level graphs. Transformer-based methods, including EIDER, implicitly capture the long-distance token dependencies via transformers. Noted that EIDER is trained on gold labels and

leverages the evidence extracted by our model in inference. EIDER (Rule) is trained on silver evidence labels constructed by rules and also leverages them in inference.

Relation Extraction Results. Tables 1 and 2 show that EIDER outperforms the DocRE baseline methods in all datasets. Our improvement is especially large on Inter F1 (e.g., 1.21/2.01 Intra/Inter F1 compared to ATLOP-BERT$_{\text{base}}$). We hypothesize that the bottleneck of inter-sentence pairs is to locate the relevant context, which often spreads through the whole document. EIDER learns to capture important sentences in training and focuses more on these important sentences in inference.

Among the baselines, the Inter F1 of GAIN is 0.70 higher than ATLOP while the Intra F1 of ATLOP is 0.16 higher than GAIN, indicating that document-level graphs may be effective in multi-hop reasoning. Although EIDER does not involve explicit multi-hop reasoning modules, it still notably outperforms graph-based models in Inter F1.

Finally, EIDER (Rule) also outperforms all the baselines in both DocRED and the two biomedical datasets which do not have evidence annotation. The improvement on DocRED and CDR is much larger than that on GDA. We hypothesize that it is because more than 85% relations in GDA are intra-sentence ones, making it trivial even for the single RE model to focus on these sentences.

Evidence Extraction Results. To our knowledge, E2GRE is the only method that has reported their evidence extraction result. The results in Table 3 indicate that EIDER outperforms E2GRE significantly (e.g., by 3.57 Dev Evi F1 under BERT$_{\text{base}}$). The results show that it may be sufficient to train the evidence classifier only on pairs with $r \in \mathcal{R}$

and over each (entity, entity, sentence) tuple instead of (entity, entity, sentence, relation) as in E2GRE.

Our ablation studies in Table 4 show that our three heuristic rules, denoted as **Rules (ours)**, already capture most of the evidence for positive entity pairs. The high quality of silver labels explains why our model can perform well using silver labels only. Furthermore, training the RE model and evidence extraction model separately (denoted as **NoJoint**) results in a sharp performance drop. As the relation and evidence classifiers share the same base encoder, discarding the relation classifier will result in insufficient training of the base encoder and harm the performance.

4.3 Performance Analysis

Ablation Study. Table 5 shows the ablation studies that analyzes the utility of each module in Eider. We observe that **NoJoint** leads to sharp performance drop in DocRE. Besides, **Eider (Rule)-Nojoint** achieves significant "free gains" (0.90/1.08 Ign F1/F1) by simply fusing the evidence constructed by rules in the inference of ATLOP. In principle, this inference process can be applied to general DocRE models.

We also remove the pseudo document (constructed from the extracted evidence) and the original document separately, denoted as **NoPseudo** and **NoOrigDoc**, respectively. We observe that removing either source will lead to performance drops. Also, the drop of Inter F1 is much larger than Intra F1 for **NoPseudo**, indicating that our inference process is effective for inter-sentence pairs where the evidence may not be consecutive.

As for **NoBlending**, we remove the blending layer and simply take the union of the two sets of results. The sharp drop of performance indicates the blending layer can successfully learn a dynamic threshold to combine the prediction results.

	Co-occur	Coref	Bridge	Total
Count	6711	984	3212	10,907
Percent	54.46%	7.99%	26.07%	88.52%

Table 6: Statistics of the 12,323 relations in the DocRED development set.

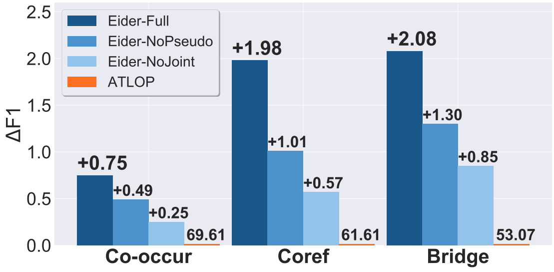

Figure 3: Performance gains in F1 by relation categories. The gains are relative to the second best baseline (ATLOP-RoBERTa$_{\text{large}}$).

Finally, we further finetune the RE model on ground truth evidence before feeding it the extracted evidence (denoted as **FinetuneOnEvi**) but the performance is not improved, probably because the encoded entity representations in evidence and original documents are already highly similar.

Performance Breakdown. To further analyze the performance of Eider on different types of entity pairs, we categorize the relations into three categories based on our three heuristic rules in Sec. 3.3: *Co-occur*, *Coref* and *Bridge*. The number and percentage of relations covered by each rule are listed in Table 6. We can see that the three categories cover over 88% of the relations in the development set. The results on each category are shown in Figure 3. We can see that our full model has the best performance in all three categories and our ablations also outperform ATLOP. For all our methods, the improvements over ATLOP is *Bridge* $>$ *Coref* $\gg$ *Co-occur*. This reveals that both modules mainly improve the model's reasoning ability from multiple sentences, either by coreference reasoning or by multi-hop reasoning over a third entity.

Table 8: Case studies of our proposed framework EIDER. We use red, blue and green to color the **head entity**, **tail entity** and **relation**, respectively. The indices of extracted evidence sentences are highlighted with yellow.

Efficiency Comparison. We benchmark the time and memory usage of EIDER on an RTX A6000 GPU. Table 7 shows that our joint model incurs only ~5% training time and ~14% GPU memory overhead. Experiments also show that EIDER can be trained on a single consumer GPU (e.g., an 11GB GTX 1080 Ti) but E2GRE is not able to.

4.4 Case Studies

Table 8 shows a few examples of EIDER. Detailed statistics and error analysis are provided in Appendix A.2. In the first example, the head entity is mentioned in the first sentence and the tail entity appears in the second. We can see that EIDER correctly extracts these sentences as evidence. Since the evidence sentences are consecutive, the predictions on both the original document and the evidence sentences are correct. In the second example, the prediction using only the original document is incorrect, possibly because the "King Louie" in the 1^{st} and 3^{rd} sentences are so far away from each other that the model fails to recognize them as coreference. Hence, it fails to distinguish "King Louie" as a bridge entity and wrongly predicts "NA". Instead, these two sentences are consecutive in the extracted evidence, making it easier for the model to find the bridge. In the last example, the 6^{th} sentence is missing in the extracted evidence, so the extracted evidence does not contain enough information to predict the relation. However, the prediction on the original document is correct, leading to the correct final result.

5 Related Work

Relation Extraction. Previous research efforts on relation extraction mainly concentrate on predicting relations within a sentence (Cai et al., 2016; Zhang et al., 2018, 2019, 2020a). Despite their effectiveness, in the real world, certain relations can only be inferred from multiple sentences. Consequently, recent studies (Quirk and Poon, 2017; Peng et al., 2017; Yao et al., 2019) started to work on document-level relation extraction (DocRE).

Graph-based DocRE. Graph-based DocRE methods generally construct a graph with mentions, entities, sentences, or documents as the nodes, and infer the relations by reasoning on this graph. Zeng et al. (2020) performs multi-hop reasoning on both a mention-level graph and an entity-level graph. Xu et al. (2021) extracts a reasoning path for each relation and encourages the model to reconstruct the path during training. Zeng et al. (2021) separately deals with intra- and inter-sentential entity pairs and performs multi-hop reasoning on a mention-level graph for inter-sentential entity pairs. However, the extracted graph may omit some important information in the text. Complicated operations on the graphs may also hinder the model from capturing the text structure.

Transformer-based DocRE. Another line of studies model cross-sentence relations by implicitly capturing the long-distance token dependencies via the transformer (Vaswani et al., 2017). Zhou et al. (2021) uses attention in the transformers to extract useful context and adopts an adaptive threshold for each entity pair. Zhang et al. (2021) views DocRE as a semantic segmentation task over the entity matrix and applies a U-Net to capture the correlations between relations. Huang et al. (2021a) guides DocRE by extracting evidence but does not leverage them after extraction. It also highly relies on evidence annotations and suffers from massive runtime and memory overhead. Huang et al. (2021b) predicts on only a few sentences selected by rules, which may miss important information and does not show consistent improvements. In comparison, we design a lightweight evidence extraction model that is significantly more efficient than Huang et al. (2021a) and can improve DocRE even trained on silver labels. EIDER also fuses the extracted evidence in inference, putting more attention to the important sentences without information loss.

6 Conclusion

In this work, we propose EIDER, an **evid**ence-**e**nhanced **R**E framework, which improves DocRE by joint relation and evidence extraction and fusion of extracted evidence in inference. In training, the RE and evidence extraction model provide additional training signals for each other and mutually enhance each other. The joint model is efficient in time and memory and does not rely heavily on the human annotation of evidence. During inference, the prediction results on both the original document and the extracted evidence are combined, which encourages the model to focus on the important sentences while reducing information loss. Experiment results demonstrate that EIDER significantly outperforms existing methods on three public datasets (DocRED, CDR, and GDA), especially on inter-sentence relations.

A Appendices

A.1 Dataset Statistics

Our model is evaluated on three benchmark datasets, where the statistics are shown in Table 9:

DocRED (**Yao et al., 2019**) is a large human-annotated document-level RE dataset constructed from Wikipedia. In the training set, around 97.03% entity pairs do not hold any explicit relations. In our experiments, the performance on the test set is validated through the Leader board[3].

CDR (**Li et al., 2016**) is a biomedical relation extraction dataset consisting of 1,500 PubMed abstracts. The only two entity types are chemicals and diseases and the only non-NA relation is the causal relation between chemicals and disease concepts.

GDA (**Wu et al., 2019**) contains 30,192 MEDLINE abstracts. It is also a biomedical dataset with two entity types only: diseases and genes, and one non-NA relation type only: the interactions between disease concepts and genes.

Statistics	DocRED	CDR	GDA
# Train	3053	500	23353
# Dev	1000	500	5839
# Test	1000	500	1000
# Relation types	97	2	2
# Avg.# entities per Doc	19.5	7.6	5.4
# Avg.# sentences per Doc	8.0	9.7	10.2
Percent of Intra Rel	54.2	75.7	84.7

Table 9: Statistics of the datasets in experiments. The percentage of intra-sentence relations is calculated from the development set of DocRED and calculated from the test set of CDR and GDA.

A.2 Error Analysis of EIDER

The detailed statistics of the predictions of our model are listed in Table 10. Among all the errors, the majority is because the model wrongly predicts the non-NA relations (i.e., $r \in \mathcal{R}$) as "NA" or predicts "NA" as some non-NA relations. Only $\frac{287}{287+4340+3613} = 3.48\%$ of the errors result from wrongly taking some non-NA relation as another.

To check the exact reason why our model makes these errors, we randomly select 50 cases from DocRED where our model predicts wrongly. We summarize the error types in Table 11 and provide one or two examples for each of the common error types in Table 12.

		Ground Truth	
Prediction		$r \in \mathcal{R}$	NA
	$r \in \mathcal{R}$ (Correct)	7,696 (✓)	3,613 (✗)
	$r \in \mathcal{R}$ (Wrong)	287 (✗)	
	NA	4,340 (✗)	380,854 (✓)

Table 10: Statistics of one run of EIDER-RoBERTa$_{\text{large}}$. "$r \in \mathcal{R}$" means non-NA relations. We use "✓" and "✗" to denote correct and wrong predictions, respectively. For example, we have 4,340 wrong predictions where the ground truth is some $r \in \mathcal{R}$ but the prediction is NA.

Reason	Count
Labeling Mistakes	18
Fail in Commonsense Reasoning	8
Fail in Coreferential Reasoning	6
Fail in Multi-hop Reasoning	4
Fail in Surface-name Reasoning	3
Wrong Evidence Extraction	1
Others	10

Table 11: Error types of EIDER in 50 randomly sampled error cases in DocRED. Where "Labeling Mistakes" means our model predicts correctly but the annotation is wrong.

Our analysis shows that 18 out of 50 "error cases" are actually correct. It suggests that labeling mistakes are still prevalent in the DocRED dataset. We show an example under ***"Error Type 1"*** in Table 12. The annotator wrongly labels *"U.S. Route 20"*, a highway, as the country of *"Capital District"*.

Another common error type is ***"Error Type 2"****: failing in commonsense reasoning*. These error examples normally require commonsense knowledge of the related entities that does not explicitly present in the document. In the first case, the document shows that the airport is located in *"Michigan"* and is near the *"Crooks Road"*. Then we still require the commonsense knowledge that a road (Crooks Road) is a rather small location compared to a state (Michigan). Finally, we can conclude that *"Crooks Road"* locates in *"Michigan"*.

The second case requires the commonsense knowledge about the church. Specifically, if a pope (Benedict XVI) can remove a priest (Maciel) from the ministry, they must be in the same church and hence share the same religion. From sentence [2] we know the priest, Maciel, is a Catholic, hence the pope, Benedict XVI, must also be a Catholic. Even though our prediction on extracted evidence is correct, the confidence is still not high, leading to the incorrect final prediction. As the logic chain of

[2] It was a common formation in **China** prior to the Second Sino-Japanese War but was discarded as a formation type by the National Revolutionary Army after 1938 (other than the 8th Route Army), in favor of the Group Army. [3] Some of the more famous of the Route Armies were: [4] 8th Route Army: Communist guerrilla force in **North China**. **...**

Final Prediction: NA (✗) **Prediction on Orig. Doc**: NA (✗) **Prediction on Extracted Evidences**: NA (✗)

Table 12: Examples for the five most common error types. We use red, blue and green to color the **head entity**, **tail entity** and **relation**, respectively. The indices of extracted evidence sentences are highlighted with yellow.

commonsense reasoning is always complicated, it is not easy to find a very similar pattern in the training set, or even during pre-training, which makes the problem difficult for a model.

In most of the cases (5 out of 6) in "***Error Type 3**: Fail in Coreferential Reasoning*", human can still identify the correct relation based on the extracted evidence only. As shown in our example in Table 12, in the first sentence, the model wrongly predicts *"Giacomo Casanova"* as the father of *"Manon Balletti"*, but her real father should be an *"Italian actor performing in France"*. It shows that even the reasoning within a single sentence can be difficult.

Similarly, the example in "***Error Type 4***" also shows that the prediction can still be wrong even if we extract the correct evidence sentences and simplify the problem to sentence-level RE. This suggests that if the performance of sentence-level RE is improved, the performance of DocRE will also improve.

Finally, as described by "***Error Type 5***", some examples require direct reasoning from the surface names of the head and tail entities. As shown in the the last case in Table 12, humans can directly identify that *"China"* is the country of *North China* without reading the document, despite that there are no clue in the document indicates this relation. However, most DocRE models, including EIDER, learn to predict the relations only based on the given document and sometimes fail in such cases.

Meta-X_{NLG}: A Meta-Learning Approach Based on Language Clustering for Zero-Shot Cross-Lingual Transfer and Generation

Abstract

Recently, the NLP community has witnessed a rapid advancement in multilingual and cross-lingual transfer research where the supervision is transferred from high-resource languages (HRLs) to low-resource languages (LRLs). However, the cross-lingual transfer is not uniform across languages, particularly in the zero-shot setting. Towards this goal, one promising research direction is to learn shareable structures across multiple tasks with limited annotated data. The downstream multilingual applications may benefit from such a learning setup as most of the languages across the globe are low-resource and share some structures with other languages. In this paper, we propose a novel meta-learning framework (called Meta-X_{NLG}) to learn shareable structures from *typologically* diverse languages based on *meta-learning* and *language clustering*. This is a step towards uniform cross-lingual transfer for unseen languages. We first cluster the languages based on language representations and identify the centroid language of each cluster. Then, a meta-learning algorithm is trained with all centroid languages and evaluated on the other languages in the zero-shot setting. We demonstrate the effectiveness of this modeling on two NLG tasks (Abstractive Text Summarization and Question Generation), 5 popular datasets and 30 typologically diverse languages. Consistent improvements over strong baselines demonstrate the efficacy of the proposed framework. The careful design of the model makes this end-to-end NLG setup less vulnerable to the accidental translation problem, which is a prominent concern in zero-shot cross-lingual NLG tasks.

1 Introduction

There are more than 7000 known living languages across the globe. 95% of the world's population does not speak English as their first language and 75% does not speak English at all[1]. Most of the languages are low-resource languages as they do not have adequate resources for natural language processing research (Joshi et al., 2020). On the other hand, a vast majority of studies in NLP research are conducted on English data (Bender, 2019). To democratize the NLP research for the benefit of the large global community, it is essential to focus on the non-English languages. However, creating/collecting task-specific annotated data for all the languages is expensive and time-consuming. Moreover, human languages are dynamic as new words and domains are added continuously. An alternate solution is to investigate NLP modeling techniques that allow to train the model with high-resource languages like English and transfer supervision to low-resource languages (with limited annotated data) or unseen languages for several NLP applications. Recently, there has been promising progress on cross-lingual transfer learning research (Hu et al., 2020; Artetxe et al., 2020) but supervision transfer is uneven across languages which leads to large performance gaps. Such performance gaps are observed because models do not account for cultural and linguistic differences in the modeling (Lai et al., 2019; Blasi et al., 2021). This paper is a step towards bridging this gap via meta-learning and language clustering.

Meta-learning or *learning to learn* (Bengio et al., 1990) is a learning paradigm where the model is trained on diverse tasks and quickly adapts to new tasks given a handful of examples. It has emerged as a promising technique for Machine Learning (Finn et al., 2017; Koch et al., 2015), Natural Language Understanding (Murty et al., 2021; Yan et al., 2020) and Machine Translation (Gu et al., 2018) tasks. This work - to the best of our knowledge - is the first attempt to study *meta-learning techniques for cross-lingual natural language generation (X_{NLG})*. Particularly, we focus on zero-shot X_{NLG} for low-resource languages. Unlike NLU tasks, we observe that zero-shot NLG is a more

---

Findings of the Association for Computational Linguistics: ACL 2022, pages 269 - 284
May 22-27, 2022

challenging setup as text should be generated in unseen languages (which often suffers from accidental translation (AT) problem (Xue et al., 2021)) and is expected to be grammatically coherent, semantically correct and fluent. We aim to address the following research problem: *Does meta-learning algorithm trained on typologically diverse languages (as training task) provide language-agnostic initialization for the zero-shot cross-lingual generation?* Our main contributions in this work are listed below:

- We propose Meta-X_{NLG}[2], a framework for effective cross-lingual transfer and generation based on Model-Agnostic Meta-Learning (MAML) algorithm.
- We use language clustering to identify a set of meta-training languages, which provides a more uniform cross-lingual transfer to unseen languages.
- We test Meta-X_{NLG} on two NLG tasks (Abstractive Text Summarization and Question Generation), five popular datasets (XL-Sum, Wikilingua, MLQA, TyDiQA and XQuAD) and 30 languages. We observe consistent improvement over strong baselines involving mT5.
- We show an effective zero-shot X_{NLG} modeling setup, which is less vulnerable to the accidental translation problem.

2 Related Work

We focus on two threads of related work in this section: (1) cross-lingual generation and (2) meta-learning for NLP. Traditional approaches for cross-lingual generation use machine translation (MT) in the modelling pipeline (Wan et al., 2010; Ayana et al., 2018; Duan et al., 2019). Such approaches have an inherent problem as translations are generally error-prone. The errors are more when at least one of the languages involved in the translation is a low-resource language. Recently cross-lingual transfer approaches are gaining attention. These methods use parallel data (Chi et al., 2020a) and small annotated datasets (Kumar et al., 2019) in zero-shot and few-shot cross-lingual generation respectively. Lewis et al. (2020a) fine-tune a pre-trained model with multiple low-resource languages and evaluate on a single target language in zero-shot setting. In the same line of research, Maurya et al. (2021) modified mBART pre-trained model with an unsupervised dataset involving monolingual data in three languages for cross-lingual transfer. This model, called ZmBART, is tested on a small set of languages - English, Hindi and Japanese. Moreover, it has been observed that such cross-lingual transfers are not uniform across the languages (Lin et al., 2019; Blasi et al., 2021). We make an attempt to bridge this gap via meta-learning.

Recently, meta-learning has been actively applied for many NLP applications (Bansal et al., 2020; Gao et al., 2019) and also for NLU tasks such as text classification (van der Heijden et al., 2021), NER (Wu et al., 2020), task-oriented dialogue and QA (M'hamdi et al., 2021), etc. Tarunesh et al. (2021) propose joint meta-learning approach on multiple languages and tasks from XTREME benchmark (Hu et al., 2020). Close to our work, Nooralahzadeh et al. (2020) propose a meta-learning approach for cross-lingual transfer on NLI and QA, both NLU tasks. The authors use one or two randomly selected languages for meta-training. In contrast, we provide a systematic approach based on language clustering to identify the right meta-training languages. Moreover, to the best of our knowledge, ours is the first effort that employs meta-learning for natural language generation.

3 Meta-Learning Algorithm: MAML

Meta-learning tries to learn structure among multiple tasks such that the new tasks are adapted quickly given few training instances. Among several meta-learning algorithms, we focus on optimization-based algorithms, i.e., Model Agnostic Meta-Learning (MAML) (Finn et al., 2017) due to its recent success in multiple NLP and computer vision tasks. MAML progresses in two phases: *meta-training* and *adaptation*. In the meta-training phase, the model learns a good initialization of parameter values by repeatedly simulating the learning process on training tasks. In the adaptation phase, these learned parameters are quickly adapted to new tasks. The underlying constraint is that *all tasks should share some common structure (or come from a task distribution)*. The world's different languages follow this constraint as they came into existence with a common goal of communication, and share some structure. For meta-learning purposes, we treat them as different tasks.

---

[2] code & pre-trained models: `https://github.com/kaushal0494/Meta_XNLG`

Unlike traditional machine learning, meta-learning has *meta-train* and *meta-test* data splits for meta-training and adaptation respectively. Each split consists of tasks that are sampled from a distribution $p(\mathcal{D})$ over task datasets $\{\mathcal{D}_1, \mathcal{D}_2, \ldots, \mathcal{D}_n\}$ where $\mathcal{D}_i$ is associated with i^{th} task $\mathcal{T}_i$. Each $\mathcal{D}_i$ has *support set* and *query set* $\mathcal{D}_i = \{\mathcal{S}_i, \mathcal{Q}_i\}$. *Support set* and *Query set* are analogous to train and test splits of the traditional machine learning. We use f_θ to denote a neural network model parameterized by θ.

Meta-training has two-levels of optimization: *inner-loop optimization* and *outer-loop optimization*. In the inner-loop optimization, for each sampled task $\mathcal{T}_i$, the task-specific model parameters θ_i^m are updated by m iterations of stochastic gradient decent (SGD) with support set $\mathcal{S}_i$. The overall model parameters θ are learned to optimize the performance of models $f_{\theta_i^{(m)}}$ on query sets $\mathcal{Q}_i$ across datasets $p(\mathcal{D})$ in the outer-loop optimization. The MAML (Finn et al., 2017) objective is:

$$\theta^* = \arg\min_{\theta} \sum_{D_i \sim p(D)} \mathcal{L}_i(f_{\theta_i^{(m)}}) \qquad (1)$$

where $\mathcal{L}_i(f_{\theta_i^{(m)}})$ is the loss obtained on query set for task $\mathcal{T}_i$ and $f_{\theta_i^{(m)}}$ is obtained after m iteration of SGD update with Task $\mathcal{T}_i$ as:

$$f_{\theta_i^{(m)}} = f_\theta - \alpha \nabla_\theta \mathcal{L}_i(f_\theta)$$

In outer-loop optimization, MAML performs *MetaUpdate* which a batch as:

$$\theta = \theta - \beta \nabla_\theta \sum_{D_i \sim p(D)} \mathcal{L}_i(f_{\theta_i^{(m)}}) \qquad (2)$$

Where α is inner-loop learning rate and β is meta (outer-loop) learning rate. In the adaptation phase, the model is initialized with with learned optimal meta-parameters θ^*, which is updated by a few steps of SGD with a support set (aka. few-shot learning) and directly evaluated on the query set of the meta-test dataset. Our aim is to perform zero-shot evaluation, so we skip the adaptation phase and directly evaluate the learned model on meta-test datasets.

4 Methodology

In the proposed Meta-X$_{\text{NLG}}$ framework, we first cluster the available languages and identify the centroid languages. Then we train a model with MAML on centroid languages to obtain an optimal initialization of parameters. Finally, the learned model is deployed to generate text in the zero-shot setting. Figure-1 provides an overview of proposed framework. We now provide details of each component of the framework.

4.1 Language Clustering

Broadly, the languages can be clustered in two ways: (1) By language family consideration and (2) By exploiting similarities among learned language representations. To learn language representations, Littell et al. (2017) used typological information from linguistic knowledge-bases like WALS (Dryer and Haspelmath, 2013) Glottolog (Hammarström et al., 2017), etc. Malaviya et al. (2017) extract learned language tag representations from tasks like machine translation. Recently, Oncevay et al. (2020) fuse typologically learned and task-learned language representations using singular vector canonical correlation (SVCC) analysis to obtain multi-view language representation. Further, the authors cluster languages using this rich multi-view language representations through hierarchical clustering. We utilize this clustering approach in our proposed framework.

Next, we aim to identify a representative language (*centroid language*) for each cluster. Formally, given a cluster $C = \{L_1, L_2, \ldots L_t\}$, where each L_i is multi-view representation of i^{th} language, the centroid language $L^* \in C$ is defined as:

$$L^* = \arg\min_{L_i \in C} \sum_{L_j \in C} d(L_j, L_i). \qquad (3)$$

We use d as the cosine distance. In the proposed meta-learning algorithm, the centroid languages act as *Meta-Training* tasks/languages and the rest of the non-centroid languages across clusters act as *Target* (aka. evaluation) tasks/languages. In this setup, the best performing model should hold two properties i.e., *Intra-cluster Generalization* and *Inter-cluster Generalization*. In the proposed framework, training with a centroid language leads to better transfer capability within cluster, and using multiple centroid languages extend the transfer capability to multiple closely-knit clusters and increase coverage. In this way the stated properties can be achieved.

However, there is a trade-off between the number of clusters (the number of meta-training languages) and generalization. If there is a single

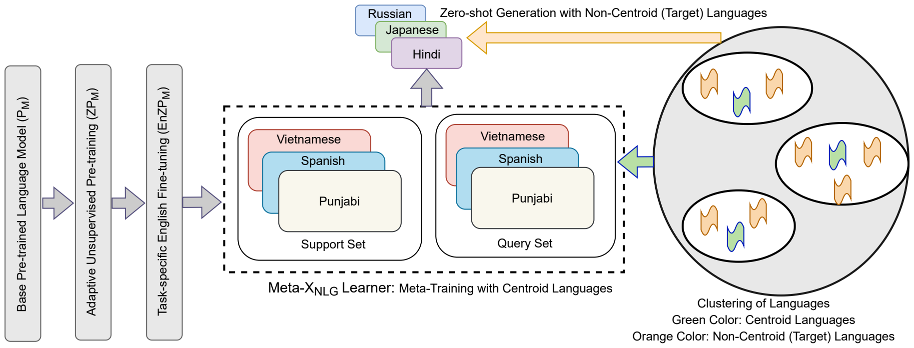

Figure 1: An overview of Meta-X$_{\text{XNLG}}$ framework

cluster (a single meta-training language), then the model tries to over-generalize for different typological structures and fails in the attempt. On the other extreme, if there are too many centroid languages (many typologically diverse structures in meta-training), then the learning possibly gets distracted. In both cases, the model will be unable to learn a reasonable structure (the required generalization) and perform poorly. Section-6.2 consists discussions and empirical evidence. Our experiments suggest that three clusters across considered languages provide the best performance. These three clusters are always fixed irrespective of the datasets and underlying tasks. Composition of the clusters (with three clusters) are shown in Table-1. See Figure-3 for more details on the clustering.

4.2 Meta-X$_{\text{NLG}}$ Training

The framework consists of five training steps: Selection of Base Pre-trained model, Adaptive unsupervised pre-training, Fine-tuning with HRL, Meta-training with LRLs, and Meta-adaptation for Zero-shot. The motivation and details of each step are included below:

1. *Selection of Base Pre-trained Model (P_M):* Our approach is model-agnostic, therefore any state-of-the-art sequence-to-sequence multilingual pre-trained language model (P_M; like mBART, mT5, etc.) can be used. We selected mT5 due to its superiority on many NLP tasks (Xue et al., 2021).
2. *Adaptive Unsupervised Pre-training (ZP_M):* Zero-shot cross-lingual generation often suffers from accidental translation (Xue et al., 2021) and other generation problems. To overcome this, we *further train* P_M on a *MultiMonoLang* corpus with mT5 denoising objective. We created *MultiMonoLang* corpus by concatenating small unsupervised samples from each of the 30 languages. We call this model ZP_M (or ZmT5). See section-4.3 for more details.

Cluster-1(14)	**Cluster-2(8)**	**Cluster-3(8)**

Table 1: Clustering of considered 30 Languages

3. *Fine-tuning ZP_M on High Resource Language (i.e., English):* It is often observed that downstream LRLs applications benefit when supervision is transferred from HRL (Hu et al., 2020). Following the trend, we fine-tune the ZP_M model with the task-specific English data and call this model as $EnZP_M$ with parameters θ_p.
4. *Meta-Training with Low-resource Centroid Languages:* We use the validation sets of each centroid language as the *meta-train* dataset. The meta-learner is initialized with the $EnZP_M$ parameters. Then, a batch of tasks/languages T_i and corresponding datasets D_i are randomly sampled. Further, each D_i is equally split into support set S_i and query set Q_i such that they are mutually exclusive. m-step gradient update is done in the inner-loop using S_i. This is repeated for all the training tasks. Finally *Meta-Update* is done using mean loss computed on Q_i as shown in Equation 2. This is repeated for all the tasks/languages over multiple batches. The batches are sampled uniformly across all centroid languages. The formal description is shown in Algorithm-1.
5. *Meta-adaptation for Zero-shot Evaluation:* The meta-learned model f_{θ^*} from the previous step can be directly evaluated on the test sets of the target languages in zero-shot evaluation. The proposed framework can be easily extended to few-shot setting. In this setting, the meta-learned model can be fine-tuned on a small number of validation set examples with standard supervised learning and evaluated on the test sets

of target languages. In this work we consider zero-shot setting only.

Algorithm 1 Meta Learning Algorithm

```
Require: Task set distribution $p(D)$, pre-trained model $EnZP_M$ (P) with parameters $\theta_P$, meta-learner $f_\theta$ with parameter $\theta$.
Require: $\alpha$, $\beta$: step size hyper-parameters
Initialize $\theta \leftarrow \theta_P$
while not done do
    Sample batch of tasks $T = T_1, T_2, \ldots T_b \sim p(D)$
    for all $T_i$ in $T$ do
        Initialize $\theta_i \leftarrow \theta$
        Split $D_i$ to form support set $S_i$ and query set $Q_i$
        for all inner_iter steps $m$ do
            Compute $\nabla_{\theta_i^{(m)}} L_{T_i}^{S_i}(P_{\theta_i^{(m)}})$
            Do SGD: $\theta_i^{m+1} = \theta_i^m - \alpha \nabla_{\theta_i^{(m)}} L_{T_i}^{S_i}(P_{\theta_i^{(m)}})$
        end for
        MetaUpdate: $\theta = \theta - \beta \nabla_\theta \sum_{j=1}^{b} L_{T_i}^{Q_i}(P_{\theta_i^{(m)}})$
    end for
end while
Do zero-shot/few-shot learning with meta-learner $f_{\theta^*}$ where $\theta^*$ is learned optimal parameters of meta-learner.
```

4.3 Avoiding Accidental Translations:

It has been observed that popular pre-trained models like mBART and mT5 suffer in well-formed generation for unseen low-resource (zero-shot) languages. Broadly, they suffer from Accidental Translation (AT), where the model generates whole/part of the output in the fine-tuning language (Xue et al., 2021). This happens when the model forgets the learning obtained before fine-tuning. This is analogous to the Catastrophic-Forgetting problem (Chi et al., 2020a) in multi-task setup, where the model forgets the learnings about the previous task. For language generation, this also leads to problems like improper predictions, structural and normalization errors, etc., as the different languages differ in morphology, phonology, subject-verb-object ordering, etc.

To mitigate/reduce these problems, Xue et al. (2021) suggested mixing a small amount of multilingual pre-training task data into the fine-tuning stage. However, it is unclear what ratio mixing should be done and how this joint training will affect generation quality. Moreover, such mixing is not a feasible solution for multi-level fine-tuning (as in our proposed setup - English fine-tuning then meta-training with centroid languages). Inspired from Maurya et al. (2021), the following solution approach are adopted in Meta-X$_{\text{NLG}}$ framework.

- *Adding Language Tag:* We concatenate <*fxx*> <*2xx*> where *xx* is language code as per ISO 693-2 standard.
- *Adaptive Unsupervised Pre-training*: Further train the base pre-trained model on *Multi-MonoLang* corpus with denoising language model objective. Unlike Maurya et al. (2021), we use mT5 denoising objective (Xue et al., 2021) instead *rand-summary* objective which leads to better performance.
- *Freezing model Components :* One of the key approaches to mitigate CF problem is freezing model parameters. Maurya et al. (2021) performed an ablation study and concluded that freezing all token embeddings and decoder parameters of the model work best. We adapted these findings while English-fine tuning and meta-training steps.

We observed that the above settings work better to mitigate (or reduce) the AT problem. See Table-12 in appendix for ablation study results.

5 Experiment Setup

We investigate Meta-X$_{\text{NLG}}$'s performance on two NLG tasks, five datasets and 30 languages. mT5 pre-trained model is used as the base model. The model performance is compared with two strong baselines in zero-shot setting.

5.1 Tasks and Datasets

5.1.1 Abstractive Text Summarization (ATS):

ATS is the task of *generating grammatically coherent, semantically correct and abstractive summary given an input document*. We use two publicly available datasets: XL-Sum (Hasan et al., 2021) and Wikilingua (Ladhak et al., 2020).

XL-Sum is a large comprehensive dataset where article-summary pairs are extracted from BBC and annotated by professional annotators. It covers 44 languages including very low-resource languages like Nepali and Swahili. Due to computational limitation, we consider only 23 languages.

Wikilingua is a large-scale dataset covering 18 languages. Article and summary pairs are extracted from WikiHow[3]. It is *how-to guides* on diverse topics written by human annotators. We consider all 18 languages in our experiments.

5.1.2 Question Generation (QG):

In QG, *given an input passage and an answer, it aims to generate semantically and syntactically*

---

[3] `https://www.wikihow.com/`

correct questions that can produce the answer. We use three publicly available multilingual question and answering (QA) datasets: MLQA (Lewis et al., 2020b), TyDiQA (Clark et al., 2020) and XQuAD (Artetxe et al., 2020). Each instance is triplet of <passage, question, answer>. We concatenated *answer* and *passage* with delimiter *</s>* in same order as input for models.

MLQA is a multi-way parallel extractive QA evaluation dataset available in 7 languages. Authors automatically extracted paragraphs from Wikipedia articles in multiple languages which have same or similar meaning. Authors crowd-source questions on English and translate into target languages by professional translators. As our frame-work is based on supervision transfer we only consider the evaluation data instance where input and target text languages are same. In this way we have 7 datasets for 7 languages.

XQuAD dataset is translated from the development set of SQuAD v1.1 (Rajpurkar et al., 2016) by professional human translators into 10 languages. Each languages has 1190 question-answer pairs. SQuAD is popular question answering dataset consisting of around 100k <passage, question, answer> triplets. We added additional Japanese language data set (Takahashi et al., 2019) which is created with similar goals and has same format.

TyDiQA is another QA dataset with 204K question-answer pairs in 11 typologically diverse languages. Unlike MLQA and XQuAD, it is directly collected in each language and does not involve any translation. We use, *TyDiQA-GoldP* datasets which is guaranteed to have extractive nature. We added Tamil as additional language that share same format and created with similar goals.

We use English data from XL-Sum and Wikilingua for English fine-tuning step while experimenting with respective dataset. MLQA, TyDiQA and XQuAD do not have any English training data. Following the trend (Lewis et al., 2020b; Clark et al., 2020) we use SQuAD v1.1 training data at English fine-tuning step.

For each dataset, we grouped the languages into three fixed clusters as per Table-1 and find the centroid language as described in Section-4.1. English is the high resource language and only used for supervised fine-tuning as described in section-4.2 so, it will not be part of any cluster. To make it more concrete, XQuAD dataset has 11 low-resource languages (excluding English), the centroid (Meta-training) languages are <tr,es,th> and non-centroid (Target) languages are <hi,ro,de,ar,vi,zh,ru,el>[4].

5.2 Baselines

Due to unavailability of prior zero-shot results for considered datasets, we design strong baselines based on recent model architectures.

- **EnZmT5:** Inspired from Maurya et al. (2021), we further train mT5 model with monolingual dataset in all 30 languages followed by task-specific English fine-tuning (similar to first three steps of Meta-X_{NLG} model proposed in section -4.2). Then it is directly evaluated on the target languages in zero-shot setting.
- **FTZmT5:** In this model we fine-tune EnZmT5 baseline on all centroid languages. This will ascertain that the improvement of Meta-X_{NLG} is not due to simply training on more datasets in different languages. This is close to the Lewis et al. (2020a)'s model but they use different dataset.

While training EnZmT5 and FTZmT5, we use all applicable precautions as suggested in sections-4.3 and grid search to find best hyper-parameters. We could not compare ZmBART performance with Meta-X_{NLG} as authors did not use officially released evaluation datasets[5].

5.3 Evaluation Metrics

Both automatic and manual evaluation metrics are used to ensure the quality of the generated text. Particularly, for automatic evaluation **ROUGE-L** (Lin, 2004) and **BLEU**[6] (Papineni et al., 2002) metrics are used for ATS and QG respectively. Similar to Chi et al. (2020b) we used three manual evaluation metrics: **Fluency** referring to *how fluent the generated text is*, **Relatedness** indicating *the degree of the input's context in the generated text* and **Correctness** measuring the *grammar and semantics of generated text*. It is often observed that NLG systems suffer from the problem of Hallucination (Nie et al., 2019); the *Relatedness* metric provides clarity in such situations. The *Correctness* metric is hard metric which considers both semantic and grammatical aspects of generated text.

We randomly sampled 50 generated examples for each <task, dataset, language> triplet based on

---

[4] see Table-11 for language distribution to the cluster for each dataset and Table-9 for datasets statistics

[5] for Wikilingua dataset, official splits are released recently.

[6] reported scores are `case − mix` BLEU-4 from modified sacreBLEU implementation, see appendix-A

qualified and available native language experts in Hindi, Telugu, Tamil and Bengali languages. In total, we selected six triplets for evaluation. To ensure the quality, each selected triplet is evaluated by two sets of annotators. We asked each annotator to rate the generated text on a scale of 1-5 (where 1 is very bad and 5 is very good) for the metrics mentioned above. We anonymously shared the generated text from two baselines and Meta-$\mathrm{X}_{\mathrm{XNLG}}$ to avoid any biased evaluation.

5.4 Implementation Details

We implemented Meta-$\mathrm{X}_{\mathrm{NLG}}$ using *higher* library[7]. SGD with learning rate (α) $1e-4$ is used as inner-loop optimizer and AdamW with learning rate (β) $1e-5$ is used as outer-loop optimizer. The inner iteration (m) value is 2 and meta-training batch size is 8. To partition the training batch into support set (S) and query set (Q), we experimented (S:Q) with [8:2, 7:3, 6:4, 5:5, 4:6] splits. The best results are obtained with equal partition, i.e., 5:5. We also experimented with [2, 5, 10, 15, 20, 25] training epochs. The best performance was observed at 10^{th} epoch. We use a standard mT5-small sequence-to-sequence Transformer architecture with 12 layers (each 16 heads). It has 1024 dimensions and approx 582M parameters. Additional layer-normalization with weight decay (0.1) was used with both the encoder and decoder. For input, the max sequence length is fixed to 512. We trained all the models on 1 Nvidia V100 GPU (32GB). Cross-entropy label smoothing is used as loss function. We use beam-search with beam size 4; max generation length is 100 for ATS (32 for QG) and min length is 1. To ensure the stated improvement on the MLQA dataset, we compute average BLEU scores across the best 5 checkpoints. We are unable to repeat such experiments for other datasets due to computational limits.

6 Results and Analysis

Automated evaluation results are shown in Table 3-6. Meta-$\mathrm{X}_{\mathrm{NLG}}$ consistently outperformed other two baselines on all five datasets and most of the languages. For the summarization task, among the 33 experiments (19 languages for XL-Sum and 14 for Wikilingua) Meta-$\mathrm{X}_{\mathrm{NLG}}$ gives best performance for 30 experiments. Wherever it loses out, it does so by small margin. We see that the performance gains for the Wikilingua are relatively smaller. This might be due to the nature of the Wikilingua dataset, we observe that the input documents are set of usage instructions for softwares/tools. For such data, many instructions need to be retained in the summary. This poses a challenge to all the models including Meta-$\mathrm{X}_{\mathrm{NLG}}$. Similar observations are made by Maurya et al. (2021).

For the question generation task, Meta-$\mathrm{X}_{\mathrm{NLG}}$ achieves better performance than others except for one experiment - Indonesian language for TyDiQA. For MLQA, improvements achieved by the proposed model are marginal (see Table-6). Upon close inspection, we notice that MLQA had small number of languages, and the centroid languages are very distinct, i.e. they have higher mean distance to other languages from same cluster as compared to the other datasets (see Table-11). This might be a possible reason for such performance.

The human evaluation scores for all the three metrics are shown in Table-7. The human evaluations (across both annotator sets) correlate with automatic evaluations. Similar to the automatic evaluation, Meta-$\mathrm{X}_{\mathrm{NLG}}$ consistently outperformed both baselines for selected languages, tasks and datasets. High *Fluency* and *Relatedness* scores for Meta-$\mathrm{X}_{\mathrm{NLG}}$ indicates that most of generated text are fluent and not hallucinated respectively. The correctness metric considers both semantic and grammatical aspects; good scores on this metric indicate the acceptable performance for the proposed model in zero-shot setting. In QG, generating well-formed interrogative sentences is challenging, particularly in zero-shot setting due to unseen interrogative syntax structure of target language (Mitra et al., 2021; Maurya et al., 2021). The above-average fluency and correctness score for Meta-$\mathrm{X}_{\mathrm{NLG}}$ indicates that the model quickly adapts such syntax and performs better.

The consistent improvement in Meta-$\mathrm{X}_{\mathrm{NLG}}$ for most the typologically diverse target languages provides evidence that supervision transfer is more uniform. Considering decent automatic and manual evaluation scores in the zero-shot setting, we conclude that our model performs reasonably well except small performance gain with the MLQA dataset. Meta-$\mathrm{X}_{\mathrm{NLG}}$ is a zero-shot framework, and we do not assume any prior training/knowledge for new unseen LRL. The only constraints are: the new language should be part of base pre-trained models (mT5) and adaptive unsupervised pre-training

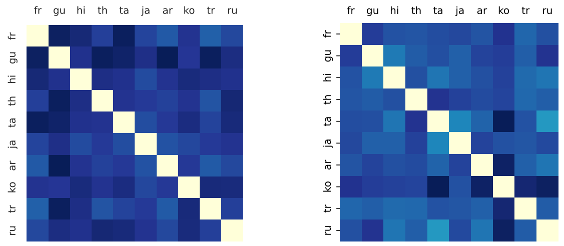
Results are shown for two annotation sets which ensure biased free evaluation. Reported scores are average of all the annotators in a annotator set.

(uses task-agnostic monolingual data only). Hence, adding new languages in Meta-X$_{\text{NLG}}$ is a simple extension exercise.

6.1 Cross-lingual Transfer:

To have a more general view of the model's learning of multiple languages, we perform similarity analysis among representations of the language tags (contextual representation of the <*fxx*> <*2xx*> tokens from the beginning of the input in language *xx*). 10 languages are randomly selected from XL-Sum dataset. Each language input is passed through the encoder part of the models (EnZmT5 and Meta-X$_{\text{NLG}}$) and language tag representations (LTRs) are extracted. Cosine distance among LTRs is shown in figure-2. Baseline EnZmT5 has a high cosine distance between LTRs and the shared latent representation space is not much aligned. Meta-X$_{\text{NLG}}$ has lower distances and shared latent representation space is more aligned across languages.



(a) Baseline (b) Meta-X$_{\text{NLG}}$

Figure 2: Cosine distance between language tags obtained from EnZmT5 and Meta-X$_{\text{NLG}}$ for 10 languges from XL-Sum dataset. Dark color indicate higher cosine distance.

6.2 Effect of Training Languages:

Table-8 shows the results with different language combinations for Meta-X$_{\text{NLG}}$ training on XQuAD dataset. For this dataset, the centroid languages are Turkish (tr), Spanish (es) and Thai (th). Results are generally good when centroid languages are in the training set. Best results are obtained using three centroid languages from three clusters. The performance dropped when we included more centroid languages (rows 12-15). As discussed in section-4.1, learning gets distracted with many centroid languages.

We now try to have a closer look at the numbers. While training with non-centroid languages (rows 4, 8, 9), the model performs poorly, which validates the importance of centroid languages. Another example is *Turkish* and *Hindi* languages share same cluster, in row 5 we did not include *Turkish* as centroid language which obtains poor performance on *Hindi*. Similar observations can be made for row-6. Overall, Meta-X$_{\text{NLG}}$ trained with three centroid languages (row 14) performs best on most of the languages and on average. We conducted more extensive ablation study with XL-Sum dataset (see Table-13 in Appendix) and similar trends are observed.

Table 8: Meta-X$_{\text{NLG}}$ zero-shot results on different training languages combinations of the XQuAD dataset. '-' indicates the language used in training, so scores are not zero-shot and not included.

7 Conclusion

In this work, we propose a novel Meta-X$_{\text{NLG}}$ framework based on meta-learning and language clustering for effective cross-lingual transfer and generation. This is the first study that uses meta-learning for zero-shot cross-lingual transfer and generation. The evaluations are done on two challenging tasks (ATS and QG), five publicly available datasets and 30 languages. Consistent improvement for both human and automatic evaluation metrics is observed over baselines. The cross-lingual transfer analysis indicates the model's ability towards uniform cross-lingual transfer across multiple low-resource languages. We will extend this study to more cross-lingual tasks and languages in the future.

Acknowledgments

We thank all the human annotators for human evaluation and the anonymous reviewers for their constructive feedback.

Appendices

A Evaluation Metric Setting

We use the multilingual version of ROUGE released by Hasan et al. (2021) where they use language-specific tokenizers and stemmers. Inspired by this, we also added the language-specific tokenizer in sacreBLEU implementation to compute BLEU Score.

B Miscellaneous

1. To the best of our knowledge, this is the first study towards meta-learning for the cross-lingual generation. The recent publications of applied meta-learning in NLP are listed here: `https://jeffeuxmartin.github.io/meta-learning-hlp/` and `https://github.com/ha-lins/MetaLearning4NLP-Papers` (accessed on 15th March, 2022)

2. In the proposed framework the data instance tag is <fxx><2xx>, where <fxx> is tag for input document language and <*2xx*> for target language for example: <fen> <2en>. In this work, the input and target document languages are the same. The tag will be easily adapted in the future, where input and target document languages are different. For example, the tag <*fen*> <*2fr*> indicates that the input document language is English (en) and target document language is French (fr).

3. We are aware that, recently adapter modules (Houlsby et al., 2019) have emerged as alternate solution for catastrophic forgetting problem. In future, we will compare Meta-X_{NLG} performance with Meta-X_{NLG} + adapters model.

4. The additional Tamil language in TyDiQA is taken from Kaggle[8]

Table 10: Size of centroid languages validation set used in the proposed Meta-X$_{\text{NLG}}$ framework. The same number of examples are sampled from each centroid language.

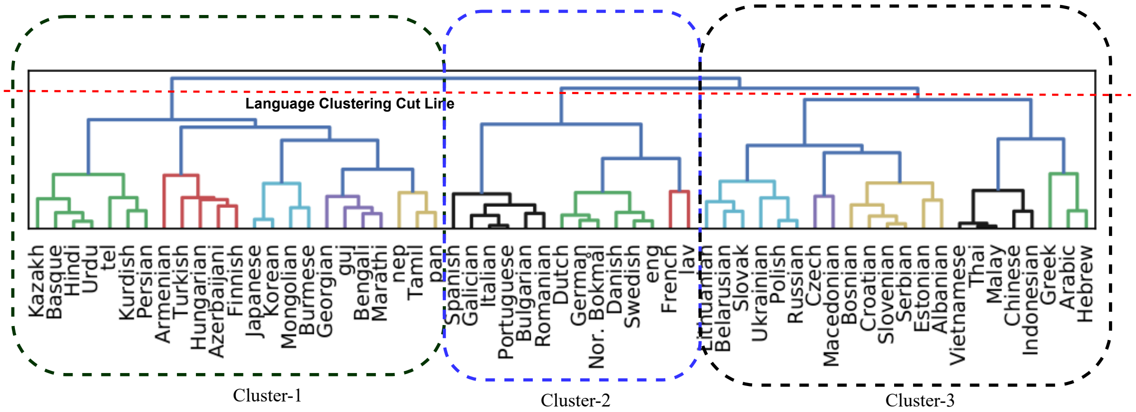

Figure 3: Language clustering based on multi-view representation proposed by Oncevay et al. (2020). We intentionally show more than 30 languages in the clustering, which will be useful for scaling the proposed work in the future. As per our application need, we added multiple languages in clustering over originally proposed by the authors. Additional languages are: Telugu (tel), Gujarati (guj), Nepali (nep), Punjabi (pan), English (eng).

Table 11: Details of language clustering for each dataset, mean cosine distance (meanCD), and centroid languages. For each dataset, we group languages into three clusters as shown in Figure 1. The Swahili language does not have any typological or task-based representations, so we added it to cluster 1 based on language typological features and heuristics. For the TyDiQA dataset, only two clusters are obtained as cluster-2 does not have any language. If a cluster has only two languages, we randomly selected any language as centroid language.

randSum Objective followed by EngFT (Maurya et al., 2021)	33.38	11.57	26.00	24.31	07.11	19.91	16.23	04.32	14.66
T5 PTObj followed by EngFT (proposed)	34.15	11.99	26.59	26.75	08.39	22.24	18.63	05.71	16.12

Table 12: Results with different adaptive pre-training objectives. mT5 is a base pre-trained model for above all experimental setups. T5 PTObj is the T5 model's pre-training objective proposed by Raffel et al. (2020). EngFT is English fine-tuning of base/adaptive pre-trained model. The results are shown on selected languages with XL-Sum dataset in standard supervised fine-tuning (English) and zero-shot setting (Hindi and Bengali). Proposed adaptive pre-training outperforms existing approaches for zero shot transfer.

Table 13: Meta-X$_{\text{NLG}}$'s zero-shot evaluation scores (Rouge-L) with different meta-training language combinations on the XL-Sum dataset. We cut the hierarchical clustering dendogram shown in Figure 3, at the lower level to obtain more clusters. In total, we obtain eight centroid languages, i.e., pa, es, vi, tr, ja, mr, fr and ru. '-' indicates the language used in training, so scores are not zero-shot and not included. Markers '*', '**', and '@' indicate meta training with all-centroid, all-non-centroid, and mix of both (centroid & non-centroid) languages.

Input Document: ভারতের অন্য অঞ্চলেও কোক, পেপসি নিষিদ্ধ করার দাবি জানাচ্ছেন কর্মীরা। স্থানীয় পণ্যের ব্যবহার নিশ্চিত করার জন্যই এই উদ্যোগ গ্রহণ করেছে ব্যবসায়ীরা। রাজ্যের শীর্ষ দুটি ব্যবসায়ী এসোসিয়েশন এই দুটি পানীয় নিষিদ্ধ করার প্রস্তাব করেছিল। তারই প্রেক্ষাপটে আজ বুধবার থেকে তামিলনাড়ু রাজ্যে নিষিদ্ধ হলো কোকা-কোলা ও পেপসি। প্রতিষ্ঠানগুলো বলছে, কোমল পানীয়ের প্রতিষ্ঠানগুলো নদী থেকে প্রচুর পানি ব্যবহার করে, সেকারণে কৃষকদের জমি সেচের সময়ও ব্যাপক ভোগান্তিতে পড়তে হয়। বিশেষ করে খরার সময় সেচে পানি সমস্যা প্রকট হয়ে দাঁড়ায়। রাজ্যের দশ লাখেরও বেশি দোকানদার এ নিষেধাজ্ঞা মেনে চলবে বলে ধারণা করা হচ্ছে। গত মাসে তামিলনাড়ুতে 'জাল্লিকাটু' নামে ঐতিহ্যবাহী ষাঁড়ের লড়াই নিষিদ্ধের বিরুদ্ধে ব্যাপক বিক্ষোভের ঘটনা দেখে রাজ্যে পেপসি, কোকা-কোলা নিষিদ্ধের প্রস্তাব করে শীর্ষ দুটি ব্যবসায়ী সংগঠন ফেডারেশন অব তামিলনাড়ু ট্রেডার্স এসোসিয়েশন (এফটিএনটিএ) এবং তামিলনাড়ু ট্রেডার্স এসোসিয়েশন। বিক্ষোভের সময় অনেকে বলছিলেন 'জাল্লিকাটু' নিষিদ্ধ করা মানে স্থানীয় ঐতিহ্য ও সংস্কৃতিকে অবমাননা করা। \"আমরা কয়েক মাস আগে কোমল পানীয়ের বিরুদ্ধে আমাদের প্রচারণা শুরু করি, কিন্তু যখন আমরা 'জাল্লিকাটু' নিষিদ্ধের প্রতিবাদে বিক্ষোভ শুরু করি, কোমল পানীয়ের বিরুদ্ধে আমাদের প্রচারণাও ভিন্ন রূপ পায়\"- বিবিসি তামিল সার্ভিসকে দেয়া এক সাক্ষাৎকারে বলছিলেন এফটিএনটিএ'র প্রেসিডেন্ট থা ভেলায়ান। \"পেপসি"

Human: ভারতের দক্ষিণাঞ্চলীয় রাজ্য তামিলনাড়ুর ব্যবসায়ীরা সেখানে কোকা-কোলা ও পেপসি বিক্রি নিষিদ্ধ ঘোষণা করেছে।

Meta-X$_{NLG}$: ভারতের তামিলনাড়ু রাজ্যে কোমল পানীয় নিষিদ্ধ করার দাবি জানিয়েছে ব্যবসায়ীরা।

Hindi-Wikilingua

Input Document: ठंडे पानी से धोते हुए दाग को कुछ हल्का करने की कोशिश करें। ठंडे पानी और एक टॉवल की मदद से धब्बे को गीला कर लें। या फिर, दाग को ठंडे पानी के नीचे भी लगाया जा सकता है। पेस्ट बनाने के लिए एक भाग ठंडा पानी और दो भाग नमक को मिलाएँ। आपको कितने नमक और पानी की जरूरत पड़ने वाली है, ये तो पूरी तरह से उस धब्बे के आकार पर निर्भर करेगा। नमक के साथ में बहुत ज्यादा पानी भी न मिलाएँ, नहीं तो ये लिक्विड बन जाएगा। पेस्ट फैलाने लायक गाढ़ा होना चाहिए। आप चाहें तो पेस्ट को दाग पर लगाने के लिए अपने हाँथ का या एक साफ कपड़े का यूज भी कर सकते हैं। पेस्ट को बहुत आराम से धब्बे के ऊपर रगड़ लें। अब आपको वो दाग हल्का होता हुआ नजर आना चाहिए। जैसे ही, ज़्यादातर या पूरा धब्बा निकल आए, कपड़े को ठंडे पानी के नीचे लगा दें। पेस्ट के पूरे साफ होने तक इसे धोते रहें। अगर दाग अभी तक पूरा नहीं निकल पाया है, तो पेस्ट को फिर से लगा दें। उस कपड़े को धोने के लिए भी उसी साबुन का यूज करें, जिसे आप नॉर्मली यूज किया करते हैं। हालाँकि, कपड़े को धोने के लिए ठंडे पानी के अलावा और किसी चीज़ का यूज बिल्कुल न करें। कपड़े को धो लेने के बाद, इसे हवा में सूखने के लिए लटका दें।

Human: दाग को ठंडे पानी से धो लें: नमक और पानी से एक पेस्ट तैयार करना: पेस्ट को धब्बे पर लगा लें: कपड़े को ठंडे पानी में धो लें: नॉर्मल जैसे ही धो लें:.

Meta-X$_{NLG}$: धब्बे को ठंडे पानी से धोने के लिए एक टॉवल का यूज कर लें। नमक और पानी का घोल बनाये। धब्बे को घोल से धोये; ठंडे पानी से धोये।

Abstract

Non-autoregressive translation (NAT) predicts all the target tokens in parallel and significantly speeds up the inference process. The Conditional Masked Language Model (CMLM) is a strong baseline of NAT. It decodes with the Mask-Predict algorithm which iteratively refines the output. Most works about CMLM focus on the model structure and the training objective. However, the decoding algorithm is equally important. We propose a simple, effective, and easy-to-implement decoding algorithm that we call MaskRepeat-Predict (MR-P). The MR-P algorithm gives higher priority to consecutive repeated tokens when selecting tokens to mask for the next iteration and stops the iteration after target tokens converge. We conduct extensive experiments on six translation directions with varying data sizes. The results show that MR-P significantly improves the performance with the same model parameters. Specifically, we achieve a BLEU increase of 1.39 points in the WMT'14 En-De translation task. Our code is available at `https://github.com/chynphh/MaskRepeat-Predict`.

1 Introduction

The autoregressive neural machine translation (AT) model based on encoder-decoder framework (Sutskever et al., 2014) has achieved great success (Bahdanau et al., 2015; Wu et al., 2016; Vaswani et al., 2017). The decoder predicts target tokens step by step conditioned on source tokens and previously predicted tokens. Such dependency between target tokens inevitably leads to the decoding latency. Non-autoregressive neural machine translation (NAT) models (Gu et al., 2018; Ghazvininejad et al., 2019) remove the dependency between tokens in the target sentence and generate all tokens in parallel, significantly improving the inference speed.

The assumption of conditional independence in target tokens makes it more difficult for NAT models to learn the target distribution. NAT models' translation is often incomplete or repetitive, especially for long sentences. An approach for alleviating this problem is to iteratively refine the model output and make a trade-off between inference speed and model performance (Lee et al., 2018; Ghazvininejad et al., 2019; Kasai et al., 2020). Many refinement-based models are based on CMLM (Ghazvininejad et al., 2019) and use the Mask-Predict (M-P) (Ghazvininejad et al., 2019) algorithm for decoding. Most works attempt to improve the model from the model structure and the training method.

In this work, we propose a novel decoding algorithm for refinement-based models that we call MaskRepeat-Predict (MR-P). Our algorithm prefers the consecutive repeated tokens when selecting tokens to mask. And the iteration will stop in advance when the target sentence converges, which reduces the number of iterations and avoid over-refinement.We verify the effectiveness of MR-P in six translation directions of three standard datasets with varying data sizes. Under the same model parameters, the model's performance is significantly improved using the MR-P decoding algorithm.

The main contributions of this work are as follows:

- We devise a new decoding algorithm that is simple, effective, and easy-to-implement. The algorithm can achieve a consistent improvement and a lower perplexity on the six translation tasks.
- The algorithm can reduce the average iteration numbers and accelerate the overall translation speed when using a large maximum number of iterations.
- The algorithm is model-agnostic and can be used as long as the conditional masked language model is used for training.

Findings of the Association for Computational Linguistics: ACL 2022, pages 285 - 296

Iteration	1	2	3	4	10
Short	2.23	0.72	0.35	0.23	0.06
Long	11.83	4.33	1.84	1.11	0.27
All	6.59	2.36	1.03	0.63	0.15

Table 1: The average number of consecutive repeated tokens per sentence with different iterations on the WMT14' De-En test set. We divide all samples into Short and Long according to whether the sentence length is less than 25.

2 Methodology

The Mask-Predict algorithm selects tokens according to the generation probabilities. There is a problem with this strategy. When the probabilities of consecutive repeated tokens are high, they will not be selected and remain in the results.

As can be seen from Table 1, there are many consecutive repeated tokens in the results of the Mask-Predict algorithm, especially in long sentences. So it is necessary to mask the consecutive repeated tokens and re-predict them. Consecutive repeated short phrases occur infrequently, so only consecutive repeated tokens are considered.

2.1 MaskRepeat-Predict

We introduce the **MaskRepeat-Predict** algorithm, a convenient and effective decoding algorithm based on Mask-Predict. In each iteration, the algorithm preferentially selects consecutive repeated tokens, retains the token with the highest confidence among them, and masks the other tokens. Secondly, the lower confidence tokens are selected to mask from other positions. It should be noted that if the target sentence converges, the iteration will be stopped early.

Formal Description The algorithm runs T iterations at most. Let $\mathbf{y}^t = \{y_1^t, ..., y_{M_y}^t\}$ represent the tokens generated in the iteration t, M_y denote the length of the target sentence, and the probability of each token correspond to $\mathbf{p}^t = \{p_1^t, ..., p_{M_y}^t\}$. Let $\mathbf{y}_k^t = \{y_{k_i}^t, i = 1, ..., M_{y_k}\}$ and $\mathbf{p}_k^t = \{p_{k_i}^t, i = 1, ..., M_{y_k}\}$ indicate the k-th group of consecutive repeated tokens and corresponding probabilities generated in the iteration t, which means that positions k_i and k_{i+1} should be actually consecutive and all the tokens in $\mathbf{y}_k^t$ are the same. M_{y_k} means the length of the k-th group of consecutive repeated tokens. $n_t = M_y \cdot \frac{T-(t-1)}{T}$ denotes the number of masked tokens in the t-th iteration.

MaskRepeat For the first iteration, we mask all the tokens. For later iterations, we mask consecutive repeated tokens firstly. For each set of consecutive repeated tokens, we reserve the token $y_{k_i}^{t-1}$ with the highest probability. All the reserved tokens constitute $\mathbf{y}_{top_r}^t$:

$$\mathbf{y}_{top_r}^t = \bigcup_k^K \left\{ y_{k_i}^{t-1} \mid k_i = \arg\max_i \left\{ p_{k_i}^{t-1} \right\} \right\}, \quad (1)$$

where K denotes the number of consecutive repeated tokens groups. All other repeated tokens $\mathbf{y}_{mask_r}^t$ are masked:

$$\mathbf{y}_{mask_r}^t = \bigcup_k^K \{\mathbf{y}_k^{t-1}\} \backslash \mathbf{y}_{top_r}^t, \quad (2)$$

Next, we mask the tokens with lower probabilities in the whole sentence:

$$\mathbf{y}_{mask_p}^t = \{y_i^{t-1} \mid p_i^t \in \operatorname{topk}(-\mathbf{p}^t, k = m), i\}, \quad (3)$$

where $m = \max\{n_t - |\mathbf{y}_{mask_r}^t|, 0\}$. Then we have

$$\mathbf{y}_{mask}^t = \mathbf{y}_{mask_p}^t \cup \mathbf{y}_{mask_r}^t, \quad (4)$$

$$\mathbf{y}_{obs}^t = \mathbf{y}^{t-1} \backslash \mathbf{y}_{mask}^t. \quad (5)$$

Predict The prediction process is the same as Mask-Predict. The model predicts the masked tokens $\mathbf{y}_{mask}^t$ conditioned on the source tokens $\mathbf{x}$ and the observed tokens $\mathbf{y}_{obs}^t$. The token with the highest probability at each masked position is selected to update prediction tokens, and the probabilities are updated accordingly. For $y_i^{t-1} \in \mathbf{y}_{mask}^t$,

$$\begin{aligned} y_i^t &= \arg\max_w P\left(y_i = w \mid \mathbf{x}, \mathbf{y}_{obs}^t\right), \\ p_i^t &= \max_w P\left(y_i = w \mid \mathbf{x}, \mathbf{y}_{obs}^t\right). \end{aligned}$$

Unmasked positions retain the same probability value as the previous iteration. For $y_i^{t-1} \in \mathbf{y}_{obs}^t$,

$$\begin{aligned} y_i^t &= y_i^{t-1}, \\ p_i^t &= p_i^{t-1}. \end{aligned}$$

Early Stop The iteration will be stopped early if the target sentence converges:

$$\mathbf{y}^t = \mathbf{y}^{t-1}.$$

In particular, we set $\mathbf{y}_{obs}^0 = \{\texttt{Mask}, ..., \texttt{Mask}\}$ to predict $\mathbf{y}^0$. We use the Mask-Predict algorithm when $t < \lfloor T/2 \rfloor$. See Alg. 1 in Appendix A for a full pseudo-code.

Figure 1: An example from the WMT'14 De-En test set illustrates how MaskRepeat-Predict (MR-P) and Mask-Predict (M-P) generate text with three iterations. The numbers below tokens represent their probabilities. The highlighted tokens are masked for the next iteration and re-predicted.

Example Figure 1 shows an example from the WMT'14 De-En test set when CMLM uses Mask-Predict and MaskRepeat-Predict to decode with three iterations. At the end of the second iteration (iter $= 1$), Mask-Predict selects nine tokens with lower confidence to mask. It can be seen that there are four consecutive `schools` with higher probabilities in the result, so they are not masked and re-predicted. However, these words should be chosen for re-prediction, regardless of their probability. The MaskRepeat-Predict algorithm starts to mask the consecutive repeated tokens in the middle of iterations. As we can see, in the second iteration, the repeated tokens `school` and `wall` that have low probabilities are masked instead of other unique tokens with lower probabilities. The result at the end of iterations also has higher quality.

For consecutive repeated tokens and corresponding probabilities, we take the sentence of the second iteration (iter $= 1$) in Figure 1 as an example:

$$\mathbf{y}_1^1 = \{\texttt{wall}, \texttt{wall}\},$$
$$\mathbf{p}_1^1 = \{0.652, 0.817\};$$
$$\mathbf{y}_2^1 = \{\texttt{school}, \texttt{school}, \texttt{school}, \texttt{school}\},$$
$$\mathbf{p}_2^1 = \{0.815, 0.811, 0.645, 0.681\}.$$

3 Experiments

3.1 Experimental Settings

We evaluate our algorithms on six directions from three standard datasets with various training data sizes: WMT'16 En-Ro (610K pairs), WMT'14 En-De (4.5M pairs), WMT'17 En-Zh (20M pairs). For a fair comparison, we used the distillation data provided by Kasai et al. (2020), and all data processing methods and hyperparameters settings are the same. Please see Appendix C for details. Our code is based on `CMLM`[1] and `DisCo`[2].

3.2 Overall Results

Table 2 shows the results on WMT'14 En-De and WMT'16 En-Ro test sets with CMLM and DisCo. We use pre-trained DisCo models provided by original authors (Kasai et al., 2020) for testing the decoding algorithm. CMLM models are implemented by ourselves. It can be seen that the results with MR-P have a different range of improvements compared to the ones with M-P for different iterations. The fewer iterations, the more obvious the pronounced performance improvement. Especially when only iterating two steps, the result on the WMT'14 En-De test set is improved by 1.39 BLEU points. Even with the ten iterations, there is an improvement of 0.39 BLEU on the WMT'16 Ro-En test set. It is worth noting that this is only a change in the decoding algorithm, no changes have been made to the model, and even the decoding algorithm parameters are the same.

Table 3 shows the results with CMLM on the WMT'17 En-Zh test set. Pre-trained models are provided by original authors (Ghazvininejad et al., 2019). There is a gain of 1.26 BLEU improvement

over M-P on Zh-En with two iterations.

Tables 9 in Appendix show more details for CMLM, DisCo, and CCAN (Ding et al., 2020).

3.3 Analysis

Iteration Numbers The MR-P algorithm will stop the iteration when the target sentence converges, so sometimes it will not reach the maximum number of iterations. As shown in Table 4, we can see that the average number of iterations is significantly reduced when the maximum number of iterations is relatively large.

Perplexity We make a more in-depth comparison from the Perplexity(PPL). We use pre-trained GPT-2 (Radford et al., 2019) provided by Hugging-Face (Wolf et al., 2020) as our language model. As we can see in Table 5, the perplexity is significantly reduced when using MR-P instead of M-P, which means that sentences generated using MR-P are more reasonable.

Remove Duplicates The problem of repeated translation can also be alleviated simply by removing all consecutive duplicated tokens in translation results. Table 6 shows the BLEU of CMLM on the WMT'14 En-De test set. Remove Duplicates(RD) can improve performance, but is not as good as using MR-P. A possible reason is that MR-P can

MaxIter.	2	3	4	10
M-P	23.97	25.99	26.58	27.26
+RD	24.53	26.29	26.77	27.30
MR-P	25.10	26.43	26.78	27.42
+RD	25.34	26.62	26.84	27.41

Table 6: The performance of whether uses RD or not.

MaxIter.	2	3	4	10
Short	0.35	0.19	0.11	0.03
Long	1.45	0.91	0.44	0.11
All	0.85	0.52	0.26	0.07

Table 7: The average number of consecutive repeated tokens per sentence on WMT'14 De-En test of MR-P.

affect the generation process, while RD cannot. It is worth noting that RD can also improve the performance of MR-P when the maximum number of iterations is relatively small.

Consecutive Repeated Translation We compute the average number of consecutive repeated tokens per sentence on the WMT14' De-En test set. The result is shown in Table 7 and Table 1. The MR-P algorithm benefits from its inherent principle and can significantly reduce the repetition rate. Especially when iterating only two steps, the repetition rate is reduced from 2.36 to 0.85.

Different Source Lengths We split the source sentences into different length buckets to analyze the effect of source input length. Figure 2 shows the BLEU of CMLM with two iterations at most on the WMT'14 En-De test set. The longer the source sentences are, the more considerable the margin between MR-P and M-P is.

4 Conclusion

In this paper, we have proposed the MR-P decoding algorithm. MR-P prefers to mask consecutive repeated tokens and stops the iteration early when target tokens converge. The experiments on different models and datasets have shown that MR-P is effective and model-agnostic. The algorithm can achieve a consistent improvement and a lower perplexity on the six translation tasks.

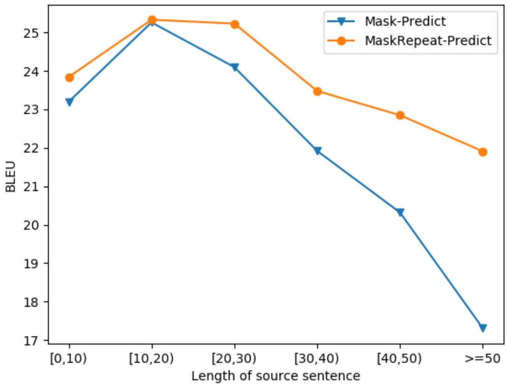

Figure 2: The BLEU points on the test set of WMT'14 En-De over sentences in different length buckets.

A Algorithm

Algorithm 1: MaskRepeat-Predict

```
Input: Source sentence: $\mathbf{x}$
Predict target length: $M_y$;
Compute $\mathbf{y}^0$ use $\mathbf{y}^0_{obs}$;
for $t \in 1, ..., T-1$ do
    if $t < \lfloor T/2 \rfloor$ then
        set $\mathbf{y}^t_{mask_r} = \emptyset$;
        compute $\mathbf{y}^t_{mask_p}$ by (3);
        compute $\mathbf{y}^t_{mask}$ by (4);
    else
        compute $\mathbf{y}^t_{top_r}$ by (1);
        compute $\mathbf{y}^t_{mask_r}$ by (2);
        compute $\mathbf{y}^t_{mask_p}$ by (3);
        compute $\mathbf{y}^t_{mask}$ by (4);
    end
    compute $\mathbf{y}^t_{obs}$ by (5);
    predict $\mathbf{y}^t$;
    if $\mathbf{y}^t = \mathbf{y}^{t-1}$ then
        return $\mathbf{y}^t$;
    end
end
return $\mathbf{y}^{T-1}$
```

B Examples

Figure 3 shows an additional example from the WMT'14 De-En test set of CMLM with different decoding algorithm.

Figure 3: An example from the WMT'14 De-En test set illustrates how MaskRepeat-Predict (MR-P) and Mask-Predict (M-P) generate text with three iterations.

C Experimental Settings

Datasets We evaluate our inference algorithms on six directions from three standard datasets with various training data sizes: WMT'16 En-Ro (610K pairs), WMT'14 En-De (4.5M pairs), WMT'17 En-Zh (20M pairs). All datasets are tokenized into subword units by BPE (Sennrich et al., 2016). Specially, use joint BPE on WMT'16 En-Ro and WMT'14 En-De. We use the same preprocessed data as Kasai et al. (2020) for a fair comparions with other models (WMT'16 En-Ro: Lee et al. (2018); WMT'14 En-De: Vaswani et al. (2017)). We evaluate performance with BLEU (Papineni et al., 2002) for all language pairs except that using SacreBLEU (Post, 2018)[3] for pair from En to Zh.

Hyperparameters We follow the hyperparameters for a transformer base (Vaswani et al., 2017; Ghazvininejad et al., 2019; Kasai et al., 2020): 6 layers for the encoder and the decoder, 8 attention heads, 512 model dimensions, and 2048 hidden dimensions per layer. We sample weights from $\mathcal{N}(0, 0.02)$, initialize biases to zero and set layer normalization parameters to $\beta = 0$, $\gamma = 1$, following the weight initialization scheme from BERT (Devlin et al., 2019). Set dropout rate to 0.3, and apply weight decay with 0.01 and label smoothing with $\epsilon = 0.1$ for regularization. We train batches of approximately $16K \cdot 8$ (8 GPUs with 16K per GPU) tokens using Adam (Diederik and Jimmy, 2014) with $\beta = (0.9, 0.999)$ and $\epsilon = 10^{-6}$. The learning rate warms up to $5 \cdot 10^{-4}$ for the first 10K steps, and the decays with the inverse square-root schedule. We train models for 300K steps with mixed precision floating point arithmetic (Micikevicius et al., 2018) on 8 TITAN RTX GPUs, and average the 5 best checkpoints as the final model. Following the previous works (Ghazvininejad et al., 2019; Kasai et al., 2020), we apply length beam with the size of 5.

D Experiments

Seen in Table 8 are the results of strong non-autoregressive machine translation models similar with CMLM on the WMT'14 En-De and WMT'16 En-Ro test set. Basic models that use the MaskRepeat-Predict decoding algorithm can achieve comparable results with other advanced models. It is worth noting that the models such as Imputer, LAT, SMART, JM-NAT, and ENGINE all employ the Mask-Predict decoding algorithm, which means that they can also use the MaskRepeat-Predict decoding algorithm.

Models	En-De	De-En	En-Ro	Ro-En
Imputer	28.20	31.80	34.40	34.10
LAT	27.35	32.04	32.87	33.26
SMART	27.65	31.27	-	-
JM-NAT	27.69	32.24	33.52	33.72
ENGINE	-	-	-	34.04
CMLM	27.03	30.53	33.08	33.31
DisCo	27.34	31.31	33.22	33.25
CCAN	27.50	-	-	33.70
+MR-P				
CMLM	27.42	31.34	33.41	34.14
CCAN	27.47	31.36	33.50	33.84

Table 8: The performance of non-autoregressive machine translation methods on the WMT'14 En-De and WMT'16 En-Ro test set.

Table 9 shows the average iteration number (AveIter.) and performance (BLEU) for Self-CMLM, Pre-trained-CMLM, DisCo, and CCAN. Our CMLM results are much better than the results reported in the original paper. The difference in the final BLEU points comes from batch size and averaging checkpoints with 5 top BLEU points on validation. These two techniques come from Kasai et al. (2020). Comparing self-implemented models and pre-trained models, we can conclude that the MaskRepeat-Predict algorithm still works after the model is enhanced.

Table 9: The performance (BLEU) of CMLM, DisCo and CCAN, with MaskRepeat-Predict (MR-P), compared to that with Mask-Predict (M-P). All Pre-trained-CMLM and DisCo models trained by the original authors (Ghazvininejad et al., 2019; Kasai et al., 2020) are used to decode without any change. Self-CMLM and CCAN are implemented by ourselves.

E Ablation Study

Strategies We compare several design strategies of MR-P. MR-P-W: MR-P without early stopping, that is, all the sentence is continually refined until the preset maximum number of iterations. MR-P-A: MR-P is used all the time, including when $t < \lfloor T/2 \rfloor$. MR-P-F: MR-P is used when $t < \lfloor T/2 \rfloor$ and M-P is used when $t \geq \lfloor T/2 \rfloor$. As shown in Table 10, we can see that most of the time, the results of the MR-P algorithm are optimal. There is a slight decline in performance without early stopping. We think this is because some sentences are over-refinement, misleading to the scoring of candidate sentences. Using M-P in the first half of iterations will lay a good foundation for the following iterations.

		En-De	De-En	En-Ro	Ro-En
MR-P -W	2	25.08	29.37	32.39	32.83
	3	26.30	30.40	33.01	33.37
	4	26.78	30.70	33.18	33.63
	10	27.29	31.06	33.53	33.89
MR-P -A	2	25.10	29.41	32.45	32.88
	3	26.42	30.65	33.08	33.57
	4	26.70	30.54	33.38	33.81
	10	27.28	31.25	33.45	34.01
MR-P -F	2	25.10	29.41	32.45	32.88
	3	26.24	30.61	32.96	33.42
	4	26.73	30.57	33.32	33.76
	10	27.29	31.21	33.49	34.03
MR-P	2	25.10	29.41	32.45	32.88
	3	26.43	30.46	33.17	33.55
	4	26.78	30.73	33.25	33.80
	10	27.42	31.34	33.41	34.16

Table 10: The performance of self-implemented CMLM with different design strategies of MR-P.

Expand to other algorithms The Easy-First (E-F) is a decoding algorithm proposed by Kasai et al. (2020) for the DisCo. The condition $\mathbf{y}_{obs}$ of each token is different. Each token can be refined conditioned on all other tokens with a lower probability than itself. The conditional dependence is determined by the probability generated in the first iteration and fixed for the following iterations. We can easily integrate the ideas of MaskRepeat into Easy-First. For repeated tokens that appear continuously, except for the token with the highest probability, the confidence is set to the lowest no matter how high their probability is. This means that consecutive repeated tokens do not become the context of any other token. Then one updates this consecutive repeated tokens part's order in the second iteration. We call that MaskRepeat-Easy-First(MR-E-F). As shown in Table 11, the performance is improved, especially in WMT'14 En-De with 0.16 BLEU points.

Alg.	En-De	De-En	Ro-En	Zh-En
E-F	27.35	31.31	33.24	23.83
MR-E-F	27.51	31.36	33.25	23.97

Table 11: The performance of DisCo (Kasai et al., 2020) decodes with Easy-First (E-F) and MaskRepeat-Easy-First (MR-E-F).

F Related Work

In order to speed up the translation process, Gu et al. (2018) introduced non-autoregressive translation for the first time. A lot of works based on iterative refinement are proposed to make a trade-off between performance and decoding speed (Lee et al., 2018; Ghazvininejad et al., 2019; Kasai et al., 2020; Guo et al., 2020b; Lee et al., 2020; Ghazvininejad et al., 2020b; Ding et al., 2020). Other approaches include improving training objectives (Libovický and Helcl, 2018; Shao et al., 2020; Ghazvininejad et al., 2020a; Saharia et al., 2020), enhancing the decoder input (Guo et al., 2019; Bao et al., 2019; Ran et al., 2019), adding regularization terms on the decoder (Wang et al., 2019; Li et al., 2019), latent variable-based model (Ma et al., 2019; Shu et al., 2020), adding a lite autoregressive module (Sun et al., 2019; Kong et al., 2020), learning or transforming from autoregressive model (Guo et al., 2020a; Sun and Yang, 2020; Tu et al., 2020; Liu et al., 2020), training with monolingual data (Zhou and Keung, 2020), and incorporating the pre-trained model (Guo et al., 2020c).

Open Relation Modeling: Learning to Define Relations between Entities

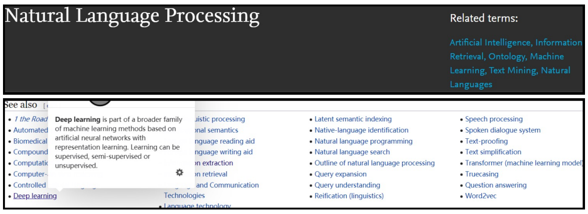
Abstract

Relations between entities can be represented by different instances, e.g., a sentence containing both entities or a fact in a Knowledge Graph (KG). However, these instances may not well capture the general relations between entities, may be difficult to understand by humans, even may not be found due to the incompleteness of the knowledge source. In this paper, we introduce the *Open Relation Modeling* problem–given two entities, generate a coherent sentence describing the relation between them. To solve this problem, we propose to teach machines to generate definition-like relation descriptions by letting them learn from defining entities. Specifically, we fine-tune Pre-trained Language Models (PLMs) to produce definitions conditioned on extracted entity pairs. To help PLMs reason between entities and provide additional relational knowledge to PLMs for open relation modeling, we incorporate reasoning paths in KGs and include a reasoning path selection mechanism. Experimental results show that our model can generate concise but informative relation descriptions that capture the representative characteristics of entities.[1]

1 Introduction

People are always interested in relations between entities. To learn about a new concept, people want to know how this concept relates to the ones they are familiar with; when getting two related entities of interest, people ask how exactly they are related.

However, although existing systems identify related entities, they do not provide features for exploring relations between entities. For instance, in Figure 1, the top is the *ScienceDirect Topics* feature of Elsevier, which lists several related terms without any annotation; the bottom is the "*see also*" feature of Wikipedia, where the annotation of *deep learning* is not specific to the context of *natural language processing*. Users cannot get how *deep learning* and *NLP* are related by reading the annotation, while *deep learning* is used heavily recently for *NLP*.



Deep learning is part of a broader family of machine learning methods based on artificial neural networks with representation learning. Learning can be supervised, semi-supervised or unsupervised.

Figure 1: Examples of two current services: *Elsevier's ScienceDirect Topics* (top) and *Wikipedia's "see also"* (bottom), both of which lack open relation modeling.

Besides, even relations are represented, they may not be interpretable to humans. There are different ways to represent relations between entities. For example, if two entities co-occur in a sentence, they are possibly related and the relation can be implied by the sentence. From a structured perspective, a relation can be represented as a fact or a multi-hop reasoning path between two entities in a Knowledge Graph (KG). However, for humans without too much prior knowledge about the entities, it is still difficult to understand the relations by reading them. For example, from sentence "*we study data mining and database.*" or fact "(data mining, *facet of*, database)", humans can guess *data mining* and *database* are related fields, but they cannot know exactly how they are related. Besides, due to the limited size of the corpus or the incompleteness of the KG, for many related entities, we may not extract a sentence or a fact containing both entities.

Based on the above observation, a system for exploring relations between entities needs to meet the following requirements: 1) **interpretability**: providing interpretable relation descriptions, with which humans can easily understand relations between entities; 2) **openness**: dealing with a wide range of related entities, including those neither co-occur in a corpus nor be connected in a knowledge

Findings of the Association for Computational Linguistics: ACL 2022, pages 297 - 308
May 22-27, 2022

graph, where types of relations are not required to be explicitly pre-specified.

To achieve a system meeting with the above requirements, we introduce a novel task– ***Open Relation Modeling***, i.e., generating coherent sentences describing general relations between entities, where types of relations do not need to be pre-specified. Different from open relation extraction, which aims to *extract* relational facts between entities from an open-domain corpus (Banko et al., 2007), open relation modeling aims to *generate* a concise but informative sentence, capturing the representative characteristics of the given entities and their relation. From the perspective of interpretability, compared to open relation extraction whose outputs are phrases with low interpretability, e.g., *(data mining methods, to be integrate within, the framework of traditional database systems)* by Ollie (Schmitz et al., 2012), open relation modeling improves the interpretability of entity relations. For example, for *data mining* and *database*, we want to generate a sentence like "data mining *is a process of extracting and discovering patterns in large data sets involving methods at the intersection of machine learning, statistics, and* database *systems*." Such a relation description is informative and easy to understand since it contains important and precise information about entities and their relation.

To solve the task, we propose to teach machines to learn from defining entities. Definitions of entities are highly summarized sentences that capture the most representative characteristics of entities, where the general relations between the defined entity and other entities in the definitions are well captured. Therefore, we suggest to ***find the general relation between two entities by defining one entity in terms of the other entity***. To achieve this, we first collect definitions of entities and extract entity pairs from the definitions. Then we teach machines to generate definition-like relation descriptions by training a language generation model to produce definitions of entities conditioned on extracted entity pairs.

To generate informative relation descriptions, machines need knowledge about entities and relations. Therefore, we apply Pre-trained Language Models (PLMs) (Radford et al., 2019; Brown et al., 2020; Lewis et al., 2020a; Raffel et al., 2020), which have recently been shown to contain rich relational knowledge of entities (Petroni et al., 2019; Roberts et al., 2020; Wang et al., 2020; Liu et al., 2021a). To utilize knowledge to describe relations between entities, machines also need to reason between entities. We incorporate reasoning paths in KGs to help PLMs do multi-hop reasoning and provide additional relational knowledge to PLMs. We also design a reasoning path selection mechanism by confidence estimation of PLMs to select interpretable and informative reasoning paths, which are then incorporated by PLMs for open relation modeling.

We conduct both quantitative and qualitative experiments. Experimental results show that, after learning from definitions of entities, PLMs have a great ability to describe relations between entities concisely and informatively. By incorporating reasoning paths and including the reasoning path selection mechanism, machines can often generate relation descriptions well capturing relations between entities, with only minor errors that do not affect the understanding of relations. We also conduct error analysis for the proposed methods and suggest several directions for future work.

2 Open Relation Modeling

2.1 Problem Statement

The problem of ***Open Relation Modeling*** can be described as: given two entities x and y, corresponding to *head* and *tail*, the task is to generate a coherent sentence s that describes the general relation between x and y, where types of relations do not need to be pre-specified. More specifically, the expected output is a concise but informative sentence that captures the representative characteristics of the entities and their relation (examples of *data mining* and *database* as shown in Section 1).

2.2 Open Relation Modeling: Learning from Definitions

We formulate open relation modeling as a conditional sentence generation task, i.e., generating sentences capturing general relations between entities conditioned on entity pairs. Formally, we apply the standard sequence-to-sequence formulation: given an entity pair (x, y), the probability of the output relation description $s = [w_1, \ldots, w_m]$ is calculated as:

$$P(s|x, y) = \prod_{i=1}^{m} P(w_i|w_0, w_1, \ldots, w_{i-1}, x, y),$$

where w_0 is a special start token.

To generate a sentence capturing the general relation between x and y, machines need to know the semantic meanings of x and y, reason between them, and learn to describe their relation in a concise but informative form. Definitions of entities, which are highly summarized (i.e., concise but informative) sentences, capture the most representative characteristics of entities. To define an entity, other entities may be included, and the relations between the defined entity and other entities are well captured.

Therefore, we propose to *teach machines to describe relations between entities by letting them learn from defining entities*. The key idea is to *find the general relation between two entities by defining one entity in terms of the other entity*. To achieve this, we first collect definitions of entities and extract entity pairs from these definitions to form entities-definition pairs (more details are in Section 3.1). After that, we teach machines to generate relation descriptions with the desired characteristics by training a language generation model to produce definitions of entities conditioned on extracted entity pairs.

With the key idea in mind, the next step is to design the generation model. Recently, Bevilacqua et al. (2020) show that, by fine-tuning with context-gloss pairs, pre-trained language generation models can generate the glosses/definitions for definiendums that are not seen in the training data. Besides, recent studies (Petroni et al., 2019; Wang et al., 2020; Liu et al., 2021a) demonstrate that pre-trained language models contain rich relational knowledge, and such relational knowledge is essential to describing relations between entities.

Therefore, we apply pre-trained language models for open relation modeling. Particularly, we employ BART (Lewis et al., 2020a)– a recent transformer-based encoder-decoder model. In our framework, we train BART to produce the definitions of entities with extracted entity pairs as input. Specifically, we encode the entity pair (x, y) as $x; y$, e.g., $Haste$; $Germany$, and fine-tune the model to generate the corresponding sentence s, e.g., "*Haste is a municipality in the district of Schaumburg, in Lower Saxony, Germany*". By fine-turning on the training data, the model can learn the knowledge about entities and learn to connect two entities in a coherent sentence based on its "knowledge". When given a new entity pair, the model can generate a definition-like relation description that possesses the desired characteristics. We refer to this model as **RelationBART-Vanilla**.

2.3 Reasoning Path-Enriched Relation Modeling

While PLMs can generate coherent relation descriptions with fine-tuning on the entities-definition pairs, their ability is still limited. Recent studies (Forbes et al., 2019; Zhou et al., 2020; Richardson and Sabharwal, 2020) show that it is difficult for PLMs to reason based on their knowledge. Besides, although PLMs contain rich relational knowledge implicitly, they cannot recover all the relational knowledge in a knowledge base.

Knowledge graphs, in contrast, contain rich relational knowledge explicitly. Relations between entities can be represented by reasoning paths extracted from KGs directly. A good reasoning path can guide PLMs to do multi-hop reasoning and provide additional relational knowledge to PLMs for open relation modeling.

Therefore, we want to inject relational knowledge of KGs into PLMs and incorporate reasoning paths to help PLMs reason between entities. We achieve this by a simple encoding scheme without changing the architecture of PLMs and re-pretraining. Given a knowledge graph G, for an entity pair (x, y), if there exists a reasoning path $p(x, y) = \{x, r_1, e_1, r_2, \ldots, r_k, y\}$ in G, we encode (x, y) as x*;* r_1*:* e_1*;* r_2*:* $\ldots$*;* r_k*:* y; if not, we encode (x, y) as x*; unknown:* y. With fine-tuning on the path-sentence pairs, the model can learn to utilize the relational knowledge in a reasoning path to reason between two entities and generate a coherent sentence describing the relation between them.

However, there may exist multiple reasoning paths between two entities in a KG, while not all reasoning paths are equally helpful. Among the reasoning paths between two entities, the shortest one usually indicates the most direct relation. For example, if two entities have a direct relation in a KG, the shortest reasoning path should be a 1-hop path $p(x, y) = \{x, r_1, y\}$. This path can represent a reasonable relation between two entities because this is the reason why the KG includes such a fact. Based on this observation, formally, given an entity pair (x, y), the selected reasoning path is

$$\hat{p}(x, y) = \underset{p(x,y) \in \mathcal{P}(x,y)}{\arg\min} \; len(p(x, y)),$$

where $\mathcal{P}(x, y)$ is the set of reasoning paths connecting x and y extracted from the KG and $len(\cdot)$

is the length of the reasoning path. We name the model trained with the shortest reasoning paths[2] as **RelationBART-SP**. To keep the presented model simple and easy to be verified, we leave the more complex mechanism of sampling reasoning paths as future work (Lao et al., 2011; Xiong et al., 2017; Chen et al., 2018). In the next section, we will show that PLMs can select interpretable and informative reasoning paths automatically based on confidence estimation.

2.4 Open Relation Modeling with Reasoning Path Selection

While shortest reasoning paths can represent the most direct relations between entities, from the perspective of human/machine understanding, these paths may not be the most interpretable and informative. For instance, given entity pair $(\textit{Haste}, \textit{Germany})$, with sentence description $s =$ "*Haste is a municipality in the district of Schaumburg, in Lower Saxony, Germany*", the shortest reasoning path in Wikidata KG is $p_1 = \{\textit{Haste}, \textit{country}, \textit{Germany}\}$. This reasoning path is not ***interpretable*** since we only know *Haste* is in *Germany*, but we have no idea whether *Haste* is a municipality or a district of *Germany*. However, from reasoning path $p_2 = \{$*Haste*, *located in the administrative territorial entity*, *Schaumburg*, *country*, *Germany*$\}$, we can know *Haste* is a smaller administrative region than *Schaumburg*–possibly a municipality. Besides, compared to p_1, p_2 is more ***informative***. With p_1, to generate s, machines need to "guess" the district of *Haste*. However, with p_2, machines can predict the district of *Haste* is *Schaumburg* with a high confidence.

A more interpretable and informative reasoning path can guide and help machines to generate a more reasonable and precise relation description with the desired characteristics. This is because machines can more easily reason between entities with the path and incorporate more important information from the path. Therefore, instead of using the shortest paths, we design a mechanism to select the most interpretable and informative reasoning paths automatically. We achieve this by the confidence estimation of PLMs, which is motivated by related work on machine translation and speech recognition for accessing the quality of the prediction (Siu and Gish, 1999; Ueffing and Ney, 2007; Niehues and Pham, 2019). Given an entity pair (x, y), with a reasoning path $p(x, y)$, a trained model $\mathcal{M}$, and the corresponding prediction $\mathcal{M}(p(x, y))$, the confidence of the prediction can be evaluated by the posterior probability $P(\mathcal{M}(p(x, y))|p(x, y))$[3]. We select the reasoning path associated with the highest confidence score:

$$\hat{p}(x, y) = \underset{p(x,y)\in\mathcal{P}(x,y)}{\arg\max}\ P(\mathcal{M}(p(x, y))|p(x, y)).$$

Reasoning path selection by confidence estimation is intuitive since 1) if a reasoning path is more ***interpretable***, which means the path is easier to convert to a precise relation description, PLMs can "reason" between entities based on their knowledge with less effort; 2) if a reasoning path is more ***informative***, which means the reasoning path provides useful relational knowledge, PLMs can incorporate such information into the prediction without guessing the necessary information. In both cases, the confidence of the prediction will be higher.

With the reasoning path selection mechanism, given an entity pair (x, y), the generated relation description is $\mathcal{M}(\hat{p}(x, y))$, where $\hat{p}(x, y)$ is the reasoning path associated with the highest confidence score. The selected reasoning path can also serve as a support of the prediction and help users to understand the relation in a structured view. To get the trained model $\mathcal{M}$, we can directly apply *RelationBART-SP* introduced in Section 2.3. We name RelationBART-SP with reasoning path selection as **RelationBART-SP + PS**[4] To make the training more robust and let PLMs learn more features from valid reasoning paths, for each entity pair, we can sample more than one reasoning path, e.g., the shortest n reasoning paths with hops $\leq k$, to train the model. We refer to this model as **RelationBART-MP + PS**.

3 Experiments

3.1 Dataset Construction and Analysis

We use Wikipedia and Wikidata (Vrandečić and Krötzsch, 2014) to build a benchmark dataset for open relation modeling.

---

[2] If there exist multiple shortest paths for an entity pair, we randomly choose one.

[3] We use the posterior probability of BART implemented by `fairseq`. The estimation may be further improved through calibration (Jiang et al., 2021).

[4] We encourage the model to select relatively short paths since long paths are likely to introduce redundant information and the reasoning will not be intuitive, e.g., $\{$*Haste*, *shares border with*, *Hohnhorst*, *shares border with*, *Bad Nenndorf*, *country*, *Germany*$\}$.

	train	dev	test	test*
number	5,434,158	27,431	55,226	7,302

	1-hop	2-hop	3-hop	$>$ 3-hop
ratio (%)	35.14	17.80	7.33	39.73

Table 1: The statistics of the data.

The first sentences of Wikipedia are definition-like sentences connecting different entities. For instance, the first sentence of page *Deep Learning* is $s =$ "*[Deep learning] (also known as deep structured learning) is part of a broader family of [machine learning] methods based on [artificial neural networks] with [representation learning].*" The head entity of this sentence is *deep learning*, and there are three tail entities: *machine learning*, *artificial neural networks*, and *representation learning*, which are linked to other pages and can be easily extracted with simple text preprocessing. Combining the head entity and the three tail entities, we can construct three entity pairs, whose expected relation descriptions are all s. The version we used is 2021-03-20 dump[5] of English Wikipedia. For each page, we extract the plain text by WikiExtractor[6] and further extract the first sentence. We randomly split entity pairs to build train/dev/test sets, where the head entities *do not* overlap in each set.

To provide reasoning paths for open relation modeling, we sample part of Wikidata to build a knowledge graph. Specifically, we keep facts whose head and tail entities both appear in Wikipedia. The extracted KG contains 5,033,531 entities and 23,747,210 fact triples. The relation between two entities is considered as k-hop if the shortest reasoning path between them is k-hop.

Analysis and Filtering. To assess the quality of the dataset, we randomly sample 100 examples from the test set and ask human annotators to judge whether each sentence well represents entity relationships. As a result, 87% of the sentences are considered as good relation descriptions.

To improve the quality of evaluation, we design a rule-based method to construct a high-quality sub-test set. Specifically, we collect dependency graph for each relation description, and calculate the *dependency coverage*: the ratio of tokens covered by the shortest dependency path from the head to the tail compared to all the tokens in the sentence; and *surface coverage*: the ratio of tokens between the head and the tail (including head and tail) compared to all the tokens in the sentence. For instance, given entity pair (*Walton East*, *parish*) and relation description "*Walton East is a small rural village and parish established around a church at least as early as Norman times.*" The shortest dependency path from the head to the tail only contains tokens {Walton, East, is, parish}, so the *dependency coverage* is $4/20$. And there are 9 tokens between the head and tail, so the *surface coverage* is $9/20$.

A low *dependency coverage* and *surface coverage* indicate that many tokens in the sentence may not be important to characterize the relation between the head and the tail; therefore, the sentence may not be a good relation description. We keep examples whose $(\text{dependency coverage} + \text{surface coverage})/2 > 0.6$. After filtering, 96% of the sentences are judged as good relation descriptions by the human annotators. Here we note that while the above method filters out bad examples, it also filters out many good relationship descriptions. Table 1 summarizes the statistics of the data (test* denotes the filtered sub-test set).

3.2 Experimental Setup

Baselines. Because our task on open relation modeling is new, there is no existing baseline for model comparison. We design the following baselines/variants for evaluation:

- **DefBART**: Since the expected output is a definition-like sentence, the model proposed in (Bevilacqua et al., 2020) can be applied directly, i.e., generating the definition of the head entity with the head entity as input. We can observe the performance gain of relation modeling compared to definition modeling in terms of generating definitions and see the difference between them.
- **RelationBART-Vanilla**: The vanilla version of our model introduced in Section 2.2.
- **RelationBART-SP**: The shortest-path version of our model introduced in Section 2.3.
- **RelationBART-SP + PS**: The shortest-path version of our model, combining with the reasoning path selection mechanism (Section 2.4).
- **RelationBART-MP + PS**: The multiple-path version of our model, combining with the reasoning path selection mechanism (Section 2.4).

Without additional notation, we apply the BART-base model and denote "Large" when using the BART-large model. "w/o PT" means the BART-

base model is not pre-trained.

Metrics. Following existing works on text generation, we apply several widely-used metrics to automatically evaluate the performance of open relation modeling, including BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004), METEOR (Banerjee and Lavie, 2005), and BERTScore (Zhang et al., 2019). Among them, BLEU (BL) and ROUGE-L (R-L) are based on simple string matches, and METEOR (MT) also incorporates word stems, synonyms, and paraphrases for matching. These three metrics mainly focus on measuring surface similarities. BERTScore (BS) is based on the similarities of contextual token embeddings. We also conduct human evaluation by asking three human annotators to assign graded values (1-4) to the sampled predictions according to Table 8.[7]

3.3 Open Relation Modeling

Tables 2 and 3 summarize the experimental results of open relation modeling with the automatic metrics. We observe that RelationBART-Vanilla achieves much better performance than DefBART, which demonstrates the necessity of the tail entity in terms of generating definition-like sentences that imply relations between entities. Besides, RelationBART variants outperform the versions without pre-training, which indicates that knowledge stored in PLMs after pre-training is helpful for open relation modeling. However, the improvement is not significant, which may be because the size of our training data is large; thus the model can learn rich knowledge about entities from definitions without pre-training. To verify this, we also train the model with smaller sizes of data in Appendix B.

Compared to RelationBART-Vanilla, the models with reasoning paths all achieve better performance, which demonstrates that reasoning paths can help PLMs reason between entities and provide additional relational knowledge to PLMs for open relation modeling. Besides, the models with reasoning path selection mechanism outperform the ones without it, which indicates PLMs can select more interpretable and informative reasoning paths based on confidence estimation, and the selected reasoning paths can guide PLMs to generate more reasonable and precise relation descriptions.

We also divide the testing examples into two groups: *reasonable*, where the entities can be reasoned within 3 hops in the Wikidata knowledge graph, and *hard-to-reason*, where the entities cannot be reasoned within 3 hops. From the results shown in Table 4, we observe that, for the *reasonable* pairs, the performance improvement is signif-

Table 5: Qualitative results of open relation modeling.

icant, while for the *hard-to-reason* pairs, there is not much difference in model performance. This is because, for *hard-to-reason* pairs, PLMs cannot incorporate additional relational knowledge from KGs only with encoding "x; *unknown:* y"– which shows the training of the model is stable and the variance of the results is low. Besides, all the models perform much better on *reasonable* pairs, which indicates if two entities can be reasoned in existing KGs with fewer hops, it is easier to generate their relation descriptions with PLMs, no matter whether a reasoning path is incorporated or not.

Qualitative Evaluation. We also perform a qualitative evaluation by asking three annotators to assign graded values to relation descriptions generated by our models according to Table 8. We randomly sample 100 *reasonable* entity pairs from the test set for evaluation. The average pairwise Cohen's kappa is 0.67, which indicates a substantial agreement (0.61-0.8) (Landis and Koch, 1977).

From Table 5, we observe the performance is satisfactory. Our best model *RelationBART-MP (Large) + PS* achieves a rating of about 3, which means the model can often generate a relation description that well captures the relation, where only minor errors that do not affect the understanding of the relation are included. In addition, the qualitative evaluation results are consistent with the quantitative evaluation results in Table 2 and Table 4, which validates the function of reasoning paths and reasoning path selection mechanism.

3.4 Reasoning Path Selection

Results in Tables 2, 3, 4, and 5 indicate machines can select better reasoning paths for open relation modeling by confidence estimation. We also test the quality of the selected reasoning paths from a human understanding perspective.

We randomly select 300 entity pairs from the test set and ensure all the pairs are associated with at least two reasoning paths with hops ≤ 3. For each entity pair, we randomly select 2 reasoning paths and manually label which one is more interpretable and informative, i.e., humans can understand the relation between two entities more easily by reading the reasoning path. We skip pairs that are difficult to judge which path is better. Among the 300 pairs, 106 pairs were skipped.

	Accuracy (%)
Random Walk	64.43
Shortest Path	61.34
RelationBART-SP (Large)	72.68
RelationBART-MP (Large)	**80.93**

Table 6: Results of reasoning path selection.

Table 6 reports the results of reasoning path selection with different methods. The *Random Walk* baseline selects the reasoning path by the probability of generating the path starting from the head entity, which is suggested by (Lao et al., 2011). The *Shortest Path* baseline selects the path with a shorter length (for 52 cases where the length of two paths is the same, we randomly choose one).

We can see the performance of RelationBART-MP (Large) is quite impressive, where machines make the same choices as humans in more than 80% of the cases. In addition, results in Table 6 are consistent with results in Table 2, which indicates a better reasoning path selection mechanism can promote machines to generate better relation descriptions.

3.5 Generation Examples and Error Analysis

Table 7 shows some generation examples via the RelationBART-MP (Large) model. The first row of each group is the reference definition in Wikipedia. 1) The first group contains reasoning paths connecting *Romeries* and *France*, we can see the second reasoning path is the most interpretable and informative, where the confidence score is the highest, and the generated relation description is the same as the ground truth. 2) The second group contains four entity pairs whose head entity is *data mining*, and the reasoning path in each row is the one associated with the highest confidence score. By reading these generated relation descriptions, humans can better understand *data mining* and its relationship with other terms. 3) The third group contains five *hard-to-reason* entity pairs whose head entity is *evaluation*. We can see the reference definition of *evaluation* is quite abstract that cannot capture the relation between *evaluation* and a specific field, while by reading the generated ones, humans can understand what *evaluation* means in different fields and how it relates to them.

Table 7: Sample of relation descriptions generated by RelationBART-MP (Large).

Error Analysis. To further understand the quality of the outputs produced by our model and identify the remaining challenges, we investigate the error cases found by examining the generated relation descriptions. As a result, we found most errors can refer to as *hallucinations*, i.e., producing irrelevant or contradicted facts. This type of error is mainly due to knowledge coming from pre-training, fine-tuning, and reasoning paths is not sufficient.

Taking entity pair $(Romeries, France)$ in Table 7 as an example, if the model takes the shortest reasoning path, i.e., *Romeries; country: France*, as input, a relation description that wrongly predicts the department of *Romeries* will be generated. This is because knowledge about the department is missing from the reasoning path, and such detailed knowledge is also difficult to obtain from the parameters of the trained model.

Another example is $(Play\ It\ Loud, rock\ music)$, where the reference relation description is "*Play It Loud is the second studio album by the British rock group Slade.*" The reasoning path selected by RelationBART-MP (Large) is $\{$*Play It Loud*, *performer*, *Slade*, *genre*, *hard rock*, *subclass of*, *rock music*$\}$. This reasoning path contains detailed knowledge about the performer; however, it is still difficult to judge whether *Play It Loud* is a song or an album. As a result, the model generates "*Play It Loud is a song by the British rock band Slade.*"

Hallucination is a common issue and challenging problem in text generation. From the results in Table 5 and the generation examples, we can observe hallucination is reduced by incorporating reasoning paths and the reasoning path selection mechanism. How to further alleviate it for open relation modeling will be our further work direction. We discuss some possible solutions in Section 4.

4 Discussion

Limitation of Definitional Sentences. Although a considerable number of relations can be well captured by definitional sentences, there are types of relations that are not natural to be represented by definitional sentences. For instance, for *Kobe Bryant* and *Shaq O'neal* (both are NBA players in Los Angeles Lakers), it is not natural to assume one would appear in the other's definition. In this case, we can include a third related entity to help users to understand their relation. For example, we can include *Los Angeles Lakers* (which can be found from a knowledge graph or a corpus); and then, we can generate two sentences: 1) "Kobe Bryant was an NBA player in Los Angeles Lakers"; 2) "Shaq O'neal was an NBA player in Los Angeles Lakers". With these two sentences, users can easily understand their relation. It is also possible to design a model to synthesize these two sentences to one (Becker et al., 2021), e.g., "Kobe Bryant and Shaq O'neal were both NBA players played in Los Angeles Lakers". We leave a comprehensive solution to solve this limitation as future work.

Open Relation Modeling with Diversity. In the real world, multiple important relations can be associated with one entity pair. Considering this, as future work, we may generate diverse relation descriptions for one entity pair with different reasoning paths selected.

Open Relation Modeling with More Knowledge. Open relation modeling is a knowledge-intensive task (Lewis et al., 2020b), where knowledge about entities and relations is essential to solving this task. In this work, we incorporate knowledge from model pre-training, definitions of entities, and reasoning paths. The proposed model can achieve impressive performance, especially for reasonable entity pairs. As future work, we can leverage more external information of entities, e.g., sentences/paragraphs containing the target entities from corpora, to provide more knowledge for open relation modeling.

5 Related Work

Previously, Voskarides et al. (2015) study the problem of extracting sentences that describe relations between entities with direct relations in a knowledge graph. They model this task as a learning to rank problem and design a supervised learning model with manually annotated sentences. As follow-up work, Huang et al. (2017) solve this task with training data built by leveraging clickthrough data from Web search, and Voskarides et al. (2017) generate the description of a relationship instance in a knowledge graph by filling created sentence templates with appropriate entities. The ability of these models is limited since they heavily rely on features of entities and relations; thus these models can only handle entities with several pre-specified types (only 10 in (Voskarides et al., 2017)) of explicit relations in KGs (e.g., *isMemberOfMusicGroup*), while our methods can deal with a large number of types of relations, including implicit ones (e.g., *evaluation* and *algorithm*), i.e., in an "open" setting.

Recently, Lin et al. (2020); Liu et al. (2021b) study a constrained text generation problem that aims to generate coherent sentences describing everyday scenarios containing the given common concepts. Different from them, we aim to generate sentences that can explain the relation between entities intuitively and explicitly. Dognin et al. (2020); Agarwal et al. (2021) study the data-to-text generation problem (Kukich, 1983) that converts the KG into natural text with language models. The focus of these works is to convert knowledge graphs into natural language, while we propose to discover relation descriptions between entities with pre-trained language models. Besides, only common concepts or entities with direct relations are studied in these works, while our methods deal with entities with multi-hop relations, even including entities that cannot be reasoned in existing KGs.

6 Conclusion

In this paper, we introduce and study the novel *open relation modeling* problem– generating coherent sentences describing general relations between entities, where the relations can be multi-hop, even cannot be reasoned in an existing KG. We achieve this by teaching PLMs to learn from defining entities and select/utilize reasoning paths. We believe this work will open a door for modeling relations between entities. As for future work, we plan to improve our model as discussed in Section 4 and apply our methods to downstream applications, e.g., a system for users to explore relations between entities, which can be further applied to explore a taxonomy or ontology. We can also use the generated relation descriptions to help some related tasks, such as relation extraction (Bach and Badaskar, 2007), knowledge graph construction and completion (Ji et al., 2021). The trained models can be further fine-tuned for open relation modeling on specific domains.

Rating	**Criterion**
4	The relation is well captured, and important information about entities is included and correctly predicted.
3	The prediction contains minor error(s) that do not affect the understanding of the relation.
2	The prediction contains major error(s) that affect the understanding of the relation, while the relation can still be inferred to some extent.
1	The prediction contains major error(s) that will mislead the understanding of the relation.

Table 8: Annotation guidelines excerpt.

A Implementation Details

We employ the `fairseq` library[8] to build the RelationBART model and adopt the key hyperparameters as suggested in (Lewis et al., 2020a). We manually set the learning rate as 5×10^{-5} and batch-size of 1,024 tokens based on some preliminary experiments and the memory size of GPUs. We set the maximum reasoning length as 3 since the number of reasoning paths with hops > 3 is very large and the quality of these paths is generally low. For RelationBART-MP and reasoning path selection, we sample at most 5 reasoning paths with hops ≤ 3. All the models were trained on NVIDIA Quadro RTX 5000 GPUs, and the training converged in 50 epochs. The training time of RelationBART-Vanilla, RelationBART-MP, and RelationBART-MP (Large) for one epoch with 3 GPUs are 80 minutes, 4 hours, and 7 hours respectively.

B Open Relation Modeling with Different Sizes of Training Data

100%	**BL**	**R-L**	**MT**	**BS**
RelationBART-Vanilla (w/o PT)	26.01	50.84	23.65	85.37
RelationBART-Vanilla	26.81	51.48	24.14	85.73
10%	**BL**	**R-L**	**MT**	**BS**
RelationBART-Vanilla (w/o PT)	22.88	48.50	22.07	84.31
RelationBART-Vanilla	24.31	49.89	22.99	85.16
1%	**BL**	**R-L**	**MT**	**BS**
RelationBART-Vanilla (w/o PT)	17.30	44.12	19.02	81.56
RelationBART-Vanilla	20.99	47.11	21.23	84.04

Table 9: Results of open relation modeling with *100%*, *10%*, and *1%* training data.

From Table 9, we observe that when the training data become smaller, the performance of the version without pre-training decreases much faster than the one with pre-training.

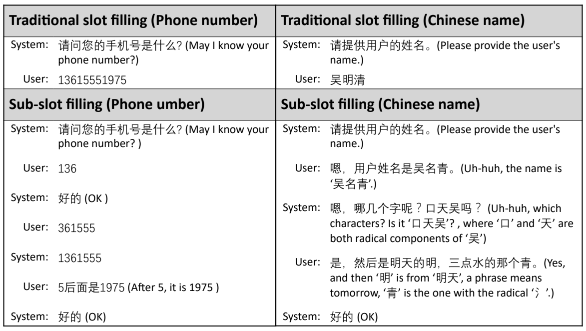
Abstract

A slot value might be provided segment by segment over multiple-turn interactions in a dialog, especially for some important information such as phone numbers and names. It is a common phenomenon in daily life, but little attention has been paid to it in previous work. To fill the gap, this paper defines a new task named **S**ub-**S**lot based **T**ask-**O**riented **D**ialog (**SSTOD**) and builds a Chinese dialog dataset SSD for boosting research on SSTOD. The dataset includes a total of 40K dialogs and 500K utterances from four different domains: Chinese names, phone numbers, ID numbers and license plate numbers. The data is well annotated with sub-slot values, slot values, dialog states and actions. We find some new linguistic phenomena and interactive manners in SSTOD which raise critical challenges of building dialog agents for the task. We test three state-of-the-art dialog models on SSTOD and find they cannot handle the task well on any of the four domains. We also investigate an improved model by involving slot knowledge in a plug-in manner. More work should be done to meet the new challenges raised from SSTOD which widely exists in real-life applications. The dataset and code are publicly available via https://github.com/shunjiu/SSTOD.

1 Introduction

Task-oriented dialogs help users accomplish specific tasks such as booking restaurants or accessing technical support services by acquiring task-related slots through multi-turn dialogs. Many advances have been achieved under an assumption that each slot value is informed or updated as a whole in a single turn by default (Li et al., 2017; Zhang et al., 2020b; Hosseini-Asl et al., 2020; Dai et al., 2021),. But in real-world dialogs, some slot values are often provided in a much more complicated manner.



Traditional slot filling (Phone number)	Traditional slot filling (Chinese name)
System: 请问您的手机号是什么? (May I know your phone number?) User: 13615551975	System: 请提供用户的姓名。(Please provide the user's name.) User: 吴明清
Sub-slot filling (Phone umber)	**Sub-slot filling (Chinese name)**
System: 请问您的手机号是什么? (May I know your phone number?) User: 136 System: 好的 (OK) User: 361555 System: 1361555 User: 5后面是1975 (After 5, it is 1975) System: 好的 (OK)	System: 请提供用户的姓名。(Please provide the user's name.) User: 嗯，用户姓名是吴名青。(Uh-huh, the name is '吴名青'.) System: 嗯，哪几个字呢？口天吴吗？ (Uh-huh, which characters? Is it '口天吴'? , where '口' and '天' are both radical components of '吴') User: 是，然后是明天的明，三点水的那个青。(Yes, and then '明' is from '明天', a phrase means tomorrow, '青' is the one with the radical '氵'.) System: 好的 (OK)

Figure 1: Comparison of traditional slot and sub-slot.

We take phone numbers as an example. Users tend to inform an agent a sequence of 0-9 digits segment by segment across several turns as exemplified in Figure 1. Accordingly, the agent needs to confirm, update or record the recognized sub-slot values. We regard these scenarios as SSTOD task.

The SSTOD is very common when people communicate telephone numbers, names and so on. Specifically, as shown in Figure 1, the SSTOD task raises several critical new challenges which have not been tackled in building dialog agents: (1) Multi-segment informing: The segments could be informed in many different complex ways. As exampled in Figure 1, the user informed two sub-slots "136" and "361555" sequentially. The agent should discriminate whether the snippet "36" in "361555" is a partial repeat of "136" or a duplicated component of a whole slot value. (2) Sub-slot locating: Differing from updating a whole slot value in traditional slot filling, in SSTOD, the agent demands to precisely locate the part of values that needs to be updated. The situation is exacerbated when there are more than one similar sub-slots. (3) Knowledge-rich relevancy: To avoid the ambiguities of speech, users usually introduce a piece of knowledge along with informing the slot values (Tsai et al., 2005; Wang, 2007). For example, the knowledge, "明天的明" is used to disambiguate character "明" (It is the similar case when

English speakers say “A as in Alpha” in phone calls). The agent should look into the knowledge in order to predict correct value.

To the best of our knowledge, the existing dialog benchmarks, such as ATIS (Hemphill et al., 1990a), MultiWOZ (Budzianowski et al., 2018), CrossWOZ (Zhu et al., 2020), and SGD (Rastogi et al., 2020) do not contain the dialogs illustrated in Figure 1, which makes the dialog agents optimized on them fail dramatically at conversing in sub-slot dialogs. To address the above challenges, we develop the **S**ub-**s**lot **D**ialog (SSD) dataset which contains most popular sub-slot dialog scenarios including phone numbers (a sequence of digits 0-9), ID numbers (much longer digit sequence), person names (a sequence of Chinese characters), and license plate numbers (a mix of Chinese characters, digits and English letters). The dataset is originated from the real-world human-to-human conversations, then richly labeled and reprocessed by crowdsourcing. Although the dataset is in Chinese, the development methodology depicted in this work is also applicable to other languages.

Under the setting of SSTOD, we present an improved model, UBAR$^+$, on the basis of UBAR (Yang et al., 2021) and the large pretrained model GPT2 (Radford et al., 2018). UBAR$^+$ equips UBAR with a knowledge prediction module to correct Automatic Speech Recognition (ASR) errors and discriminate the ambiguities, and achieves better performance on SSD. We also provide a rule-based user simulator to evaluate the system.

Our main contributions are:

- We propose a novel sub-slot based dialog task which exists widely in real-world conversations but has been neglected in previous work.
- We build a large-scale high-quality spoken Chinese dataset SSD for SSTOD, covering four common scenarios including phone numbers, ID numbers, Chinese names and license plate numbers collection, which will essentially benefit future research on SSTOD.
- We design a knowledge prediction module together with knowledge retrieval which helps UBAR achieve significant improvement on the name domain. Otherwise, a user simulator is provided to facilitate the evaluation of the system.

2 Task and Dataset

We first give a defination of SSTOD, then introduce how to build the SSD dataset, and give some analyses on the dataset.

2.1 Task Defination

We proposed sub-slot based dialog system as a one slot filling task. A user may provide a slot via multiple turns in oral conversations. In each turn, only a piece of the value, which is regarded as a sub-slot, is given. It is because the values like phone numbers are usually too long for a user to inform in one turn or the segments in values like surnames in names are often accompanied with extra explanations to disambiguate homonyms.

2.2 Dataset Creation

Since information such as phone numbers and names is private, real data cannot be used directly. We design a semi-automatic method to obtain a large-scale high-quality dialog dataset while avoiding privacy issues. We build a dataset in four domains including Phone Number, Name, ID Number and License Plate Number. We demonstrate the building process of the dataset by taking Name as an example.

System action	request, continue, req more, implicit confirm, explicit confirm, ack, req correct, compare, ask restart, bye, how signal, good signal, robot, other
User action	offer, inform, update, affirm, deny, ack, ask state, restart, ask repeat, finish, wait, doubt identity, how signal, bad signal, good signal, other

	inform	update	affirm	deny	ack	ask state	restart
request	0.89	0	0	0	0.04	0	0
req more	0.93	0	0	0	0	0	0
implicit confirm	0.49	0.16	0.25	0.07	0	0	0.01
explicit confirm	0	0.30	0.66	0	0	0	0.01
ack	0.94	0	0	0	0.04	0.02	0
compare	0.60	0.39	0	0	0	0	0
ask restart	0	0	0	0	0.15	0.33	0.50

Figure 2: All actions in the phone domain (above) and part of transition probabilities (below). Each row in the table below is the probability of user action when a system action is given.

Human-to-Human (H2H) dialog. We sample $47,252$ H2H dialogs from a business service by considering different time of service and different genders of customers, and obtain $4,489$, $8,873$ and $5,827$ fragments of dialog for phone numbers, names and license plate numbers respectively. We analyze the H2H dialogs carefully, summarize some dialog actions and dialog policy, and estimate the transition probabilities between different

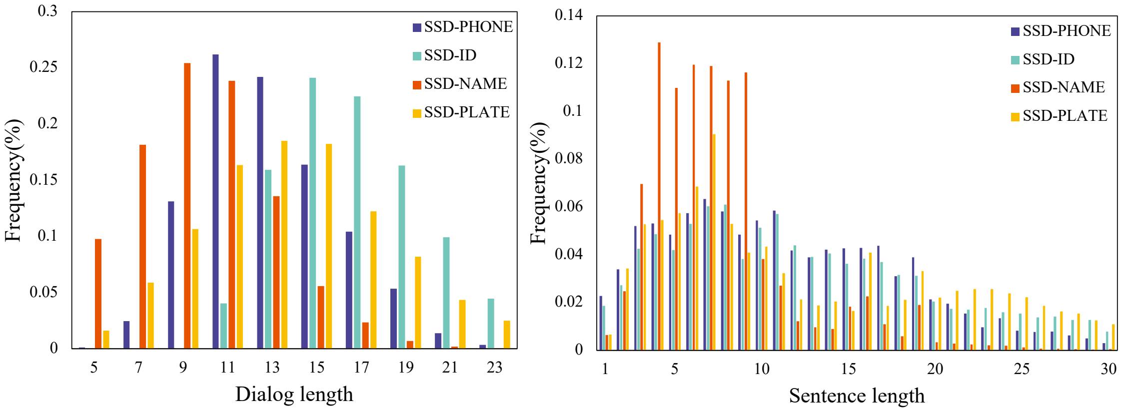

Figure 3: The distribution of numbers of sentences in a dialog (left) and the distribution of numbers of characters in a sentence (right).

actions. Taking phone numbers as an example, we have 30 actions. Figure 2 gives part of transition probabilities between those actions.

Knowledge Base. Chinese characters in names cannot be disambiguated by context in spoken conversations. For example, when someone says, “我姓吴 (my surname is Wu)”, different Chinese characters which share the same pronunciation of “wu”, including “吴”, “武”, “伍”, etc., are all possible to be the surname to the listeners. People therefore always employ some external knowledge to distinguish different characters. For example, “我姓吴,口天吴 (my surname is ‘吴’, ‘口’ and ‘天’ compose ‘吴’)”, where “口天吴” is a piece of external knowledge. It gives components (normally some simple characters) of a character. People also use knowledge of character combination (i.e. words or phrases) to identify a Chinese character. For example, “我姓吴,东吴的吴 (my surname is ‘Wu’, ‘Wu’ as in ‘DongWu’) ”, where “DongWu” is a word which only “吴” fits the word well. “DongWu” is another piece of knowledge for Chinese character “吴”. Almost all frequent Chinese Characters have several pieces of knowledge as above. Appendix A gives some pieces of knowledge on Chinese characters. Knowledge is widely used in name telling. We thus build 20, 547 pieces of knowledge for 2, 003 common used Chinese characters. On average, each Chinese character is with more than 10 pieces of knowledge. We give more examples in Appendix A.

Data generation. Based on the analysis of H2H dialogs, two probabilistic FSA-based simulators are built for System and User respectively, both with a template-based Nature Language Generation (NLG) module for generating natural language sentences from actions sampled from probabilistic FSA. We give some examples of NLG modules in Appendix B. Part of FSAs is given in Appendix C. An error simulator is also built for modeling errors brought by ASR. Two FSAs as well as a NLG module and an error model work together to generate various dialogs. At the beginning, the FSA for users initializes a target slot value which is composed of several sub-slot segments. The two probabilistic FSAs then interact based on the sampled actions. At each step, when FSA chooses current dialog action and sub-slot values, a NLG template is randomly chosen to generate a sentence. The error model might also be triggered randomly to twist the values with a defined probability. When the system thinks it collects a complete slot value, it ends the dialog. If the slot value collected is consistent with the slot value initialized by the user, the dialog succeeds; otherwise, the dialog fails. Appendix D illustrates several example dialogs generated by FSAs.

Domains→ Types↓	PHONE	ID	NAME	PLATE
Templates	8, 578	7, 350	3, 031	5, 179
Sentences	3, 849	-	29, 874	10, 000
Knowledge	-	-	34, 302	-

Table 1: Numbers of crowdsourced data.

Data crowdsourcing. To make our dialog data more natural and diverse, we hired crowd workers to paraphrase user utterances in the generated dialogs. New utterances bring more templates, knowledge pieces and real ASR errors. Table 1 gives the numbers of crowdsourced data.

	SSD-PHONE	SSD-ID	SSD-NAME	SSD-PLATE
No. of dialogs	$11,000$	$8,000$	$15,000$	$6,000$
No. of actions	30	30	29	27
Avg. turns per dialog	13.01	16.86	9.86	13.90
Avg. tokens per sentence	11.61	13.13	7.70	13.84
Avg. sub-slots per dialog	2.90	4.15	2.84	2.03
No. of different paths	$3,135$	$5,412$	$2,475$	$3,965$
Vocabulary size	677	629	$3,519$	915

Table 2: Analysis of the SSD dataset.

2.3 Data Statistics

We finally obtained a large and high-quality data for SSTOD in four domains. Some statistics are shown in Table 2.

As we can seen in Table 2, the SSD dataset has 40K dialogs and the number of dialogs exceeds that of most available task-oriented datasets (the largest dialog dataset SGD (Rastogi et al., 2020) commonly used today contains $16,142$ dialogs). The number of actions is at least 27 in each domain, which is more than that in any single domain of the currently commonly used dataset MultiWOZ (Budzianowski et al., 2018).

The average turn per dialog is no less than 10, as well as the average character per sentence. The distribution of dialog length is shown in Figure 3 (left) and the distribution of dialog sentence length per domain is shown in Figure 3 (right).

A path is the action sequence in a dialog. Two dialogs with distinct paths means they have different ways to complete a task. The larger the number of different paths, the more diversity of action sequences. The SSD dataset shows adequate diversity of dialogs.

The average number of sub-slots per dialog is the average number of pieces that a full slot value is segmented. It can be seen that names are averagely segmented into 2.84 pieces. Considering a Chinese name normally includes 2-3 Chinese characters, people say their names character by character.

Finally, it should be noticed that data contains a wealth of annotation information. For each user utterance, we annotate an action and the sub-slot values provided by the user. For each system utterance, we annotate an action and the state which is the sub-slot value collected by the system. The annotation information allows our data to be used for the following tasks: natural language understanding (NLU), dialog state tracker (DST), dialog policy, NLG, etc. We will also release our FSA-based User simulator, which can be used to evaluate the system.

2.4 New Challenges

The dataset includes many new phenomena that are seldom seen in other datasets which bring some new challenges to build agents for SSTOD. Most of the new phenomena are brought by the sub-slot telling way. Table 3 gives some of these new phenomena as well as a sample utterance for each phenomenon.

Most of the phenomena listed in Table 3 are seldom seen in the previous dialog datasets. They raise some new challenges on at least three sides: The first one is to locate and record each segment and even each element in each segment, since all of them might be updated separately or as a whole. The second one is to identify the various external knowledge, especially when ASR errors are involved. The third one is that the context of the sub-slot might be helpless when there are ambiguities. The knowledge might be the major source of disambiguation, including those explicitly noticed in utterances, as well as implicitly used in dialogs.

3 Method

3.1 Benchmark Models

Since the new task raises critical challenges, we firstly verify whether the current state-of-the-art (SOTA) models on normal task-oriented dialog task can meet the challenges, then we take a small step on improving one SOTA model by introducing a specific plug-in component to make it handle some of the challenges.

Recently, many strong models have been proposed to tackle the MultiWOZ benchmark (Hosseini-Asl et al., 2020; Yang et al., 2021; He et al., 2022). In this paper, we chose three SOTA dialog models for our SSTOD evaluation as follows:

Description	**Example**
Inform (quantifier)	1，4个3 (1, four 3’s.)
Inform (correct)	嗯1820，呃，不是是1860 (Uh-huh1820, hmm, no it’s 1860.)
Inform (repeat)	7127 7127
Inform (stretched)	1，1044
Inform (overlap)	User：嗯，您那麻烦，您记一下的手机号码，181 (Well, would you mind writing down the phone number? 181.) System：嗯，181 (Uh-huh, 181.) User：1814104
Update (refer)	最后4位是5664 (The last 4 digits are 5664.)
Update (delete)	去掉7 (Delete 7.)
Update (add)	9后面少个4 (Behind 9, 4 is missing.)
Update (part)	System：133 4777 3029，好，我知道了，谢谢啊(133 4777 3029, okay, I see. Thanks!) User：529才对 (It is 529.)
Sub-slot update	2不对啊，是R，RST里面的R才对 (2 is not right, it’s R as in RST.) (note: 2 and R have the same pronunciation in Chinese.)
Comparison of homophonic characters	是字母E还是数字1？(Is it the letter E or number 1?) (note: “E” and “1” have the same pronunciation in Chinese.)
Using external knowledge (character combination)	艳是艳丽的艳 (“艳” is from “艳丽”, a two-character word means showy.)
Using external knowledge (structure)	艳是一个丰字，一个色字 (“艳” is composed of “丰” and “色”.)
ASR errors of a character or(and) its knowledge	ASR outputs：验是严厉的严，一个风字，一个色字 Original utterance：艳是艳丽的艳，一个丰字，一个色字 (“验” and “严” are badly recognized characters of “艳”, “风” is a badly recognized character of “丰”, and “艳丽” (showy) is the correction of “严厉” (servere).)
Two identical characters in one name	我叫李壮壮，状是状元的状，两个状都是 (My name is “李壮壮” (Li Zhuangzhuang), the last two words are both “状” as in “状元” (top students).)
Two characters from one knowledge	我叫业勤，业精于勤的业勤 (My name is “业勤” (Ye Qin) as in Chinese idiom “业精于勤” (Excellence in work lies in diligence).)

Table 3: Part of the diversity cases and their examples.

TRADE (Wu et al., 2019) utilizes the generative approach and copy-generator mechanism for slot filling tasks. We construct a complete dialog system using TRADE and a rule-based policy module as a baseline.

SimpleTOD (Hosseini-Asl et al., 2020) uses a single, causal language model to aggregate dialog state tracking, policy deciding, and response generating a cascaded generator. Leveraging the large pre-trained model such as GPT2, SimpleTOD achieved competitive results on MultiWOZ.

UBAR (Yang et al., 2021) presents variants on Ham et al. (2020); Peng et al. (2020); Zhang et al. (2019) to parameterize the dialog system as an auto-regressive model. It models the task-oriented dialog system on a dialog session level, instead of using all user and system utterances as inputs. Conditioned on all previous belief state, system acts and response, UBAR is easier to make inference and planning in current turn and achieves the state-of-the-art performance on MultiWOZ.

3.2 Plug-in Module

As described above, one of the challenges in SSD is that the disambiguation of the slot values intensely relies on both the context and the extra knowledge. For example, users might inform a person name by making use of character knowledge to distinguish the target characters from alternatives.

We therefore design a simple plug-in unit to execute Knowledge Prediction (KP) and Knowledge Retrieve (KR) on demand. Taking UBAR as a testbed, we proposed a UBAR with the plug-in unit (hereafter UBAR$^+$) whose framework is illustrated in Figure 4.

Given a user input utterance U_t, UBAR$^+$ first generates knowledge snippets $K_t = [k_t^1, ..., k_t^m] \subset U_t$, where m is the number of extracted snippets. Each snippet corresponds to a target sub-slot value. For instance, if utterance U_t=“我叫张艳，张是弓长张，艳是严厉的艳”, the extracted knowledge snippets $K_t = [k_t^1, k_t^2]$ = [“弓长张”, “严厉的艳”].

Both extracted knowledge snippets and the knowledge items in extra knowledge base are embedded via TF-IDF (Jones, 1972) vectors both in

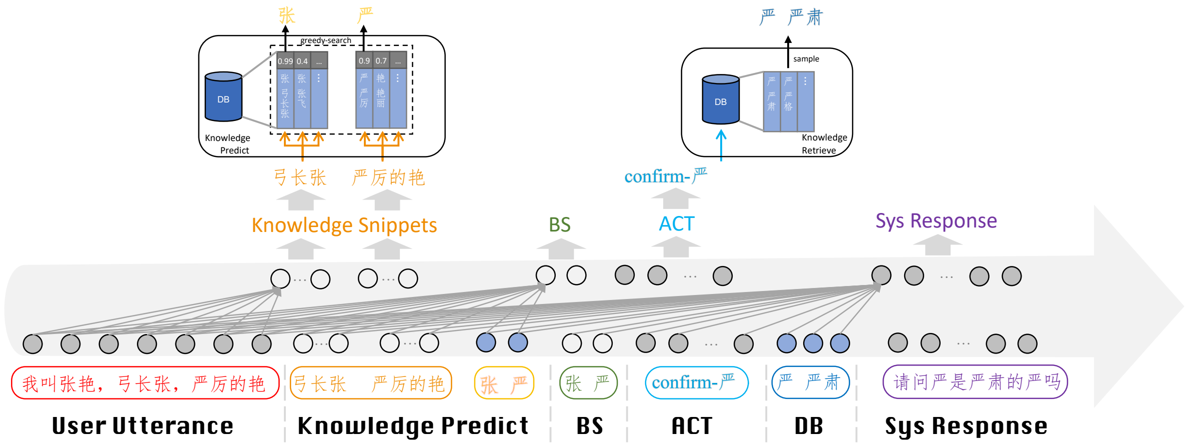

Figure 4: The structure of UBAR^{+}.

char-level and pinyin-level (which is the phonetic transcription of a Chinese character).

Finally, the cosine similarities between the snippet $k_t^i \in K_t$ and each candidate knowledge item kd_j from the knowledge base, are calculated as follows:

$$e_c(k_t^i) = \text{TF-IDF}_{char}(k_t^i), \tag{1}$$

$$e_p(k_t^i) = \text{TF-IDF}_{pinyin}(k_t^i), \tag{2}$$

$$\begin{aligned} score(k_t^i, kd_j) &= \alpha \cos\left(e_c(k_t^i), e_c(kd_j)\right) \\ &+ (1-\alpha)\cos\left(e_p(k_t^i), e_p(kd_j)\right), \end{aligned} \tag{3}$$

where $e_c(k_t^i)$ and $e_p(k_t^i)$ have the length of vocabulary size of characters and pinyin, respectively.

For knowledge item kd_k with the maximum similarity score, its corresponding character w_k is used as the disambiguated character of k_t^i, yielding the predicted target sub-slot sequence $C_t = [w_1, \ldots, w_m]$.

Hereto we finish the disambiguation of one sub-slot value. By repeating the above procedures, all sub-slots are assigned their predicted target char, thereby the belief state (BS in Figure 4) is updated accordingly. To rationally navigate the following dialog, the agent then learns to plan its following acts of whether confirming a sub-slot or continuously requesting a sub-slot. We apply cross-entropy and language modeling objective (Bengio et al., 2003) to optimize the plug-in unit:

$$L_{plug-in} = \sum_i \log P(w_t | w_{<t}). \tag{4}$$

$L_{plug-in}$ is added to the loss applied in UBAR, making the final loss of the UBAR^{+}.

4 Experiments

Using the SSD dataset as a dialog state tracking benchmark, we conduct a comprehensive analysis of the challenges through an empirical approach and validate the effectiveness of the proposed UBAR^{+} method.

4.1 Experimental Setup

Dataset. We split the SSD dataset into a training set, a validation set and a test set in the ratio of 7:1:2 on each of the four domains and conduct experiments on them.

Evaluation Metrics. We evaluate model performances on SSD with several popularly used metrics. **Joint acc** is the accuracy of all sub-slot values at each turn. The output is considered as an accurate one if and only if all the sub-slot values are exactly consistent with the ground truth values. **Slot acc** means whether each sub-slot is correctly collected at each turn. **Dialog succ** measures whether the collected slot value is consistent with the user's goal at the end of the dialog. To have a comprehensive comparison, we also test our model by online interacting with FSA-based user simulators with two evaluation metrics: **Dialog succ** and **Avg turn**. **Dialog succ** is the main metric, which means the ratio of successful dialogs. A dialog is successful if and only if the slot is correctly collected by system within limited turns. **Avg turn** is used to measure the average turn number of successful dialogs.

Implementation Details. We initialize our proposed UBAR^{+} model with ClueCorpus-small (Xu et al., 2020) and fine-tune it on SSD. The max length of an input sequence is set to 1024 and the excess parts are truncated. The α in the plug-in

Model	SSD-PHONE			SSD-ID			SSD-NAME			SSD-PLATE		
	Joint acc	Slot acc	Dialog succ	Joint acc	Slot acc	Dialog succ	Joint acc	Slot acc	Dialog succ	Joint acc	Slot acc	Dialog succ
TRADE*	56.14	73.54	32.32	40.10	62.51	5.01	65.45	83.36	28.29	12.56	13.85	2.89
SimpleTOD	**72.56**	**85.80**	**48.27**	**70.17**	**86.81**	**43.50**	**79.22**	**91.24**	**51.50**	**48.55**	61.20	**36.58**
UBAR	71.62	85.23	46.00	69.70	86.60	40.70	63.58	82.58	34.40	47.70	**61.76**	35.20

Table 4: Comparisons of DST metrics and dialog succ on SSD on the four domains.

Model	SSD-PHONE		SSD-ID		SSD-NAME		SSD-PLATE	
	Avg turn	Dialog succ	Avg turn	Dialog succ	Avg turn	Dialog succ	Avg turn	Dialog succ
TRADE*	9.77	30.45	16.68	26.39	6.75	5.71	6.50	20.26
SimpleTOD	**8.18**	**63.20**	**10.94**	**46.70**	4.79	**15.80**	**6.29**	**32.70**
UBAR	11.39	57.7	10.97	41.50	**4.41**	11.50	6.63	25.10

Table 5: Results of different models on interaction with a FSA-based user simulator on four domains.

unit is set to 0.09. AdamW (Loshchilov and Hutter, 2018) optimizer is applied and the learning rate is initialized as 0.0001.

4.2 Results and Analysis

We implement three different evaluations on model performances: The first one is offline test where models are evaluated using SSD test data, the second one is online test where models interact with FSA-based user simulator, and the third one is human evaluation where models interact with humans.

The offline evaluation results of the three baseline models across all domains on SSD are summarised in Table 4. As we can see, all three models perform poorly, and nearly all the dialog success rates are lower than 50%. Remind that the success rate of UBAR on MultiWOZ is higher than 70%. Among them, GPT2 based models (SimpleTOD and UBAR) achieve relatively good performance on SSD owing to the efficacy of large pre-trained language models. Although SimpleTOD achieves the best results on all four domains. Nevertheless, SimpleTOD only reaches nearly 40% dialog success on SSD-PHONE and SSD-ID, 51.50% on SSD-NAME, and 36.58% on SSD-PLATE. Table 5 illustrates the results of online evaluations. The similar observations are concluded as those in offline evaluations. Even the most efficient SimpleTOD model achieves poor success rates.

From the detailed analysis of the results, we observe that one of the major factors affecting the performance is the difficulty of sub-slot locating, especially when updating a fragment of the sub-slot. In the phone number domain and ID number domain, the system should compare the updated fragment with the collected value to determine which fragment is similar to that one. As shown in Figure 5, the system is required to change “307” to “807”, but it wrongly updates “4307” to “807”. For the name slot, the system changes “侯” to “何” by mistake. When taking the ASR noise into account, the scenarios would become much more complicated.

Domain		**Dialog**
Phone	Last System State	[159, 4307]
	Last System Utterance	那应该是多少？(What should that be?)
	User Utterance	我记错了，是807，307错了 (I misremembered, it is 807, 307 is wrong.)
	Generated Belief State	[159, 807]
	Oracle Belief State	[159, 4807]
Name	Last System State	陈,侯,河
	Last System Utterance	请问河是什么河？(Which ‘河’?)
	User Utterance	何炅的何(‘何’ is from ‘何炅’.)
	Generated Belief State	陈,何,河
	Oracle Belief State	陈,侯,何

Figure 5: Typical bad cases of UBAR. In the phone domain, the system ought to update part of the second sub-slot “307” to “807” but it updates the whole sub-slot by mistake. In the name domain, system indexes a wrong sub-slot “侯” and changes it to “何”.

4.3 Performance of plug-in unit

Table 6 shows the performance of our knowledge plug-in unit on SSD-NAME. UBAR$^+$ performs the best, with 23% improvement over UBAR and 6% improvement over SimpleTOD in terms of dialog succ. We claim that the knowledge plug-in unit enables the model to obtain relevant knowledge by querying the knowledge base, which is beneficial to complete slot value acquisition and response generation.

Further investigation is conducted through interaction between the model and the user simulator. Table 6 shows UBAR$^+$ harvests a great improvement in name collecting, yielding an accuracy rate of 45.8%, which further proves the efficiency of knowledge-rich disambiguation. The same trend is

Model	Offline Test			Online Test	
	Joint acc	Slot acc	Dialog succ	Avg turn	Dialog succ
SimpleTOD	79.22	91.24	51.50	4.79	15.80
UBAR	63.58	82.58	34.40	**4.41**	11.50
UBAR$^+$	**84.96**	**93.12**	**57.73**	4.60	**45.80**

Table 6: Comparisons between UBAR$^+$ and the SOTA models in both offline and online tests on the Chinese name domain.

also observed for the other three domains.

4.4 Human Evaluation

Model	Dialog succ	App	Diversity
UBAR	28.00	2.82	3.10
UBAR$^+$	**50.00**	**2.89**	**3.96**

Table 7: Performance on human evaluation on Chinese name domain. App indicates the average appropriateness scores.

For human evaluation, 10 postgraduates are recruited to evaluate UBAR$^+$ and UBAR on Chinese name domain. During the interaction, the students randomly change the characters to those with similar pronunciations in the sentences. The same name and knowledge with errors are used on both models. At the end of the conversation, the evaluators are asked to check whether the dialog is successful. The postgraduates also score each system response to evaluate the appropriateness of the system response (Zhang et al., 2020a). The points range from 1 to 3, which respectively represent *invalid*, *ok*, and *good*. Another score on a Likert scale of 1-5 evaluates the diversity of the whole dialog. The results are shown in Table 7 and prove that UBAR$^+$ yields a much higher dialog success rate.

5 Related Work

We can group the datasets for task-oriented dialog systems by whether the two parts involved in the dialogs are humans or machines: human-to-human (H2H), machine-to-machine (M2M) and human-to-machine (H2M) collecting methods. H2H corpora are derived by asking a human user to talk with a human agent. To mimic the conversations between human and machine, H2H datasets ubiquitously apply the Wizard-of-Oz approach (Hemphill et al., 1990b; El Asri et al., 2017; Budzianowski et al., 2018; Zhu et al., 2020), which a human agent pretends as machine to talk to a human user and the human user believes the other side is a machine. However, it costs tremendous effort to construct such a H2H dataset. M2M datasets which are generated by simulated systems and simulated users take much less work to construct than H2H datasets with the same scale. However, the naturalness and diversity of M2M datasets are questioned (Peng et al., 2017; Shah et al., 2018; Rastogi et al., 2020; Dai et al., 2020). H2M (Raux et al., 2005; Williams et al., 2013; Henderson et al., 2014a,b; Kim et al., 2016) hires crowd workers to chat with a machine system and the conversations are more diverse and natural than M2M. We integrate the M2M and H2M approaches by boosting the generated M2M datasets through crowdsource rewriting to obtain more diverse and natural dialogs with less effort.

The datasets might be also grouped by the single-domain and the multi-domain. The early datasets are mostly single-domain. For example, ATIS (Hemphill et al., 1990b), by M2M strategy, is a system to help people make air travel plans; a H2M corpus, Let's Go Public (Raux et al., 2005), contains consultation dialogs of bus schedule information; two datasets for buying a movie ticket and reserving a restaurant table are collected by M2M (Shah et al., 2018). Single-domain systems generally fill slots within a single turn and thereby slot values are relatively independent. Recently, multi-domain datasets grab more attention. MultiWOZ (Budzianowski et al., 2018), one of the most popular datasets, consists of Wizard-of-Oz large-scale multi-domain conversations. A M2M dataset, SGD (Rastogi et al., 2020), generates multi-domain dialogs, guided by the predefined schema. CrossWOZ (Zhu et al., 2020) states how slots in one domain relate to the following domains by reference. Nevertheless, none of the above datasets, with single domain or multiple domains, look into sub-slot cases as SSD does. In SSTOD, we have to not only locate the related previous sub-slots through complicated expressions, but also tile the pieces of value into a correct sequence without duplication, missing, and errors under the assistance of external knowledge.

6 Conclusions and Future Work

In this paper, we propose a sub-slot based task SSTOD which has not brought to the public. To help the exploration of the task, we build a textual dialog dataset SSD which covers four popular domains and contains natural noise brought by ASR module. SSD stems from the real human-to-human dialogs and can be utilized as a benchmark for slot filling, dialog state tracking and dialog system that matches the real-world scenarios.

Ethical Considerations

The collection of our SSD dataset is consistent with the terms of use of any sources and the original authors' intellectual property and privacy rights. The SSD dataset is collected with ALIDUTY[1] platform, and each HIT requires up to 10 minutes to complete. The requested inputs are general language variations, speech voices, and no privacy-related information is collected during data collection. Each HIT was paid 0.1-0.2 USD for a single turn dialog data, which is higher than the minimum wage requirements in our area. The platform also hires professional reviewers to review all the collected data to ensure no ethical concerns e.g., toxic language and hate speech.

Acknowledgements

The authors would like to thank anonymous reviewers for their suggestions and comments, as well as professors for great inspiration. The authors are also grateful for all teammates, especially Yinpei Dai, for their productive and constructive advice.

A Knowledge

char	knowledge
黄	草头黄 (‘黄’ has the radical ‘艹’.)
林	双木林 (‘林’ has double ‘木’.)
王	三横一竖王 (Three horizontal bars and one vertical bar ‘wang’.)
赢	亡口月贝凡 (‘赢’ is composed of ‘亡’, ‘口’, ‘月’, ‘贝’ and ‘凡’.)
赛	下面一个贝的赛 (‘赛’ has the component ‘贝’)
怡	竖心旁加一个台湾的台的那个怡 (‘怡’ is a combination of the radical ‘忄’ and ‘台’ from Taiwan.)

Figure 6: Some different types of knowledge on Chinese characters.

char	knowledge	explanation
宝	**宝**宝	Baby
	宝贵	Precious
	宝马	BMW
	淘**宝**	Taobao
	宝石	Gemstone
	宝藏	Treasure
	珠**宝**	Jewelry
	宝玉	Precious jade
	宝物	Gems
	宝箱	Treasure Chest
	支付**宝**	Alipay
	宝盖头	Chinese radical ‘宀’
	小宝**贝**儿	Little Baby
	上面一个宝盖头，下面一个玉字	‘宀’ above, ‘玉’ below
	宝字盖加个玉	‘宀’ and ‘玉’
	宝盖下面一个玉的宝	‘玉’ under ‘宀’

Figure 7: Some pieces of knowledge about 宝’.

Figure 6 shows some different types of knowledge. The word “黄” is described with its radical. And it is necessary to use whole components to explain “林”, “王” and “赢” . In the fourth row, only a part of the word “赛”, “贝”, is enough to disambiguate homonyms. In the last example, “台” also needs explanation besides “怡”. Overall, the knowledge description is challenging for systems to get the correct char.

Some pieces of knowledge about “宝” are shown in Figure 7. It contains phrase-based knowledge, structure-based knowledge and hybrid knowledge. The way to explain one character is various and the number of one character’s knowledge is large.

PHONE	sys	那留个电话号码吧，好吧 (Please leave a phone number.)
	user	155，哦哦，是154 (155, ohh, it’s 154.)
	sys	哦，154，我已经记住了(OK, 154, I got it.)
	user	你弄错了，是155 (Not really. It’s 155.)
	sys	已经记住了155 (I got it. 155.)
	user	你弄好了对吧，然后是53639 (You got it, right. And then it’s 53639.)
	sys	1553639、15553639这两个，能再说下哪个是对的吗? (1553639, 15553639, which is correct?)
	user	对对，第一个是的 (Yep, the first one.)
	sys	嗯嗯 (OK)
	user	好的，尾号是7，7266 (Good. The last is 7, 7266.)
	sys	嗯嗯，15536397266，有没有问题？(OK, 15536397266. Anything wrong?)
	user	嗯呢，没问题 (OK, everything is good.)
	sys	拜拜 (Bye.)
ID	sys	我记录下您的身份证号 (I would like to record your ID number.)
	user	身份证号是34，3403 (My ID number is 34, 3403.)
	sys	好的， 接着说 (Good. Go on.)
	user	往下4034119 (The following digits are 4034119.)
	sys	4119，我知道了，好的。(4119, I see. Good.)
	user	211呀，不是411 (211, not 411.)
	sys	我已经记下了34032119 (Gotcha, 34032119.)
	user	请登记，接着是19771008 (And then, it’s 19771008.)
	sys	771008，哦 (771008, OK.)
	user	3个0，X，念完了(Triple 0, X. That’s it.)
	sys	呃，34032119771008000X是吗？(Hmmm, 34032119771008000X, correct?)
	user	最后改成800X就可以了(Change the last part to 800X.)
	sys	谢谢您的配合，34032119771008800X，好的，知道了 (Thank you! 34032119771008800X, I see.)
	user	嗯，是的 (Yeah, right.)
	sys	那这边不打扰你嗯 (Thank you for your time! Bye bye!)

Figure 10: Examples of dialogs of phone number collection and identity number collection.

Domain		Dialog
NAME	sys	你留一个你的名字吧 (May I have your name?)
	user	理灵，华菱的菱 (Li Ling. “菱” as in “华菱”.)
	sys	菱的话，草字体下面加一个上陵的右侧的菱吗？(Is “菱” the one “艹” with a bottom which is the right part of “陵” as in “上陵”?)
	user	对的，对的。(Yes, yes.)
	sys	理的话，王里理吗 (Is “理” composed of “王” and “里”?)
	user	不是，错了错了 (No, nope, nope.)
	sys	那应该是什么？(What should it be?)
	user	是李白的吕 (It’s “Lv” as in “Li Bai”.)
	sys	再见 (Bye.)
PLATE	sys	你先车牌号给我吧，你车牌号多少？(Could you tell me your license plate number?)
	user	好的，是GPSC你先记下来 (Sure. It’s “GPSC”.)
	sys	车牌第1个是呃，北京的京，对吗？(The first digit is “京” as in “北京”, right?)
	user	嗯是这个 (Yes, it is.)
	sys	我核对一下，你的车牌第4位是呃，CDE里面的C，对吧？(Let me double check. The fourth digit is “C” as in “CDE”, right?)
	user	第4位糟糕，记错了。麻烦你更正一下，是K，不是什么C，JKLM里面的K才对 (The fourth digit, damn, I got it wrong. Please recorrect it. It is “K”, not “C”, “K” as in “JKLM”.)
	sys	接着说 (You can go on.)
	user	再到6幺1 (Then, it’s “6 wan 1”.)
	sys	那个车牌第5个是不好意思，是123456的6还是最大的一位数的那个9？(I’m sorry. Is the fifth digit “6” as in “123456” or the largest digit “9”?)
	user	第5位哦，好像是5，不是6呀，567的5才对 (The fifth? It’s “5”, not “6”, “5” as in “567”.)
	sys	您的车牌号第6位是呃 2前面的那个1，对吗？(The sixth digit is “1” which is before “2” when counting number, right?)
	user	对的。(Yes.)
	sys	好的，拜 (OK. Bye.)

Towards Transparent Interactive Semantic Parsing via Step-by-Step Correction

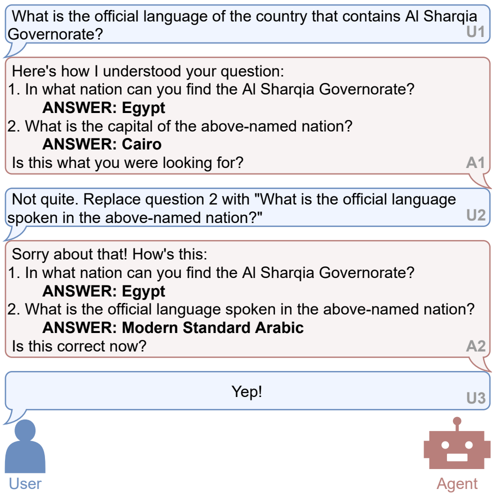
Lingbo Mo, Ashley Lewis, Huan Sun, Michael White
The Ohio State University
`{mo.169,lewis.2799,sun.397,white.1240}@osu.edu`

Abstract

Existing studies on semantic parsing focus on mapping a natural-language utterance to a logical form (LF) in one turn. However, because natural language may contain ambiguity and variability, this is a difficult challenge. In this work, we investigate an interactive semantic parsing framework that explains the predicted LF *step by step* in natural language and enables the user to make corrections through *natural-language feedback* for individual steps. We focus on question answering over knowledge bases (KBQA) as an instantiation of our framework, aiming to increase the transparency of the parsing process and help the user trust the final answer. We construct INSPIRED, a crowdsourced dialogue dataset derived from the COMPLEXWEBQUESTIONS dataset. Our experiments show that this framework has the potential to greatly improve overall parse accuracy. Furthermore, we develop a pipeline for dialogue simulation to evaluate our framework w.r.t. a variety of state-of-the-art KBQA models without further crowdsourcing effort. The results demonstrate that our framework promises to be effective across such models.[1]

1 Introduction

Semantic parsing aims to map natural language to formal meaning representations, such as λ-DCS, API calls, SQL and SPARQL queries. As seen in previous work (Liang et al., 2013; Yih et al., 2014, 2015; Talmor and Berant, 2018b; Chen et al., 2019; Lan and Jiang, 2020a; Gu et al., 2021), parsers still face major challenges: (1) the accuracy of state-of-the-art parsers is not high enough for real use, given that natural language questions can be ambiguous or highly variable with many possible paraphrases, and (2) it is hard for users to understand the parsing process and validate the results.



What is the official language of the country that contains Al Sharqia Governorate?

Here's how I understood your question:
1. In what nation can you find the Al Sharqia Governorate?
ANSWER: Egypt
2. What is the capital of the above-named nation?
ANSWER: Cairo
Is this what you were looking for?

Not quite. Replace question 2 with "What is the official language spoken in the above-named nation?"

Sorry about that! How's this:
1. In what nation can you find the Al Sharqia Governorate?
ANSWER: Egypt
2. What is the official language spoken in the above-named nation?
ANSWER: Modern Standard Arabic
Is this correct now?

Yep!

Figure 1: Example dialogue from our dataset (dubbed INSPIRED). The agent turns (A_i's) illustrate our emphasis on transparency by explaining the predicted logical form step by step in natural language, along with intermediate answers, to the user for feedback.

In response to the challenges above, recent work (Li and Jagadish, 2014; He et al., 2016; Chaurasia and Mooney, 2017; Su et al., 2018; Gur et al., 2018; Yao et al., 2019a; Elgohary et al., 2020) explores *interactive semantic parsing*, involving human users to give feedback and boost system accuracy. For example, Su et al. (2018) show that fine-grained user interaction greatly improves the usability of natural language interfaces to Web APIs. Yao et al. (2019a) allow their semantic parser to ask users clarification questions when generating an If-Then program. And recently, Elgohary et al. (2020) crowdsources the SPLASH dataset for correcting SQL queries using natural language feedback.

Compared with these approaches, we aim to enhance the transparency of the parsing process and increase user confidence in the final answer. Figure 1 shows a desired dialogue between user and agent. We design an interactive framework for semantic parse correction that can explain the predicted complex logical form (LF) in a step-by-step manner and enable the user to make corrections to individual steps in natural language. To demonstrate the advantages of our interactive framework, we propose

---

Findings of the Association for Computational Linguistics: ACL 2022, pages 322 - 342

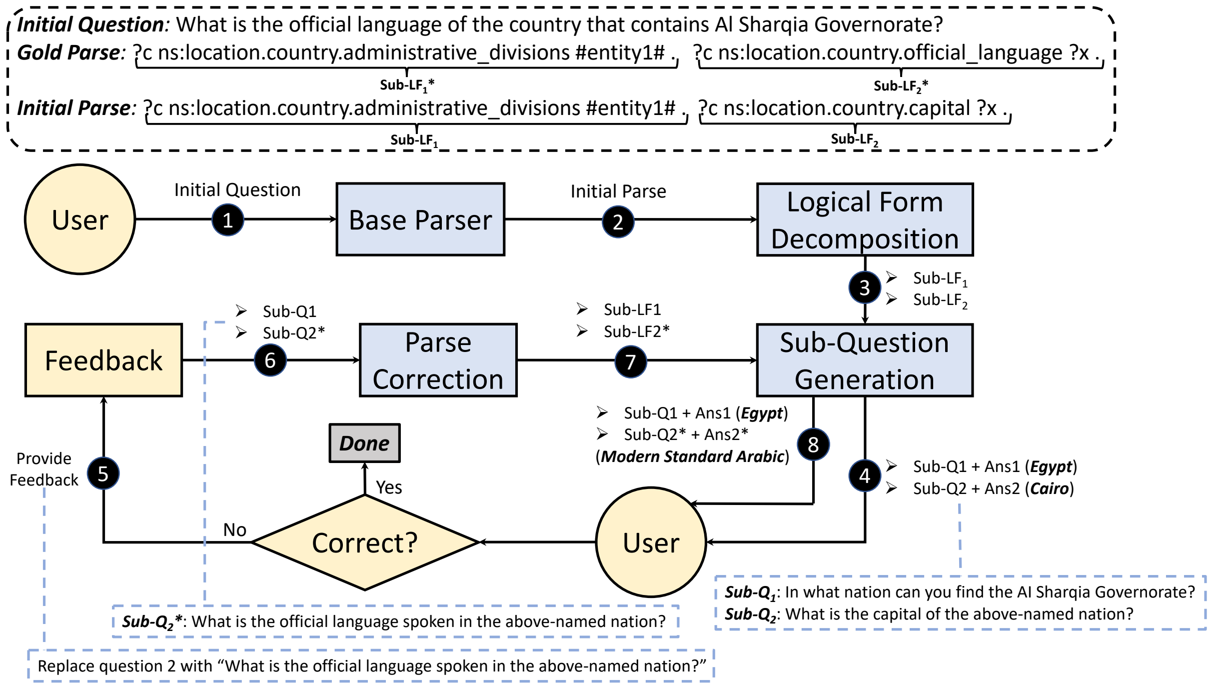

Figure 2: Illustration of our interactive semantic parsing framework for KBQA. The box on the top lists a running example. The prefix of a SPARQL query (i.e., LF used for KBQA in this paper) in this example is omitted for brevity. The figure on the bottom shows the entire workflow of our framework using the example above.

to instantiate it for complex question answering over knowledge bases (KBQA), where interactive semantic parsing has remained largely unexplored.

Figure 2 illustrates our framework with a concrete example: A base parser predicts an initial parse, which we decompose into sub-LFs and translate to natural-language questions (i.e., *Sub-Question Generation*). This shows the steps of answering the question, allowing the user to see exactly how a final answer is found and be confident that it is correct or give feedback in natural language to correct the steps. If any user feedback is given, our framework uses it to correct errors in the current parse (i.e., *Parse Correction*).

To build models for Sub-Question Generation and Parse Correction, we construct a dataset via crowdsourcing, based on the COMPLEXWEBQUESTIONS (CWQ) dataset (Talmor and Berant, 2018b), which is widely used for complex QA. To make LFs understandable to crowdworkers, we translate each sub-LF into a templated sub-question using a rule-based method. During crowdsourcing, workers paraphrase the templated question into a natural one. We create a dialogue for each complex question, an example of which is shown in Figure 1. Our dataset, dubbed INSPIRED (**IN**teractive **S**emantic **P**ars**I**ng for Cor**RE**ction with **D**ecomposition), will facilitate further exploration of interactive semantic parsing for KBQA.

Our main contributions are as follows: (1) We design a more transparent interactive semantic parsing framework that explains to a user how a complex question is answered step by step and enables them to make corrections in natural language and trust the final answer. (2) To support research on interactive semantic parsing for KBQA, we release a high-quality dialogue dataset using our framework. (3) We establish baseline models for two core subtasks in this framework: Sub-Question Generation and Parse Correction. (4) Although INSPIRED is constructed using a selected base parser, we are able to train models to simulate user feedback, allowing us to study the promise of our framework to correct errors made by other semantic parsers without more annotation effort. With these contributions, we hope to inspire many directions of future work, which we discuss in the end.

2 Dataset Construction

In this section, we describe the workflow for dataset construction following the design of our framework (Figure 2). We prepare pairs of complex questions and SPARQL parses predicted by a base semantic parser (Section 2.1.1). Then, we decompose the gold and predicted parses and determine *correction operations* (Section 2.1.2). The sub-LFs are translated to questions using templates (Section 2.1.3) and we employ crowdworkers to paraphrase these questions using natural language (Section 2.2).

2.1 Dialogue Preparation for Crowdsourcing

2.1.1 Preparing Questions and SPARQL

We start with the COMPLEXWEBQUESTIONS 1.1 (CWQ) dataset (Talmor and Berant, 2018a,b), which contains complex questions paired with gold SPARQL queries for Freebase (Bollacker et al., 2008). We adopt a transformer-based seq2seq model (Vaswani et al., 2017) as the base semantic parser to prepare a predicted SPARQL query for each complex question (see the second and third paragraphs in Section 4 for our rationale).

As a simplifying assumption, we take gold named entities mentioned in a question as given. Specifically, we replace named entities in a SPARQL query with special tokens such as *#entityX#*, where X is a number corresponding to the order in which the entity appears. After parsing, we replace these tokens with the gold entities. The challenge of addressing errors caused by named entity recognition and linking in a real KBQA system is left as an important piece of future work.

In order to reduce data collection cost, we select a subset of questions in the training data of CWQ to create dialogues in INSPIRED's training set. We conduct an analysis of repeated predicates and question types, and ensure that each predicate occurs at least three times in INSPIRED's training set when possible. We include every question where the base parser makes an error and ensure coverage of the four multi-hop reasoning types (Talmor and Berant, 2018b). Different reasoning types require different translation strategies in order to represent their logical forms in English (see Section 2.1.3 and Appendix A.3). We create 10,374 dialogues in total, based on 3,492 questions from the training set, 3,441 from the validation set, and 3,441 from the test set of CWQ. We omit a small set of questions from the original validation and test sets that are consistently confusing to crowdworkers. Table 1 shows a breakdown of the CWQ question types in the INSPIRED dataset, along with the average number of corrections and sub-questions.

2.1.2 Logical Form Decomposition

An important goal of creating INSPIRED is to make the process of question answering transparent to the user. Each dialogue features a decomposition process by which our framework transforms the complex question into an initial parse, breaks it into sub-LFs, retrieves answers, and presents this whole process to the user for correction. The overarching strategy of the decomposition process is to identify the predicates that express distinct components in the LF of the complex question, which correspond to individual sub-questions. Typically, these components appear as a *triple* in the logical form such as $\textit{Sub-LF}_1$ in Figure 2, which is comprised of a head entity, a predicate, and a tail entity. Logical forms in CWQ typically contain two or three of these components. There can be multiple predicates that group together to express one component, for example those connected by a CVT[2] (Compound Value Type) node, in which case the two predicates and their two entities will form one component. Within these, there can be filters and/or restrictions, which provide additional information about entities of the main predicate and are typically merged to the corresponding component. Details about how we deal with these logical form components are in Appendix A.3.1 and more concrete examples about decomposition are shown in Table 12.

Using this strategy, we decompose both the parser's predicted SPARQL query and the gold one into sub-LFs, and compare those sub-LFs to determine the sequence of operations needed to transform the predicted parse into the gold parse, including inserting, deleting, or replacing a sub-LF, which is to be paraphrased by crowdworkers (Section 2.2) based on our templated sub-question. These operations determine the "correction" steps in each

Number of	**Train**	**Dev**	**Test**	**Overall**

Range of the number of gold sub-questions				2 - 4
Average number of edits				1.4
Dialogues with 0 edits				5,016

Table 1: Statistics for our INSPIRED dataset: the number of complex questions for each reasoning type, the average number of sub-questions and edit operations in a dialogue (excluding those that do not have edits).

---

[2] CVT is a Type within Freebase which is used to represent data where each entry consists of multiple fields.

dialogue, where the agent asks the user if any corrections are needed (Figure 1, turn A1), and the user either confirms that the initial parse is correct or provides corrections (turn U2). Though any new sub-questions that are introduced use natural and varied language, the correction operations are given using templates (i.e., *replace question #X with Y, delete question #X, insert question Y*). More details about how dialogues are formed around complex questions can be found in Appendix A.1.

2.1.3 Explaining SPARQL

We develop a strategy for how to represent the sub-SPARQL queries in a form that crowdworkers can understand after decomposition, for which we create a template corpus and a rule-based translation method to do so. The corpus consists of 772 different predicates that appear in the CWQ dataset and translations of each into a basic template that conveys the content. More details about the translation of LFs with different reasoning types into sub-questions are found in Appendix A.2 and A.3.

2.2 Crowdsourcing

To make queries understandable for an average user, as in Figure 1, we translate the decomposed LFs into English questions using templates as mentioned in Section 2.1.3. To obtain natural sounding questions, we conduct crowdsourcing on Amazon Mechanical Turk (AMT), in which crowdworkers are employed to rephrase sub-questions from the clunky, templated form into more concise and natural English in the context of a dialogue. The task is conducted using ParlAI (Miller et al., 2017), which allows us to set up a versatile dialogue interface.

In each dialogue, every turn of the interlocutors has prescribed content. A total of 14 crowdworkers are employed to express the content in natural language and complete a maximum of 1,800 dialogues. Because the crowdsourcing task for this dataset requires extensive, detailed instructions, we design the task quite carefully with multiple stages of checkpoints to ensure quality of data collection. An overview of these phases can be seen in Table 2 and other details are presented in Appendix A.4. We recruit and retain a small set of exemplary workers for this task (see item 4 in General Principles in Table 2). This phased strategy, while requiring more effort, proves to be effective in ensuring overall data quality which will be shown in Section 3.

Phased Crowdsourcing Protocol
Phase 1: Tutorial
1. Worker reads examples and explanations of the task.
2. Worker receives specific instructions for how to rephrase questions of different types.
Phase II: Qualification Quiz
1. Worker completes an 8-question multiple choice quiz. Quiz questions are based on the tutorial content.
2. Worker must achieve at least 7 out of 8 to pass. They may take the quiz more than once, but there is a ten minute wait period between attempts.
Phase III: Trial Period
1. Worker completes 10 predetermined tasks which were chosen as representative examples for all the tasks.
2. Tasks are manually graded. If the work is overall good, the worker receives specific feedback on anything that was done incorrectly.
3. If quality is not good, worker is eliminated.
4. Workers get paid the regular rate for each task and upon completing the 10 tasks, receive a bonus for the time spent on the tutorial and qualification quiz.
Phase IV: Batches of Tasks
1. Worker is given access to a batch of 100 tasks, which are spot-checked for quality. A bonus is given as the worker passes each set of 100 tasks.
2. If quality is good, workers are given a second batch of 100 questions, also spot checked.
3. Batch size increases based on worker quality and speed.
4. Worker completes up to 1800 tasks.
General Principles
1. Prompt feedback, payment, and release of new batches
2. Provide a link to the tutorial so that it can be accessed at any time.
3. Higher than average payment.
4. Keep pool of workers small for better communication and quality control.
5. Verify that workers are native English speakers.

Table 2: The phased crowdsourcing protocol for our Amazon Mechanical Turk task.

3 Dataset Analysis

In this section, we conduct a thorough quality analysis of INSPIRED dataset and highlight aspects that contribute to overall quality, including paraphrasing characteristics and contextual awareness.

Overall Data Quality. In each dialogue, the crowdworker is required to rephrase the original complex question and each templated sub-question. Overall, we believe the quality of the data to be high for a few reasons. In the collection process, our crowdworkers read a detailed tutorial, pass two qualification tasks, and have their work spot-checked at each stage of collection. Because we keep our pool of workers small, we are able to maintain frequent communication with them throughout the process, giving feedback in an ongoing fashion.

Furthermore, we use a semi-automatic data cleaning method to identify inaccurate paraphrases for manual repair, resulting in edits to 325 sub-questions in total. Based on our observation on a held-out subset of the data, we estimate that only 3.1% of all sub-questions still have inaccuracies, after cleaning. More details are in Appendix B.1.

Paraphrasing Characteristics. Table 3 shows the difference between the vocabularies (unique words) of all the templates in INSPIRED and the rephrased versions of sub-questions, which are calculated using GEM evaluation scripts (Gehrmann et al., 2021). Further, the mean length of the templated questions is 17.3 words, while the mean

	Template Corpus	Rephrased Corpus
Avg Length	17.3	10.7
Unigrams	8,465	9,864
Bigrams	21,072	44,085
Trigrams	31,838	81,479

Table 3: Comparison of average length (in words) of templated and rephrased questions as well as the size of vocabulary for 1-, 2-, and 3-grams across all templates and rephrased questions, demonstrating the increased diversity of rephrased questions.

length of the rephrased questions is 10.7 words. These comparisons demonstrate that the rephrased questions show much more diversity in phrasings and lexical choices, but are also more concise. More GEM metrics can be seen in Appendix B.2.

In order to better understand how crowdworkers rephrased templates, 100 randomly selected sub-questions are studied in terms of lexical relationships between the template and rephrased versions. We find that they are using synonmy, hypernymy and hyponymy in rephrasings of the templates, in addition to changing word order. This analysis can be found in Appendix B.3.

Contextual Awareness. Additionally, crowdworkers are encouraged to incorporate contextual information of a given sub-question into their rephrasings, thus improving the contextual richness of the dataset. In order to demonstrate contextual awareness, Table 4 shows the average ROUGE-1 and ROUGE-2 scores of all sub-questions in their actual contexts (the complex question and any preceding sub-questions), in comparison to the same sub-questions in a randomly assigned context that utilizes the same sub-logical form. Entities are masked with *#entity#* tokens to prevent the actual context from being advantaged by overlap in entity names. The higher scores for the actual context indicate that the wording of sub-questions reflect the context from which they are derived.

In general, it is natural for human users to consider the context when making utterances in a dialogue. From the perspective of model development, providing contextual information enriches the input by providing relevant information that may not be present in a given sub-question or sub-LF. We provide concrete examples and analysis to show the effect of context dependency in Table 16 in Appendix B.4. Moreover, experiments considering different contexts in Section 4 further validate the impact of context dependence on parse correction and sub-question generation performance.

	ROUGE-1	ROUGE-2
Random Context	22.8	3.4
Actual Context	**27.7**	**6.2**

Table 4: Comparison of the n-gram overlap between the paraphrase and the context for a sub-LF vs. other randomly chosen context for the same sub-LF.

Models	**EM**	**F1**
*Transformer (Vaswani et al., 2017)	52.3	58.6
BART-large (Lewis et al., 2020)	60.9	65.8
QGG (Lan and Jiang, 2020b)	-	49.0

Table 5: Performance of different semantic parsers on CWQ test set.[4] The asterisk (*) denotes the initial semantic parser we choose for constructing INSPIRED.

4 Experiments

In this section, we explore several base semantic parsers and show how we choose one as the initial parser to construct INSPIRED. Then, we conduct extensive experiments on those two core sub-tasks (i.e., sub-question generation and parse correction) in our framework. Finally, in order to study the promise of our framework for other parsers (beyond the one used to construct INSPIRED) without introducing extra crowdsourcing effort, we simulate dialogues based on our trained models for sub-question generation and parse correction. We train all models on 4 GTX 1080 Ti 11 GB GPUs.

Firstly, we explore Transformer (Vaswani et al., 2017), BART-large (Lewis et al., 2020) and QGG (Lan and Jiang, 2020b) as base parsers. In the official leaderboard[3] of CWQ, QGG is the best-performing method in the line of query graph generation approaches. Models like NSM+h (He et al., 2021) and PullNet (Sun et al., 2019) directly output final answers without LFs, which cannot be made more transparent or interactive with our framework. CBR-KBQA (Das et al., 2021) is the SOTA model on this dataset as of the submission time, but as its code is not available, we choose Transformer and BART-large as the two candidate parsers. We input the complex question to these two seq2seq models and output the LF. Since entities are masked in the LFs for these models, we provide QGG with gold entities for fair comparison. We report their LF exact match (EM) and F1 scores in Table 5.

We finally select Transformer as the initial parser

---

[3] `https://www.tau-nlp.org/compwebq-leaderboard`

[4] Since INSPIRED excluded a small set of questions from CWQ, for fair comparison, scores here are calculated using questions in CWQ test set which are included in INSPIRED.

because it is neither state-of-the-art nor has overly poor performance. As the intention is to create a dataset that represents a wide range of parsing errors and correction strategies, a "middle-of-the-road" parser is best for achieving good coverage but also being of decent quality. We report the characteristics of errors made by Transformer in Appendix B.5. We will explore the other two models in Table 5 through simulation (Section 4.3).

In the following two sections, we explore two sub-tasks under our framework. We treat both of them as seq2seq tasks, then present and evaluate several baseline models including Seq2Seq (Sutskever et al., 2014), Transformer (Vaswani et al., 2017), BART-base and BART-large (Lewis et al., 2020) for each task, in which we use INSPIRED for training and testing. After that, we conduct error analysis for both sub-tasks by examining 100 examples respectively. Details of the analysis are in Appendix C.

4.1 Parse Correction with NL Feedback

Given a sub-question q, the parse correction task is to convert it into a new sub-LF p. By parsing the templates used by correction operations as mentioned in Section 2.1.2, we extract the operation (i.e., replace, delete, or insert a sub-question) and apply it to the appropriate step. Then, sub-LFs are compiled accordingly to form a correction parse P for the entire question. We predict the sub-LF based on q without considering contexts, and present the results of several baselines in Table 6. We report both the turn-level accuracy—the accuracy of sub-LFs in correction turns—and the dialog-level accuracy—the end-to-end accuracy of the entire LFs after correction—on our test set.

Since models like BART adopt a subword tokenization scheme, the validness of predicates generated by concatenating subwords can not always be guaranteed. We use beam search of size 10 to generate LFs as candidates, filtering those with invalid predicates and excluding erroneous predictions previously made by the parser. We additionally compare with a baseline named 2nd-Beam, which applies beam search on the base parser to obtain two initial parses and uses the second for parse correction. It has some performance gains over the setting without correction, but is much lower than those settings with human feedback. Results in Table 6 further suggest: (1) incorporating human feedback can substantially improve the parse accuracy and (2) using BART-large with pretraining as the correction model achieves the best performance, achieving 19.0 points higher than the initial parser in terms of the dialog-level EM score.

Correction Models	**Turn-level EM**	**Dialog-level EM**
w/o Correction	-	52.3
2nd-Beam	-	55.8
Seq2Seq(LSTM)	78.9	65.0
Transformer	81.2	68.0
BART-base	82.3	70.3
BART-large	**82.9**	**71.3**

Table 6: Turn-level and Dialogue-level accuracy of different models after incorporating feedback (where applicable).

Context	**Dialog-level EM**	**Turn-1 (3441)**	**Turn-2 (3441)**	**Turn-3 (345)**	**Turn-4 (56)**
w/o Correction	52.3	-	-	-	-
BART-large					
w/o Context	71.3	84.6	81.5	85.5	53.6
+ h_q	72.2	84.7	82.2	89.3	**100.0**
+ h_{lf}	72.0	84.3	82.1	89.3	**100.0**
+ h_q & h_{lf}	**73.5**	**86.4**	**83.2**	**91.0**	**100.0**

Table 7: Parse correction performance when considering different contexts. h_{lf} and h_q denote the dialogue history of sub-LFs and sub-questions respectively.

Then, using BART-large as the correction model, we further study the correction process by concatenating different contexts to the input, including the history of sub-questions h_q and sub-LFs h_{lf}. We report both the accuracy for each turn of correction and the end-to-end accuracy. As shown in Table 7, we find that: (1) Adding contexts into the input can further improve the correction accuracy. (2) As the number of turns goes up, context contributes more to the correction process, which indicates that including the full dialogue history in the input leads to the best results. (3) The BART-large model with inputs that leverage h_q and h_{lf} achieves the best performance, with a 21.2 increase under dialog-level EM compared to the initial parser.

4.2 Sub-Question Generation

Sub-question generation aims to translate a sub-LF p into a natural sub-question q. Table 8 lists generation performance from five baselines without considering contexts. We explore an off-the-shelf paraphrasing model,[5] which takes corresponding templated sub-question q^t as the input and outputs q. It is fine-tuned on BART-large using three paraphrasing datasets including Quora,[6] PAWS (Zhang et al., 2019) and MSR paraphrase corpus (Dolan

Generation Models	BLEU-2	BLEU-4	BERTScore
BART-paraphrase	10.6	2.7	88.0
Seq2Seq(LSTM)	17.8	6.4	90.8
Seq2Seq(LSTM)^t	18.7	6.7	91.3
Transformer	21.1	8.4	91.7
Transformer^t	23.4	9.1	92.6
BART-base	30.7	15.0	93.8
BART-base^t	32.0	15.9	94.1
BART-large	31.5	15.4	94.0
BART-large^t	**32.4**	**16.2**	**94.2**

Table 8: Question generation performance of different models. t denotes that the input incorporates templated sub-question, as well as the current sub-logical form.

Context	BLEU-2	BLEU-4	BERTScore
BART-large^t			
w/o Context	32.4	16.2	94.2
+ h_{q^t}	33.3	16.5	94.6
+ Q	33.4	16.6	94.6
+ Q & h_{q^t}	**34.1**	**17.1**	**94.8**

Table 9: Comparison of question generation performance when considering different contexts in the input.

and Brockett, 2005). The low scores demonstrate that sub-question generation is more challenging than a simple paraphrasing task. For the other models, we explore two scenarios with different inputs: (1) sub-LF p only and (2) a concatenation of p and q^t. We report BLEU scores based on n-grams overlap and BERTScores measuring semantic similarity. The results in Table 8 suggest that: (1) Using BART-large as the generation model achieves the best performance and (2) incorporating the templated sub-questions into the model input can improve performance on all baselines, which makes sense because some tokens in q^t can be directly copied into the output question.

Furthermore, we use the best-performing model (i.e. BART-large with both p and q^t as the input) in Table 8 as the basic setting to explore the modeling of different contexts including the complex question Q and the history of templated sub-questions h_{q^t}. As shown in Table 9, we find that (1) adding context into the model's input can obtain higher metric scores, which suggests that context can help in a dialogue. (2) Those settings that incorporate the original complex question Q generally perform better than the others, since the complex question contains the semantics of the sub-question to be generated. (3) BART-large with the input containing both Q and the history of templated sub-questions achieves the best performance. We also tried incorporating the history of sub-LFs h_{lf}, but it does not help further improve the performance.

	BART-large	QGG
EM	60.9	-
EM*	**75.1**	-
F1	65.8	49.0
F1*	**75.7**	**56.5**

Attempt	EM	F1
BART-large		
1	75.1	75.7
2	78.7	79.9
3	**79.0**	**80.1**

Table 10: The left table shows the performance of two types of semantic parsers after correction through simulation process, BART-large and QGG. * denotes results after correction. The right table shows BART-large's performance after multiple attempts of correction.

Because automatic metrics like BLEU scores do not necessarily paint a full picture of the model performance, we manually check 100 generated questions. They are indeed of high quality and semantically similar to the human-written ones; see details in the second part of Appendix C.

4.3 Simulation

In this section, we demonstrate that our framework can pair with other KBQA parsers and use simulated user feedback to correct their errors. To simulate a dialogue, we develop a pipeline: (1) Automatically translate a parser's predicted LFs into natural questions using the sub-question generation model equipped with the best-performing setting in Table 9. (2) Use oracle error detection and train a generator to simulate a human user's corrections for these dialogues. This generator is a BART-large model that leverages the complex question and templated sub-questions as input to generate human feedback. (3) Correct erroneous parses using the previously trained parse correction model under the best-performing setting in Table 7.

We conduct simulation experiments on BART-large (Lewis et al., 2020) and QGG (Lan and Jiang, 2020b) respectively from two mainstream methodologies for KBQA as mentioned. We report both F1 and EM for BART-large before and after the correction process using the simulation pipeline. For QGG, since its generated query graphs do not take exactly the same format as SPARQL queries, we report F1 score only. As shown in the left part of Table 10, BART-large achieves a 14.2 EM and 9.9 F1 score gain after correction. Meanwhile, the correction process brings 7.5 F1 score improvement for QGG. The results show that INSPIRED can help train effective sub-question generation and parse correction models, which makes our framework applicable to KBQA parsers beyond the one used for constructing INSPIRED. Simulating user feedback makes it easy and far less costly to understand the potential of any base parser (as long as it outputs LFs) under our framework.

Moreover, we expand the simulation experiment to include multiple attempts of correction to simulate situations in which the model does not repair the parse correctly on the first attempt. We use the same human feedback generator to decode several of the highest scoring sequences as candidates for different attempts at correction. We evaluate this strategy after a maximum of three attempts.

Given that sequences decoded by plain beam search (Sutskever et al., 2014) often differ only slightly from each other, we adopt diverse beam search (Vijayakumar et al., 2018) instead to decode more diverse feedback. As shown in the right part of Table 10, F1 scores are up to 80.1 after three attempts of correction. We expect CBR-KBQA (the SOTA model mentioned earlier) to do even better given the advantages it has over plain seq2seq models. For example, their retrieval module can alleviate errors caused by sparse predicates. We envision the combination of our framework and theirs as interesting future work.

5 Related Work

Conversational Semantic Parsing. Conversational semantic parsing (CSP) is the task of converting a sequence of natural language utterances into LFs through conversational interactions. It has been studied in task-oriented dialogues, question answering and text-to-SQL. In task-oriented systems, datasets like MWoZ (Budzianowski et al., 2018; Eric et al., 2020) and SMCalFlow (Andreas et al., 2020) help users with a specific task (e.g., booking a hotel). CSQA (Saha et al., 2018) and CoQA (Reddy et al., 2019) are built for conversational systems to answer inter-related, simple questions. Meanwhile, ATIS (Hemphill et al., 1990; Dahl et al., 1994), SPARC (Yu et al., 2019) and CoSQL (Yu et al., 2020) are constructed for conversational text-to-SQL tasks. Our work shares a similar objective, i.e., how to represent natural language utterances while considering the multi-turn dynamics of the dialogue. We differ from them in that our task aims at soliciting and applying human feedback to correct generated initial parses.

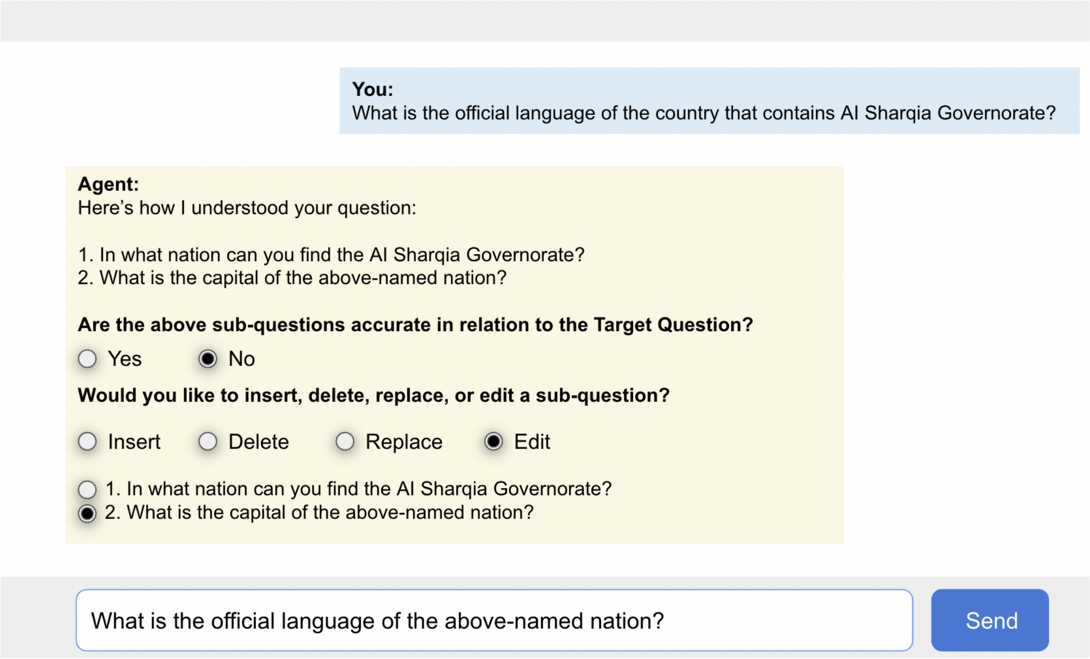
Interactive Semantic Parsing. Multiple works have studied involving human feedback in the parsing process. Gur et al. (2018) ask multiple choice questions about a limited set of predefined errors. Yao et al. (2019b) ask yes/no questions about the presence of SQL components when generating one component at a time. Elgohary et al. (2020) introduce SPLASH, a dataset for correcting parses in text-to-SQL with free-form natural language feedback. They observe that most mistakes made by neural text-to-SQL parsers are minor, which correspond to editing a schema item (table or column name), a SQL keyword, etc. They can thus be resolved by simply editing a single token or two. Corrections in SPLASH are given in one turn and applied to the entire initial parse. Elgohary et al. (2021) convert feedback in SPLASH into a canonical form of edits that are deterministically applied.

In contrast, we find that parse errors in KBQA are more challenging to resolve. KB relations like ‘location.country.capital’ need to be correctly identified among thousands of candidates, while the table schema in Elgohary et al. (2020) usually contains only a few table/column names. To make error correction easier in this setting, we break down the parse into a sequence of sub-components and enable the user to provide step-by-step feedback, thereby simplifying the task of parse correction and increasing the likelihood of an accurate parse.

Question Decomposition. Question decomposition has been successfully used in complex QA. Iyyer et al. (2016) propose to answer questions based on tables by decomposing them into interrelated simple questions. Talmor and Berant (2018b) and Min et al. (2019) train a model directly to produce sub-questions using question spans. Recent works (Wang et al., 2020b; Wolfson et al., 2020) introduce explicit annotation for the decomposition of multi-hop questions into a series of atomic operations. Wolfson et al. (2020) construct the BREAK dataset and propose QDMR, where questions are decomposed into a series of simpler atomic textual steps. QDMR is an intermediate representation of natural language and LFs, and is not executable on knowledge bases. In our work, we decompose the LF of the complex question into sub-components, which can be directly executed on the KB to retrieve answers. Moreover, we use decomposition to correct the initial parse at a finer-grained level.

6 Discussion and Future Work

We are planning to conduct a user study to validate our framework's viability for real use. In this study, human users will utilize the framework to correct parsing errors and query a knowledge base for answers in real time. As shown in Figure 3, users



You:
What is the official language of the country that contains Al Sharqia Governorate?

Agent:
Here’s how I understood your question:

1. In what nation can you find the Al Sharqia Governorate?
2. What is the capital of the above-named nation?

Are the above sub-questions accurate in relation to the Target Question?

○ Yes ● No

Would you like to insert, delete, replace, or edit a sub-question?

○ Insert ○ Delete ○ Replace ● Edit

○ 1. In what nation can you find the Al Sharqia Governorate?
● 2. What is the capital of the above-named nation?

What is the official language of the above-named nation?

Figure 3: User study interface. In addition to inserting/deleting/replacing sub-questions, we provide a new operation ‘edit’ to support minor changes, where the original sub-question is auto-filled into the response box after the user makes the selection. In this example, the user only needs to change *capital* into *official language*.

can specify edit operations in a couple clicks, then type in the response box to insert, replace or edit a sub-question. Note that we add a new ‘edit’ operation to make it easier for users to enter replacement sub-questions that require only small edits.

While we acknowledge that in a spoken dialogue system, pure natural language feedback may be the most natural, such a system may also suffer from errors caused by automatic speech recognition (ASR) (Wang et al., 2020a; Chang et al., 2021). By contrast, our interface design allows the user to partially specify feedback operations through mouse clicks, which can help mitigate this issue. To evaluate the system, we will use parse accuracy after correction to verify the usefulness of human feedback. We will also use survey questions to measure the subjective quality of the generated explanations, intermediate and final answers, accessibility of the system, etc.

In this work, the INSPIRED dataset and experiments provide a foundation for many directions of future work. For example, this could take the shape of gains in parse accuracy as well as improvements to the correction strategy through decomposition. The simulation pipeline provided can also be used for further experimentation. Other complementary work could include handling errors introduced by named entity recognition and linking. Lastly, applying our framework to other query languages like SQL could be an exciting direction.

7 Conclusion

We have proposed an interactive semantic parsing framework and instantiated it with KBQA in this work. Using this framework, we crowdsourced a novel dataset, dubbed INSPIRED, and experimentally showed that it can greatly increase the parse accuracy of an initial parser. Moreover, we designed a simulation pipeline to explore the potential of our framework for a variety of semantic parsers, without further annotation effort. The performance improvement shows interactive semantic parsing is promising for further improving KBQA in general.

8 Ethical Considerations

IRB Approval. Prior to collection of the INSPIRED dataset, we obtain IRB (Institutional Review Board) approval at our institution. This data collection is considered Exempt Research, meaning that our human subjects are presented with no greater than minimal risk by their participation. Participants’ personal information is not collected, aside from minimal demographic information including their native language, which is used to ensure native-speaker level proficiency in the dataset.

No identifying information is included. Further, all participants are required to read and agree to an *informed consent* form before proceeding with the task. AMT automatically anonymizes crowdworkers' identities as well.

Compensation to Crowdworkers. In order to ensure both quality data collection and fair treatment of our crowdworkers, we carefully review our payment plan for the AMT task. After a pilot study we gauge the average amount of time we expect a task to require and adjust the payment amount per task according to the minimum wage amount in our state, resulting in a 70 cent payment per task. Further, we ensure compensation for the time spent on the tutorial and qualification task by awarding \$10 bonuses after completion of their first 10 tasks. They also receive \$10 bonuses upon every 100 tasks they complete. In total, the cost of creating the INSPIRED dataset is approximately \$13,300.

Acknowledgments

We thank the Clippers and Pragmatics groups at OSU for helpful discussion. We also thank Yu Su, Xiang Deng, Luke Song and Vardaan Pahuja for their valuable feedback. Question
What is the official language of the country that contains Al Sharqia Governorate?
SPARQL Query
<sparql-header-1> ?c ns:location.country.administrative_divisions #entity1# . ?c ns:location.country.official_language ?x .
Answer
Modern Standard Arabic

Table 11: Example question from the CWQ dataset. The entity "Al Sharqia Governorate" is replaced with "#entity1#". Entities are delexicalized in order to increase generalizability across questions in training.

A Dataset Creation Details

The creation of the INSPIRED dataset requires careful selection of questions, design of a decompositional approach, and a translation strategy between logical forms and human-readable language. Further, we carefully design a crowdsourcing task to gather more natural-sounding questions to enhance the quality and versatility of our framework.

A.1 Forming Dialogues from CWQ

We utilize the COMPLEXWEBQUESTIONS 1.1 (CWQ) dataset (Talmor and Berant, 2018a,b), as this is a common dataset used for complex question-answering over knowledge bases. This dataset is formed by combining questions from the WEBQUESTIONSSP dataset (Yih et al., 2016) to form multi-hop complex questions, meaning that they require more than one step to answer. Each question has an associated SPARQL query that functions as a meaning representation of the question. Table 11 shows an example of a complex question, its associated SPARQL query, and its answer.

We envision that a human user will ask a complex question, the system will predict a SPARQL query for that question, decompose it into pieces, translate those pieces into English to show to the user to solicit feedback. The system will then use that feedback to correct the initial parse, if necessary. Figure 1 shows illustrations of this process.

In order to model this type of dialogue, we utilize a transformer-based seq2seq model (Vaswani et al., 2017) to predict a SPARQL query for each complex question and decompose the predicted and gold query into pieces, then use these pieces as editable chunks which can be deleted, replaced, or inserted to transform the predicted query into the gold. This process is the framework around which each dialogue is constructed. We translate each step from SPARQL into English to be comprehensible to a human user, thus resulting in dialogues like the one shown in Figure 1, all stemming from questions that occur in the CWQ dataset. Note that the parser used for this purpose is not state-of-the-art, as part of the goal is to have a broad coverage of error types for correction.

A.2 Translation of SPARQL Using Templates

As this dataset leverages SPARQL queries, we then develop a strategy for how to represent these queries in a more comprehensible form that humans can understand. Thus we create a template corpus and develop a rule-based translation method to do so. The corpus consists of 772 different predicates that appear in the CWQ dataset and translations of each into a basic template that conveys the content. The strategy of using templates to make content more human-friendly has a long history, both utilizing handcrafted templates (Kukich, 1983; McKeown, 1985; McRoy et al., 2000) and rule-based template formation (Angeli et al., 2010; Kondadadi et al., 2013). We use a blend of both approaches to create templates to represent logical forms in a way that is understandable to our crowdworkers. As can be seen in Table 11, SPARQL queries contain predicates that appear in the form of triples with each component separated by periods, such as *location.country.administrative_divisions* and *location.country.official_language*. These triples consist of a domain (*location*), a type (*country*) that represents a class within the domain, and a property (*administrative_divisions* and *official_language*) that specify more granular information. These predicates represent content information about the question and can appear in multiple, different questions. For example, the *location.country.administrative_divisions* predicate maps to the template *the country/countries that contain(s) <PH>*, where <PH> ("placeholder") gets replaced with a specific entity.

In the parsing process, we delexicalize these specific entities in order to make questions more generalizable and reduce noise during training. For

Composition	
Question	What is the mascot of the team that has Nicholas S. Zeppos as its leader?
SPARQL	<sparql-header-1> ?c ns:organization. organization.leadership ?k . ?k ns:organization.leadership.person #entity1# . ?c ns:education.educational _institution.mascot ?x .
Templates	1. the organization whose leadership includes a person named <PH> 2. the educational institution with the mascot <PH>
Translation	1. **What is/are** the organization whose leadership includes a person named **Nicholas S. Zeppos**? 2. **That entity is/are** the educational institution with the mascot **what**?
Conjunction	
Question	What country with the capital of Hagåtña is where Sam Shepard lives?
SPARQL	<sparql-header-2> #entity1# ns:people.person.places_lived ?y . ?y ns:people.place_lived.location ?x . ?x ns:location.country.capital #entity2# .
Templates	1. the person(s) who lived in <PH> 2. the location with the capital city named <PH>
Translation	1. **Sam Shepard is/are** the person(s) who lived in **what**? 2.**Of which, what is/are** the location with the capital city named **Hagåtña?**
Comparative	
Question	What country is in the Caribbean with a country calling code higher than 590?
SPARQL	<sparql-header-2> #entity1# ns:location.location.contains ?x . ?x ns:common.topic.notable_types #entity2# . ?x ns:location.country.calling_code ?num . filter (xsd:integer (?num) > 590) .
Templates	1. the location(s) containing <PH> (<RSTR>) 2. the country/countries whose calling code is/are <PH>
Translation	1. **Caribbean is/are** the location(s) containing **what (country)**? 2. **Of which, what is/are** the country/ countries whose calling code is/are **greater than 590**?
Superlative	
Question	Which pro athlete started his career earliest and was drafted by the Cleveland Browns?
SPARQL	<sparql-header-2> #entity1#ns:sports. professional_sports_team.draft_picks ?y . ?y ns:sports.sports_league_draft_pick. player ?x . ?x ns:sports.pro_athlete. career_start ?num . } order by ?num limit 1
Templates	1. the team(s) that drafted the athlete(s) <PH> 2. the pro athlete(s) who started their career(s) in <NUM>
Translation	1. **Cleveland Browns is/are** the team(s) that drafted the athlete(s) **what**? 2. **These entities are** the pro athlete(s) who started their career(s) in **what**? 3. **Of these, which is the entity associated with the earliest date?**

Table 12: Question types from the CWQ dataset and the translation process to templated sub-questions.

example, in the SPARQL query in Table 11, the replacement token *#entity1#* appears, which we replace with *Al Sharqia Governorate* when the template is invoked.

The remaining components of the SPARQL query specify the question type and any additional components, which we leverage to transform the template into a full sentence. The components will be discussed more fully in A.3. Thus, this particular SPARQL query translates to the following sub-questions:

1. *What is/are the country/countries that contain(s) [Al Sharqia Governorate]?*

   ANSWER: Egypt

2. *That entity is/are the country/countries whose official language is what?*

   ANSWER: Modern Standard Arabic

A.3 Question Types

Each of the questions in CWQ can be categorized into one of four major reasoning types: composition, conjunction, comparative, and superlative (Talmor and Berant, 2018b). Each type can be identified by the SPARQL query and translated accordingly. Table 12 shows the translation process of the four types with examples of each. The general strategy is to append content to the beginning of the template and replace the <PH> token to form a complete question and express the appropriate question type. As seen in Table 12, this is quite straightforward for composition- and conjunction-type questions.

Composition questions are composed of two simple questions, where the answer to the first is used to form the second question. As an example, in order to answer the question *What is the mascot of the team that has Nicholas S. Zeppos as its leader?*, one must first answer *In which organization is Nicholas S. Zeppos a leader?* to have all the content necessary to answer *What is the mascot of that organization?*. To translate these question types to templated sub-questions, we simply append *What is/are* before the first template and insert the named entity where the <PH> token appears in the template. Then, *That entity is/are* is appended to the beginning of the second template and *what* replaces the placeholder. Note that these positions can be reversed depending on what content is provided in the question. For example, a question could be either of the two options, depending on the goal of the target question:

1. ***What is/are** the organization whose leadership includes a person named **Nicholas S. Zeppos**?*
2. ***Vanderbilt University is/are** the organization whose leadership includes a person named **what**?*

Conjunction questions follow a very similar process, though because their goal is to find the intersection of two categories, the first question returns a list of answers. To account for this, we simply append *Of which* to the second question before following the same set of rules as the composition questions.

Comparative questions generally have a comparative operator (<, >) and a number contained in their SPARQL query, which we translate simply to *less than X* or *greater than X*, as appropriate. Note that the comparative example in Table 12 contains a "restriction predicate", marked by the <RSTR> token. This will be discussed in Section A.3.1.

Superlative questions require a slightly more complicated strategy. The first sub-question of a superlative type question always generates a list of answer options, while the second sub-question must pair those answer options with numerical information, such as dates or integers. Then, these numbers are ordered, either from smallest-to-largest or vice versa, and the first is returned as the final answer. To account for this, we append *These entities are* to front of the second template, to make it clear that multiple entities are involved, and return a paired list of entities and their corresponding values as an answer. Then we append a third sub-question that specifies how the questions are sorted and returns a single answer.

A.3.1 Logical Form Features

Within the four main types of questions (composition, conjunction, comparative, and superlative), there are a variety of features that appear. These features include filters, restriction predicates, and union predicates.

Filters act to restrict a list of entities in some fashion by assigning numerical boundaries. An example of this can be seen in Table 12 in the comparative question's SPARQL query, starting with the word *filter*. This sequence limits the list of entities by ones whose calling codes are larger than 590.

Restriction predicates can appear as auxiliary pieces to regular predicates and typically provide categorical information about an entity. For example, in Table 12, the comparative-type question *What country is in the Caribbean with a country calling code higher than 590?* has two entities in its SPARQL query, though *Caribbean* is the only entity that seems to appear in the original question. The two main predicates are *location.location.contains* and *location.country.calling_code*, but a third predicate, *common.topic.notable_types* appears in between them. This predicate acts as a restriction upon the first main predicate; in this case *#entity2#* corresponds to *country* and restricts the locations that can appear as answers to the category of countries.

Because restriction predicates are not standalone pieces that could be translated into their own sub-questions, we develop a strategy for incorporating them into the templates of the predicates they restrict. First, we create a corpus of "mini-templates" that correspond to all the restriction predicates that could appear. Much of the time, these mini-templates simply place the entity (like *country* in the previous example) into parentheses, though in some cases they situate the entity into a prepositional phrase.

Meanwhile, the main template corpus has tokens in place to define where the mini-template should be placed in the main template. One can see in the comparative example of Table 12 that there is an <RSTR> token in the template of the first sub-question. Every main template that can appear with a restriction predicate has this token in its template; though it needs not always appear with one. Consequently, if the restriction token does not get replaced, it simply gets deleted. If the *location.location.contains* predicate appeared without a restriction predicate, it would simply read *Caribbean is/are the location(s) containing what?*

Union predicates are a bit of a misnomer, as they are actually a group of predicates that function as though they are a single predicate, and thus correspond to a single template. In Table 13, one can see that the SPARQL query is quite long, with all of the content in bold corresponding to the first sub-question and the remainder corresponding to the second. Within this first sub-LF, there are several predicates that are joined together by *} union {*. Col-

Composition	
Question	Who is both a member of the Kennedy family and the Order of the British Empire?
SPARQL	**filter (?x != #entity1#) { # parents #entity2# ns:people.person.parents ?x . } union { # children #entity3# ns:people.person.children ?x . } union { # siblings #entity4# ns:people.person.sibling_s ?y . ?y ns:people.sibling_relationship.sibling ?x . } union { #spouse #entity5# ns:people.person.spouse_s ?y . ?y ns:people.marriage.spouse ?x . ?y ns:people.marriage.type_of_union #entity6# . filter (not exists { ?y ns:people.marriage.to []}) }** ?x ns:royalty.chivalric_order_member.belongs_to_order ?c . ?c ns:royalty.chivalric_order_membership.order #entity7# .
Templates	1. the family of <PH> 2. the member(s) of the order of <PH>
Translation	1. **Who is/was** the family of **John F. Kennedy**? 2. **Of which, what is/are** the member(s) of the order of **Order of the British Empire**?

Table 13: Example of a question whose SPARQL query includes a union predicate.

lectively, these templates encompass the concept of *family* by defining all the various relationship roles that are involved in that concept. Theoretically, we could enumerate all of these in template form, separated by *or* (*the brother of John F. Kennedy* ***or*** *the mother of John F. Kennedy* ***or*** *the child of John F. Kennedy*...) but this seems to be an unnecessarily complicated and inconcise way of representing these. Instead, we enumerate the various types of union predicates that could appear and create a small corpus of templates that express the overall concept represented by each collection of predicates, thus crowdworkers will see questions with this feature in the same format as a regular question.

A.4 Crowdsourced Data Collection

As mentioned in Section 2.2, the crowdsourcing task for this dataset is primarily a paraphrasing task in which crowdworkers work through a structured dialogue, rephrasing templated sub-questions at each step.

Each task takes the form of a dialogue involving three entities: the "user", which is an automated dialogue partner, an automated "director" that guides the dialogue and provides detailed instructions, and the "agent", which is the role performed by the crowdworker. Upon entering a task, the worker is shown the "target question", or the original question from CWQ, and asked if the question was sensible to them. If so, they are asked to rephrase it using different language. If not, they proceed with the dialogue in the hopes that the decomposition process will make the meaning of the question clear. In these cases, the crowdworker is asked to rephrase the target question at the end of the dialogue. This process is included to encourage better understanding of the target question and to help us recognize confusing questions in the original dataset and replace them with higher-quality questions when appropriate.

Next, the target question is automatically decomposed into templated sub-questions which are displayed to the worker, who rephrases them into English. These rephrased questions are sent to the automated user, who provides corrections as necessary. The worker rephrases any new questions and the edits are automatically made. At the end of the dialogue, the worker is asked for any feedback regarding the dialogue. This feedback is later used to make corrections and flag any problems that might have arisen. Screenshots of the dialogue interface can be seen in Figure 4.

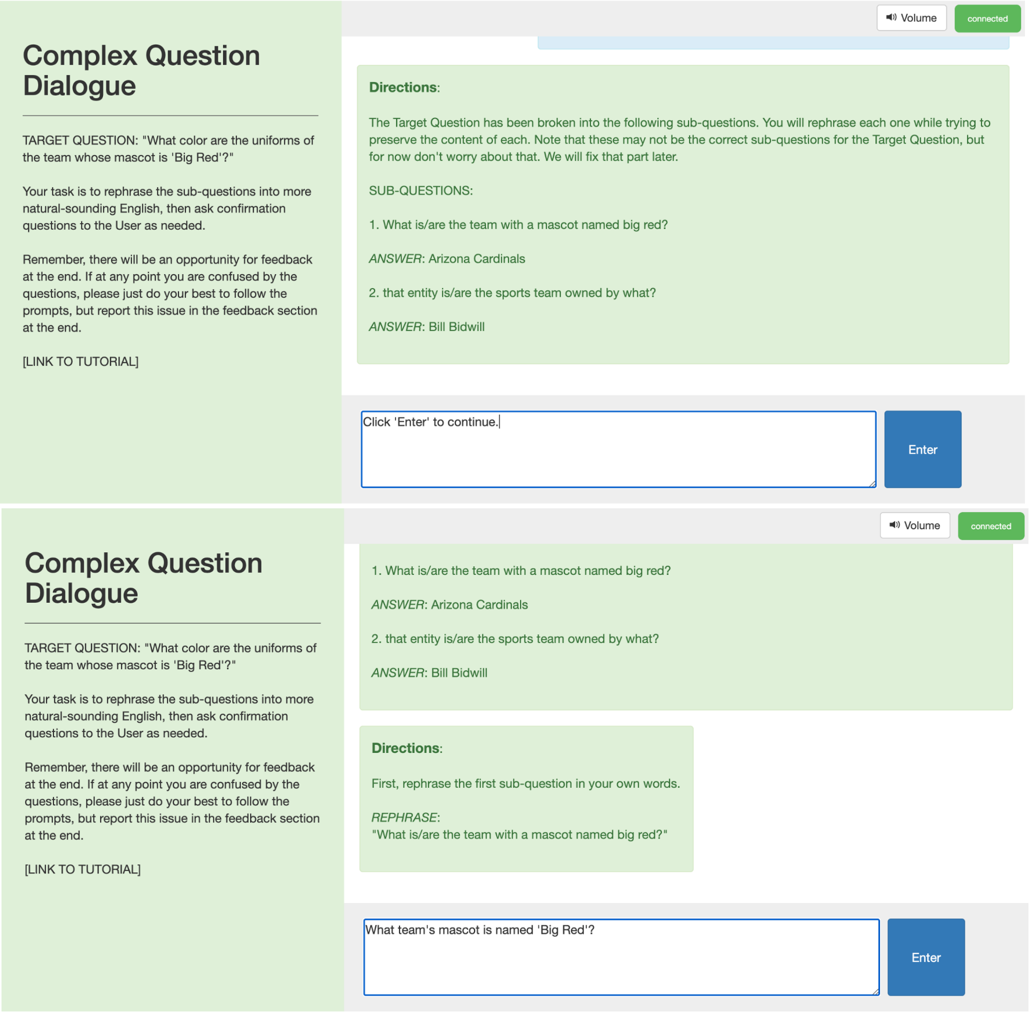
B Dataset Analysis

B.1 Cleaning the Dataset

As mentioned in Section 3, we employ a semi-automatic data cleaning method to reduce the error rate in the INSPIRED dataset. Because data cleaning can be an expensive and time-consuming process, the goal is to develop a method that would reduce the number of items in the dataset that need to be manually reviewed. Thus we use an automatic method to identify a small subset of the entire dataset that contain as many errors as possible to then manually review. To this end, we utilize a pre-trained sequence-to-sequence model that employs the idea of *cycle consistency* (Zhu et al., 2017), to identify poor paraphrases by retrieving meaning representations (MRs) from questions rephrased by the workers. Then these MRs are used to compare against the original MRs and evaluated for similarity.

In order to evaluate the effectiveness of the strategy, a random 5% subset of the entire dataset is selected for annotation, using a binary classification of whether or not the rephrased question was an accurate paraphrase of the original templated question (and by extension, its original logical form). This annotation effort revealed that 4.4% of the rephrased questions contain errors, which we expect is representative of the entire dataset.

We then fine-tune Hugging Face's implementa-



Complex Question Dialogue

TARGET QUESTION: "What color are the uniforms of the team whose mascot is 'Big Red'?"

Your task is to rephrase the sub-questions into more natural-sounding English, then ask confirmation questions to the User as needed.

Remember, there will be an opportunity for feedback at the end. If at any point you are confused by the questions, please just do your best to follow the prompts, but report this issue in the feedback section at the end.

[LINK TO TUTORIAL]

Directions:

The Target Question has been broken into the following sub-questions. You will rephrase each one while trying to preserve the content of each. Note that these may not be the correct sub-questions for the Target Question, but for now don't worry about that. We will fix that part later.

SUB-QUESTIONS:

1. What is/are the team with a mascot named big red?

ANSWER: Arizona Cardinals

2. that entity is/are the sports team owned by what?

ANSWER: Bill Bidwill

Click 'Enter' to continue.

ANSWER: Arizona Cardinals

2. that entity is/are the sports team owned by what?

ANSWER: Bill Bidwill

Directions:

First, rephrase the first sub-question in your own words.

REPHRASE:
"What is/are the team with a mascot named big red?"

What team's mascot is named 'Big Red'?

Figure 4: Data collection interface on AMT, using the ParlAI framework (Miller et al., 2017).

tion of T5 in a seq2seq model to generate MRs, in this case templated sub-questions, to compare to the original MRs (Wolf et al., 2020; Raffel et al., 2020). These pairs of MRs then need to be sorted in a ranked list that filters paraphrases that are more likely to contain errors to the top of the list. This allows us to use a *precision at K* measure, which, given a rank K, the precision is calculated over the set of retrieved items with a rank of K or less. For the annotated test set, K equals 75, the number of observed errors. After ranking the list, we can evaluate the quality of the method by checking the top K data points and checking to find how many errors appear in that set, compared to a random baseline of 4.4% (the observed error rate), or about 3 errors.

We employ two ranking methods to sort the pairs. First, we calculate the negative log-likelihood of the target MRs relative to the model and then do the same for the generated MRs.

$$S(y) = -\sum_{y_i \in Y} \log p(y_i | y_{<i}, x; \theta) \tag{1}$$

$$y = \langle y_1, ..., y_{|y|} \rangle$$
$$y_{<i} = \langle y_1, ..., y_{i-1} \rangle$$

$S(y)$ refers to the score of a given output sequence y, which is the sum of the negative log-likelihood of each y_i given the sequence of y tokens that come before. θ refers to the model parameters.

Once the negative log-likelihoods are determined for each candidate y, the best candidate is determined based on the lowest score.

$$y* = argmin(S(y|x)) \tag{2}$$

Here, $y*$ refers to the best generated output sequence, and x is a given input sequence. A score for output sequence $y*$ is determined, as well as a score for the target sequence t.

$$D = |S(y*) - S(t)| \tag{3}$$

While these two scores are comparable to each other, they are not comparable across other item pairs. In order to assign a ranking for every item in the dataset, we calculate the difference D between the negative log-likelihoods of the target MR and generated MR for each question in the dataset and sort them based on the largest difference score, as shown in Equation 3.

Second, we calculate an edit distance score between the target MR and generated MR and sort based on the largest score. If the model has predicted an MR that is substantially far from the target MR in its phrasing, it likely has a different meaning.

Using the first ranking method, 17.3% of the errors are recovered, while the second recovers 32% of the errors. However, because the two ranking methods appear to be identifying different errors with little overlap, both are used to identify the final set of questions for manual review, drawing from the methods equally.

Then the method is applied to the entire INSPIRED dataset, using cross-validation with a series of 90% training, 10% testing splits to generate MRs for every rephrased question. Then, because the annotated dataset has a 4.4% error rate which we expect to be representative of all the data, the top-ranked 4.4% of data is selected for manual review. This review results in 17.7% of items being revised, meaning that authors change the rephrasing to more accurately reflect the original meaning.

B.2 GEM Metrics

	Template Corpus	Rephrased Corpus
Unigrams		
Vocab Size	8,465	9,864
Distinct	0.012	0.022
Unique	1,003	1,258
Entropy	6.532	8.090
Bigrams		
Vocab Size	21,072	44,085
Distinct	0.031	0.109
Unique	2,949	8,723
Entropy	8.976	12.484
Cond Entropy	2.295	3.918
Trigrams		
Vocab Size	31,838	81,479
Distinct	0.050	0.224
Unique	5,332	20,971
Entropy	10.291	14.529
Cond Entropy	1.250	1.986

Table 14: GEM n-gram metrics for the template corpus and rephrased question corpus.

Lexical Relationship	Percentage(%)
Lexical Match	58
Synonymy	31
Hypernymy	5
Hyponymy	20

Table 15: Lexical analysis of 100 randomly sampled sub-questions and their templates. Note that *Lexical Match* refers to the percentage of words in all sub-questions that appear in their corresponding templated question.

Table 14 shows the N-gram statistics of all the templates in the dataset (template corpus) and all the rephrased questions (rephrased corpus). These metrics are calculated using the GEM evaluation scripts (Gehrmann et al., 2021). In this table, *Vocab Size* refers to the total number of distinct N-grams, while *Distinct* refers to the ratio of distinct N-grams divided by the total number of N-grams in the dataset. *Unique* specifies the number of N-grams that occur only once in the dataset, *Entropy* is the Shannon entropy over N-grams, and *Cond(itional) Entropy* is the entropy conditioned on $\text{N}_{\text{-}1}$-grams.

B.3 Lexical Analysis

In order to better understand the methods by which crowdworkers rephrased templates, 100 randomly selected sub-questions are studied in terms of the lexical relationships between the template and rephrased versions. Table 15 shows the results of this analysis. “Lexical match” refers to the average proportion of words in the rephrased version that also appear in the template, relative to the total number of words in the rephrased version. Synonymy, hypernymy, and hyponymy refer to the number of questions in the 100 selected items that contain an instance of one of these lexical relations. It is clear, therefore, that crowdworkers are using these strategies in their rephrasings of the templates, in addition to simply changing word order. On average, a bit less than half the words in a rephrased question are newly introduced by the crowdworker, and 56% of the time they are using synonmy, hypernymy, hyponymy, or some combination of these to rephrase the templated question.

B.4 Contextual Awareness

In a given dialogue, we provide answers to the sub-questions when possible, making the dialogue context-rich and providing the user with as much

Sub-question predicate	Actual Context	Random Context
film.film_subject.films	Complex Question: **Who was** the wife of **the subject of the** film #entity#? Sub-Questions: *1. Who was the subject of the movie #entity#? 2. Who was that person married to?	Complex Question: Where did the topic **of the** film #entity# pass away at? Sub-Questions: *1. Who was the main focus in the movie called #entity#? 2. Where did this individual die?
influence.influence_node. influenced_by	Complex Question: Which peer of #entity# **inspired the work of** #entity#? Sub-Questions: *1. Who inspired the work of #entity#? 2. Of the above named people, which had a peer relationship with #entity#?	Complex Question: What person **who** influenced #entity# 's **work** was born on #entity#? Sub-Questions: *1. #entity# inspired which people's work? 2. Which of these people were born on #entity#?

Table 16: Examples of sub-questions in their actual context vs. a random context that utilizes the same predicate in its logical form. The sub-question was substituted for the one that used the same logical form (marked with *) in the random context when calculating ROUGE scores. Lexical overlap of the sub-question with each context is represented by bold text. Entities have been replaced with #entity# tokens in order to avoid disadvantaging the random context due to overlap in named entities.

information as possible to help them understand the decomposition process of their original query.

This context-awareness can also be seen in the sub-question paraphrases. Our crowdworkers are encouraged to paraphrase questions in a manner that accounts for the overall context of the question, particularly with regard to named entities. For example, when a second sub-question references the answer of the first sub-question, we ask the Turkers to reference that entity without naming it explicitly, but also using a more specific phrase than *entity*. An example of this can be seen in Figure 1, where instead of directly incorporating the answer of the first question (*Egypt*) into the second question, they reference it using the phrase *the above-named nation*. The goal of this strategy is to create a dataset of dialogues that are context-aware and grounded, on which generation models can be trained to mirror this behavior. By using less specific phrases than entity names, our model is better able to generalize across examples during training.

However, one can envision that in a real-use situation, it might be more natural for a user to simply use *Egypt* instead of *the above-named nation* when correcting sub-question 2. While our current framework is not able to accommodate this behavior, a simple data augmentation procedure in which referring expressions are replaced with the named entities should allow our system to accommodate this. We leave this data augmentation for future work, but plan to implement it upon conducting a study with real users.

In order to demonstrate contextual awareness, Table 4 in Section 3 shows the average ROUGE-1 and ROUGE-2 scores of all sub-questions in their actual contexts compared with the same sub-questions in a randomly assigned context that utilizes the same sub-logical form. The higher scores for the actual context indicate that the wording of sub-questions reflect the context from which they are derived. Moreover, Table 16 shows examples of sub-question with these context comparisons.

	Conjunction	Composition	Comparative	Superlative	Total
Delete	49	94	9	3	155
Insert	1835	765	208	208	3016
Replace	2207	1757	341	393	4698
No Action	2172	2240	301	310	5023

Table 17: Distribution of error types within the sub-questions of the four main question types.

B.5 Error Characteristics of Initial Parser

It is important to note that our initial parser is purposefully not state-of-the-art, as we want to have a wide distribution of errors around which we could create dialogues. (See Section 4 for details about the initial parser.) Similar to other interactive semantic parsing work, we envision that the user will provide corrections to the sub-questions, though we at this stage require the user to use the three operations of deleting, replacing, or inserting a whole sub-question. Table 17 shows the distribution of sub-questions whose original complex question is of each of the four main types. Within these types, the distribution of edit operations per sub-question is shown. Though many of sub-questions do not need any edits, the *replace* operation is most frequent of edit operations, appearing in roughly 36.5% of each type, while *insert* is roughly 23.3% and *delete* is around 1.2%, with *no action* making up the remaining 39%. These distributions indicate the parser is more likely to predict something incorrect or leave out a sub-question, rather than predict

Sub-Q:
What tourist attractions are by the grand canyon?
Gold Sub-LF:
#entity1# ns:travel.tourist_attraction.near_travel_destination ?x .
Generated Sub-LF:
#entity1# ns:travel.travel_destination.tourist_attractions ?x .

Sub-Q:
What is that country's national anthem?
Gold Sub-LF:
?c ns:location.country.national_anthem **?y . ?y** ns:government.national_anthem_of_a_country.anthem ?x .
Generated Sub-LF:
?c ns:location.country.national_anthem ?x .

Table 18: Two error cases about wrongly generated predicates in an analysis of 100 generated sub logical forms. $?y$ in the logical form is an example of CVT node which connects two predicates that operate as a single, compound predicate.

Human-Written	*Which of the above named people did the voice of toki?*
Machine-Generated	*Which of these people played the role of toki?*
Error Explanation	Generated question does not specify that the role was a voice acting one.
Human-Written	*What famous person has addison's disease?*
Machine-Generated	*who has suffer from addison's disease?*
Error Explanation	Grammatical error
Human-Written	*What district does that politician represent?*
Machine-Generated	*What district does that person represent?*
Error Explanation	Generated question is slightly less specific

Table 19: Three instances of errors in an analysis of 100 generated sub-questions compared to human-written versions.

a sub-question that is not present in the gold.

C Sub-Task Error Analyses

Parse Correction. We sample 100 erroneous predictions of BART-large under the best-performing setting in Table 7. In this analysis, it becomes clear that longer, more complicated logical forms are more likely to be mispredicted. Only 21 of the errors involve single predicates, while 54 erroneous parses occur with *CVT (Compound Value Type)* predicates, which are essentially two predicates combined together via *CVT nodes* (for example *?y* in Table 18) that function as a single predicate. 13 errors occur on *restriction* predicates, which co-occur with single or *CVT* predicates to further limit the entity type. For example, predicates of the *location* domain might occur with a restriction that limits that predicate to locations of the type *country*. The remaining 12 errors all occur due to only partially generating a long logical form that contains filters. Details regarding restriction predicates and filters can be found in A.3.1.

Sub-Question Generation. We conduct an analysis on 100 randomly selected pairs of human-written question and machine-generated question that correspond to the same logical form. We first examine questions from the best-performing model in Table 9 according to BLEU scores and BERTScores, which use the current sub-logical form, the current templated sub-question, the complex question and the history of templated sub-questions from previous steps as context. Questions in which the machine-generated and human-written versions exactly match each other were excluded. This analysis reveals that only three generated questions (3%) are of perceptibly worse quality than the human-written questions, as can be seen in Table 19. Further, there are four cases in which the human-written questions contain grammatical errors, whereas the machine-generated ones do not. An analysis of all generated questions which do not exactly match their human-written counterpart reveals that 64% of the generated questions are shorter in terms of number of words.

Better Model	Neither	Model 1	Model 2
Number	74	20	6
EXAMPLES			
Human-Written	who were walt disney's kids?	kevin hart went to what schools?	what is the name of the currency used in that country?
Model 1 (w/context)	who are the children of walt disney?	what **schools** did kevin hart go to?	what kind of currency do they use?
Model 2 (w/o context)	what are the names of walt disney's children?	what did kevin hart go to?	what is the currency used **in that country**?

Table 20: Comparison of 100 generated sub-questions from models with and without context in their inputs. The bolded text in columns 2 and 3 highlight what enhanced the quality of the generation in comparison to its counterpart. Model 1 refers to the model that used the complex question and previous templated questions as context (row 4 in Table 9) and Model 2 refers to the model that did not use context at all (row 1 in Table 9).

Because BLEU scores do not necessarily paint a full picture of the model performance, we then examine the generated responses from the model that produced the lowest BLEU scores, which is the model with no context. By examining the same 100 samples as in the previous analysis, we note twenty cases in which the best-performing model that leverages context better reflects that context in its rephrasing than the model that does not leverage context. There are, however, 6 cases in which the model without context does this better and in the remaining cases there is no discernible difference between the quality of the generations from the two models. Table 20 shows examples of each of these cases, for illustration.

While these results are based our observations and certainly require further future investigation and human annotation by people other than the authors, these preliminary results show that the generated questions can be more concise and of comparable quality.

MINER: Multi-Interest Matching Network for News Recommendation

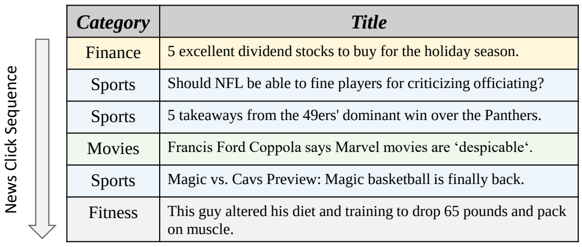
Abstract

Personalized news recommendation is an essential technique to help users find interested news. Accurately matching user's interests and candidate news is the key to news recommendation. Most existing methods learn a single user embedding from user's historical behaviors to represent the reading interest. However, user interest is usually diverse and may not be adequately modeled by a single user embedding. In this paper, we propose a *poly attention scheme* to learn multiple interest vectors for each user, which encodes the different aspects of user interest. We further propose a *disagreement regularization* to make the learned interests vectors more diverse. Moreover, we design a *category-aware attention weighting* strategy that incorporates the news category information as explicit interest signals into the attention mechanism. Extensive experiments on the MIND news recommendation benchmark demonstrate that our approach significantly outperforms existing state-of-the-art methods.

1 Introduction

Online news platforms such as Google News[1] and Microsoft News[2] have become a prevalent way for users to access news information (Das et al., 2007). The large amount of news generated every day make it hard for users to find their interested news. To alleviate information overload and improve reading experience, personalized news recommendation has become an essential part of these platforms (Liu et al., 2010; Phelan et al., 2011).



Category	*Title*
Finance	5 excellent dividend stocks to buy for the holiday season.
Sports	Should NFL be able to fine players for criticizing officiating?
Sports	5 takeaways from the 49ers' dominant win over the Panthers.
Movies	Francis Ford Coppola says Marvel movies are 'despicable'.
Sports	Magic vs. Cavs Preview: Magic basketball is finally back.
Fitness	This guy altered his diet and training to drop 65 pounds and pack on muscle.

Figure 1: The news click history of one user, who has various interests including finance, sports and movies.

Accurate matching between users' interests and candidate news is the key to personalized news recommendation. Existing methods usually learn a *single* user interest vector by aggregating the previously browsed news via sequential or attentive models and then match it with candidate news vectors. For example, Okura et al. (2017) employ a GRU network to model user interest from the sequence of clicked news with the last hidden state of GRU being the user interest representation. An et al. (2019) also use a GRU network to aggregate clicked news sequence as an interest vector and combine it with the user ID embedding. Wu et al. (2019a) and Wu et al. (2019c) apply attentive pooling on the sequence of clicked news vectors to obtain user representations. However, user interest is usually varying and diverse. As the example shown in Figure 1, a user may be interested in different types of news (with distinct background colors) such as finance, sports, and movies. Therefore, it is insufficient for the above methods to accurately model user interest via a *single* user embedding, especially when the user has multiple interests with a long browsing history.

In this paper, we propose a **M**ulti-**I**nterest Matching **N**etwork for n**E**ws **R**ecommendation (namely MINER), which can effectively capture the diverse nature of user's reading interests. Specifically, we first employ pre-trained BERT (Devlin et al., 2019) as the news encoder which is highly effective in modeling the text semantics. With the encoded news representation sequence, we propose a *poly attention scheme* to extract multiple interest vectors for each user. A matching score is calculated for each interest vector and the final matching score is aggregated by the individual scores. We study various aggregation methods including maximum, average, and weighted sum. Furthermore, to make the

extracted user interest representations more diverse, we propose a *disagreement regularization* (Li et al., 2021) which enlarges the distance among different interest vectors. In addition, news category information is usually available as shown in Figure 1, which reveals explicit user interest signals. To capture such signals, we propose a *category-aware attention weighting* strategy in the poly attention where historical news are re-weighted based on the category similarity to candidate news. We conduct extensive experiments and analysis on the real-world MIND news recommendation dataset (Wu et al., 2020), and the results show that MINER significantly outperforms the existing approaches.

The main contributions of this work can be summarized as follows:

- We propose a poly attention scheme in news recommendation to extract multiple interest vectors for each user. We further improve it with a disagreement regularization to make the extracted vectors more diverse.
- We propose a category-aware attention weighting strategy in the poly attention, which captures explicit category signals for user interest modeling.
- MINER achieves new state-of-the-art on the MIND benchmark and ranked the first on official leaderboard[3] in September 2021.

2 Related Work

2.1 Traditional Recommendation Methods

In recommender systems, most features are categorical and represented as IDs (e.g., itemID, cityID), leading to many studies that focus on modeling feature interactions. For example, FM (Rendle, 2012) models feature interactions with pairwise inner products. Wide&Deep (Cheng et al., 2016) and DeepFM (Guo et al., 2017) further make improvements by integrating both shallow and deep networks. DCN (Wang et al., 2017) models feature interactions via deep and cross sub-networks. Recent research pays more attention to the sequential recommendation problem, which aims to capture users' sequential behaviors via sequence modeling, such as RNN (Hidasi et al., 2016), CNN (Tang and Wang, 2018), and self-attention networks (Kang and McAuley, 2018; Sun et al., 2019). While most studies represent user via a single embedding vector, Li et al. (2019a) propose a capsule routing method (Sabour et al., 2017; Li et al., 2019b) to extract multiple user interest vectors. Yet, the model is specially designed for the matching stage of e-commerce recommendation. In contrast, we aim to learn users' multi-interest representations from news content via a novel poly attention scheme.

2.2 Neural News Recommendation

For news recommendation, traditional ID-based methods often suffer from the cold-start problem since news articles update very quickly (Wu et al., 2020). Consequently, many content-based methods explore neural networks to automatically learn and match news and user representations (Okura et al., 2017). For example, An et al. (2019) apply CNN to encode news and a GRU network to capture user interests from users' historical clicks. Attention mechanisms have been widely adopted in news recommendation to learn news and user representations, such as attentive multi-view learning (Wu et al., 2019a), personalized attention networks (Wu et al., 2019b), and multi-head self-attentions (Wu et al., 2019c). Some methods also incorporate knowledge graph information from news entities (Wang et al., 2018; Liu et al., 2020). Recent work have also applied the pre-trained BERT (Wu et al., 2021; Zhang et al., 2021) to encode news due to its superiority on text understanding. Yet, most methods learn a single user embedding which may not adequately model the diverse user interests. Accordingly, Qi et al. (2021) propose to utilize the news category labels to build hierarchical user interest representations. However, their representations are fixed at the three-level hierarchy. In contrast, the number of interest vectors in our MINER is a tunable hyper-parameter.

3 Our Approach

In this section, we first formulate the problem of personalized news recommendation. Then we introduce our proposed MINER in detail, whose overall framework is shown in Figure 2.

3.1 Problem Formulation

Given a user u and a candidate news n^c, our goal is to calculate the interest score s measuring the interest of user u in the content of news n^c. Then a set of candidate news N^c are ranked based on the interest scores and top ones are recommended to

---

[3] `https://msnews.github.io/#leaderboard`

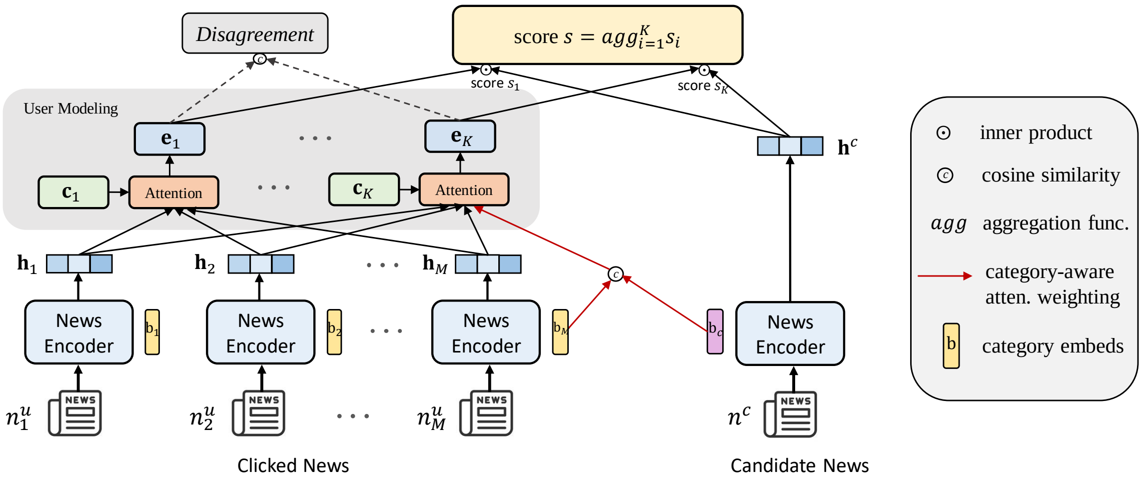

Figure 2: The overall framework of MINER, which consists of a news encoder, a multi-interest user modeling module, and a click score predictor. Disagreement regularization is introduced to make the multiple interest representations more diverse. Category-aware attention weighting is used to re-weight historical news according to the category similarity to candidate news.

user u. The user u consists of a list of historical clicked news $N^u = [n_1^u, n_2^u, ..., n_M^u]$, where M is the number of clicked news. Each news n is associated with its title texts T and a category ct.

3.2 News Encoder

News encoder is one of the core components in news recommendation that aims to learn the embeddings of news from their texts. It can be implemented by various NLP methods such as CNN (Kim, 2014) and Transformer (Vaswani et al., 2017). In this paper, we adopt the pre-trained BERT (Devlin et al., 2019) as news encoder, which can effectively capture the deep semantics of news texts. BERT has been successfully applied in various text ranking problems (Khattab and Zaharia, 2020; Karpukhin et al., 2020). Specifically, we feed tokenized news text into BERT model and use the output of `[CLS]` token as the news embedding $\mathbf{h}$. Thus the user u and candidate news n^c are encoded as $\mathbf{H}^u = [\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_M]$ and $\mathbf{h}^c$, respectively.

In ablation experiments (§4.4), we will also employ shallow word embeddings (Pennington et al., 2014) and self-attention networks to replace BERT.

3.3 Multi-Interest User Modeling

Another core component in news recommendation is user modeling, which receives a sequence of clicked news embeddings as input and outputs user representation $\mathbf{u}$ that summarizes user interest information. Traditionally, a *single* embedding vector is learned via sequential or attentive methods (An et al., 2019; Wu et al., 2019b). However, user interest is usually varying and diverse. We argue that representing user interests by one representation vector can be a bottleneck for news recommendation, since we have to compress all the information related with diverse interests of user into one representation vector. Instead, we propose to learn multiple representation vectors to express the distinct interests of user.

Specifically, we develop a *poly attention scheme* that extracts K interest vectors for each user through K additive attentions. Our method is inspired by the recently proposed Poly-Encoder (Humeau et al., 2020), and we generalize its idea from word sequence to user behavior sequence. In particular, we introduce K learnable context codes, i.e., $\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_K$, where each $\mathbf{c}_i$ extracts an interest embedding $\mathbf{e}_i$ by attending over the sequence of clicked news embeddings:

$$\mathbf{e}_i = \sum_{j=1}^{M} w_j^{c_i} \mathbf{h}_j, \quad w_j^{c_i} = \mathrm{softmax}(\phi_h^{c_i}(\mathbf{h}_j)), \quad (1)$$

where $w_j^{c_i}$ denotes the attention weight of the j-th historical news. $\phi_h^{c_i}(\cdot)$ is a dense network over the context code $\mathbf{c}_i$ and news representation $\mathbf{h}$:

$$\phi_h^{c_i}(\mathbf{h}_j) = \mathbf{c}_i^\top \tanh(\mathbf{W}^h \mathbf{h}_j), \quad (2)$$

where $\mathbf{c}_i$ and $\mathbf{W}^h$ are both trainable parameters.

In this way, we extract multiple user interest vectors $\mathbf{E}^u = [\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_K]$ with each representing certain aspect of user interests. Note the interest vectors are learned via soft attentions thus they may not have explicit meanings.

Disagreement Regularization Since the proposed *poly attention* aims to capture the distinct nature of user interests, it is beneficial to make the extracted interest representations more diverse. To this end, we further propose a *disagreement regularizaiton* (Li et al., 2018) to improve the poly attention, that enlarges the distance among different interest vectors during training. Specifically, we calculate the cosine similarity between each pair of interest vectors through the dot product of the normalized vectors. Then our training objective is to *minimize* the average cosine similarity (i.e., *maximize* the distance) among all interest vector pairs. The regularization term is formally expressed as:

$$\mathcal{L}_D = \frac{1}{K^2} \sum_{i=1}^{K} \sum_{j=1}^{K} \frac{\mathbf{e}_i^\top \mathbf{e}_j}{\|\mathbf{e}_i\| \|\mathbf{e}_j\|}, \tag{3}$$

where K is the number of interest vectors.

Click Predictor For each interest vector $\mathbf{e}_i$, we calculate a matching score with the candidate news representation $\mathbf{h}^c$ via inner product:

$$s_i = \mathbf{e}_i^\top \mathbf{h}^c. \tag{4}$$

We propose several ways to aggregate the K matching scores as a final user click score, including:

- MINER-*max* takes the maximum value of the individual scores, i.e. $s = \max_{i=1}^{K} s_i$.
- MINER-*mean* takes the average value of the individual scores, i.e. $s = \text{mean}_{i=1}^{K} s_i$.
- MINER-*weighted* adopts a *target-aware attention* network (Wang et al., 2018) to weighted sum the individual scores according to the relevance between candidate news $\mathbf{h}^c$ and interest vector $\mathbf{e}_i$, i.e.:

$$s = \sum_{i=1}^{K} w_i s_i,$$
$$w_i = \text{softmax}(\mathbf{e}_i^\top \text{gelu}(\mathbf{W}^e \mathbf{h}^c)),$$

where $\text{gelu}(\cdot)$ is the activation function and $\mathbf{W}^e$ is trainable parameter.

3.4 Category-aware Attention Weighting

In news recommendation dataset, category labels (e.g., Sports, Health) are usually available as shown in Figure 1. Besides the *implicit* user interests learned by soft attentions, the category information can be regarded as *explicit* user interest signals. Intuitively, a user tends to click certain categories of news. For example, the user in Figure 1 frequently clicks Sports news. Thus we can infer that he has a high probability to click another Sports news or similar type like Fitness news. Therefore, we propose a *category-aware attention weighting* strategy to re-weight historical news according to their category similarity to the candidate news, i.e., similar types of news have higher weights. [4]

Specifically, we first transfer the category words (e.g., Sports) of each news to word embedding through the pre-trained Glove (Pennington et al., 2014) vectors. Then we revise the attention weight $w_j^{c_i}$ over historical news in Equation 1 with an additional bias term:

$$w_j^{c_i} = \text{softmax}(\phi_h^{c_i}(\mathbf{h}_j) + \underline{\lambda \cos(\mathbf{b}_j, \mathbf{b}_c)}), \tag{5}$$

where $\mathbf{b}_j$ and $\mathbf{b}_c$ denote the category embedding of the j-th historical news and the candidate news. $\cos(\cdot)$ denotes the cosine similarity between the two category embeddings and λ is a learnable scalar. Note that, due to the exponential operation in *softmax* function, adding the original logit similarity $\phi_h^{c_i}(\mathbf{h}_j)$ with a bias term $\lambda \cos(\cdot)$ equals to multiplying the attention distribution by a scaling factor. In this way, we learn to re-weight the historical news according to category information.

3.5 Model Training

Following previous work (Huang et al., 2013; Wu et al., 2019c), we employ the NCE loss to train our ranking model. For each clicked news in the training dataset $\mathcal{D}$ which is termed as a positive sample n_i^+, we randomly select L non-clicked news in the same news session as negative samples $[n_i^1, ..., n_i^L]$. We then jointly predict the click scores of the positive news s^+ and L negative news $[s_i^1, ..., s_i^L]$. The loss $\mathcal{L}_{NCE}$ is the negative log-likelihood of all positive samples in $\mathcal{D}$:

$$\mathcal{L}_{NCE} = -\sum_{i=1}^{|\mathcal{D}|} \log \frac{\exp(s_i^+)}{\exp(s_i^+) + \sum_{j=1}^{L} \exp(s_i^j)}. \tag{6}$$

Together with the disagreement regularization in Equation 3, our final loss function is:

$$\mathcal{L} = \mathcal{L}_{NCE} + \beta * \mathcal{L}_D, \tag{7}$$

---

[4] We also tried simply concatenating the category embeddings with news embeddings, which underperforms the proposed method in this paper.

where β is a hyper-parameter and is set to 0.8 based on validation set performance.

4 Experiments

4.1 Experiment Setup

Dataset We evaluate our approach on a real-world news recommendation dataset MIND (Wu et al., 2020), which is collected from the user behavior logs of Microsoft News. There are two versions of the dataset, namely MIND-large and MIND-small. The MIND-large contains more than 15 million impression logs generated by 1 million users, from which the MIND-small randomly samples 50,000 users. An impression log records the clicked and non-clicked news that are displayed to a user at a specific time and his historical news click behaviors before this impression. Besides, MIND contains off-the-shelf category label of each news. Table 1 summarizes the data statistics.

	MIND-small	MIND-large
# News	65,238	161,013
# Categories	18	20
# Impressions	230,117	15,777,377
# Clicks	347,727	24,155,470

Table 1: Statistics of the two datasets.

Settings Following previous work (Wu et al., 2019b; Qi et al., 2021), we utilize users' most recent 50 clicked news to learn user representations. We only use news title for the experiments in this paper and the maximum length is set to 20.[5] The *bert-base-uncased* is used as the pre-trained model to initialize news encoders. The number of context codes K is set to 32 and we will show its influence in the analysis part. The dimension of the context code vectors is 200. The category embeddings are initialized by the 300-dimensional Glove (Pennington et al., 2014) vectors and are fixed during training. The negative sampling rate L is set to 4 during training, i.e., each positive news is paired with 4 negative news. We train MINER for 5 epochs with batch size being 128. The learning rate is set to $2e^{-5}$ and linearly decayed with 10% warmup steps. We employ Adam (Kingma and Ba, 2015) as the optimization algorithm. As previous work (Wu et al., 2020), we employ four ranking metrics, i.e., AUC, MRR, nDCG@5, and nDCG@10, for performance evaluation.

4.2 Comparison Baselines

We compare our proposed MINER against the following baseline methods:

Feature-based Methods: Traditional recommendation methods based on manual features and user-item interactions, including (1) *LibFM* (Rendle, 2012), that employs factorization machine on user ID, news ID, and TF-IDF features extracted from news titles; (2) *DeepFM* (Guo et al., 2017), a model combines factorization machine and deep neural network with the same features as *LibFM*.

Neural Recommendation Methods: Neural networks specially designed for news recommendation, including (1) *DKN* (Wang et al., 2018), using CNN to learn news representation and a target-aware attention network to learn user representation; (2) *NPA* (Wu et al., 2019b), using personalized attention networks on words and clicked news to learn news and user representations; (3) *NAML* (Wu et al., 2019a), using multi-view learning to obtain news representation and attentive pooling to learn user representation; (4) *LSTUR* (An et al., 2019), using a GRU network to learn short-term user interests and user ID embeddings as long-term interests; (5) *NRMS* (Wu et al., 2019c), leveraging multi-head self-attentions to learn news and user representations; (6) *HieRec* (Qi et al., 2021), learning hierarchical user interests including subtopic-level, topic-level, and user-level.

BERT-enhanced Methods: (1) Wu et al. (2021) apply BERT as the news encoder on several above methods. *LSTUR+BERT* and *NRMS+BERT* are included here; (2) *UNBERT* (Zhang et al., 2021), the SOTA news recommendation method with BERT that models multi-grained user-news matching.

We implement most baseline methods via the code and settings on Microsoft Recommenders[6].

4.3 Main Results

The overall performance of all baselines and three MINER variants (i.e. *-max, -mean, -weighted*) are summarized in Table 2. All the numbers in the table are percentage numbers with '%' omitted. The overall best and previously best results are boldfaced and underlined respectively. We have several observations from Table 2.

First, all neural news recommendations methods (Rows 3-14) consistently outperform manual feature-based methods (Rows 1-2). This is because

Table 2: Performance of different methods. Previously best results are underlined (the higher, the better) and MINER significantly outperforms all baselines ($p < 0.01$). †: results are from Qi et al. (2021). ‡: results on MIND-large are from Wu et al. (2021). §: results are from Zhang et al. (2021). Our ensemble model on MIND-large ranked the first on official leaderboard: `https://msnews.github.io/#leaderboard` in September 2021.

the handcrafted features may not be optimal and the neural networks can learn implicit semantic features to better model the news and users.

Second, BERT-enhanced methods (Rows 9-11) perform generally better than traditional neural methods that are based on word embeddings (Rows 3-8). The reason is that the deeply stacked and large-scale pre-trained BERT model can better model text semantics than the shallow word embeddings, which is crucial for contents understanding in news recommendation. For example, *LSTUR+BERT* and *NRMS+BERT* significantly outperform *LSTUR* and *NRMS*, respectively.

Third, among the three MINER variants (Rows 12-14), MINER-*weighted* performs the best. This is because MINER-*weighted* incorporates the candidate news signal to adaptively select important interest vectors. Note MINER-*mean* slightly underperforms MINER-*weighted* but outperforms MINER-*max*. Potential reason is that one candidate news may match multiple extracted interests (e.g., diet news matches Health and Food), and the overall assessment based on all the interest vectors would be more accurate than matching a single one.

Last, MINER significantly outperforms other baseline methods in terms of all metrics on the two datasets. The significant improvements can be attributed to the multi-interests modeling and BERT news encoder. Other BERT-enhanced methods such as *LSTUR+BERT* and *NRMS+BERT* only lean a single user embedding to represent user interests, whose expressiveness may be insufficient. Instead, MINER learns multiple representation vectors to express the diverse user interests. Compared against *UNBERT* that concatenates all the history news and candidate news as BERT input, MINER is more flexible as *UNBERT* is restricted by the maximum length of BERT input. Note *HieRec* also incorporates category labels to build hierarchical user interests but it is fixed at the three-level interests hierarchy. In contrast, the number of interest vectors in MINER (i.e. K) is a tunable hyper-parameter.

Model	AUC	MRR	nDCG@10
HieRec (Qi et al., 2021)	67.95	32.87	42.53
MINER w/o BERT	68.07	32.93	42.62
w/o disagreement	67.42	32.38	42.12
w/o category	67.13	32.06	41.73
MINER with BERT	69.61	33.97	43.90
w/o disagreement	69.49	33.46	43.56
w/o category	69.38	33.60	43.60

Table 3: Effects of different MINER components.

4.4 Ablation Study

In this section, we study the effectiveness of different MINER components by removing them. The results on MIND-small are illustrated in Table 3.

We first show the effect of deeply stacked BERT encoder (§3.2) by replacing it with shallow word embeddings (Pennington et al., 2014). For a fair comparison, we take the SOTA non-BERT model *HieRec* (Qi et al., 2021) as reference and implement their knowledge-aware news encoder in our

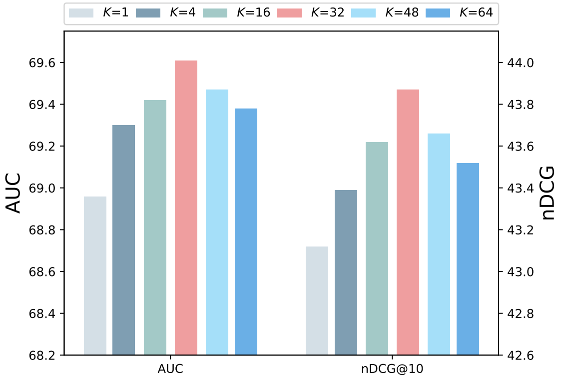

Figure 3: Influence of the number of interest vectors.

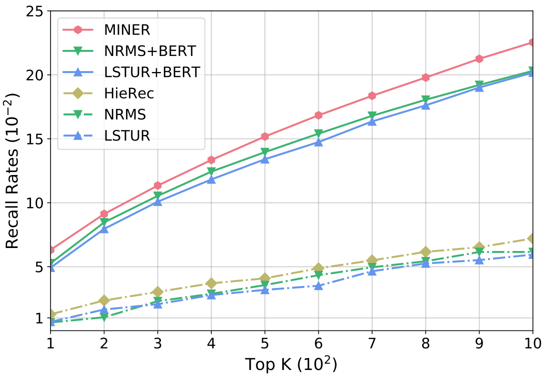

Figure 4: The performance on news recall.

MINER framework. The encoder consists of an word embedding layer, an entity embedding layer, and self-attention networks to learn text representation. The results in Table 3 demonstrate that BERT plays a crucial role in MINER and the performance largely decreases if we employ word embeddings. Nevertheless, this variant model is still able to outperform the SOTA non-BERT model *HieRec*, demonstrating the superiority of multi-interest user modeling and other components.

We further remove the proposed disagreement regularization (§3.3) and category-aware attention weighting (§3.4) from our MINER framework, respectively. The decreased performances in Table 3 respectively verify the benefits of diversifying the extracted interest vectors and incorporating category as explicit interest signals. Note MINER w/o BERT (above the dashed line) suffers more performance drop than MINER with BERT (below the dashed line). Potential reason is that the two techniques may have some overlapping effects with BERT thus it is hard to get further performance gain when BERT has already improved a lot. Besides, the performance drop from removing category-aware attention weighting is much larger than removing disagreement regularization, demonstrating the importance of category signals.

4.5 Number of Interest Vectors

In this section, we show the influence of hyperparameter K, i.e., the number of extracted interest vectors in MINER. We vary this number and plot the results on MIND-small in Figure 3. We can see that with the increase of value K, the news recommendation performances first go up and then decline. The best results are achieved when $K = 32$. We conjecture the reason is that the expressiveness of MINER gradually increases when K is increasing. However, too large K may introduce more redundant parameters thus harm the overall performance. Besides, the best value of K may depend on the length of news browsing history M, and the longer browsing history requires more model capacity thus larger value of K. Note that when we set $K = 1$, i.e., MINER degrades to single user embedding, we still obtain a good AUC of 68.92 and we attribute it to the use of BERT news encoder and category-aware attention weighting.

4.6 Effectiveness on News Recall

To further verify the effectiveness of MINER , we also conduct experiments on news recall (or news retrieval). Instead of ranking a given list of candidate news, the aim of news recall is to retrieve certain number of candidate news from a large news pool which is usually the first stage in news recommendation. Therefore, efficiency is a key issue in news recall task. Conventional way is to build a bi-encoder model to *decouple* the modeling of user interests and candidate news thus all the news representations can be pre-computed and cached. Accordingly, we employ MINER-*mean* without the category-aware attention weighting and average the extracted interest vectors for news recall.

Following Qi et al. (2021), we do experiment on MIND-small and report the accuracy of top K recalled candidate news (i.e., recall rate) of each method. The results are shown in Figure 4 where the conclusions are generally consistent with Table 2. First, incorporating pre-trained BERT as news encoder significantly improves the recall rates, due to its superiority on text semantic modeling. Second, our MINER consistently achieves the best performance compared to other baseline methods. This is because MINER extracts user interests from multiple aspects, which is more ex-

pressive than methods like *NRMS* and *LSTUR* that only learn a single user interest representation.

4.7 Case Study and Visualization

We conduct a case study to further shed light on the effectiveness of MINER. We compare MINER with *NRMS+BERT* since it is effective and also employs BERT news encoder but with single user embedding. In Figure 5, we show a sampled impression where the user has previously clicked 8 news. The news category is listed before the news title. We also show the top 3 recommended news by the two methods and the actually clicked news. We can see that both *NRMS+BERT* and MINER rank Sports news on the top, since the user has frequently clicked Sports news in the history. However, *NRMS+BERT* only learns a single user interest representation thus it is hard to capture other user interests. In contrast, our MINER extracts user interests from multiple aspects through the poly attention scheme, which can effectively find that the user is also keen to Food news. So MINER ranks a Food news in the second which is actually clicked by the user. Besides, MINER also recommends a Health news in the third place which is a related category to the Sports and Food, and we attribute this to our proposed category-aware attention weighting.

In addition, to show the effectiveness of disagreement regularization, we plot the attention map of this case in Figure 6. Specifically, we train a MINER with 4 interest vectors (i.e., $K = 4$) and visualize the attention weights (as Equation 5) before and after applying disagreement regularization. The vertical axis represents each interest extractor (i.e., additive attention) and the horizontal axis denotes the attention weights on historical news. We can find that before applying disagreement regularization, the attentions are mostly focused on the second and the sixth news which are Sports news, and the four attention distributions are quite similar. However, after the employment of disagreement, the four attention distributions become more *discriminative* and *diverse*, explicitly focusing on more news such as the fourth and the eighth news that are in the Food category.

5 Conclusion

In this paper, we propose a news recommendation method named MINER to capture the diver user interests from the historical reading behaviors, rather than most existing methods that learn a single user embedding to represent the reading interest. Specifically, we propose a *poly attention scheme* to learn multiple user interest vectors through soft attentions, which encode the different aspects of user interest. We further propose a *disagreement regularization* to improve the poly attention, that makes the learned interests vectors more diverse. Moreover, we design a *category-aware attention weighting* strategy to re-weight historical news according to the category similarity. Extensive experiments on the MIND news recommendation benchmark demonstrate the superiority of MINER over existing state-of-the-art methods. In addition, MINER ranked the first on the MIND leaderboard in September 2021.

Future work includes extending MINER to multi-modal and multi-task scenarios (Bi et al., 2022).

KSAM: Infusing Multi-Source Knowledge into Dialogue Generation via Knowledge Source Aware Multi-Head Decoding

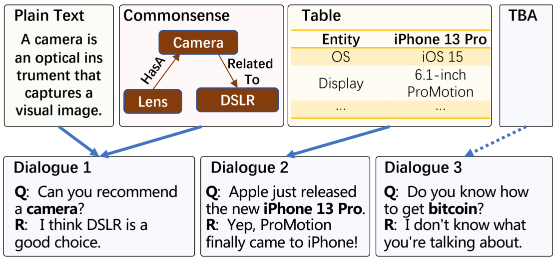
Abstract

Knowledge-enhanced methods have bridged the gap between human beings and machines in generating dialogue responses. However, most previous works solely seek knowledge from a single source, and thus they often fail to obtain available knowledge because of the insufficient coverage of a single knowledge source. To this end, infusing knowledge from multiple sources becomes a trend. This paper proposes a novel approach *Knowledge Source Aware Multi-Head Decoding*, *KSAM*, to infuse multi-source knowledge into dialogue generation more efficiently. Rather than following the traditional single decoder paradigm, *KSAM* uses multiple independent source-aware decoder heads to alleviate three challenging problems in infusing multi-source knowledge, namely, the diversity among different knowledge sources, the indefinite knowledge alignment issue, and the insufficient flexibility/scalability in knowledge usage. Experiments on a Chinese multi-source knowledge-aligned dataset demonstrate the superior performance of *KSAM* against various competitive approaches.

1 Introduction

Conversational AIs play an indispensable role in the human-computer interaction (Chen et al., 2017). Humans can use their learned knowledge to understand the context, reason the intrinsic semantic, and generate informative responses. However, traditional dialogue generation methods can only use dialogue history that carries limited knowledge to generate responses (Sutskever et al., 2014), bringing meaningless responses and frustrating user experience (Li et al., 2016; Ghazvininejad et al., 2018). To bridge such a gap, incorporating external knowledge into the dialogue generation is a feasible way (Zhou et al., 2018).



Q: Can you recommend a **camera**?
R: I think DSLR is a good choice.

Q: Apple just released the new **iPhone 13 Pro**.
R: Yep, ProMotion finally came to iPhone!

Q: Do you know how to get **bitcoin**?
R: I don't know what you're talking about.

Figure 1: Examples. *Diversity*: the above three knowledge sources have different structures; *Indefinite Alignment*: each case uses different knowledge sources. *Scalability:* case #3 may require a new knowledge source.

Compared to the traditional non-knowledge-enhanced methods, the advantages of knowledge-enhanced methods come from the adopted external knowledge source (Wu et al., 2022). If a knowledge-enhanced model fails to seek available knowledge from the given knowledge source, it can only degenerate into a traditional manner. However, most previous works (Zhang et al., 2020a; Yu et al., 2020) only seek knowledge from a single source. The knowledge coverage [1] of a single knowledge source is always insufficient (Wu et al., 2021a); thus, dialogues often can not benefit from the given knowledge source. Meanwhile, a single knowledge source is also difficult to meet the various requirements in the real scenarios (Liu et al., 2019). Recently, researchers began to seek knowledge from multiple sources to alleviate such issues. *GOKC* generates dialogues conditioned on both the background knowledge and the goal knowledge (Bai et al., 2021); The recent *MSKE* leverages heterogeneous knowledge from multiple sources (Wu et al., 2021a). With more knowledge sources, they have successfully improved the performance of knowledge-enhanced dialogue generation.

Nonetheless, as illustrated in Figure 1, many challenges in infusing multi-source knowledge into

Findings of the Association for Computational Linguistics: ACL 2022, pages 353 - 363
May 22-27, 2022

dialogue generation have not been well solved: 1) *Knowledge Diversity:* Notable differences inevitably appear among different types of knowledge sources, which can be attributed to the different structures (i.e., text knowledge (Dinan et al., 2019) vs. commonsense knowledge graph (Zhang et al., 2020a)), different domains (i.e., open-domain (Speer et al., 2017) vs. specific-domain (Liu et al., 2018a)), and many other factors (Yu et al., 2020). Previous works only considered the difference in the encoding stage by using different knowledge-specific encoders, but failed to handle the difference in the decoding stage; 2) *Indefinite Alignment:* Due to the limitation of knowledge coverage, a single dialogue usually can not fully use all n provided knowledge sources. Depending on the situation, each case may use an arbitrary number $\in [0, n]$ of sources, bringing more complexities; 3) *Insufficient Flexibility and Scalability:* A model itself should not be limited to a knowledge combination of specific types and a specific amount.

This paper proposes a *KSAM* (*Knowledge Source Aware Multi-Head Decoding*) approach for multi-source knowledge-enhanced dialogue generation, which explicitly considers the three challenges mentioned above. Besides the dialogue history, *KSAM* uses three different knowledge sources, i.e., plain text knowledge, commonsense fact knowledge, and table attribute knowledge, to generate the target response. We propose four *Source-Specific Encoders* to encode such four input sources[2]. In the decoding stage, unlike previous works that only adopt a single-head decoder, we assign an independent *Source-Aware Decoder Head* for each input source. Each decoder head is a source-aware and fully functional decoder network, generating a source-aware response independently. Thus, we can handle the differences among multiple sources by tuning the source-specific encoder or the source-aware decoder head without impacting other encoders/heads. Subsequently, we propose a *Source Fusion Network (SFN)* to make the final prediction by collecting and fusing the outputs from decoder heads. With source-aware decoder heads and the fusion gates outputted by *SFN*, *KSAM* can alleviate the issue of indefinite knowledge-alignment. Meanwhile, *SFN* does not limit the number of decoder heads or the type of a decoder head; thus, *KSAM* theoretically supports the use of any combination of knowledge sources.

We evaluate *KSAM* and baseline models on a previously released Chinese dataset (Wu et al., 2021a), which is aligned to three knowledge sources, i.e., a plain text knowledge base, a commonsense knowledge base, and a table knowledge base. Both the automatic and human evaluation results demonstrate the superior performance of *KSAM* against various competitive baselines. We also conduct extensive experiments to analyze *KSAM* further.

2 Approach

2.1 Problem Statement and Overview

The goal is to generate a response Y conditioned the dialogue history X and a set of knowledge $\{K_i\}$. Each $X = (x_1, \cdots, x_{l_X})$ / $Y = (y_1, \cdots, y_{l_Y})$ is a word sequence; each knowledge $K_i = (k_{i,1}, \cdots, k_{i,l_{K_i}})$ is a set/list of entries that are retrieved from the i-th knowledge source.

As illustrated in Figure 2, this paper proposes a novel *Knowledge Source Aware Multi-Head Decoding approach (KSAM)*, which consists of three parts: *1) Source-Specific Encoders:* We propose a history encoder Enc_X and several knowledge encoders $\{Enc_{K_i}\}$ to encode the X and $\{K_i\}$ into $\mathbf{H_X}$ and $\{\mathbf{K_i}\}$; *2) Source-Aware Decoder Heads:* For alleviating the interference among sources and improving the scalability, each X or K_i has an independent and fully functional decoder head Dec_{H/K_i}; *3) Source Fusion Network:* It stepwisely collects the predicted outputs from decoder heads and makes the final prediction.

2.2 Source-Specific Encoders

2.2.1 Dialogue History Encoder

Dialogue history encoder Enc_X aims at encoding the dialogue history X into hidden states; thus, a bi-directional GRU (g) (Cho et al., 2014) is adopted. At each time step t, the forward/backward GRU reads x_t and the last state $\mathbf{h^f_{t-1}}/\mathbf{h^b_{t+1}}$:

$$\mathbf{h_t} = [\mathbf{h^f_t}; \mathbf{h^b_t}] = [\overrightarrow{g}(\mathbf{x_t}, \mathbf{h^f_{t-1}}); \overleftarrow{g}(\mathbf{x_t}, \mathbf{h^b_{t+1}})] \tag{1}$$

where $\mathbf{x}$ is the word embedding of x, $[\cdot;\cdot]$ is the concatenation. The result is $\mathbf{H} = (\mathbf{h_1}, \cdots, \mathbf{h_{l_X}})$.

2.2.2 Knowledge Encoders

This paper studies three knowledge sources: plain text knowledge K_P, commonsense fact knowledge K_C, and table key-value attribute knowledge K_T.

---

[2] *source* means the dialogue context or a knowledge input.

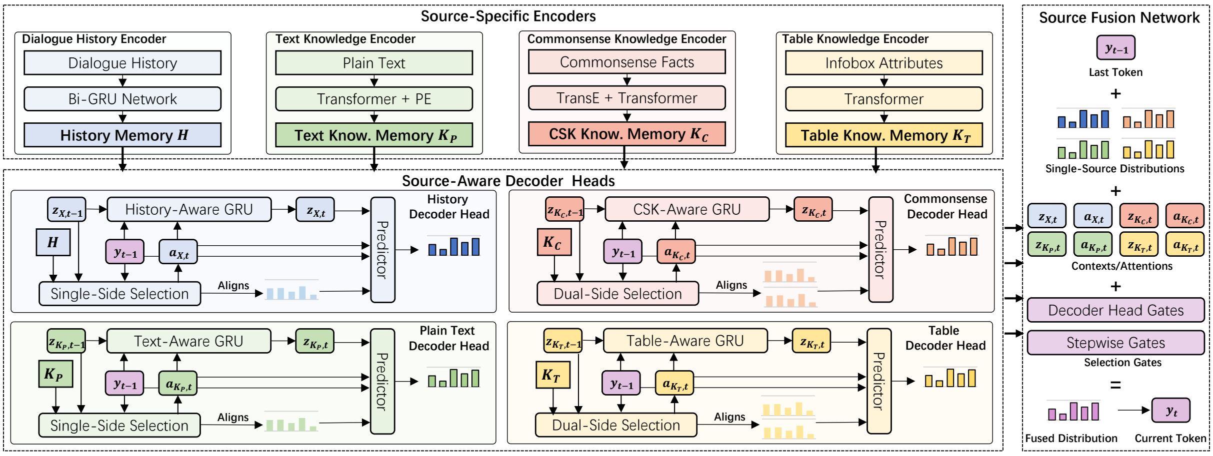

Figure 2: The architecture of *KSAM*. In this paper, the implementation considers three knowledge sources, i.e., text knowledge, commonsense knowledge, and table knowledge; thus, there are four source-specific encoders and four source-aware decoder heads. Each source-specific encoder or source-aware decoder has its own unique internal independent network. At each time step, the *Source Fusion States* first gathers the predictions of all decoder heads, then makes a fused final prediction.

Plain Text: Each text K_P is a word sequence $(k_{P,1}, \cdots, k_{P,l_P})$; therefore, we embed K_P to $\mathbf{K^e_P} = (\mathbf{k^e_{P,1}}, \cdots, \mathbf{k^e_{P,l_P}})$ using word embedding.

Commonsense Facts: Each K_C is a set of facts $\{k_{C,i}\}$, where each $k_{C,i}$ has a head entity $e_{C,i,h}$, a relation $e_{C,i,r}$, and a tail entity $e_{C,i,t}$. Thus, $k_{C,i}$ can be embed as $\mathbf{k^e_{C,i}} = [\mathbf{e_{C,i,h}}; \mathbf{e_{C,i,r}}; \mathbf{e_{C,i,t}}]$ using embedding pretrained by TransE (Bordes et al., 2013) or other learning approaches. Finally, K_C is embed to a set of embedding, i.e., $\mathbf{K^e_C} = \{\mathbf{k^e_{C,i}}\}$

Table Attributes: Each table K_T is a set of key-value attribute pairs $\{k_{T,i} = (a^k_i, a^v_i)\}$, where the key a^k_i is a word and the value $a^v_i = (a^w_{i,1}, \cdots, a^w_{i,j} \cdots)$ is a text sequence. Such a structure is inconvenient for the encoding. Thus, following (Wu et al., 2021a), K_T is first decomposed into to a set of key-word pairs $\{k^{kw}_{T,i,j}\}$, and each key-word pair is embedded as:

$$\mathbf{k^{kw}_{T,i,j}} = [\mathbf{a^k_i}; \mathbf{a^w_{i,j}}; \mathbf{pos_{i,j}}] \tag{2}$$

where a^k_i is the word embedding of the i-th key, $\mathbf{a^w_{i,j}}$ is the word embedding of the j-th word of the i-th value, $\mathbf{pos_{i,j}}$ is the positional embedding to indicate the structure information. Finally, K_T is embed to a set of embedding, $\mathbf{K^e_T} = \{\mathbf{k^{kw}_{T,i,j}}\}$.

Encoders: Three knowledge encoders Enc_{K_P}, Enc_{K_C}, Enc_{K_T} are implemented as three independent Transformer networks (Vaswani et al., 2017):

$$\begin{aligned}\mathbf{K_P} &= Enc_{K_P}(POS(\mathbf{K^e_P}))\\ \mathbf{K_C} &= Enc_{K_C}(\mathbf{K^e_C})\\ \mathbf{K_T} &= Enc_{K_T}(\mathbf{K^e_T})\end{aligned} \tag{3}$$

where an output $\mathbf{K_*}$ can be viewed as a list or a set of vectors depending on the input $\mathbf{K^e_*}$. We use a set to pack $\mathbf{K^e_C}/\mathbf{K^e_T}$ because no strong sequential correlation appears; thus, their encoders do not use the positional layer POS. While the plain text $\mathbf{K^e_P}$ is a sequence, unlike encoding the dialogue history X, we use a Transformer with POS because $\mathbf{K^e_P}$ has a significantly longer length.

2.3 Multi-Head Decoding

Previous knowledge-enhanced works (Wu et al., 2020; Bai et al., 2021) often use the single decoder paradigm. However, when using multiple sources, a single decoder always faces more challenges; namely, *Knowledge Diversity*, *Indefinite Alignment*, and *Insufficient Flexibility and Scalability*.

Thus, we propose to use multiple source-aware decoder heads, allocating one independent and fully functional decoder head for using the dialogue history or each knowledge source. The results of such decoder heads are subsequently fused by *Source Fusion Network*. The advantages can be summarized as 1) Each decoder head is independent; we can easily tune each network based on the source-specific characteristics without impacting other heads; 2) Each head does not need to consider the complex combinations of knowledge usage. Each head only considers the usage of the corresponding input source. Thus, we can employ the more professional *Source Fusion Network* to alleviate the impact of indefinite alignment more efficiently; 3) Higher flexibility and scalability because *Source Fusion Network* does not limit the number and the knowledge-type of heads.

2.3.1 Source-Aware Decoder Head

Each decoder head $Dec_* \in \{Dec_H, Dec_{K_P}, Dec_{K_C}, Dec_{K_T}\}$[3] uses the corresponding source-specific dialogue/knowledge memory $\mathbf{M}_* \in \{\mathbf{H}, \mathbf{K_P}, \mathbf{K_C}, \mathbf{K_T}\}$ to predict the target response with own networks/parameters θ_*:

$$Dec_*(\mathbf{M}_*; \theta_*), * \in \{H, K_P, K_C, K_T\} \quad (4)$$

State Updating: At time t, each Dec_* first updates its state $\mathbf{z}_*$ with a GRU network (g_*):

$$\mathbf{z_{*,t}} = g_*(\mathbf{z_{*,t-1}}, \mathbf{y_{t-1}}, \mathbf{a_{*,t}}), \mathbf{z_{*,0}} = \mathbf{h_{l_X}} \quad (5)$$

where each initial state $\mathbf{z_{*,0}}$ is universally initialized by the last dialogue history state $\mathbf{h_{l_X}}$, $\mathbf{y_{t-1}}$ is the embedding of the last generated token, $\mathbf{a_{*,t}}$ is the attentive readout of the corresponding $\mathbf{M}_*$.

Memory Selection: To obtain the attentive readout $\mathbf{a_{*,t}}$ by selecting the memory $\mathbf{M}_*$, we propose a *Single-Side Attention* for selecting the X or K_P (i.e., $\mathbf{M}_* = \mathbf{H}/\mathbf{K_P}$), and a *Dual-Side Attention* for selecting the $K_{C/T}$ (i.e., $\mathbf{M}_* = \mathbf{K_{C/T}}$).

1. Single-Side Attention: we use a distribution $\mathbf{align_{*,t}}$ to measure the relevance between each memory slot[4] $\mathbf{m} \in \mathbf{M}_*$ and the current context:

$$\mathbf{align_{*,t}} \in \mathbb{R}^{1\times l_{M_*}} = F^S([\mathbf{y_{t-1}}; \mathbf{z_{*,t-1}}]\mathbf{W^A_*}\mathbf{M^T_*}) \quad (6)$$

where F^S is $softmax$, $\mathbf{W^A_*}$ is a parameter, $\mathbf{align_{*,t}}$ is an align distribution, i.e., weights. Then, the attentive readout $\mathbf{a_{*,t}} = \mathbf{align_{*,t}}\mathbf{M}_*$ is the weighted sum of the memory $\mathbf{M}_* \in \mathbb{R}^{l_{M_*}\times dim}$.

2. Dual-Side Attention: The commonsense knowledge K_C and the table knowledge K_T have two value sides (head/tail entities, attribute key/words). Considering this, similar to the multi-head attention, the corresponding attentive readout adopts two different side-aware align distributions:

$$\mathbf{a_{K_C,t}} = [\mathbf{align^{head}_{K_C,t}}\mathbf{K_C}; \mathbf{align^{tail}_{K_C,t}}\mathbf{K_C}]$$
$$\mathbf{a_{K_T,t}} = [\mathbf{align^{key}_{K_T,t}}\mathbf{K_P}; \mathbf{align^{value}_{K_T,t}}\mathbf{K_P}] \quad (7)$$

The computations of $\mathbf{align}$s in Equation 7 still follow the same way in Equation 6. In each head, two $\mathbf{align}$s use the same network but the different parameters; the differences and the uniqueness of two $\mathbf{align}$s come from the following copy mechanism.

Token Perdition: Each source-aware decoder head in *KSAM* can generate a complete probability distribution to predict the next token.

First, a decoder head can generate a token by selecting a word from the fixed vocabulary V using the distribution $\mathbf{P^V_{*,t}}(\mathbf{w})$, which is given by:

$$F^S(tanh([\mathbf{z_{*,t}}; \mathbf{y_{t-1}}; \mathbf{a_{*,t}}]\mathbf{W^{V1}_*})\mathbf{W^{V2}_*}) \quad (8)$$

Next, to address the OOV issue and improve the informativeness, a decoder head can also copy a word from the corresponding source by using the previous attentive distribution $\mathbf{align}_*$. In Dec_H and Dec_{K_P}, $\mathbf{align_{H/K_P,t}}(w)$ points out the probability to copy the word w from X/K_P. In Dec_{K_C}, $\mathbf{align^{head/tail}_{K_C,t}}(w)$ points to the head/tail entity of the corresponding commonsense fact w. In Dec_{K_T}, $\mathbf{align^{head/tail}_{K_T,t}}(w)$ points to the attribute key/word of the corresponding attribute key-word pair w.

Finally, we use the following fusion gate $\mathbf{f}_*$ to fuse all generation modes for each head:

$$\mathbf{f}_* \in \mathbb{R}^{1\times 2/3} = F^S([\mathbf{z_{*,t}}; \mathbf{y_{t-1}}; \mathbf{a_{*,t}}]\mathbf{W^M_*}) \quad (9)$$

then, the aggregated probability is given by:

$$\mathbf{P_{*,t}}(\mathbf{w}) = \sum_i \mathbf{f}_*[i]\mathbf{align^i_{*,t}}(w) + \mathbf{f}_*[-1]\mathbf{P^V_{*,t}}(w) \quad (10)$$

2.3.2 Source Fusion Network

Each head takes the responsibility for a single-source-aware prediction. For generating multi-source knowledge-enhanced responses, we propose a *Source Fusion Network*, which uses two gates, $\mathbf{f^h}$ and $\mathbf{f^s_t}$, to fuse the probability distributions outputted by decoder heads:

$$\mathbf{P_t}(\mathbf{w}) = \textstyle\sum_{\mathbf{P_{i,t}}} \mathbf{f^h}[\mathbf{i}]\mathbf{f^s_t}[\mathbf{i}]\mathbf{P_{i,t}}(\mathbf{w}) \quad (11)$$
$$\mathbf{P_{i,t}} \in \{\mathbf{P_{H,t}}, \mathbf{P_{K_P,t}}, \mathbf{P_{K_C,t}}, \mathbf{P_{K_T,t}}\}$$

where the decoder head gates $\mathbf{f^h} \in \mathbb{R}^{1\times 4}$ are:

$$F^S(tanh([\{\mathbf{a_{*,1}}\}]\mathbf{W^{H1}})\mathbf{W^{H2}})) \quad (12)$$

and the step-wise gates $\mathbf{f^s_t} \in \mathbb{R}^{1\times 4}$ are given by:

$$F^S(tanh([\mathbf{y_{t-1}}; \{\mathbf{z_{*,t}}\}; \{\mathbf{a_{*,t}}\}]\mathbf{W^{S1}})\mathbf{W^{S2}})) \quad (13)$$

---

[3] $*$ refers to a source

[4] In other words, each slot is an encoded vector $\in \mathbf{K}_*$

Training: The objective function has two terms:

$$\mathcal{L} = \mathcal{L}_{fused} + \sum_{head_i} \mathcal{L}_{head_i} \tag{14}$$

The first adopts the aggregated $\mathbf{P_t}(\mathbf{w})$ to compute the overall negative log-likelihood (NLL) :

$$\mathcal{L}_{fused} = -\sum_{t} \log \mathbf{P_t}(y_t | y_{1:t-1}, X, \{K\}) \tag{15}$$

The next term sums the NLLs of all heads:

$$\sum_{head_i} \mathcal{L}_{head_i} = -\sum_{head_i} \sum_{t} \log \mathbf{P_{i,t}}(y_t | y_{1:t-1}, X, M_i) \tag{16}$$

The first $\mathcal{L}_{fused}$ can optimize the whole model, and the second $\sum_{head_i} \mathcal{L}_{head_i}$ makes sure that each head can move towards a better direction.

3 Experiment

3.1 Settings

Dataset: As reported in Table 1, we use a multi-source knowledge-aligned conversational dataset[5] released by Wu et al. (2021a), which collected dialogues from three weibo datasets (Shang et al., 2015; Ke et al., 2018; Cai et al., 2019), commonsense knowledge from ConceptNet (Speer et al., 2017), and plain text/table knowledge from the Wikipedia. The vocab size is 21,924.

Baselines: Depending on the knowledge source:

1.Traditional: The attentive *Seq2Seq* (Luong et al., 2015), and the improved Pointer-Generator Network (*PGN*) (See et al., 2017); a GPT-based model *CDial-GPT* (Wang et al., 2020b) , which has been pre-trained on 1.3B words+6.8M dialogues.

2.Plain Text: RefNet uses a reference network to use the text-based knowledge (Meng et al., 2020).

3.Commonsense: The first work *CCM* (Zhou et al., 2018), and two prior STOAs *ConcpetFlow* (Zhang et al., 2020a), *ConKADI* (Wu et al., 2020).

4.Table: SA-S2S (Liu et al., 2018b) and *TransInfo* (Bai et al., 2020) use table knowledge via a SA-LSTM/Transformer encoder, respectively.

5.Heterogeneous: GOKC is a recent knowledge-enhanced approach (Bai et al., 2021). It supports a variety of knowledge types. We disable the use of goal knowledge because we study the open-domain dialogue and no goal is provided in the dataset. *MSKE* (Wu et al., 2021a) is a multi-source knowledge-enhanced approach, which supports to use multiple sources at the same time.

Implementations: For *Seq2Seq* and *PGN*, we use our re-implemented PyTorch codes; for *ConKADI*, *GOKC*, and *MSKE*, we use the official codes; for the remaining baselines, the experimental results are collected from *MSKE* (Wu et al., 2021a). Therefore, in our (re-)implementations, we keep the same hyper-parameter setting as *MSKE* if available. In short, all dialogue history encoders are a 512-dimensional bi-GRU, all Transformers of knowledge encoders are 2-layer 8-head and 512-dimensional, all decoders are a 512-dimensional GRU. We use a 200-dimensional pretrained Chinese embedding (Song et al., 2018) to initialize all word embedding matrix, a 100-dimensional pre-trained TransE embedding (Bordes et al., 2013) to initial the embedding of commonsense knowledge entities/relations. We use Adam as the optimizer. The mini-batch size is 32; the learning rate is 0.0001. If the loss on the validation set starts to increase after an epoch, the learning rate will be halved. The training will be automatically stopped if the loss on the validation set increases in two successive epochs. Consequently, our model costs about two days on an Nvidia RTX 3090 GPU. In the inference stage, we apply the beam-search decoding strategy, where the beam width is 10.

3.2 Automatic Metrics

For measuring the relevance between the ground-truth response and the generated responses. We use the sentence-level embedding-based *Embed-A/G/X* (Average / Greedy / Extreme) (Liu et al., 2016; Bai et al., 2021), the character-level uni-gram *CharF1*, the word-level *BLEU-1/2/3/4* (Papineni et al., 2002), and the word-level *Rouge-L* (Lin, 2004). Following Zhang et al. (2020a), we use the uni/bi-gram DISTINCT (*DIST-1/2*) to evaluate the word-level diversity, and the 4-gram *Ent-4* to evaluate the word-level informativeness.

3.3 Results

3.3.1 Automatic Evaluation

We report the results in Table 2. For *MSKE* and our *KSAM*, we evaluate their single-source ablated variants at the same time. For *KSAM*, we additionally evaluate some ablated/modified variants.

Single-Source Knowledge: Compared to traditional models, most single knowledge-enhanced

Table 2: Automatic results. The last section evaluates the ablated/modified *KSAM* variants. * is collected from Wu et al. (2021a), - is not available or comparable (GOKC$_{CSK}$ outputs a abnormally large PPL) , ↓ indicates lower is better, and PPL refers to *perplexity*. We use different colors to indicate the best performance in each group; and we use **colored** to indicate the **best score among models except the ablated/modified *KSAM***.

models have notable improvements, indicating the external knowledge is quite helpful in the open-domain dialogue generation. The recent *GOKC*, *MSKE*, and our *KSAM* are not limited to a specific type of knowledge, and such three models are almost the best three in each group. It implies that they do not improve flexibility at the expense of performance. Meanwhile, our *KSAM* is undoubtedly better: 1) *KSAM* has more the best results in every group; 2) The results among the three knowledge sources are pretty stable and deliver similar trends; on the contrary, *GOKC* is not stable because it has quite different results with different knowledge. Consequently, we can say that every source-specific encoder and source-aware decoder in *KSAM* are well-designed and more efficient.

Multi-Source Knowledge: Only *MSKE* and *KSAM* can use all three knowledge sources at the same time. Two models have the best and the most balanced performance among all models. Comparing them, *MSKE* only achieves slight advantages in three metrics (Embed-G/X & ROUGE-L), but *KSAM* has more notable leaderships in the remaining metrics. In addition, the automatic evaluation can not fully reflect our advantages. Compared to *MSKE*, *KSAM* has better scalability and flexibility in using knowledge sources, due to the design of independent source-aware heads.

The Partial Degradation of *KSAM*: The full *KSAM* brings notable improvements except in DIST-1/2 (diversity) and Ent-4 (informativeness). Such performance degradation does not surprise us: 1) Copying words besides the fixed vocabulary is a crucial way to improve diversity and informativeness. In *KSAM*, the probability distribution used to copy is already fused in each decoder head; therefore, *Source Fusion Network* can not explicitly perceive all copy distributions when fusing single-source distributions to make the final prediction. This may impact the enthusiasm/chance of copying words when appending more decoder heads; 2) The adopted beam-search decoding algorithm can only consider one distribution; thus, we have no chance to leverage such source-aware distributions. 3) DIST and Ent do not consider fluency and rationality, higher is not always better. For example, DIST/Ent will give high scores if we randomly generate some disordered sentences. We should comprehensively consider every dimension. We verified 1) and 3) in our model variant $-\mathbf{P}^{\mathbf{V}}_{\mathbf{K}_*}$, where three knowledge source-aware heads only output the copy probability without being fused with the vocab probability $\mathbf{P}^{\mathbf{V}}_{\mathbf{K}_*}$. It can be seen that $-\mathbf{P}^{\mathbf{V}}_{\mathbf{K}_*}$ increased diversity/informativeness, but decreased the relevance and fluency. We will continue to improve this in the future.

The Coupling among Heads: In *KSAM*, each decoder head Dec_* is an independent and fully functional network. The internal state of a head can not communicate with each other. Does *KSAM* need to strengthen the coupling between heads? To verify this, we design a model variant $+Link$. Similar to the (Kim et al., 2020; Zhao et al., 2020), we use a GRU to manage a global sequential state $\mathbf{s_t}$, which is updated with the memory readouts and the states of heads: $\mathbf{s_t} = GRU(\mathbf{s_{t-1}}, [\mathbf{y_{t-1}}; \{\mathbf{z}_{*,\mathbf{t}}\}; \{\mathbf{a}_{*,\mathbf{t}}\}])$. Then, we replace $\mathbf{y_t}$ by $[\mathbf{s_{t-1}}; \mathbf{y_{t-1}}]$ when operating each head, where $\mathbf{s_t}$ can be regarded as a link to strengthen the coupling. As reported in Table 2, the performance has decreased. It indicates that there may be interference among different sources, and our decoupled design is helpful to alleviate this issue.

3.3.2 Human Evaluation:

The comparison is pair-wise and we select 5 better baselines in the automatic evaluation. We employed 3 well-educated native speakers as volunteers to score 200 sampled cases (1,000 comparisons in total) from three criteria: 1) *Fluency* considers the fluency; 2) *Rationality* measures the relevance and rationality; 3) *Informativeness* measures the quality of the information offered in the generated response. Following (Wu et al., 2021a), we count the agreement among volunteers. The 2/3 agreements for three metrics are 98.7%, 93.7%, and 94.1%; the 3/3 agreements are 61.0%, 52.7%, 51.6%.

Table 3 reports the averaged human evaluation score. Notably, *KSAM* significantly outperforms baselines in all dimensions, demonstrating the same advantage as in the automatic evaluation. In terms of fluency, the results are less distinguishable than the other two metrics (except *GOKC*$_{CSK}$), indicating most models can already generate fluent responses in most cases. In terms of rationality and informativeness, the results are more distinguishable and can reflect the advantage of using external knowledge. *GOKC*$_{CSK}$ does not perform well in human evaluation because the generated responses are always disordered and unnatural.

(%)	Fluency			Rationality			Informativeness		
vs.	-	0	+	-	0	+	-	0	+
Seq2Seq	11.2	55.2	**33.6**	21.8	25.6	**52.5**	21.0	24.0	**55.0**
PGN	7.7	57.8	**34.5**	2.0	26.0	**54.0**	20.3	20.7	**59.0**
GOKC$_{CSK}$	3.0	20.0	**77.0**	5.7	9.3	**85.0**	9.8	10.8	**79.4**
ConKADI	7.5	64.3	**28.2**	26.5	20.8	**52.7**	34.5	16.7	**48.8**
MSKE	7.7	65.7	**26.7**	18.7	32.8	**48.5**	19.6	26.2	**54.2**

Table 3: Human evaluation. *-/0/+* means the ratio that *KSAM* is worse/tie/better. **Score** means significantly better (sign test, p-value $<$ 0.0001, ties are removed).

3.4 Analyses and Discussions

Fused	Each Head Dec				Case-Level		Bounds	
SFN	X	K_C	K_P	K_T	Best	Worst	Upper	Lower
77.7	104.5	124.3	116.7	119.4	93.1	133.7	47.9	258.0

Table 4: Perplexities. 'Fused' considers the prob (probability) fused by *SFN* . ' Dec' considers the prob predicted by each head. 'Case-Level' selects the best/worse prob from four source-aware heads for each response. 'Bounds' uses the ground-truth to select the best/worse prob from four heads for each token, which can roughly show the theoretically best/worst fusion performance. All results are computed on the same full *KSAM*.

Metrics	$Base$	Dec_H	Dec_{K_P}	Dec_{K_C}	Dec_{K_P}	$Full$
PPL↓	98.0	92.1	96.6	94.6	95.3	77.7
Embed-A	0.848	0.848	0.852	0.850	0.851	0.856
BLEU-4	0.95	2.03	1.04	0.99	1.03	2.15
DIST-2	8.56	36.8	10.4	12.5	9.9	30.2

Table 5: Head Ablation. Each is trained separately.

***Source Fusion Network (SFN)*:** We analyze it with Table 4: 1) The PPL of each source-aware head, even we select the best head case by case, is significantly worse than the fused one, which shows a) *SFN* can effectively and step-wisely select/fuse results from various heads; b) independent source-aware decoder heads can work together; 2) Although *SFN* has achieved promising results, the upper bound is still significantly better. It means fusing multiple complete distributions is quite challenging, there is still have great potential to study. We will continue to explore this in the future.

Decoder Head Ablation: Table 5 reports the performance if only using a single source-aware head.

Case #1:	**History:**吃什么可以瘦身？ How to lose weight through diet? **Text Know.**: 节食指限制吃的食物分量，通常是以减肥瘦身作为目的。 Dieting refers to limiting the amount of food eaten, usually with the goal of losing weight. **Commonsense:**(多喝水 Drinking more water, MotivatedByGoal, 瘦身 Loosing weight)
Seq2Seq	吃减肥药最容易发胖. Taking diet pills is the easiest way to gain weight.
ConKADI	可以吃一些东西 喝就可以了. You can eat something and drink on it.
MSKE	少吃什么都可以瘦身. You can lose weight if you eat less.
KSAM	多喝水, 多吃蔬菜, 少吃油腻的食物. Drink more water, eat more vegetables, and eat less greasy food
Case #2:	**History:** 您认为“吸烟有害健康”的宣传教育有效果吗？ Do you think the publicity and education of "Smoking is harmful to health" is effective? **Table Attributes of *Smoking***:(Category, 习惯 habit), (Category, 烟草 tobacco)
Seq2Seq	吸烟有害健康。 Smoking is harmful to health.
ConKADI	吸烟有害健康,不知道[...]吗？ Smoking is harmful to health. Don’t you know smoking is harmful to health?
MSKE	吸烟有害健康。 Smoking is harmful to health.
KSAM	吸烟有害健康，戒烟戒酒！ Smoking is harmful to health. Quit smoking and alcohol!

Table 6: Case Study. ‘[...]‘=吸烟有害健康’ in #2. Besides the history, we show the related available knowledge.

$Base$ removes the usage of the history memory $\mathbf{H}$ from Dec_H, and we regard it as the baseline. 1) Compared to $Base$, Dec_{K_*} further adopts a single-source memory and achieves improvements. The dialogue history memory $\mathbf{H}$ is undoubtedly more crucial than the external knowledge; 2) Commonsense knowledge memory $\mathbf{K_C}$ brings more improvements than the other two knowledge memories; 3) Using all heads ($Full$) has the best performance, indicating the necessity of using multi-source knowledge. Meanwhile, the improvement of PPL is significantly more than other metrics, indicating the decoding algorithm (beam search) should be improved in the future.

Case Study: Table 6 provides two cases for four better models in human evaluation. As a whole, we can find the *Indefinite Alignment* issue appears, where case #1 is aligned to both plain text knowledge and commonsense knowledge, and #2 is aligned to table knowledge. In addition, we can also notice the *Knowledge Diversity*, where such three knowledge sources have different characteristics. In case # 1, *Seq2Seq* and *ConKADI* generated irrational responses. The response generated by *KSAM* is more informative than *MSKE* while both two responses are acceptable. In case # 2, the provided knowledge is not straightforward; all baselines repeated the question. *KSAM* provided new information by reasoning on the table knowledge.

4 Related Work

Dialogue Systems: Dialogue systems have achieved promising results (Vinyals and Le, 2015; Chen et al., 2017). However, traditional models tend to generate safe but meaningless responses (Li et al., 2016). To this end, massive efforts are devoted to diversity the generated dialogues: leveraging the large-scale pretrained model (Zhang et al., 2020b; Gu et al., 2021), incorporating visual features (Das et al., 2017; Wang et al., 2021), employing topics (Xu et al., 2021; Zhong et al., 2021), and many others (Zhao et al., 2021).

Knowledge-Enhanced Methods: Recently, researchers noticed that a crucial reason that results in meaningless responses is the insufficient knowledge carried by the dialogue history (Ghazvininejad et al., 2018; Yu et al., 2020). Thus, infusing external knowledge into the dialogue generation has become a trend. Knowledge sources are diverse. The text knowledge can be easily collected and can provide rich information (Dinan et al., 2019; Ren et al., 2020; Meng et al., 2020). The commonsense knowledge includes the every knowledge (Speer et al., 2017; Zhou et al., 2018; Zhang et al., 2020a; Wang et al., 2020a). The table knowledge (Wu et al., 2019, 2021b) provides the entity-centric information. To improve the knowledge coverage and combine the advantages of different sources. (Liu et al., 2019) uses both text+commonsense knowledge; (Liang et al., 2021) uses different emotional sources; (Bai et al., 2021) treats goal knowledge as an additional source. (Wu et al., 2021a) does not limit the number/type of knowledge in theory; however, it ignored the *Knowledge Diversity* / *Indefinite Alignment* issue. In addition, the proposed multi-head decoding is different from the multi-processor decoding (Zhao et al., 2020): 1) our *head* is a fully functional decoder rather than a partially functional module; 2) we do not use a sequential state to strengthen the decoupling of heads; 3) our approach is not a single-source method.

5 Conclusion & Future Work

This paper studies the multi-source knowledge-enhanced dialogue generation. We find three challenging problems, i.e., *1) Knowledge Diversity*, *2) Indefinite Alignment*, and *3) Insufficient Flexibility and Scalability*. Consequently, this paper proposes a novel *Knowledge Source Aware Multi-Head Decoding* approach, *KSAM*, which employs multiple source-aware decoder heads to handle each knowledge source more efficiently. In the future, we will continue to improve the applicability and the performance of multi-source knowledge-enhanced dialogue generation. For example, improving the fusing the predictions of heads.

Ethical Considerations: We did not propose a new dataset or use any private dataset. In addition, this work did not involve any sensitive topic. Thus, we believe no ethical concern in this paper.

Abstract

When building NLP models, there is a tendency to aim for broader coverage, often overlooking cultural and (socio)linguistic nuance. In this position paper, we make the case for care and attention to such nuances, particularly in dataset annotation, as well as the inclusion of cultural and linguistic expertise in the process. We present a playbook for responsible dataset creation for polyglossic, multidialectal languages. This work is informed by a study on Arabic annotation of social media content.

1 Introduction

Natural language processing (NLP) is the foundation of numerous automated decision-making systems in a growing number of scenarios and languages, including content moderation on platforms with global reach and consequence (Gillespie, 2020). Thus it is highly pertinent to address how practitioners can build responsible NLP systems, models, and workflows for languages beyond English (Bender, 2019; Mielke, 2016; Husain and Uzuner, 2021). In doing so, it is essential that these systems are designed with the inclusion of domain experts and stakeholder groups with native fluency and local/regional knowledge (Bender, 2009; Ovadya and Whittlestone, 2019). This will not only ensure the presence of the deep problem understanding necessary to create accurate systems and anticipate potential harms, but foster earned trust and legitimacy in the system (Martin Jr et al., 2020).

Many performant machine learning/NLP algorithms to date are supervised, relying on large scale annotated training data, thus the veracity and curation of the data labels can have significant impact on model performance (Bender et al., 2021; Northcutt et al., 2021). And further, even unsupervised and semi-supervised systems require labeled data for evaluation as a bare minimum to allow visibility into any blindspots in the system performance.

In this position paper, we focus on NLP datasets, highlighting the potential for compounding harms to at-risk populations and calling for greater care and attention to annotation and annotator support (Denton et al., 2021). This is demonstrated via the varieties of Arabic.[1]

2 Arabic Varieties and NLP

Arabic is a Semitic language, spoken by over 420M people globally with the highest concentration in the Middle East and North Africa (MENA) where it is the dominant or official language of over twenty nations. Arabic is better described as a family of languages as the so-called "dialects" are highly variable and often have low inter-dialect comprehensibility (Al-Wer and Horesh, 2018). *e.g.* Moroccan and Egyptian varieties are about as mutually intelligible as Spanish and Romanian. Importantly, Arabic should not be considered as an analog to English, *i.e.* one language with closely related dialects (*e.g.* British, American, and Australian English). This comparison buries the polyglossic (when languages co-exist in a community) and heterogeneous characteristics of Arabic that are crucial to take into account when building effective Arabic NLP systems. We describe several relevant features of Arabic in this section.

First, while these varieties share the same root in Classical Arabic, varying historical and cultural experiences across the Arab world have led to the divergence in spoken practice, leading to frequent cases of "faux amis," *a.k.a.* false cognates. This phenomenon refers to words or phrases that appear or sound the same between the varieties but have different meanings. For example, the word

---

[1] We primarily use the term "varieties" of Arabic to refer to what are often colloquially called Arabic "dialects," "forms" of Arabic, or Arabic "languages." Referring to the varieties of Arabic as "dialects" does not do justice to (and even obfuscates) the fact that many are mutually incomprehensible (§2). On the other hand, using the term "languages" minimizes the close connection between the Arabic varieties.

Findings of the Association for Computational Linguistics: ACL 2022, pages 364 - 371
May 22-27, 2022

zahry[2] means *my luck* in Tunisian Arabic, however the same word refers to the color pink in Levantine. Faux amis have implications for detecting objectionable speech, *e.g.* a common slur in Moroccan Arabic is *zamel*, however in Yemeni it is a type of singing that has become popular in recent years with the war in Yemen. Notably, this phenomenon is not only on the lexical level but also on the phrasal level, *e.g.* *yETyk AlEfyap* in Levantine dialects means "may you have good health," however in Moroccan it translates to "go to hell."

Second, Arabic exemplifies one of the best known cases of diglossia,[3] where the formal Modern Standard Arabic (MSA) or *fuSHY*, and the regional spoken vernaculars co-exist in virtually every speech community. Today, MSA is used in practice primarily for international news and legal contracts. It is generally the language of education, and thus only fully accessible to those with a certain level of literacy and training. In fact, MSA is a formal language akin to Shakespearean English and is not spoken colloquially. Despite that, MSA is considered a relatively high-resource language (Bender, 2019) due to its status as the shared language in the Arab world, as such it is often the variety used in Arabic language technologies. Moreover, it is the prevalent Arabic variety of language-learning courses across the world. Notably, L2 language learners of MSA often have trouble communicating with native Arabic speakers due to considerable divergences between MSA and spoken varieties. Due to these factors, when NLP systems are built for MSA a large portion of Arabic speakers cannot benefit fully from the technology, creating an access disparity between those with and without a more advanced education.[4]

The third feature to highlight is the fact that the colloquial varieties of Arabic greatly differ from one another along a geographic and social continuum, however general consensus splits Arabic into six broad groupings. Following Habash (2010) these are: **Iraqi** (Iraq), **Levantine** (Syria, Jordan, Lebanon, Palestine), **Maghrebi** (Morocco, Tunisia, Algeria, Libya,[5] Western Sahara, Mauritania), **Peninsular/Gulf** (Oman, Qatar, Saudi Arabia, Bahrain, United Arab Emirates, Kuwait[6]), **Yemeni** (Yemen), **Egyptian** (Egypt & Sudan[7]).

These broad dialect groupings of course do not fully account for the heterogeneous political and cultural aspects of MENA or the Arabic speaking diaspora. This can be a pitfall in annotation given that contextual knowledge is often necessary for full semantic and pragmatic understanding. As an example, the Maghrebi dialect may be more appropriately broken down further, as Algerian is often unintelligible to Moroccan and Tunisian variety speakers due to the infusion of novel, contextually-based vocabulary that correspond to the country's particular political context. This is a common phenomenon across MENA, and of course for other languages. The unique country-level situations for Arabic dialects – not to mention contexts and groupings that are sub-national or transcend country borders – are important to take into account as NLP practitioners strive to produce systems that capture how humans naturally use language.

A final element to mention is the fact that there are no standard orthographies for Arabic dialectal text and the written variants exhibit pervasive code switching. This property is of course particularly important in the context of text annotation. Such a language profile pushes the boundaries of NLP, and perceptions away from Arabic as a monolith.[8]

3 Motivational Case Study: Arabic on Social Media

To highlight the necessity for a more nuanced treatment of polyglossic, multidialectal languages, we study annotation of Arabic content on the Facebook platform. The text-based samples in the study are in native Arabic script (*i.e.* non-romanized), created by users in ten Arabic nations: Algeria, Morocco, Libya, Syria, Iraq, Lebanon, Egypt, Saudi Arabia, Sudan, and Yemen. We select these nations to cover all broad dialect groups in the region (§2), with some inter-dialect comparisons, *e.g.* Syria and Lebanon. Country-level groupings are employed in the study, rather than the broad dialects, to capture the contextual nature of content in each nation.

---

[2] We use the Buckwalter transliteration standard to render Romanized Arabic text throughout the paper.

[3] *Diglossia* refers to polyglossia with only two varieties.

[4] In the Arab world, basic literacy levels are 80% for adults over 15 years and 75% for females-only. (The World Bank: Literacy rate, adult total (% of people ages 15 and above) - Middle East & North Africa, 1973-2020.)

[5] Libyan Arabic is often in its own dialect grouping.

[6] Kuwait is sometimes placed with the Iraqi dialect.

[7] This Egyptian & Sudani grouping is standard, yet questionable due to linguistic differences and further fraught when considering the history of the region (Troutt Powell, 2003).

[8] For a well-structured review of Arabic language detection, see Husain and Uzuner (2021). For an intro text on Arabic NLP, see Habash (2010), and for a fundamental introduction to Arabic sociolinguistics, see Al-Wer and Horesh (2018).

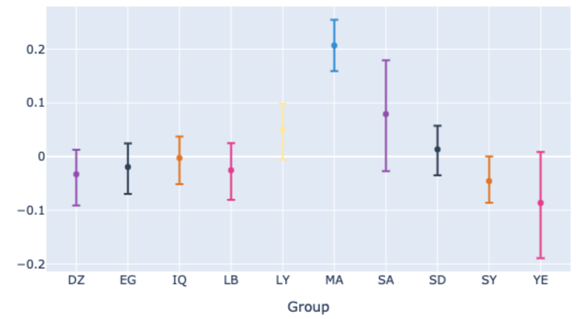

Figure 1: Aggregate implied threshold per country of the AiM using Signal Detection Theory (reduced by the overall aggregate implied threshold for all countries combined). Note that a relatively *higher* threshold indicates greater *leniency*, or alternatively that a *lower* relative threshold indicates greater *strictness*.

Approximately 3000 pieces of content are sampled per country from a source dataset created for the purpose of hate speech classification evaluation. For content from each country, we compare data labeled by annotators residing in Morocco (AiM) to reviews by annotators with native fluency and expertise for each country in the study, *a.k.a.* country experts (CE). For example, for Syrian content, annotation by AiM is compared to that by CE who are verified Syrian annotators. It is worth noting that the CE annotation consistency as measured by intra CE agreement – inter-annotator agreement or IAA – is quite high ranging from 64% for Egyptian to 92% for Moroccan Arabic.[9] The overlap sample sizes for the CE IAA measurement ranged in size from 91 unique items corresponding to 26% of the total Saudi Arabic dataset to 975 unique items corresponding to 41% of the total Iraqi dataset.

To achieve this, the content is first sampled and sorted primarily by IP into per-country queues. CE then choose the dominant language variety and country of the sample. From there, the data is filtered to only Arabic content from the country. After filtering, the CE label the content (previously labeled by AiM) with one of two classes: "delete" (*i.e.* the content is deemed hateful) or "ignore" (*i.e.* the content is deemed benign) per a predefined set of content guidelines.

The main findings of this study are as follows: (1) For every country dataset, the majority of the content is found to be in the Arabic dialect of that nation, rather than MSA. This tracks with the understanding that users communicate informally on social media (Habash, 2010; McCulloch, 2019), (2) The Saudi and Algerian datasets show a significantly higher presence of MSA content (31% and 27%, respectively) than other country datasets. Additionally, 74% of the Arabic samples in the Saudi dataset are identified by CE as *non*-Saudi content, a property of that could be explained by inward migration.[10] Thus after filtering the Saudi dataset is significantly smaller than that of any other country dataset. (3) Signal Detection Theory (SDT) models decision-making as a mixture of Gaussians (one for benign content and another for violating content) and determines the *implied* threshold of the reviewers in aggregate (Bakalar et al., 2021). Employing SDT, we find the AiM reviewers are labeling Moroccan content more leniently with statistical significance (Figure 1) as compared to all other country datasets, with the notable exception of the Saudi dataset.

Of further note, considering the CE labeling for each dataset as ground truth, the Morocco dataset had the most accurate labeling by the AiM cohort at 87%. This is an intuitive result that was verified in this study. This finding, coupled with the SDT results shown in Figure 1, point to two potential interpretations: When reviewers understand the linguistic and contextual content of the samples, they

1. Are more likely to understand the nuances of the content that make it benign (*e.g.* sarcastic or idiomatic speech);
2. May feel comfortable giving a certain benefit-of-the-doubt (*a.k.a.* leniency) to the content creator, whereas they may not for groups in which they are not a member.

This observed leniency, alone, *could* imply that reviewers should not review content within their own variety, however when coupled with the sociolinguistic knowledge presented in Section 2 on the distance between the varieties and the finding that, for the Morocco dataset, the the AiM cohort and CE had the highest agreement, these findings instead point to the fact that reviewers could be misunderstanding other-variety content or are relatively more strict on out-group member content.

This study highlights the impact of Arabic variety differences on annotation. Accordingly we gather observations and formalize the process rendering it applicable across similar scenarios,

---

[9] Variations in CE agreement is outside the scope of this investigation. For this, we defer to future research.

[10] United Nations Population Division, World Population Prospects: 2019 Revision.

namely, dataset creation for polyglossic, multidialectal languages such as Indo/Malay, varieties of German, etc.

4 A Playbook for Dataset Creation

For accurate annotation of natural language content, it is important for NLP practitioners to consider the entire flow of content to the training or evaluation datasets.[11] Here, we propose general recommended practices for annotation, with further information for Arabic NLP dataset creation, informed by the case study in Section 3. The guidelines aim to: (1) ensure there is sufficient expertise to – at minimum – understand the variety and context of the annotation samples; (2) route samples to experts who are best equipped to field and process them; and, (3) provide expert support and inclusion in the process of NLP design and implementation. These recommendations could seem obvious to some, however they are worth crisply laying out to set expectations of expert inclusion and support in NLP development. They are as follows:

(1) Data sample collection and curation that is representative of the speech/orthographies of the user cohort for the developers' intended systems, and refreshed periodically to capture changing relevant events ensuring concurrent and temporal sensitivity (DeVries et al., 2019; Rancic et al., 2021). Such measures can reduce the potential for harms due to group under-representation in datasets (Barocas et al., 2019; Buolamwini and Gebru, 2018).

For the case study, we employed a stratified sampling technique to endeavor to capture the linguistic landscape of Arabic variety-speakers, and relevant context coverage for Arabic content from the countries and communities in focus.

(2) Training materials and interface design to support the annotators in understanding their task. For the case study (§3), this included prototyping and iterations on the training materials and interface, with multi-stage feedback from a subset of annotators. Additionally, there was select translation of training materials and the annotation interface into the Arabic varieties to assist understanding (localization).[12]

(3) Annotator representation: Reviewers are adequately representative of the users whose content they are labeling, and have necessary fluency in the language and context of the samples they are vetting. Ideally, proficiency is validated with testing and responsible hiring practices.[13]

(4) Annotator proficiency assessment to verify both language proficiency and an understanding of context and culture to the relevant level for the task at hand. This has the added benefit of demonstrating legitimacy and trustworthiness of the dataset. Evaluations should be designed carefully as many speakers of one variety have passive knowledge (vs. deep/native understanding) of other varieties. Arabic speakers may consider themselves fluent enough in the passive variety however it is important that their proficiency level is carefully assessed.[14]

Furthermore, evaluations per-variety in many of these polyglossic multidialectal language families should include contextual elements relevant to the country or region. At present, many out-of-the-box Arabic proficiency tests are specific to MSA, which is not recommended unless employed as a supplement.

For the case study (§3), a major difference between the Morocco-based annotators and country experts is their verified relevant expertise. The country experts are proficient in the Arabic variety and regional contexts relevant to the labeling tasks, with sufficient cultural understanding to accurately interpret content from the community. Broad groupings (§2) *could* be employed, depending on the granularity of contextual content and goals of the model. Setting aside the vast in-homogeneity of cultures and complex contexts across the Arabic-speaking world, there can be a misconception that if an individual can speak one Arabic dialect/variety they can accurately label content for any or adjacent varieties. This should not generally be assumed (Al-Wer and Horesh, 2018; Habash, 2010).

(5) Sample routing and queues are recommended such that annotators are reviewing content within

---

[11] As has previously been described for some social media platforms, content can be added to manual (or human) review queues through proactive identification by an ML classifier or reporting from a user (Facebook, 2020). This content is then de-duplicated, ranked, and routed to the proper queue for manual inspection and labeling (Vincent, 2020).

[12] For example, in prototyping with experts, we changed the term "MSA" in annotation questions to the Arabic term "*fuSHY*."

[13] If other languages are needed for labeling, *e.g.* to understand the training materials, examples, or prompts, proficiency standards are recommended for those languages as well (if the instructions are in English while the actual text to be annotated is Swahili, for instance).

[14] Arabic speakers often have passive knowledge of Egyptian Arabic, the dominant variety in Arabic language media. However passive learning from media can lead to missing Egyptian specific vernacular/cultural nuance.

their expertise. For systems aiming to cover multiple dialects or language groupings (*e.g.* multiple Arabic varieties), content could be divided by a manual or automated language identification system and routed to designated annotator queues.

For Arabic varieties, queues and routing at least at the granularity level of each broad grouping (§2) is generally essential, due to the low inter-variety comprehension. If country context is deemed relevant for the type of samples and application, *e.g.* political contexts/social value content, further subdivisions (*e.g.* country, age, gender identity, etc.) are likely to be important for accuracy and consistency in labeling. For systems with automated routing, language and geographic identification could be employed to detect and separate dialects and contexts. A possible starting point is the groupings as described in §2, enhanced with guiding per-variety word lists.

These elements bring up the difficult question of granularity: Not just how, but *how deeply* should practitioners divide datasets and annotation, in order to ensure sufficient coverage and understanding of the content? This is a deceptively challenging question as languages most commonly exist on a continuum and practitioners can often divide the natural language groups further with no clear ideal stopping point. This question of granularity presents the need for a careful deliberation of trade-offs, often around resource expenditure vs. annotator expertise and data coverage. Data availability or the cost of obtaining high-quality labeling will frequently become a limiting factor. The overarching recommendation in this work is to prioritize high quality annotation over breadth of coverage, indicating that in the cases where researchers do not have the resources for high quality annotation and annotator support they instead reduce coverage by tightening the goals of their NLP technology/application.

(6) Sample re-routing capabilities are relevant to capture routing errors, especially as errors in language identification can be surprising. It's important to build flexibility into the annotation system to allow annotators to route/skip samples outside their expertise, as well as a mechanism to surface such routing failures to improve the system. For the case study, we provided a mechanism to filter or surface routing errors.

(7) Data evaluation for faithful and accurately-labeled evaluation and training (if applicable), such that a resulting model can report real patterns (Northcutt et al., 2021). This includes label evaluation and auditing systems to measure accuracy, sensitivity, and any potential bias (*e.g.* sampling biases, statistical biases, or stereotypes) encoded in the datasets (Bakalar et al., 2021; Barocas and Selbst, 2016). A multi-evaluation system for the stability of the labels, or uncovering ambiguity, could be significant (Caliskan et al., 2017).

For multidialectal, polyglossic languages such as Arabic, it is important that data evaluations account for the language variety and contextual differences, particularly with tricky faux amis. For the case study, we employed a multistage process with adjudication using multiple expert reviewers of content to check annotation quality.

(8) Reviewer well-being support systems, including but not limited to rest periods and psychological support, are important for any type of annotation, and especially-so when the dataset is composed of disturbing or traumatic content. These means of support are even more essential for the well-being of Arabic annotators, given the high rate of PTSD in the Arab world (Suto, 2016; Syria Relief, 2021).

Care is needed when constructing Arabic natural language datasets, due to the prevalence of faux amis, Modern Standard Arabic and pervasive linguistic code switching, as well as the complex cultural and political contexts of Arabic-dominant countries. This is not to mention the potentially dire consequences of errors for economically disadvantaged and vulnerable groups in MENA (Amnesty International, 2020; Human Rights Watch, 2017; Shea and al-Hassani, 2021; Johnsen, 2021). The guidelines in this section serve the additional purpose of surfacing failure modes in labeling that could scale when training classifiers, or obfuscate issues with model outcomes for evaluation datasets.

5 Conclusion

Polyglossic and multidialectal languages present both challenges and opportunities to the NLP community, chief among them are the trade-offs inherent in dataset creation. From developing best practices with Arabic, we can apply the guidelines to other polyglossic, dialectal languages – such as Chinese, Indonesian/Malay, and German – with the understanding that with each language comes new challenges.

6 Ethical Considerations

This paper fits in to the body of responsible and fair AI research by offering best practices towards ensuring the annotation ecosystem for dataset creation is responsive to the relevant groups in the Arabic-speaking world, and by extension local communities. The general goals of this work are to limit representational and potential downstream allocative harms (Barocas et al., 2019). Moreover, the work strives to advise on building NLP systems that allow annotators to be a voice for their local communities, where they are appreciated for their skill and ability to provide deep problem understanding.

Expert Inclusion: Regional/country experts with Arabic variety proficiency are included in all stages of the guideline formulation, research design and implementation, and producing the comparative annotation results in Section 3. Their expertise is critical to the entire research process.[15]

Audience: This work is targeted for the NLP community. The guidelines are formulated with an understanding that practitioners may not have the resources to implement them all to the fullest extent. They are north stars to aim for, however if language/content understanding and reviewer support are not achievable with the resources at-hand, the practitioner can reduce the dialect/variety coverage of the annotation accordingly. We advocate for a nuanced approach in dataset creation over comprehensive coverage.

Scope: This work is limited to Arabic varieties, with the hope that researchers can gain insight into handling other polyglossic, multidialectal global languages as well as a sense for the complexities of dataset creation for NLP. There are certainly nuances to Arabic annotation that are not covered in this work that affect annotation such as code switching and orthographic considerations.

Furthermore, we focus on the broad Arabic dialects when discussing representation in the guidelines (§4). We recognize that there are other, deeply important areas of diversity and representation including gender, political stance, religion, etc., however we considered these outside the scope of this particular paper. What we describe here are recommended *minimal* representation requirements considering language at as high of a level as possible. Of course other groupings have particular manners of language use that could be required for fully accurate annotation.

Broader Impacts: NLP systems are embedded in our multifaceted, ever-changing societies, and it is therefore necessary to consider the model's potential or realized impacts, as well as the productive and adversarial manners in which the world can feedback to the model (Sambasivan et al., 2020; Hagerty and Rubinov, 2019). The primary scope of this paper is data, however in what follows we discuss elements of model support that can provide constructive feedback to the system.

First, this paper calls for soliciting stakeholder input, particularly through working with annotators who are of the community the model aims to capture. But further consultation with groups such as regional user-advocacy groups can be important to garner a higher-level view and broader problem understanding to prevent potential issues and low performance for underserved groups (Martin Jr et al., 2020; Caliskan et al., 2017; Bruckman, 2020; Ovadya and Whittlestone, 2019; Abid et al., 2021).

Other practices to aid the practitioner in envisioning the possible impacts of their work include: staged system roll-out or prototyping to get ahead of any unforeseen issues before full launch, and performing an impact investigation. Impact investigations are worthwhile, though they are neither simple nor straightforward and there are no clear norms (Prunkl et al., 2021; Partnership on AI, 2021).

The nature of statistical prediction means careful error handling is of the highest importance, as these systems will never be mistake-free, and in fact NLP systems can have surprising or unanticipated errors. In creating NLP systems, practitioners can ask what can be done to minimize potential negative impacts of errors (Hellman, 2019). At the massive scales at which AI can operate, even a small error rate could affect many people (Sullivan, 2016).

And, to garner constructive feedback, meaningful transparency measures are important (Diakopoulos, 2016; Mitchell et al., 2019), as are mechanisms for external feedback for model improvement in order to allow the model to be responsive to external events.

These practices are generally important, but especially-so for the Arab world, as much of MENA is in-conflict, afflicted by ongoing tensions and political violence (Amnesty International, 2020; Johnsen, 2021) that can be amplified by tech-

nology (Shea and al-Hassani, 2021) or harnessed by violent and/or authoritarian state actors (Human Rights Watch, 2017).

Acknowledgements

This research would not have been possible without the invaluable expert guidance and contributions from colleagues from across the Arabic-speaking world, including Amine Dehimi, Hasan Ali, Hamoud Agha, Fajr Sabouni, Raed Jamil, Anthony Akoury, Sarah Nasr, and Mohammad Zaher. The authors are sincerely grateful for their support.

The authors would like to further thank Amine Dehimi, Miranda Bogen, Molly FitzMorris, Khalid El-Arini, Edmund Tong, Renata Barreto, Jenny Hong, Jonathan Tannen, and Kate Vredenburg for the insightful conversations and feedback on the paper. Moreover, we would like to acknowledge valuable feedback from several anonymous ARR and ACL reviewers.

Abstract

Warning: *this paper contains content that may be offensive and distressing.*

Hate speech classifiers exhibit substantial performance degradation when evaluated on datasets different from the source. This is due to learning spurious correlations between words that are not necessarily relevant to hateful language, and hate speech labels from the training corpus. Previous work has attempted to mitigate this problem by regularizing specific terms from pre-defined static dictionaries. While this has been demonstrated to improve the generalizability of classifiers, the coverage of such methods is limited and the dictionaries require regular manual updates from human experts. In this paper, we propose to automatically identify and reduce spurious correlations using attribution methods with dynamic refinement of the list of terms that need to be regularized during training. Our approach is flexible and improves the cross-corpora performance over previous work independently and in combination with pre-defined dictionaries.[1]

1 Introduction

The relative sparsity of hateful content in the real world requires crawling of many of the standard hate speech corpora through keyword-based sampling (Poletto et al., 2021), rather than random sampling. Thus, hate speech classifiers (D'Sa et al., 2020; Mozafari et al., 2019; Badjatiya et al., 2017) often learn spurious correlations from the training corpus (Wiegand et al., 2019) leading to a substantial performance degradation when evaluated on a corpus with a different distribution (Yin and Zubiaga, 2021; Bose et al., 2021; Florio et al., 2020; Arango et al., 2019; Swamy et al., 2019; Karan and Šnajder, 2018).

Recent work has proposed regularization mechanisms to penalize spurious correlations by attempting to explain model predictions using feature attribution methods (Ross et al., 2017; Rieger et al., 2020; Adebayo et al., 2020). These methods assign importance scores to input tokens that contribute more towards a particular prediction (Lundberg and Lee, 2017). For instance, Liu and Avci (2019) penalize the attributions assigned to tokens contained in a manually curated dictionary consisting of group identifiers (e.g. women, jews) that are often known to be targets of hate. Kennedy et al. (2020) extract group identifiers manually from the top tokens indicated by a bag-of-words logistic regression model trained on the source corpus. However, regularizing only group identifiers limits the coverage of such approaches, and may not capture other forms of corpus-specific correlations learned by the classifier limiting its performance on a new corpus. Moreover, such manually curated lists may not always remain up-to-date because new terms emerge frequently (Grieve et al., 2018). While Yao et al. (2021) do not use such lists for refining models in different target-domains, their method still requires input from human annotators.

Target corpus utterances	Actual	Predicted
Genocide is never ok	non-hate	hate
Women are goddesses	non-hate	hate

Table 1: Spurious correlations learned by the source classifier between the shaded tokens and the hate label.

In this paper, we hypothesize that the classification errors in a small annotated subset from the target can reveal spurious correlations between tokens and hate speech labels learned from the source (see Table 1). To this end, we propose Dynamic Model Refinement (D-Ref), a new method to identify and penalize spurious tokens using feature attribution methods. We demonstrate that D-Ref improves the overall cross-corpora performance independently and in combination with pre-defined dictionaries.

2 Dynamic Model Refinement (D-Ref)

In this section, we describe the general theoretical framework of the proposed approach. We assume that during training our hate speech classification model has access to the source training corpus D_S^{train} and a small validation set D_T^{val} from a target corpus with different distribution, following a similar setting to Maharana and Bansal (2020). Our Dynamic Model Refinement (D-Ref) approach consists of 2 recurring steps across epochs: (i) we first extract a set of spurious tokens using D_T^{val} at the end of every epoch; and (ii) then we penalize the extracted tokens during the next epoch.

2.1 Extraction of Spurious Tokens

Global token-ranking in source corpus: We first begin with identifying the tokens from D_S^{train} that are highly correlated with hate/non-hate labels. These tokens are suitable candidates for causing source-specific spurious correlations, restricting generalizability to a new corpus.

For that purpose, at the end of every training epoch ep_i, we first obtain the global class-specific ranked list of tokens from D_S^{train}. This is achieved by computing global attributions per token tok and class c (gl-atr$_{tok}^{c}$) from its attribution per instance j (loc-atr$_{tok}^{j}$) averaged across all training instances classified as c by the source model trained until ep_i:

$$\text{gl-atr}_{tok}^{c} = \frac{\sum_{j=1}^{|D_S^{train}|} \mathbb{1}_{\hat{y_j}=c} \text{loc-atr}_{tok}^{j} \forall \text{occurrence of } tok \text{ in j}}{\sum_{j=1}^{|D_S^{train}|} \mathbb{1}_{\hat{y_j}=c} \#(\text{occurrence of } tok \text{ in j})} \quad (1)$$

Here $c \in \{\text{hate, non-hate}\}$, $\hat{y}$ is the predicted class and $\mathbb{1}$ is the indicator function. Prior to this, loc-atr$_{tok}^{j}$ are individually normalized using sigmoid to obtain values in a closed range. Rarely occurring tokens and stop-words are not considered for the global ranking. The gl-atr$_{tok}^{c}$ values are sorted from the highest globally attributed token to the lowest, which yields two ranked token-lists $[gl\text{-}hate, gl\text{-}nhate]_{ep_i}$.

Instance-level local ranking in target corpus: We hypothesize that tokens highly correlated with hate/non-hate classes in the source, but also causing mis-classifications in the target, should most likely contribute to spurious source-specific correlations, and may not be important for hate speech labels. Thus, we identify the tokens that cause misclassifications in D_T^{val}, and then obtain a list of spurious tokens *dynamically* after every epoch ep_i.

We rank the tokens in the target instances from D_T^{val} based on their loc-atr$_{tok}^{j}$, starting from the highest attributed token per instance j to the lowest. The top k tokens in j is given by $tok_{top_k}^{j} = top_k[\text{argsort}(\text{loc-atr}_{tok}^{j})]$, where k is a hyper-parameter in D_T^{val}. We treat the two error cases of False Positives (FP) and False Negatives (FN) separately. Here the hate class is considered as the positive class.

Since the tokens responsible for FP may also be important for the True Positives (TP), we only extract those that have high attributions for FP, but not for TP. Further, another filtering step is applied, where only the tokens common to the top N from the ranked $gl\text{-}hate$ are extracted. This results in discarding the tokens that may not be globally correlated with a class with respect to the source model. So $tok_{FP} = [tok \in tok_{top_k}^{j_{FP}} \;\&\; tok \notin tok_{top_k}^{j_{TP}}] \cap top_N(gl\text{-}hate) \; \forall$ instances j in D_T^{val}. Similarly, top k tokens corresponding to FN instances are extracted, wherein those common to TN are discarded, and subsequent filtering based on the $gl\text{-}nhate$ is performed, i.e. $tok_{FN} = [tok \in tok_{top_k}^{j_{FN}} \;\&\; tok \notin tok_{top_k}^{j_{TN}}] \cap top_N(gl\text{-}nhate) \; \forall \; j$. This step thus yields a list of possible spurious tokens at the end of ep_i, $S_{ep_i} = [tok_{FP}, tok_{FN}]_{ep_i}$.

2.2 Penalizing the Extracted Spurious Tokens

In this step, we attempt to reduce the importance assigned, by the source model, to the extracted spurious tokens by penalizing the terms in S_{ep_i} during the next epoch ep_{i+1}. We propose three different ways for token penalization:

Tok-mask: In this case, we simply mask the tokens from S_{ep_i} present in D_S^{train} after every ep_i and then train the source model during ep_{i+1}.

Reg: Since token masking might eliminate substantial information, we regularize the model using S_{ep_i}. The attributions assigned to these terms are pushed towards zero by the following learning objective on D_S^{train}:

$$\mathcal{L} = \mathcal{L}' + \lambda \mathcal{L}_{\text{atr}} \left(\text{t}\right); \text{t} \in \mathcal{S}_{\text{ep}_\text{i}}; \mathcal{L}_{\text{atr}} = \sum_{\text{t} \in \mathcal{S}_{\text{ep}_\text{i}}} \phi \left(\text{t}\right)^2 \quad (2)$$

where $\mathcal{L}'$ is the classification loss and $\mathcal{L}_{\text{atr}}$ is the attribution loss. Here $\phi\left(\text{t}\right)$ is the attribution score for the token t. Intuitively, this should reduce the importance of tokens contributing to source-specific patterns and encourage learning more general information. Both losses are computed over D_S^{train}.

Comb: We finally combine S_{ep_i} with the pre-defined group identifiers from Liu and Avci (2019) and Kennedy et al. (2020) to perform regularization using Equation 2.

We surmise that repeating these steps at the end of every epoch should reduce the source-specific correlations while the source model gets trained. We use three different attribution methods:

(i) Scaled Attention ($\alpha\nabla\alpha$) (Serrano and Smith, 2019): Here attention weights α_i are scaled with their corresponding gradients $\nabla\alpha_i = \frac{\delta\hat{y}}{\delta\alpha_i}$, where $\hat{y}$ is the predicted label. Serrano and Smith (2019) show that combining an attention weight with its gradient can better indicate token importance for model predictions, compared to only using the attention weights.

(ii) Integrated Gradients (IG) (Sundararajan et al., 2017): This method is based on the notion that the gradient of a prediction function with respect to input can indicate the sensitivity of the prediction for each input dimension. As such, it aggregates the gradients along a path from an uninformative reference input (e.g. zero embedding vector) towards the actual input such that the predictions change from uncertainty to certainty.

(iii) Deep Learning Important FeaTures (DeepLIFT/DL) (Shrikumar et al., 2017): This aims to explain the difference in the output from a reference output in terms of the difference of the input and a reference input. Given a target output neuron t, a reference activation t^0 of t, and $\Delta t = t - t^0$, it computes the contribution scores $C_{\Delta x_i \Delta t}$ of each input neuron x_i that are necessary and sufficient to compute t, such that $\sum_{i=1}^{n} C_{\Delta x_i \Delta t} = \Delta t$. The reference input could be the zero embedding vector.

3 Experiments and Results

3.1 Experimental Setup

Data We use three standard hate speech corpora: *HatEval* (Basile et al., 2019), *Waseem* (Waseem and Hovy, 2016) and *Dynamic* (Vidgen et al., 2021). Following previous work by Wiegand et al. (2019); Swamy et al. (2019), we consider the detection of hate vs non-hate, where the hate class covers all forms of hate. We split *Waseem* (26.8% hate) into train (80%; 8720), val (10%; 1090) and test (10%; 1090) sets as no standard splits are provided. We use the original splits for *HatEval* (42.1% hate; train: 8993[2], val: 1000; test: 3000) and *Dynamic* (54.4% hate; train: 32497, val: 1016, test: 4062). We reduce the size of available D_T^{val} in *Dynamic* by randomly sampling 25% of the validation set (4064). We remove URLs, split hashtags into words using the CrazyTokenizer[3], remove infrequent Twitter handles, punctuation marks and numbers, and convert text into lower-case. See Appendix A for a detailed discussion on the corpora.

Baselines We compare D-Ref with the following baselines: **(i) BERT Van-FT** (Devlin et al., 2019): vanilla fine-tuning on D_S^{train} without regularization; **(ii)** Convolutional Neural Network with regularization of pre-defined group identifier terms using IG for feature attribution (Liu and Avci, 2019); **(iii)** BERT using two variations for regularization: (a) all the mentioned group identifiers, (b) group identifiers extracted from the top features of a bag-of-words logistic regression trained on each individual corpus (Kennedy et al., 2020)[4]; **(iv) χ^2-test** with one degree of freedom and Yate's correction (Kilgarriff, 2001) to extract tokens tok from D_S^{train} that reject the null hypothesis with 95% confidence. The null hypothesis states that in terms of tok, both D_S^{train} and D_T^{val} are random samples of the same larger population. We, then, regularize the attribution scores[5] assigned to these terms, with BERT. **(v) Pre-def**: BERT with regularizing the combined pre-defined group identifiers from (ii) and (iii).

Model training We use pre-trained BERT (Devlin et al., 2019) for our approach. We train all the models over D_S^{train} from the source and evaluate over D_T^{test} from the target. The best model for all the baselines and D-Ref are selected by tuning over D_T^{val}. See Appendix B on hyper-parameter tuning.

3.2 Cross-corpora Predictive Performance

Table 2 presents macro-F1 scores across five random initializations of each experiment using six cross-corpora pairs. We observe that overall, all feature-attribution methods with D-Ref yield improved performance compared to Van-FT and other baselines. While χ^2 yields improvements over Van-FT, D-Ref still displays better performance in most of the cases. This could be attributed to the fact

---

[2] We remove the instances that contain only URLs, reducing the train instances from 9000 to 8993.

Table 2: Macro-F1 (±std-dev) on source →target pairs (H : HatEval, D : Dynamic, W : Waseem). **Bold** denotes the best performing approach in each column for every feature attribution method. * denotes statistical significance compared to Van-FT with paired bootstrap (Dror et al., 2018; Efron and Tibshirani, 1993), 95% confidence interval.

that although the terms obtained through the χ^2 test from the source indicate differences across domains, they may not necessarily be important for the prediction of hate/ non-hate labels by the source model, and may not contribute to source-specific spurious correlations.

We find that D-Ref-Reg with IG and DL achieves better average macro-F1 of 58.9 and 58.4 respectively, compared to the corresponding Pre-def (IG) and Pre-Def (DL) that obtain an average of 57.6. D-Ref-Reg ($\alpha\nabla\alpha$) provides an average macro-F1 of 58.7, comparable to Pre-def ($\alpha\nabla\alpha$) with 58.8. However, D-Ref-Reg achieves significantly improved scores in more cases, as compared to Pre-def using all the attribution methods, i.e. 4/6 cases ($\alpha\nabla\alpha$), 3/6 cases (IG) and 3/6 cases (DL) with D-Ref-Reg, compared to 3/6 ($\alpha\nabla\alpha$), 1/6 (IG) and none (DL) with Pre-def. D-Ref-Tok-mask exhibits improvements on average ($\alpha\nabla\alpha$: 57.8, IG: 58.2, DL: 57.8) over Van-FT (57.3), demonstrating the effectiveness of the token extraction mechanism of D-Ref. Finally, D-Ref-Comb displays the best overall performance, with the highest average score of 59. We attribute this improvement from D-Ref to its increased coverage with dynamic token extraction, and reduction of spurious source-specific correlations, while the baselines only penalize the group identifiers. A dynamic approach also corrects the model during training before it can get fully biased towards these tokens. Finally, it can incorporate the pre-defined lists along with the extracted tokens, and further improve the performance.

3.3 Domain-Adaptation Approaches

We further compare D-Ref-Reg with various Domain Adaptation (DA) methods. However, such methods typically leverage the unlabeled train set from the target domain (D_T^{train}). We first continue pre-training BERT model on D_T^{train} following Rietzler et al. (2020). Then, we perform supervised fine-tuning and regularization on D_S^{train} using D-Ref-Reg (**M**asked **L**anguage **M**odel + D-Ref-Reg). We compare against the following methods:

(i) BERT Van-MLM-FT : MLM training of BERT on D_T^{train} and supervised fine-tuning on D_S^{train}.

(ii) BERT PERL (Pivot-based Encoder Representation of Language) (Ben-David et al., 2020): This performs pivot based fine-tuning using the MLM objective of BERT by masking and predicting the pivot terms present in the combination of D_S^{train} and the unlabeled D_T^{train}. Here pivots are terms that are frequently present in the unlabeled data of both the source and target corpora, and are predictive of the source labels.

(iii) BERT-AAD (Adversarial Adaptation with Distillation) (Ryu and Lee, 2020), This is a domain adversarial approach with BERT where a target encoder is adapted with an adversarial objective that leverages D_S^{train} and D_T^{train}.

(iv) HATN (Hierarchical Attention Transfer Network) (Li et al., 2018, 2017) This approach uses attention and a domain adversarial pivot extraction mechanism.

(v) Sarwar and Murdock (2021): This adopts a data-augmentation strategy leveraging a negative emotion dataset (Go et al., 2009), for cross-domain hate-speech detection. They construct a weakly labeled augmented dataset by training a sequence

Approaches	**H →D**	**D →H**	**H →W**	**W →H**	**D →W**	**W →D**	**Average**

Table 3: Comparison of DA approaches with D-Ref + MLM. Macro-F1 (±std-dev) on different source →target pairs. H : HatEval, D : Dynamic, W : Waseem. * denotes the significantly improved scores w.r.t. Van-MLM-FT.

tagger on D_S^{train} and a TF-IDF based template matching with D_T^{train}.

(vi) χ^2-test using D_S^{train} and D_T^{train}.

For a fair comparison, we initialize (v) and (vi) with the MLM trained BERT on D_T^{train}, while the other methods already make use of D_T^{train} for adaptation. We use D_T^{val} from target for model selection for all the above methods.

Table 3 shows the results on comparing against other DA approaches. We note that the average performance of all the other DA approaches in this task is lower than Van-MLM-FT, as discussed in our previous work (Bose et al., 2021). χ^2-test, on an average, fails to surpass the Vanilla baseline. Besides, the DA approach proposed for cross-domain hate-speech detection by Sarwar and Murdock (2021) also yields an overall drop in performance. They perform data-augmentation by replacing relevant words from an external negative emotion dataset with tagged hateful terms from the target domain. We find that a major portion of the augmented instances lack meaning, and this negatively impacts the adaptation. However, across all feature attribution methods, D-Ref-Reg improves the cross-corpora performance compared to Van-MLM-FT and the DA approaches, with average macro-F1 of 59.6 ($\alpha\nabla\alpha$), 59.8 (IG), and 60.8 (DL), compared to 58.1 from Van-MLM-FT. Since D-Ref-Reg and Van-MLM-FT use identical MLM pre-training on D_T^{train}, the improvements can be attributed to the dynamic token extraction of our method.

More generally, when the larger set of target domain unannotated instances D_T^{train} are unavailable, D-Ref can identify and correct spurious correlations on source using a small amount of annotated instances from the target D_T^{val}, as demonstrated in Section 3.2. When sufficient number of unannotated instances from the target corpus are available, D-Ref can yield further cross-corpora improvements by leveraging the unannotated target instances with the MLM pre-training.

Blacks are savages .	Blacks are savages .
Queers can't be truly happy .	Queers can't be truly happy .

Table 4: Change in attributions with D-Ref-Reg (IG).

3.4 Qualitative Analysis

Table 4 shows the change in attributions for some instances in D_T^{test} from *Dynamic* that were misclassified by Van-FT but correctly classified by our D-Ref-Reg (IG). Van-FT wrongly attributes higher importance to 'f*cking' and 's*cks' for the hate class in the first example, and 'blacks' and 'queers' for non-hate in the second due to source-specific correlations. However, D-Ref-Reg (IG), extracts and penalizes abusive tokens like {s*ck, a**hole, d*ck} for the former causing FP and {africans, dark, queer} for the latter causing FN. Our approach not only penalizes the exact tokens, but also those with similar meaning (e.g. 'blacks' is contextually close to 'dark', 'africans'), giving more importance to the context around the spurious tokens. See Appendix C for the token-lists.

4 Conclusion

We proposed a dynamic approach for automatic token extraction with regularization of the source model such that the spurious source specific correlations are reduced. Our approach shows consistent cross-corpora performance improvements both independently and in combination with pre-defined tokens. Future work includes applying our method on other cross-domain text classification tasks and exploring how explanation faithfulness can be improved in out-of-domain settings (Chrysostomou and Aletras, 2022).

Ethical Considerations

The approach proposed in the paper is aimed at supporting robust and accurate detection of online hate speech. The datasets used in the work are publicly available and referenced appropriately. The dataset creators have presented, in detail, the data collection process and annotation guidelines in peer-reviewed articles. The offensive terms presented, as examples, are only intended for better analysis of the models for research purposes.

A Data Description

While *HatEval* and *Waseem* are sampled from Twitter, *Dynamic* is generated using a human-and-model-in-the-loop process. These corpora have been collected across different time frames, and hence they involve different topics of discussion, which are also determined to a large extent by the keywords used for sampling. As such, the problem of dataset bias with spurious correlations are induced with such focused sampling procedures (Wiegand et al., 2019) used in *Waseem* and *HatEval*. For instance, in *Waseem*, a large amount of tweets, available at the time of our experiments, consist of hate tweets directed against women, which results in False Positives for instances from other corpora that contain women related terms. We observed that most of the racist tweets were already removed and were unavailable for experiments. *HatEval*, on the other hand, has a mix of tweets directed against women and immigrants, and hence it demonstrates decent performance when evaluated over *Waseem* that consists of sexist tweets. On the contrary, *Dynamic* contains annotator-generated tweets that includes challenging perturbations. For instance, it includes non-hate instances like 'It's wonderful having gay people around here', 'I hate the concept of hate', 'Tea is f*cking disgusting', which can easily fool a classifier learned on biased datasets, and result in classifying these instances as hateful. Moreover, this corpus covers different targets of hate. As such, when *Dynamic* is used as the target corpus, the spurious correlations learned by the source classifier become relatively well-visible, which are captured and penalized by D-Ref while the source model gets trained.

The data used in the work are publicly available, and download links are provided in the respective original articles, which are referenced in this paper. However, in the case of *Waseem*, where only tweet IDs are provided, some tweets might be unavailable.

B Implementation Details

We leverage the pretrained BERT-base model[6] for our experiments. We use a batch size of 8, learning rate of 1×10^{-5} and Adam optimizer with decoupled weight decay regularization (Loshchilov and Hutter, 2019) for Van-FT, Van-MLM-FT, D-Ref and Pre-def. For Integrated Gradients, following Liu and Avci (2019), the interpolated embeddings are treated as constants while back-propagating the loss from the regularization term. An all zero embedding vector is used as the baseline input for both Integrated Gradients and DeepLIFT. We use the original code, as provided by the respective authors, for all the prior-arts. For Pre-Def, we combined the pre-defined lists from Kennedy et al. (2020) and Liu and Avci (2019) and regularized their attribution scores over BERT with $\alpha\nabla\alpha$, IG, and DL as feature attribution methods.

We implement the data-augmentation approach

---

[6] `https://github.com/huggingface/transformers`

proposed by Sarwar and Murdock (2021) ourselves due to the absence of an available implementation. Following the description present in the paper, we prepare the training data for the sequence tagger by labeling all the terms in the hateful instances from the source corpus that are also present in the lexicon from hatebase.org[7]. However, we do not tokenize the lexicon obtained from hatebase.org while searching for the corresponding matching terms in the source corpus. We convert the lexicon into lower-case and look for the exact match in the source corpus.

For D-Ref, we set the value of top N tokens used from ranked {glist-hate, glist-nhate} as 500. The values of $k \in$ top {10%, 20%, 30%, 40%} of the instance-length in D-Ref, and λ in both D-Ref and Pre-def are selected through hyper-parameter tuning over D_T^{val} using a random seed. For $\alpha\nabla\alpha$ and DeepLIFT, $\lambda \in \{0.1, 0.5, 1, 10, 20, 30, 40, 50, 60\}$ and for IG, $\lambda \in \{1, 10, 20, 30, 40, 50, 60\}$. We run supervised fine-tuning on D_S^{train} for 6 epochs with all the BERT models (prior-arts and D-Ref). We select the models (prior-arts and D-Ref) by tuning over D_T^{val} from the target corpus, with respect to macro-F1 scores. Table 5 presents the macro-F1 scores obtained on the validation set for D-Ref and the prior arts.

C Tokens extracted in different epochs

The list of error-causing tokens for False Positives (FP) and False Negatives (FN) in D_T^{val}, extracted for the cases presented in Section 3.4, is given below. We underline the tokens present in the visualization examples (both Table 4 in Section 3.4 and below) and ones similar in meaning to them.

HatEval →Dynamic

- **Epoch 1: FP:** {idiots, conservative, countries, p*ssy, bloody, americans, move, a**hole, hating, beings, feminist, africans, resources, d*ck, resist, females, attacks, dude, anger } **FN:** {hitler, plague, ##urs, crisis, rescue, funding, gorgeous, treason, journalist, lawyers, agenda, roles, principles, bloody, intern}
- **Epoch 2: FP:** {race, hating, flights, sheep, females, ignorant, feminist, resist, attacks, d*ck, kill, boat, countries, p*ssy, refugee, bloody} **FN:** {president, foreigners, illegal, betrayal, lgbt, riots, gorgeous, treason, joking, chris, intelligent, arguments, humans}
- **Epoch 3: FP:** {countries, race, hating, females, feminist, africans, ridiculous, d*ck, express, comments, organized, s*ck, allow, bloody} **FN:** {illegal, hitler, generally, david, intelligent, secret, chris, equality, dating, yellow, treason, abuses, ##gb, humans, plague, dear, nonsense}
- **Epoch 4: FP:** {isis, genocide, indians, society, supported, females, feminist, attacks, s*ck, destroy, migrants } **FN:** {hitler, opportunities, sister, betrayal, ##ame, gorgeous, ##heads, dating, riots, bank, murders, arguments, humans, fights, plague, influence, targeting, supporters, coordination, lies, ##boys}
- **Epoch 5: FP:** {clean, ignorant, slave, feminist, punish, africans, ##ache, d*ck, ##fs, ars, destroy, status, race, p*ssy, western, send} **FN:** {statement, gross, hitler, sending, yellow, waste, hopefully, trapped, riots, bait, sister, coordination, humans}
- **Epoch 6: FP:** {soft, suicide, countries, p*ssy, bloody, genocide, punish, destroy, migrants, vile, beings, savage, feminist, tory, awful, ignorant, ##ists, spend, send} **FN:** {gross, secret, influence, yellow, crime, abuses, participate, approach}

A non-hate comment in *Dynamic* test set for the above case, wrongly classified as hate by Van-FT and correctly classified as non-hate with D-Ref-Reg (IG), is given below. Darker the shade, higher is the attribution:

Van-FT: There is so much cancer patients in the world but it is mostly the young females who are worstly affected by this disease.

D-Ref-Reg: There is so much cancer patients in the world but it is mostly the young females who are worstly affected by this disease.

Waseem →Dynamic

- **Epoch 1: FP:** {female, ##ists, fe, sex, feminist, rap} **FN:** {cast, coward, queer, equality, ##bi , cost, ##sy, born, asian, nazis, kids, cancer, gender, hiring, funded}
- **Epoch 2: FP:** {##ists, her, sex, worse, feminist, ##nt, outraged} **FN:** {welcome, caused, cancer. drag, ##bi, pressure, parent, nazis, troll, cast, trash, ruins, lesbian, attacking, chinese}

Table 5: Validation set (D_T^{val}) macro F1 (±std-dev) on source →target pairs (H : HatEval, D : Dynamic, W : Waseem).

Approaches	HatEval		Dynamic		Waseem		Average
BERT Van-FT	43.3±1.8		85.1±0.5		85.4±0.7		71.3
In-corpus performance on source (left of arrows) while refining the source model for the target (right of arrows)							
	H →D	H →W	D →H	D →W	W →H	W →D	
D-Ref-Reg ($\alpha\nabla\alpha$)	39.7±3.2	38.4±1.7	84.1±1.0	84.2±0.8	84.4±0.7	78.8±8.0	68.3
D-Ref-Reg (IG)	40.5±2.0	37.7±2.1	84.0±0.4	84.5±0.4	84.6±1.0	85.3±1.4	69.4
D-Ref-Reg (DL)	37.1±1.8	38.1±2.9	84.7±0.6	84.3±1.2	84.4±0.5	80.7±6.4	68.2

Table 6: In-corpus macro F1 (±std-dev), i.e. the source corpus performance, obtained after refining the source model for the target corpus (present at the right hand side of the arrows) using D-Ref-Reg. H : HatEval, D : Dynamic, W : Waseem. For D-Ref-Reg, model-selection and early-stopping is done over the validation set from the target corpus.

- **Epoch 3: FP:** {female, ##ja, might, men, feminist} **FN:** {quoting, govt, referring, nazis, troll, lesbian, rogue, date, chinese, typically}

- **Epoch 4: FP:** {communism, her, openly, intelligent, many, barbie, chicks, females, arguing} **FN:** {date, suggest, ##lat, referring, police, chinese, cancer, voice, native, lesbian}

- **Epoch 5: FP:** {term, f*ck, ##ng, woman, ##ist, feminist, females, prison} **FN:** {removed, educate, freaking, queer, wow, ending, referring, dye, ##wat, issues, africans, vast, chinese, dark}

- **Epoch 6: FP:** {whore, her, ##ots, role, sweden, pay, d*ck, trump, feminist, females, american, arguing} **FN:** {bat, everyday, freak, argument, movement, chinese, tho, feature, lesbian}

A hate comment in *Dynamic* test set for the above case, wrongly classified as non-hate by Van-FT and correctly classified as hate with D-Ref-Reg (IG), is given below. Darker the shade, higher is the attribution:

Van-FT: Don't get me wrong I don't hate asians, but I definitely don't like them

D-Ref-Reg: Don't get me wrong I don't hate asians, but I definitely don't like them

Since, the *Waseem* dataset is made available as tweet IDs, we observed that it mostly contains sexist comments, while most of the racist content must have been removed before we could crawl it. Hence, the tokens related to race mostly occur in non-hate contexts causing FN.

Even though some error-causing tokens remain in the list until the end, their overall effect should be reduced as the regularization is performed throughout the training procedure, which causes improvement in macro F1.

D In-corpus performance

We present the in-corpus performance, i.e. the performance on the source corpus in terms of macro-F1 scores, obtained when the source model is refined for the corresponding target corpus using D-Ref-Reg, in Table 6. For D-Ref-Reg, the model is tuned over the target corpus validation set. Here

Approaches	**HatEval**	**Dynamic**	**Waseem**
BERT Van-FT	1 m 25 s	3 m 52 s	2 m
D-Ref-Reg ($\alpha\nabla\alpha$)	1 m 39 s	7 m	3 m 33 s
D-Ref-Reg (IG)	9 m 37 s	59 m	19 m 7 s
D-Ref-Reg (DL)	4 m 4 s	18 m 36 s	8 m 44 s

Table 7: Per epoch training time on different source corpora.

BERT Van-FT gives the original performance of the source model, when no refinement is performed, as a reference. In this case, the model is tuned over the in-corpus validation set. The *HatEval* corpus is part of a shared task and involves a challenging test set with low in-corpus performance. The drop across in-corpus performance with D-Ref-Reg is expected, as the main goal of the proposed approach is to make the source model best suited for the target corpus.

E Pre-defined group identifiers

The combined list of pre-defined group identifiers from Liu and Avci (2019) and Kennedy et al. (2020) are given below:

{lesbian, gay, bisexual, trans, cis, queer, lgbt, lgbtq, straight, heterosexual, male, female, nonbinary, african, african american, european, hispanic, latino, latina, latinx, canadian, american, asian, indian, middle eastern, chinese, japanese, christian, buddhist, catholic, protestant, sikh, taoist, old, older, young, younger, teenage, millenial, middle aged, elderly, blind, deaf, paralyzed, muslim, jew, jews, white, islam, blacks, muslims, women, whites, gay, black, democrat, islamic, allah, jewish, lesbian, transgender, race, brown, woman, mexican, religion, homosexual, homosexuality, africans}

F Computational Efficiency

We present the per epoch training time for D-Ref-Reg with different source corpora in Table 7. The training times of D-Ref-Reg ($\alpha\nabla\alpha$) are less than 2 times of that with Van-FT. With D-Ref-Reg (DL), the training time is approximately 4.5 times of that with Van-FT. This demonstrates the computational efficiency of our approach. In the case of D-Ref-Reg (IG), the computation time is indeed high. This occurs due to the aggregation of gradients using a path integral and computing gradients over gradients, as also discussed in Kennedy et al. (2020); Liu and Avci (2019). However, our approach is not dependent on any particular feature attribution method, as demonstrated with our experiments.

Towards Large-Scale Interpretable Knowledge Graph Reasoning for Dialogue Systems

Abstract

Users interacting with voice assistants today need to phrase their requests in a very specific manner to elicit an appropriate response. This limits the user experience, and is partly due to the lack of reasoning capabilities of dialogue platforms and the hand-crafted rules that require extensive labor. One possible way to improve user experience and relieve the manual efforts of designers is to build an end-to-end dialogue system that can do reasoning itself while perceiving user's utterances. In this work, we propose a novel method to incorporate the knowledge reasoning capability into dialogue systems in a more scalable and generalizable manner. Our proposed method allows a single transformer model to directly walk on a large-scale knowledge graph to generate responses. To the best of our knowledge, this is the first work to have transformer models generate responses by reasoning over differentiable knowledge graphs. We investigate the reasoning abilities of the proposed method on both task-oriented and domain-specific chit-chat dialogues. Empirical results show that this method can effectively and efficiently incorporate a knowledge graph into a dialogue system with fully-interpretable reasoning paths.

1 Introduction

Nowadays, dialogue systems are ubiquitous in customer service and voice-based assistants. One of the main uses of this technology is supporting humans in accomplishing tasks that might require accessing and navigating large knowledge bases (e.g., movies search). A dialogue system architecture is typically composed of a natural language understanding (NLU) module, a dialogue management (DM) module, and a natural language generation (NLG) module (Jurafsky and Martin, 2009; Williams et al., 2016). First, the NLU component extracts a meaning representation from the user utterance based on which the DM generates the next system action by reasoning over the meaning representation and communicating with external applications if necessary. For example, the DM may retrieve information from external knowledge graphs (KG) to answer the user's query based on the dialogue history. This process requires the DM to convert the output of NLU to a query to be issued to the backend. Given the difficulty of this step, which is often domain-dependent, the DM component might require the design of hand-crafted rules. However, such rules are usually not scalable to different applications. They could require considerable effort to cover all possible cases/dialogue flows, leading to expensive costs to design new applications. Moreover, in several cases, users interacting with such assistants are forced to formulate specific queries in order to accomplish their objective, which might break user engagement.

To alleviate the problem of having to design expensive hand-crafted rules and breaking user experience, recent works have explored the possibility of building end-to-end dialogue systems (Wen et al., 2017) and all-in-one response generation models (Serban et al., 2016). Among them, since graph is one of the main structure to store knowledge, recent research (Ghazvininejad et al., 2018; Zhou et al., 2018; Moon et al., 2019; Tuan et al., 2019; Yang et al., 2020) has proposed methods to generate natural language responses according to both the dialogue history and external knowledge graph. Despite these innovative and inspiring methods, there are some shortcomings. For instance, these methods are either not fully-interpretable or limited to small-scale knowledge graphs.

In this paper, we propose a novel dialogue differentiable knowledge graph model (DiffKG). The DiffKG is a single transformer model that directly (1) generates a sequence of relations to perform multi-hop reasoning on a reified KG representation proposed by (Cohen et al., 2019), and then (2) generates responses using the retrieved entities. To the best of our knowledge, this is the first dialogue

Findings of the Association for Computational Linguistics: ACL 2022, pages 383 - 395
May 22-27, 2022

model that can directly walk on a large-scale KG with flexibility and interpretability. DiffKG allows having flexible entity values in the KG and handling novel entity values with an arbitrarily defined number of tokens. The reasoning path of DiffKG consists of the predicted relations, thus allowing for transparency.

We run extensive experiments to test DiffKG performance on KG-grounded dialogues. We select Stanford Multi-domain Dialogues (SMD) (Eric et al., 2017) and propose a new dataset, SMD-Reasoning, to simulate scenarios requiring multiple reasoning types and select the OpenDialKG (Moon et al., 2019) to simulate scenarios requiring large-scale KG reasoning without preprocessing. We then compare DiffKG with state-of-the-art models on SMD and OpenDialKG and an additional baseline that flattens KGs into a textual form from which transformers can learn. Empirically, our experiments show that DiffKG can effectively be trained on large-scale KGs and demonstrate its robustness with modified triplets in a KG. From the perspective of computation, DiffKG leads to relatively low extra time and memory usage compared to transformer models not using any KG information.

In summary, our contributions are: 1) We propose DiffKG, a novel method that can effectively and flexibly incorporate large-scale KG; 2) We demonstrate that DiffKG is a model-agnostic method and can be applied to different model architectures; 3) We show that DiffKG is an interpretable method with low add-on latency at inference time. Our code and processed datasets are released in `https://github.com/Pascalson/DiffKG-Dialog`.

2 Related Work

Recent years have seen a surge of new methods proposing end-to-end models that try to both understand natural language input text and search information. Two of the widely explored tasks are question-answering (QA) and dialogue generation.

QA. Multiple QA methods (Weston et al., 2015; Yin et al., 2016; Hao et al., 2017; Rajpurkar et al., 2018; Verga et al., 2020; Eisenschlos et al., 2021) have been proposed to tackle tasks that go beyond what is explicitly stated in the linguistic context (Storks et al., 2019). For example, the benchmarks (Mihaylov et al., 2018; Reddy et al., 2019; Khot et al., 2020; Lin et al., 2021) are particularly useful for the model to extract information from external knowledge bases to answer questions. Nonetheless, these studies mostly take the retrieved information from KG as the answer to a single question, while in dialogue we have to formulate an informative response to multi-turn dialogue history.

Dialogue Generation. Recent works have investigated the grounded dialogue generation. These methods can be divided into three main categories. First, Dinan et al. (2018); Zhao et al. (2019); Tuan et al. (2020); Kim et al. (2020) extract useful knowledge from unstructured data to generate responses, such as information contained in passages and speaker's profiles. Second, Sordoni et al. (2015); Long et al. (2017); Zhu et al. (2017); Ghazvininejad et al. (2018); Zhou et al. (2018); Veličković et al. (2018); Joshi et al. (2020); Hosseini-Asl et al. (2020); Wang et al. (2021) utilize information from knowledge bases (either graphs or tables) to enhance the dialogue system. They usually train the entities and relations embeddings of the knowledge bases and incorporate these embeddings into the input representation to predict the response. Third, Moon et al. (2019); Tuan et al. (2019); Jung et al. (2020) formulate the reasoning process more explicitly, as a path traversal over knowledge graphs. These methods further improve the transparency and explainability of the conversational agent and share the most similar idea with us. However, they either only predict the reasoning path without generating responses or need subgraph sampling to reduce the scale of KG. In this work, our approach uses a transformer model to jointly predict explicit reasoning paths over a large-scale knowledge graph and generate dialogue responses based on the reasoning results.

3 Background

3.1 Knowledge Graph for Dialogue System

We assume that the knowledge of the system can be represented by a knowledge graph (KG) $\mathcal{G} = \{\mathcal{E}, \mathcal{R}\}$, where $\mathcal{E}$ denotes the entities and $\mathcal{R}$ denotes the relations. The knowledge graph $\mathcal{G}$ contains multiple triples describing the connections among entities and relations. We denote the k-th triple of this graph as (e_k^h, r_k, e_k^t) , where e_k^h, r_k, e_k^t are respectively the head entity, relation, and tail entity. The total numbers of triples, entities, and relations

Reasoning Type			**Example**	**Related Info. in KG**
Semantic Form		KG reasoning	U: I need unleaded gas. R: inform Valero, 4 miles		Logical Reasoning	True/False	U: Is it going to snow this week at Corona? R: Yes			Selection	U: give me the direction to the nearest shopping mall. R: inform Stanford Shopping Center, 3 miles			Extraction	U: What gas stations are here? R: include poi_type gas station	No gas station in the available KG
NL Form		KG reasoning	U: Have you listen to any of the singer Kesha's song? R: I do enjoy in her music, especially "Your Love Is My Drug"	
Table 1: Example of different reasoning types and output formats (semantic and natural language forms) in a dialogue system with the related information in the accessible KGs.

are denoted as $N_{\mathcal{T}}$, $N_{\mathcal{E}}$, $N_{\mathcal{R}}$, respectively.[1]

3.2 Response Generation in Dialogue System

If we define the dialogue history as a sequence of tokens that occurred during the user and system interactions, then a flattened dialogue history can be written as:

$$\mathbf{x} = (x_1, x_2, ..., x_m, ..., x_M) \tag{1}$$

where x_m is the m-th token in the dialogue history with M tokens. In an end-to-end dialogue system, we assume a dialogue system parameterized by θ exists that can predict a probability distribution of responses $P_\theta(\cdot|\mathbf{x}, \mathcal{G})$. The generated responses are sampled from this probability distribution.

4 Problem Statement

We focus on understanding the ability of language models in performing reasoning during a conversation. We consider two tasks that are usually required in dialogue scenarios and call them semantic form and natural language (NL) form in Table 1. First, given a dialogue history and a user's query, the task of semantic form is to predict the next system action, corresponding to the output of the DM module, based on the available knowledge. In this case, we assume the expected output is the essential knowledge for an NLG module. We argue that this task could help better evaluate if the response is correct or not and which type of reasoning can be more successfully handled. Second, given a dialogue history and a user's query, the task of the NL form could be to directly output the response given by the system. This setting with annotated reasoning path can shed light on understanding if the model can learn to support chit-chat and reasoning at the same time.

Moreover, we aim to understand models' reasoning capability both in the form of logical reasoning and over the provided knowledge. As illustrated in Table 1, by KG reasoning, we refer to the ability of the model to retrieve information from an arbitrary scaled KG in multiple hops. Meanwhile, we refer to logical reasoning as the ability of the model to conduct operations such as evaluating whether a statement is true or false, selecting min/max from a list of alternatives, and extracting constraints.

We formulate the task that we focus on as follows: given the dialogue history $\mathbf{x}$ and currently accessible KG $\mathcal{G}$, can we extend a transformer model to predict a correct response y in either semantic or NL form? As illustrated in Table 1, this task not only requires the model to accurately retrieve information from the KG, but also needs to do further logical operations on the information. To solve this task, a model should also be able to effectively integrate the dialogue history $\mathbf{x}$ with the KG $\mathcal{G}$.

5 Proposed Approach

Figure 1 illustrates our proposed architecture which contains four main parts: a dialogue history encoder, a differentiable KG reasoning module, a learnable logical operations module, and a response decoder (the transformer model). Note that we experiment with two types of transformers: a causal language model GPT2 (Radford et al., 2019) and an encoder-decoder model T5 (Raffel et al., 2020). For GPT2, we reuse the same encoder that is used at the beginning of the process, i.e., f_{enc} in Figure 1, as the final transformer that generates the response

---

[1] An example of the triples in $\mathcal{G}$ is a triple e_k^h = gas station, r_k = IsTypeOf, and e_k^t = Chevron. That is, "gas station is the type of Chevron" to this system.

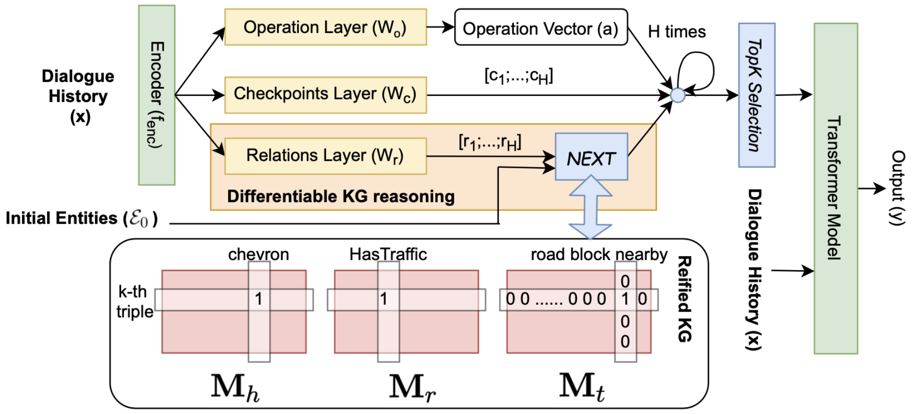

Figure 1: The illustration of proposed DiffKG, which leverages a pretrained transformer model (T5 or GPT2) and the Reified KG. The model generates the response depending on the predicted relation sequence $[r_1; ...; r_H]$, thus being fully interpretable in terms of the used reasoning path.

token by token. For T5, we reuse the same encoder as the encoder of the final transformer with a separate decoder that generates the response. Therefore, this method contains a single transformer model. In following sections we present each module in detail.

5.1 Dialogue History Encoder

We use encoder model to project $\mathbf{x}$ and obtain the dialogue history embedding through $\tilde{\mathbf{x}} = f_{enc}(\mathbf{x}) \in \mathbb{R}^d$, where d is the hidden size of the encoder. The embedding $\tilde{\mathbf{x}}$ is first fed into an operation layer with parameters $\mathbf{W}_o \in \mathbb{R}^{d \times d}$. The operation layer predicts the operation vector $\mathbf{a} = \mathbf{W}_o^T \tilde{\mathbf{x}} \in \mathbb{R}^d$. At the same time, the embedding $\tilde{\mathbf{x}}$ is also fed into a relation layer with parameters $\mathbf{W}_r \in \mathbb{R}^{d \times N_{\mathcal{R}} H}$. The relation layer predicts the concatenation of a sequence of relations $\mathbf{r} = \{\mathbf{r}_h | 1 \leq h \leq H\}$, where $\mathbf{r}_h \in \mathbb{R}^{N_{\mathcal{R}}}$ is the relation to be used at the h-th hop in the programmed walking block and H is the maximum number of hops. The embedding $\tilde{\mathbf{x}}$ is also fed into a checkpoints layer with parameters $\mathbf{W}_c \in \mathbb{R}^{d \times 2H}$. This layer produces the concatenation of a sequence of walk-or-check vectors $\mathbf{c} = \{c_h | 1 \leq h \leq H\}$, where $c_h \in \mathbb{R}^2$ is the walk-or-check vector at the h-th hop to determine the weights of the programmed walking module and the operation vector.

$$\begin{aligned} \tilde{\mathbf{x}} &= f_{enc}(\mathbf{x}) \,, \\ \mathbf{a} &= \mathbf{W}_o^T \tilde{\mathbf{x}} \,, \\ \mathbf{r} &= \mathbf{W}_r^T \tilde{\mathbf{x}} \,, \\ \mathbf{c} &= \mathtt{softmax}(\mathbf{W}_c^T \tilde{\mathbf{x}}) \,. \end{aligned} \tag{2}$$

5.2 Differential Knowledge Graph Reasoning

To ensure that our model can scale to larger KGs, we adopt the reified KG representation proposed by (Cohen et al., 2019). The reified KG represents the graph $\mathcal{G}$ using three sparse matrices: head matrix $\mathbf{M}_h \in \mathbb{R}^{N_{\mathcal{T}} \times N_{\mathcal{E}}}$, relation matrix $\mathbf{M}_r \in \mathbb{R}^{N_{\mathcal{T}} \times N_{\mathcal{R}}}$, and tail matrix $\mathbf{M}_t \in \mathbb{R}^{N_{\mathcal{T}} \times N_{\mathcal{E}}}$. An entry (i, e) in $\mathbf{M}_h$ or $\mathbf{M}_t$ with value 1 indicates that the i-th triple in the KG has entity e as the head or the tail; an entry (i, r) in $\mathbf{M}_r$ with value 1 indicates that the i-th triple in the knowledge graph has the relation r. Since often in practical settings most entries in the three matrices are zero, saving them into sparse matrices can significantly reduce memory consumption (Cohen et al., 2019).

After predicting the relation sequence $\mathbf{r}$, we start the graph traversal from a given set of initial entities $\mathcal{E}_0 \subseteq \mathcal{E}$. We first map the initial entities into a vector $\mathbf{e}_1 = [\mathbb{1}(e \in \mathcal{E}_0), \forall e \in \mathcal{E}]$. That is, each entry of $\mathbf{e}_1 \in \mathbb{R}^{N_{\mathcal{E}}}$ has value 1 if that entity is in the initial entities list $\mathcal{E}_0$, otherwise, the entry is zero. We then predict the next (temporary) entity vector $\mathbf{e}_2$ by conducting a `Next` module:

$$\mathbf{e}_{h+1}^r = \mathtt{Next}(\mathbf{e}_h, \mathbf{r}_h) \,, \tag{3}$$

where

$$\mathtt{Next}(\mathbf{e}_h, \mathbf{r}_h) = \frac{\mathbf{M}_t^T(\mathbf{M}_h \mathbf{e}_h \odot \mathbf{M}_r \mathbf{r}_h)}{||\mathbf{M}_t^T(\mathbf{M}_h \mathbf{e}_h \odot \mathbf{M}_r \mathbf{r}_h)||_2 + \epsilon} \,, \tag{4}$$

Here ϵ is an arbitrary small number to offset the denominator and prevent division by zero. We introduce the normalized `Next` to solve the issue with the method proposed by (Cohen et al.,

2019) for knowledge graph completion defined as $\texttt{Follow}(\mathbf{e}_h, \mathbf{r}_h) = \mathbf{M}_t^T(\mathbf{M}_h\mathbf{e}_h \odot \mathbf{M}_r\mathbf{r}_h)$; since in a dialogue model, we can seldom predict the relation vectors that perfectly match the entity vectors. That is, if directly using the `Follow` module in (Cohen et al., 2019), the $||\mathbf{e}_h||_2$ will not be one and will vanish as the hop number h increases. Specifically, note that in our proposed module, the predicted relations $\mathbf{r}_h$ are independent of the traversed entities $\mathbf{e}_h$. For instance, finding the "distance" of "the nearby gas station" is independent of whether the nearby gas station is "Chevron" or "Shell".

To allow the model to dynamically select the number of reasoning hops, we add a relation type "ToSelf" into $\mathcal{R}$ and connect each entity to itself by "ToSelf". More specifically, the KG will contain triples (e_k^h, r_k, e_k^t) for all $e_k^h = e_k^t \in \mathcal{E}$ and $r_k =$ `ToSelf`.

5.3 Entity Embeddings

At each hop, we further conduct the operation vectors $\mathbf{a}$ on the entities weighted by the entity vector $\mathbf{e}_h$. First, we tokenize each entity and represent it by the concatenation of its token embeddings. This step allows (1) representing entities with longer texts such as phrases and sentences, and (2) eliminating the effort to retrain entity embeddings whenever new entity values are added. The entity embeddings can then be represented as a tensor $\mathbf{E} \in \mathbb{R}^{N_{\mathcal{E}} \times d \times m}$, where m is the maximum number of tokens of entities[2].

5.4 Learnable Logical Operation and Checkpoints

We compute the transformed entity embeddings by element-wise multiplication of the entity embeddings $\mathbf{E}$ with the entity vector $\mathbf{e}_h$ at the h-th hop. Next, the dot product of the operation vectors and the transformed entity embeddings is passed to a softmax layer as the entity vector at the next hop:

$$\mathbf{e}_{h+1}^a = \texttt{softmax}\left(\mathbf{a}(\mathbf{E} \odot \mathbf{e}_h)\right) , \qquad (5)$$

Further, at the h-th hop we use the walk-or-check vector $\mathbf{c}_h$ to combine the `Next` and operation modules above. The combined entity vector is given by:

$$\begin{aligned} \mathbf{e}_{h+1} &= \mathbf{c}_h^T \begin{bmatrix} \mathbf{e}_{h+1}^r \\ \mathbf{e}_{h+1}^a \end{bmatrix} \\ &= \mathbf{c}_h^T \begin{bmatrix} \texttt{Next}(\mathbf{e}_h, \mathbf{r}_h) \\ \texttt{softmax}\left(\mathbf{a}(\mathbf{E} \odot \mathbf{e}_h)\right) \end{bmatrix} , \end{aligned} \qquad (6)$$

5.5 Response Decoder

After H hops reasoning is done, the entities with top-k values in the entity vector $\mathbf{e}_H$ are selected, indicating that they have the highest probability to be retrieved from the graph. These entities are converted into their embeddings in E and multiplied by their values in $\mathbf{e}_H$. These entity embeddings are then concatenated with the dialogue history $\mathbf{x}$. The concatenated vectors are fed as the input into the transformer model to predict the response token by token. The predicted probability distribution over the output space can be written as $P(\cdot|\mathbf{x}, \mathbf{M}_h, \mathbf{M}_r, \mathbf{M}_t)$. Since all components are differentiable, all modules can be trained end-to-end with the dialogue history $\mathbf{x}$ and the reified KG representation $\{\mathbf{M}_h, \mathbf{M}_r, \mathbf{M}_t\}$ using the cross-entropy loss with the ground-truth output y as the labels.

$$L = \sum_{(\mathbf{x},y)} -\log P(y|\mathbf{x}, \mathbf{M}_h, \mathbf{M}_r, \mathbf{M}_t) \,. \qquad (7)$$

During the inference time, the reasoning modules (relation layer, operation layer, and checkpoints layer) work exactly the same as the training stage, the only difference is that the response decoder is fed with predicted tokens in previous time steps (inference stage) instead of the ground-truth output (training stage).

6 Experiments

6.1 Datasets

We evaluate our proposed approach on three datasets. Among them, we use Stanford Multi-domain Dialogues (SMD) (Eric et al., 2017) and OpenDialKG (Moon et al., 2019) to test the methods generalizability on different dialogue types (task-oriented / chit-chat) and scales of structured knowledge (pairwise database / universal KG). To further analyze the reasoning ability, we propose a new dataset, SMD-Reasoning, by modifying the output of SMD dataset from natural language responses to actions paired with their reasoning types.

---

[2] In our experiments, we compute the maximum length of all entities and pad shorter entities to the length of m.

Stanford Multi-domain Dialogues (SMD) The SMD dataset (Eric et al., 2017) is composed of two-speaker conversations, where a driver talks with the car assistant to tackle tasks in three domains: scheduling, navigation, and weather forecasting. Each dialogue focuses on one domain and is paired with a database having the related information. We convert the original database into two formats: (1) the natural language descriptions (NLD) and (2) the KG. The NLD form allows us to investigate the ability of the model to interpret unstructured knowledge, while the KG form could be a more extensible structured knowledge compared to tables.

OpenDialKG OpenDialKG dataset (Moon et al., 2019) is composed of two-speakers recommendation and chit-chat style conversations. Each turn in a dialogue is annotated with the reasoning path on the provided KG, which is filtered from Freebase (Bollacker et al., 2008). The resulting KG has 1,190,658 triples, 100,813 entities and 1,358 relations. We randomly split 70/15/15% for train/valid/test sets as described in (Moon et al., 2019; Jung et al., 2020) since they do not release their splits.

SMD-Reasoning To make SMD dataset suitable for more precise evaluation of reasoning abilities, we manually label and convert it to the SMD-Reasoning dataset. We first remove the natural language part from the original responses and only leave the action word (e.g., inform) along with the information being conveyed. We divide the dataset into three main reasoning types: informing items, selecting min/max, and evaluating true/false. To validate if the models can identify whether the needed knowledge is in the database, we add a new reasoning type for extracting constraints, by removing the needed knowledge from the database and changing the output to "include [knowledge description]" as shown in Table 1. See Appendix A,B for statistics of these datasets.

6.2 Evaluation Metrics

We use different evaluation methods for the three datasets. For SMD, we follow prior work (Yang et al., 2020) and use BLEU (Papineni et al., 2002), and Entity F1 scores on each domain. For OpenDialKG, we follow the descriptions in prior works (Moon et al., 2019; Jung et al., 2020) to evaluate the path@k scores, i.e., if the ground-truth path is ranked top-k in the predicted paths probabilities. Moreover, since our method not only can predict the reasoning path as prior works but also can predict the response, we also use the BLEU score to get the approximated evaluation of the response quality compared to ground-truth. Note that prior work has discussed that BLEU scores may not match human intuition (Liu et al., 2016), but we use them here as an approximated evaluation for reference.

For SMD-Reasoning, the output is more deterministic and does not include diverse sentence structures. Therefore, we compute the F1 score and the *exact match (EM)* score of prediction and the ground-truth. The EM score is calculated by removing the order of the prediction since the labels of SMD-Reasoning dataset follow the order of knowledge description appearing in the original ground-truth responses and may not have the same order as generated outputs. The EM score can be written as:

$$\mathtt{EM} = \frac{1}{T} \sum \mathbb{1}(\mathtt{sort}(\hat{y}) = \mathtt{sort}(y)) . \qquad (8)$$

where $\hat{y}$ is inferred from the model using argmax sampling and T is total number of examples.

6.3 Implementation Details

Since the proposed method is model-agnostic, we implement it on GPT2 (Radford et al., 2019) and T5 (Raffel et al., 2020). Specifically for the T5 model, we use the unifiedQA-T5 model (Khashabi et al., 2020) which is pretrained on question answering tasks that also need to do reasoning. However, we empirically find that T5 generally has better performance than GPT2, thus using T5 model in most experiments. For OpenDialKG, since the ground-truth relations exist, we take them as an additional supervision signal as (Moon et al., 2019). Also, since we observe that there is only KG reasoning type in OpenDialKG, we do not use operation layer and checkpoints layer for the dataset. The hyperparameter settings are in Appendix C.

6.4 Baselines

We compare our proposed DiffKG model with the state-of-the-art models on OpenDialKG reported in (Moon et al., 2019; Jung et al., 2020) and the state-of-the-art graph-based model on SMD (Yang et al., 2020; Gou et al., 2021) with their reported baselines including sequence-to-sequence models with and without attention (S2S and S2S+Attn) (Luong et al., 2015), pointer to unknown (Ptr-Unk) (Gulcehre et al., 2016),

Model	BLEU	Entity F1			
		All	Sche.	Wea.	Nav.
S2S	8.4	10.3	9.7	14.1	7.0
S2S+Attn	9.3	19.9	23.4	25.6	10.8
Ptr-Unk	8.3	22.7	26.9	26.7	14.9
GraphLSTM	10.3	50.8	69.9	46.6	43.2
BERT	9.13	49.6	57.4	47.5	46.8
Mem2Seq	12.6	33.4	49.3	32.8	20.0
GLMP	12.2	55.1	67.3	54.1	48.4
GraphDialog	13.7	57.4	71.9	59.7	48.6
COMET-graph	14.4	56.7	71.6	48.7	50.4
T5-DiffKG	16.04	56.2	67.2	61.5	46.7

Table 2: The results on SMD dataset. S2S, S2S+Attn, Ptr-Unk, GraphLSTM, BERT, Mem2Seq, GLMP, GraphDialog are reported from (Yang et al., 2020) and COMET-graph from (Gou et al., 2021). Our DiffKG achieves the highest BLEU and comparable F1 scores with baselines.

Model	path@1	path@5	path@10	BLEU
Seq2Seq	3.1	29.7	44.1	-
Tri-LSTM	3.2	22.6	36.3	-
EXT-ED	1.9	9.0	13.3	-
DialKG	13.2	35.3	47.9	-
Seq2Path	14.92	31.1	38.68	-
AttnFlow	17.37	30.68	39.48	-
AttnIO-AS	23.72	43.57	52.17	-
T5-NoInfo	-	-	-	14.51
T5-DiffKG	26.80	54.33	61.75	15.37

Table 3: The results on OpenDialKG dataset. The four baselines from Seq2Seq to DialKG Walker are reported from (Moon et al., 2019) and the other three baselines from Seq2Path to AttnIO-AS are reported from (Jung et al., 2020). Our DiffKG achieves the highest path@k scores and is the only one that can simultaneously generate responses.

GraphLSTM (Peng et al., 2017), BERT (Devlin et al., 2019), Mem2Seq (Madotto et al., 2018) and GLMP (Wu et al., 2019). We follow their metrics and train our model on their preprocessed data for fair comparisons. To further analyze the reasoning ability, we propose two more baselines based on different ways of leveraging pretrained language models. (1) **NoInfo** model does not take any format of knowledge as the input, aiming to test the performance of a fine-tuned vanilla transformer model on each dataset. (2) **FlatInfo** model constructs the input by concatenating the dialogue history with the NLD form of knowledge as (Beygi et al., 2022), allowing us to investigate the ability of the model to interpret unstructured knowledge.

Test KG	**Method**	**EM**	**F1**
Fixed	GPT2-NoInfo	10.71	43.78
	GPT2-FlatInfo	14.08	47.57
	GPT2-DiffKG	16.39	51.06
	T5-NoInfo	10.50	44.27
	T5-FlatInfo	28.99	66.15
	T5-DiffKG	27.52	63.93
Shuffled	T5-FlatInfo	17.02	54.51
	T5-DiffKG	27.52	64.00

Table 4: The results on SMD-Reasoning dataset.

6.5 Results

The results on SMD and OpenDialKG are shown in Table 2 and Table 3. On SMD dataset, we observe that DiffKG outperforms the baselines on BLEU by 11.4% (relative change of 16.04 and 14.4) and achieves comparable entity F1 scores with GLMP, GraphDialog and COMET-graph. DiffKG might not improve the entity F1 scores because that prior works group the text inside an entity together (e.g., “road block nearby” becomes a single word “road_block_nearby” in vocabularies). In contrast, we use a universal tokenizer so as to prevent heavy preprocessing and specialized vocabularies. This means that DiffKG can perform similarly with state-of-the-art to retrieve knowledge without a tokenizer specified for each dataset. On OpenDialKG dataset, we observe that DiffKG outperforms the baselines in terms of path@k scores and can simultaneously outperform T5 in terms of Entity F1 and BLEU. These demonstrate that DiffKG can retrieve accurate paths for reasoning and effectively incorporate reasoning into response generation.

We also investigate the results of SMD-Reasoning dataset as shown in Table 4. We find that DiffKG improves NoInfo by 16.6% and 44.4% F1 scores respectively on GPT2 and T5 models. This demonstrates that DiffKG can utilize knowledge effectively to improve the generation without access to information. In contrast, although FlatInfo gives similar performances as DiffKG on the SMD-Reasoning dataset, it cannot be run on OpenDialKG due to computational costs. More specifically, FlatInfo requires the knowledge graph to be transformed into sentences, which will result in at least a million tokens as the model inputs for OpenDialKG (since the number of triples is a million without designed subgraph sampling), which is not a practical number.

Table 5: Detailed Evaluation Results of SMD-Reasoning dataset

SMD-Reasoning	User: check the date and time of my doctor's appointment (Reasoning Path: Doctor Appointment $\xrightarrow{\text{HasDate, HasTime, ToSelf}}$ Tuesday, 11am, doctor appointment) DiffKG: inform 11 am tuesday doctor appointment
	User: Car I need to get to a gas station, please show me the nearest one Assistant: There is Valero 7 miles away with moderate traffic on our way User: Alright, where is it located? (Reasoning Path: Gas Station $\xrightarrow{\text{IsTypeOf}}$ Valero $\xrightarrow{\text{HasAddress, ToSelf}}$ 200 Alester Ave, Valero) DiffKG: inform 200 Alester Ave Valero
OpenDialKG	Speaker A: Do you have any info on Toni Kroos? (Reasoning Path: Toni Kroos $\xrightarrow{\sim\text{Player Statistics}}$ Germany national football team) DiffKG: Toni Kroos is German footballer who plays for the Germany national football team.

Table 6: Generated examples and the reasoning path.

6.6 Quantitative Analysis

To test the robustness of the methods towards accurately locating information, we shuffle the information order. This evaluation is to simulate the cases that extra information is arbitrarily added when deploying a dialogue system. Specifically, the order of the knowledge context for FlatInfo and the order of knowledge triples are changed during inference time. As shown in the last two rows in Table 4, the performance of FlatInfo drops while DiffKG remains about the same. This indicates that the slight superior performance of FlatInfo with the original order can come from the blackbox tricks to group the nearby knowledge in the inputs. When this implicit trick is broken down, the DiffKG shows much better robustness and performance.

To investigate the difficulty of each domain and reasoning type, we divide the results accordingly in Table 5. As presented in the domains part, the models achieve the highest EM and F1 on the weather domain. We conjecture the reason is that the weather domain includes more reasoning types (weather:4, navigate:3, schedule:2 as in Appendix A Table 9), thus reflecting more balanced reasoning ability. In the reasoning types part, we observe that true/false is less well coped by DiffKG; however, DiffKG improves the extraction. This shows that DiffKG can effectively check the existence of required knowledge and then query the database.

Regarding to the computational costs (on SMD-Reasoning dataset using T5 model), we found that DiffKG requires about 5.85GB memory during training and has 30ms inference latency. This could be an acceptable add-on memory usage and inference time compared to a model without knowledge reasoning (3.13GB; 30ms). Especially when a baseline like FlatInfo consumes much more (18.56GB; 50ms).

6.7 Qualitative Analysis

We visualize the generated examples and the symbolic reasoning path by DiffKG on SMD-Reasoning and OpenDialKG datasets in Table 6. The examples show that DiffKG can capture some naturally occurring phenomena in this dataset: (1) the KG reasoning path can be 1 to multiple hops; (2) the reasoning will diffuse to multiple paths (e.g., DiffKG simultaneously applies "HasDate","HasTime","ToSelf" to "Doctor Appointment"). Along with analyses in previous subsections, we observe that DiffKG can extract interpretable reasoning paths and generate corresponding outputs using reasonable computational costs.

However, even though DiffKG can maintain or improve performance while doing interpretable reasoning on any scaled KG, errors might happen in

Error Type	Example
Unclear Information Requirement	User: What gas stations are here? Ground-truth: inform Chevron DiffKG: inform 5 miles, Chevron (Our comment: Although this prediction is considered wrong for the EM metric, the "5 miles" of DiffKG output is the correct distance from "Chevron" and might be needed in a good response.)
Incomplete Reasoning but Faithful Response	User: Where is the closest grocery store? Ground-truth: Inform 4 miles, Whole Foods, Safeway. DiffKG: inform 4 miles, grocery store, 819 Alma St, Whole Foods (Our comment: The 4 miles, grocery store, 819 Alma St are all correct entities about Whole Foods. Nonetheless, this reasoning process neglects another grocery store Safeway which is also 4 miles away.)
Correct Reasoning but Wrong Response	Speaker A: Do you know Don Hall? Ground-truth: Don Hall wrote the Princess and the Frog a romance story starring Jenifer Lewis. Do you like Romance? Reasoning Path: Don Hall $\xrightarrow{\sim\text{written by}}$ The Princess and the Frog DiffKG: Yes, he wrote The Little Dolls. (Our comment: The reasoning path is correct to find out the script written by Don Hall. However, the generation process fails to properly utilize the retrieved entity.)

Table 7: The error analysis with three major error types across datasets.

some cases. As listed in Table 7, we found that across the datasets, the three main error types of DiffKG are: (1) unclear information requirement in the dataset, (2) incomplete reasoning ability but faithful response generation, and (3) correct reasoning but hallucinated response prediction. We argue that the first error type mainly comes from the mismatch among data points in the dataset and may not be able to be dealt with by models. The second error type indicates that the KG reasoning module sometimes cannot retrieve all the needed information. The third error type indicates that the module producing final output may not fully utilize the retrieved information. These three points might provide a direction for further improvement.

7 Conclusion and Future Work

For a dialogue system, an effective reasoning method over structured databases is important. In this work, we proposed DiffKG, an end-to-end model-agnostic method that does symbolic reasoning on any scale of KGs to enhance response generation. Experiments demonstrated that using DiffKG, models are able to generate responses with interpretable KG reasoning paths at a modest extra cost.

This work can be extended in various ways. While we solely consider efficient large-scale KG reasoning in dialogue generation, future work can incorporate domain fusion methods to consider the generalizability over domains or simultaneously use relation information. Moreover, since DiffKG is a simple large-scale structured knowledge-empowered transformer with flexible entity values, future work can extend it to dialogue generation that needs to do table and text mixed reasoning and that needs to do both KG reasoning and other goals such as personalized dialogues, storytelling, etc.

A Dataset Details

The statistics of datasets are in Table 8 and Table 9. The OpenDialKG dataset is under CC-BY-NC-4.0 license. These datasets can be used for research purposes.

Data	Train	Validation	Test
SMD	2425	302	304
OpenDialKG	10971	2351	2351

Table 8: The number of dialogues in each data split.

	Schedule	Navigation	Weather
Inform	364	1133	236
Selection	-	686	39
True/False	-	-	543
Extraction	173	474	214

Table 9: The statistics of SMD Reasoning dataset with respect to domains and reasoning types. Note that since reasoning types are classified on turn-level, the total number in this table is larger than in Table 8 that counted on dialogue-level.

B SMD KG Construction

We write a simple, automatic program to construct KGs for SMD dataset mapped from the original annotated tables.

For the schedule and navigation domains in SMD, we directly map their table attributes to the relations $\mathcal{R}$ in our constructed KG. For the weather domain, we split each weather report into low temperature, high temperature, and weather. The resulting number of relations is 29, and the relations are listed in Table 10.

In the schedule and navigation domain, each item in the original database with multiple attributes are transformed to KG triples as (event/point-of-interest, attribute, attribute value), e.g., `(tennis activity, HasTime, 7pm)` in schedule domain or `(Chevron, HasType, gas station)` in navigation domain.

In the weather domain, we add additional entities named "ReportID$digits$", where $digits$ will be replaced with an ID number. Each item in the original database is in the format: (item, location, $location), (item, $date, $weather_report), where the $weather_report contains multiple information not simultaneously needed. To make the KG of weather consistent with the KGs of schedule and navigation, we transform each item into (ReportID, location, $location), (ReportID, HasDate, $date), (ReportID, HasWeather, $weather), (ReportID, HasLowTemp, $low_temparature), (ReportID, HasHighTemp, $high_temparature).

Domain	Relations
Schedule	HasTime, HasDate, HasParty, HasRoom, HasAgenda, IsTimeOf, IsDateOf, IsPartyOf, IsRoomOf, IsAgendaOf
Navigation	HasAddress, HasType, HasTraffic, HasDistance, IsAddressOf, IsTypeOf, IsTrafficOf, IsDistanceFrom
Weather	IsEqualTo, HasLocation, HasWeather, HasLowTemp, HasHighTemp, HasDate, IsWeatherOf, IsLowTempOf, IsHighTempOf, IsLocationOf, IsDateOf

Table 10: The relations used in each domain in SMD dataset.

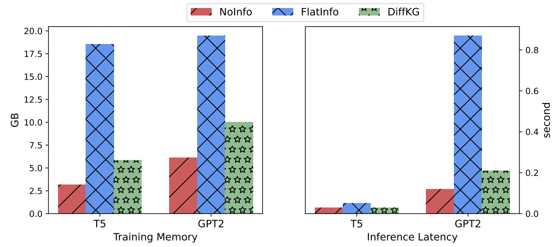

Figure 2: The comparison of the consumed training memory and inference latency.

C Experiment Details

The hyperparameters we set for DiffKG are d=the hidden size of the used pretrained trasnformer (T5-small: d=512; GPT2:d=768), H=5, max norm=1.0, batch size=16, and gradient accumulation steps=2 for at most 50 epochs and train the model learning rate$\in$ $\{5 \times 10^{-5}, 6.25 \times 10^{-5}\}$ (found that 6.25×10^{-5} is better) without learning rate decay. Our experiments were single runs with random initialization and were not further fine-tuned.

D Computational Cost Analysis

As plotted in Figure 2, on SMD-Reasoning dataset, the consumed memory of FlatInfo is thrice the memory needed for DiffKG at training time, and its latency is about twice at inference time. The difference in inference latency is even larger with GPT2 as the backbone model. The reason is that the computational cost of a causal language model such as GPT2 largely depends on the input sequence length, which is one of the main issues of FlatInfo.

MDERank: A Masked Document Embedding Rank Approach for Unsupervised Keyphrase Extraction

Abstract

Keyphrase extraction (KPE) automatically extracts phrases in a document that provide a concise summary of the core content, which benefits downstream information retrieval and NLP tasks. Previous state-of-the-art (SOTA) methods select candidate keyphrases based on the similarity between learned representations of the candidates and the document. They suffer performance degradation on long documents due to discrepancy between sequence lengths which causes mismatch between representations of keyphrase candidates and the document. In this work, we propose a novel unsupervised embedding-based KPE approach, Masked Document Embedding Rank (MDERank), to address this problem by leveraging a mask strategy and ranking candidates by the similarity between embeddings of the source document and the masked document. We further develop a KPE-oriented BERT (KPEBERT) model by proposing a novel self-supervised contrastive learning method, which is more compatible to MDERank than vanilla BERT. Comprehensive evaluations on six KPE benchmarks demonstrate that the proposed MDERank outperforms state-of-the-art unsupervised KPE approach by average 1.80 $F1@15$ improvement. MDERank further benefits from KPEBERT and overall achieves average 3.53 $F1@15$ improvement over the SOTA SIFRank. Our code is available at `https://github.com/LinhanZ/mderank`.

1 Introduction

Keyphrase extraction (KPE) automatically extracts a set of phrases in a document that provide a concise summary of the core content. KPE is highly beneficial for readers to quickly grasp the key information of a document and for numerous downstream tasks such as information retrieval and summarization. Previous KPE works include supervised and unsupervised approaches. Supervised approaches model KPE as sequence tagging (Sahrawat et al., 2019; Alzaidy et al., 2019; Martinc et al., 2020; Santosh et al., 2020; Nikzad-Khasmakhi et al., 2021) or sequence generation tasks (Liu et al., 2020; Kulkarni et al., 2021) and require large-scale annotated data to perform well. Since KPE annotations are expensive and large-scale KPE annotated data is scarce, unsupervised KPE approaches, such as TextRank (Mihalcea and Tarau, 2004), YAKE (Campos et al., 2018), EmbedRank (Bennani-Smires et al., 2018), are the mainstay in industry deployment.

Among unsupervised KPE approaches, embedding-based approaches including EmbedRank (Bennani-Smires et al., 2018) and SIFRank (Sun et al., 2020) yield the state-of-the-art (SOTA) performance. After selecting keyphrase (KP) candidates from a document using rule-based methods, embedding-based KPE approaches rank the candidates in a descending order based on a scoring function, which computes the similarity between embeddings of candidates and the source document. Then the top-K candidates are chosen as the final KPs. We refer to these approaches as *Phrase-Document-based* (PD) methods. PD methods have two major drawbacks:

(i) As a document is typically significantly longer than candidate KPs and usually contains multiple KPs, it is challenging for PD methods to reliably measure their similarities in the latent semantic space. Hence, PD methods are naturally biased towards longer candidate KPs, as shown by the example in Table 1.

(ii) The embedding of candidate KPs in the PD

---

[*] Work is done during the internship at Speech Lab, Alibaba Group.

Findings of the Association for Computational Linguistics: ACL 2022, pages 396 - 409
May 22-27, 2022

methods is computed without the contextual information, hence further limiting the effectiveness of the subsequent similarity match.

In this paper, we propose a novel unsupervised embedding-based KPE method, denoted by Masked Document Embedding Rank (**MDERank**), to address above-mentioned drawbacks of PD methods. The architecture of MDERank is shown in Figure 1. The basic idea of MDERank is that a keyphrase plays an important role in the semantics of a document, and its absence from the document should cause a significant change in the semantics of the document. Therefore, we propose to compare the embeddings of the original document and its variant where the occurrence(s) of some candidate KPs are masked. This leads to a new ranking principle based on the *increasing* order of the resulting similarities, i.e., a *lower* semantic similarity between the original document and its masked variant indicates a higher significance of the candidate.

Our proposed method can be deemed as *Document-Document* method and it addresses the two weaknesses of the *Phrase-Document* methods: (i) Since the sequence lengths of the original document and the masked document are the same, comparing their similarities in the semantic space is more meaningful and reliable. (ii) The embedding of the masked document is computed from sufficient amount of context information and hence can capture the semantics reliably using the SOTA contextualized representation models such as BERT. Inspired by (Lewis et al., 2020; Zhang et al., 2020; Han et al., 2021), where pre-trained language models (PLMs) trained on objectives close to final downstream tasks achieve enhanced representations and improve fine-tune performance, we further propose a novel self-supervised contrastive learning method on top of BERT-based models (dubbed as **KPEBERT**).

The main contributions of this work include:

- We propose a novel embedding-based unsupervised KPE approach (MDERank) that improves the reliability of computing KP candidate embeddings from contextualized representation models and improves robustness to different lengths of KPs and documents.
- We propose a novel self-supervised contrastive learning method and develop a new pre-trained language model KPEBERT.
- We conduct extensive evaluations of MDERank on six diverse KPE benchmarks and demonstrate the robustness of MDERank to different lengths of documents. MDERank with BERT achieves 17.00, 21.99 and 23.85 for average F_1@5, F_1@10, F_1@15 respectively, as 1.69, 2.18 and 1.80 absolute gains over the SOTA results from SIFRank (Sun et al., 2020), and 4.44, 3.58, and 2.95 absolute gains over EmbedRank with BERT. MDERank with KPEBERT achieves further absolute gains by 1.70, 2.18 and 1.73. Ablation analysis further provides insights on the effects of document lengths, encoder layers, and pooling methods.

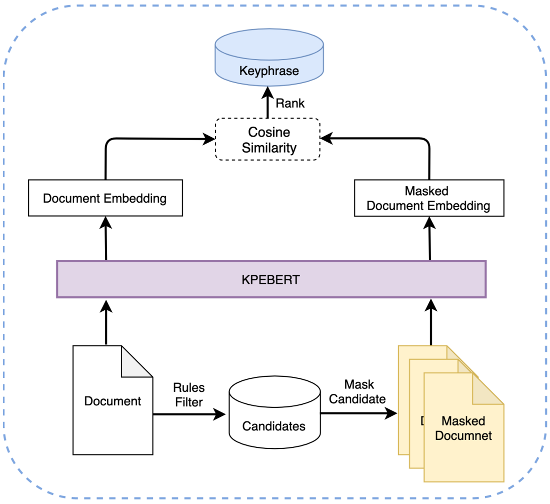

Figure 1: The architecture of the proposed MDERank approach.

2 Related Work

Unsupervised KPE Unsupervised KPE approaches do not require annotated data and there has been much effort in this line of research, as summarized in (Papagiannopoulou and Tsoumakas, 2020). Unsupervised KPE approaches can be categorized into statistics-based, graph-based, and embedding-based methods. The statistics-based models such as YAKE (Campos et al., 2018), EQPM (Li et al., 2017), and CQMine (Li et al., 2019) explores both conventional position and frequency features and new statistical features capturing context information. TextRank (Mihalcea and Tarau, 2004) is a representative graph-based method, which converts a document into a graph based on lexical unit co-occurrences and applies PageRank iteratively. Many graph-based methods could be considered as modifica-

Document	The paper presents a method for pruning frequent itemsets based on background knowledge represented by a Bayesian network . Table 1: An example shows the bias of Phrase-Document (PD) methods towards longer candidate keyphrases at $K = 5$. Keyphrase extracted are shown in a ranked order and those matching the gold labels are marked in red.

tions to TextRank by introducing extra features to compute weights for edges of the constructed graph, e.g., SingleRank (Wan and Xiao, 2008), PositionRank (Florescu and Caragea, 2017), ExpandRank (Wan and Xiao, 2008). The graph-based TopicRank (Bougouin et al., 2013) and MultipartiteRank (Boudin, 2018) methods enhance keyphrase diversity by constructing graphs based on clusters of candidate keyphrases. For embedding-based methods, (Wang et al., 2015) first attempted on utilizing word embeddings as external knowledge base for keyphrases extraction and generation. Key2vec (Mahata et al., 2018) used Fasttext to construct phrase/document embeddings and then apply PageRank to select keyphrases from candidates. EmbedRank (Bennani-Smires et al., 2018) measures the similarity between phrase and document embeddings for ranking. SIFRank (Sun et al., 2020) improves the static embeddings in EmbedRank by a pre-trained language model ELMo and a sentence embedding model SIF (Arora et al., 2017). KeyBERT[1] is a tooltik for keyphrase extraction with BERT, following the PD based methods paradigm. AttentionRank (Ding and Luo, 2021) used a pretrained language model to calculate self-attention of a candidate within the context of a sentence and cross-attention between a candidate and sentences within a document, in order to evaluate the local and global importance of candidates. As analyzed in Section 1, for embedding-based methods, using contextualized embedding models to compute candidate embeddings could be unreliable due to lack of context, and these methods lack robustness to different lengths of keyphrases and documents. Our proposed MDERank approach could effectively address these drawbacks.

Contextual Embedding Models Early emebdding models include static word embeddings such as Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and FastText (Bojanowski et al., 2017), phrase embedding model HCPE (Li et al., 2018), and sentence embeddings such as Sent2Vec (Pagliardini et al., 2018) and Doc2Vec (Lau and Baldwin, 2016), which render word or sentence representations that do not depend on their context. In contrast, pre-trained contextual embedding models, such as ELMo (Peters et al., 2018), incorporate rich syntactic and semantic information from context for representation learning and yield more expressive representations. BERT (Devlin et al., 2019) captures better context information through a bidirectional transformer encoder than the Bi-LSTM based ELMo, and has established SOTA in a wide variety of NLP tasks. In one line of research, RoBERTa (Liu et al., 2019), XLNET (Yang et al., 2019) and many other BERT variant PLMs have been proposed to further improve the language representation capability. In another line of research, Longformer (Beltagy et al., 2020), BigBird (Zaheer et al., 2020) and other efficient transformers are proposed to reduce the quadratic complexity of transformer on sequence length in order to model long-range dependencies. In this paper, we mainly use BERT as the default contextual embedding model. We also evaluate the performance of MDERank with these efficient transformers on long documents.

3 MDERank

In this section, we describe the proposed Masked Document Embedding Rank (MDERank) approach. Given a document $d = \{w_1, w_2, \dots, w_n\}, d \in D$ where D denotes a dataset, and a set of selected candidate KPs $C = \{c_1, \dots, c_i, \dots, c_m\}$, where a candidate c_i consists of one or multiple tokens, as $c_i = \{c_i^1, \dots, c_i^l\}$, and $m \leq n$, KPE aims to select K candidates from C, where $K \leq m$. Following the common practice (Bennani-Smires et al., 2018; Sun et al., 2020), after tokenization and POS tag-

---

[1] https://maartengr.github.io/KeyBERT/

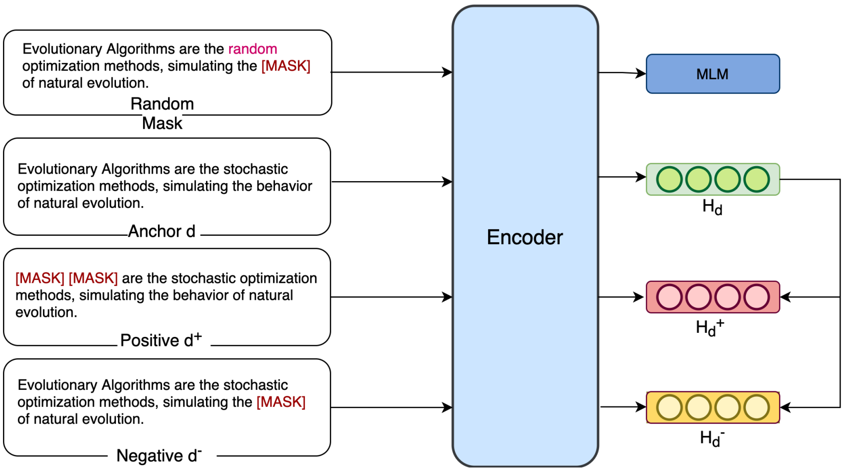

Figure 2: The multi-task pre-training for KPEBERT includes two tasks. One is teaching the encoder to distinguish documents masked with keyphrases and non-keyphrases. The other is further pre-training the encoder with a MLM task. The word in pink is an example to illustrate the random masking in MLM.

ging, candidates are selected with continuous regular expression `<NN. *|JJ> * <NN.*>`, which are mostly noun phrases.

To address the mismatch between sequence lengths of a document and a candidate phrase as well as lack of contextual information in PD methods as mentioned in Section 1, we hypothesize that it is more reasonable to conduct the similarity comparison at the *document-document* level rather than at the *phrase-document* level.

Based on this hypothesis, for each candidate KP c_i for a document d, given its occurrence positions in d as $[p_1, p_2, \dots, p_t]$, MDERank replaces all occurrences of $p^t_{i=1}$ by a special placeholder token `MASK`. It is noted the number of `MASK` used for masking p_t is as same as the number of tokens in c_i. And then we construct a masked variant of the original document as $d^{c_i}_M$. We define the similarity score $f(c_i)$ for ranking the significance of candidates as the cosine similarity between $E(d)$ and $E(d^{c_i}_M)$, where $E(\cdot)$ represents the embedding of a document. Note that a higher $f(c_i)$ value indicates a lower ranking for c_i, which is opposite to the PD methods. This is because the higher similarity the less important the candidate c_i is. The semantic of masked document is not changed much compared with original one as only a trivial phrase is masked. We use BERT (Devlin et al., 2019) as the default embedding model and investigate other contextual embedding models in Section 5.4. BERT is pre-trained through self-supervised tasks of masked language modeling (MLM) and next sentence prediction (NSP), on large-scale unlabeled text of English Wikipedia (2500M words) and Bookscorpus (800 words). A document $d = \{w_1, w_2, \dots, w_n\}$ is prepended with a special token `[CLS]` and then encoded by BERT to obtain the hidden representations of tokens as $\{H_1, H_2, \dots, H_n\}$. The document embedding $E(d)$ is computed as follows:

$$E(d) = \mathrm{MaxPool}(H_1, \dots, H_n) \tag{1}$$

We also investigate average pooling in Section 5.4 and other masking methods in Appendix A.

Datasets	N_{KP}	L_{KP}	L_{Doc}
Inspec	9.82	2.31	121.84
SemEval2010	15.07	2.11	189.90
SemEval2017	17.30	3.00	170.38
DUC2001	8.08	2.07	724.63
NUS	11.66	2.07	7702.00
Krapivin	5.74	2.03	8544.57

Table 2: Statistics of the datasets. N_{KP} is the average number of gold keyphrases. L_{KP} is the average length of gold keyphrases. L_{Doc} is the average number of words per document.

4 KPEBERT: KPE-oriented Self-supervised Learning

BERT and many other BERT variant PLMs can effectively capture syntactic and semantic information in language representations for downstream NLP tasks, through self-supervised learning objectives such as MLM. However, these self-supervised learning objectives neither explicitly model the significance of KPs nor model ranking between KPs. In this paper, we propose a novel PLM KPEBERT trained with a novel self-supervised learning objective to improve the capabilities of PLMs for ranking KPs. This new task is defined as minimizing the triplet loss between positive and negative examples (See Figure 2). After obtaining a set of pseudo-KPs for documents using another unsupervised KPE method θ, we define documents masking out pseudo-KPs as positive examples while those masking out "non-pseudo-KPs" as negative examples. Following SimCSE (Gao et al., 2021), we encode the original document d (anchor), the positive example d^+, and negative example d^- through a PLM encoder, respectively, and obtain their hidden representations as H_d, H_{d^+}, and H_{d^-}.

Finally, we define the triplet loss as:

$$\begin{aligned}\ell_{CL} = &\max(sim(H_d, H_{d^+}) \\ &- sim(H_d, H_{d^-}) + m, 0)\end{aligned} \tag{2}$$

where $sim(H_x, H_y)$ denotes the similarity between embeddings of the document x and y. We use cosine similarity (same as used for MDERank). m is a margin parameter.

We initialize KPEBERT from BERT-base-uncased[2] and then incorporate the standard MLM pre-training task as in BERT into the overall learning objective to avoid forgetting the previously learned general linguistic knowledge, as follows:

$$\ell = \ell_{CL} + \lambda \cdot \ell_{MLM} \tag{3}$$

where λ is a hyper-parameter balancing the two losses in the multi-task learning setting. KPEBERT differs from SimSCE in two major aspects: (i) KPEBERT uses pseudo labeling and positive/negative example sampling strategies (below), different from standard dropout used by SimCSE to construct pair examples; (ii) KPEBERT uses triplet loss whereas SimCSE uses contrastive loss.

Absolute Sampling For a document d, we first select candidate keyphrases C using POS tags with regular expressions as described in Section 3. Then we obtain a set of keyphrases C' extracted by another unsupervised KPE approach θ on d, as pseudo labels. We define "keyphrases" as C' and "non-keyphrases" as $C \setminus C'$. We mask a "keyphrase" from a document with a `MASK` to construct a positive example d^+ for d. We select a "non-keyphrase" and perform the same mask operation to construct a negative example d^-.

Relative Sampling In this approach, after obtaining a set of KP C' extracted by θ, we randomly select a pair of KPs from C' and choose the one ranked higher to construct a positive example and the other one to construct a negative example through the mask operation. On one hand, the decisions of "keyphrases" and "non-keyphrases" are fully based on the ranking predicted by θ, hence relative sampling may increase the impact from θ on the inductive bias of KPEBERT. On the other hand, relative sampling mines more hard negative samples which may improve performance of triplet loss based learning. We study the efficacy of these two sampling approaches on KPEBERT in Section 5.3.

5 Experiments

5.1 Datasets and Metrics

The pre-training data for KPEBERT are the WikiText language modeling dataset with 100+ million tokens extracted from a set of verified Good and Featured articles on Wikipedia[3]. We use six KPE benchmarks for evaluations. Four of them are scientific publications[4], including Inspec (Hulth, 2003), Krapivin (Krapivin et al., 2009), NUS (Nguyen and Kan, 2007), and SemEval-2010 (Kim et al., 2010), all widely used for evaluations in previous works (Meng et al., 2017; Chen et al., 2019; Sahrawat et al., 2019; Bennani-Smires et al., 2018; Meng et al., 2021). We also evaluate on the DUC2001 dataset (news articles) (Wan and Xiao, 2008) and SemEval2017 dataset (science journals) (Augenstein et al., 2017)[5]. Table 2 shows data statistics. For a fair comparison with SIFRank, we use the entire documents, including abstract and main body. Following previous works, predicted KPs are deduplicated and the KPE performance is evaluated as F_1 at the top K KPs ($K \in \{5, 10, 15\}$). Stemming is applied for computing F_1.

5.2 Baselines and Training Details

The first group for each K in Table 3 shows performance of the eight baseline unsupervised KPE approaches. We evaluate TextRank, SingleRank, TopicRank, MultipartiteRank, YAKE, EmbedRank using their implementations in the widely used toolkit

Table 3: KPE performance as $F_1@K, K \in \{5, 10, 15\}$ on the six benchmarks. For each K, the first group shows performance of the baselines and the second group shows performance of our proposed MDERank using BERT for embedding and MDERank using KPEBERT for embedding. EmbedRank(BERT) denotes the Phrase-Document based methods for a fair comparison. The best results are both underlined and in bold. The second-best results are in bold. **Ab** and **Re** denote absolute and relative sampling, respectively. **AVG** is the average $F_1@K$ on all six benchmarks. **AvgRank(STD)** is the mean and std of the rank of a method among all methods on all six benchmarks (hence the lower the better).

PKE[6] with the default parameter settings. We evaluate SIFRank using the codebase [7] and the same parameters suggested by the authors (Sun et al., 2020). The original EmbedRank (Bennani-Smires et al., 2018) uses Sent2Vec for embedding and introduces embedding-based maximal marginal relevance (MMR) for improving diversity among selected KPs. For a fair comparison between the Phrase-Document method and our Document-Document MDERank, we design a new baseline EmbedRank(BERT) by replacing Sent2Vec with BERT and removing MMR. Some previous works have inflated results caused by ignoring deduplication and stemming, which are not fair in practice. Therefore, SIFRank and EmbedRank, which exclude such biases, are strong baselines for unsupervised keyphrase extraction with SIFRank considered to be the previous SOTA.

We use YAKE (Campos et al., 2018) as θ to extract "keyphrases" for a document for KPEBERT pre-training, due to its high efficiency and consistent performance. Effects of the choice of θ on KPEBERT are analyzed in Section 5.4 where we compare YAKE and TextRank as θ. The number of pseudo labels for absolute and relative sampling for KPEBERT pre-training are 10 and 20, respectively. The λ is set to 0.1. The default parameter setting is the same as (Gao et al., 2021) except that we set the margin m for triplet loss to 0.2 and the learning rate to 3e-5. We use 4 NVIDIA V100 GPUs for training, the batch size is 2 per device and the gradient accumulation is 4. We train 10 epochs.

[7] `https://github.com/sunyilgdx/SIFRank/tree/master`

5.3 Performance Comparison

Table 3 shows F_1 at the top $K \in \{5, 10, 15\}$ predictions. For each K, the first group shows the baseline results, and the second group shows results from our MDERank(BERT) (default using BERT for embedding) and MDERank using KPEBERT for embedding, MDERank(KPEBERT). MDERank(BERT) and MDERank(KPEBERT) perform consistently well on all benchmarks. MDERank(BERT) outperforms EmbedRank(BERT) by 2.95 average F_1@15 and outperforms the previous SOTA SIFRank by 1.80 average F_1@15. MDERank further benefits from KPEBERT and MDERank(KPEBERT) achieves 3.53 average F_1@15 gain over SIFRank, especially on long-document datasets NUS and Krapivin. We also compute the average recalls of KPs with different phrase lengths (PL) in top-15 extracted KPs on all 6 benchmarks, for both EmbedRank(BERT) and MDERank(BERT), as shown in Table 4. We observe that EmbedRank has a strong bias for longer phrases, with PLs of its extracted KPs concentrated in [2,3]; whereas, PLs of KPs extracted by MDERank are more evenly distributed on diverse datasets. This analysis confirms that MDERank indeed alleviates the bias towards longer phrases from EmbedRank.

However, we observe that MDERank(BERT) has a large gap to SIFRank on DUC2001 and performs worse than EmbedRank(BERT) on Inspec. We investigate the reasons for these poorer performance. Different from other datasets collected from scientific publications, DUC2001 consists of open-domain news articles. The previous SOTA SIFRank introduces domain adaptation by combining weights from common corpus and domain corpus in the weight function of words for computing sentence embeddings, which may contribute significantly to its superior performance on DUC2001. As the default embedding model for MDERank, BERT is pre-trained on open-domain Wikipedia and BooksCorpus. However, as explained in Section 4, BERT does not emphasize learning significance of KPs or ranking between KPs. KPEBERT is designed to tackle this problem. Although the training data for KPEBERT, the open-domain WikiText language modeling dataset, is much smaller than English Wikipedia, with KPE-oriented representation learning in KPEBERT, the performance of MDERank(KPEBERT) improves remarkably and is comparable to SIFRank. For Inspec, the average PLs of gold labels of this dataset is relatively high (see Table 2). Also, on this dataset, when we move candidates with only 1 token to the end of ranking, MDERank(BERT) improves F_1@5, F_1@10, F_1@15 to 29.71 ,38.15, 39.46, an improvement of 3.54, 4.34 and 3.29, respectively. These analyses show that gold labels for Inspec are biased towards long PL. Therefore, EmbedRank with inductive bias for long PL may benefit from this annotation bias and perform well. However, MDERank still outperforms baselines based on its best average F_1 and top average rank among all methods on all datasets, proving its robustness across domains without any domain adaptation.

Method	**EmbedRank(BERT)**				**MDERank(BERT)**			
PL / Data	1	2	3	>3	1	2	3	>3
Inspec	24.80	54.53	46.11	21.57	27.90	48.71	43.20	21.17
SemEval2017	24.91	53.68	48.05	9.84	37.28	47.07	43.99	9.76
SemEval2010	9.35	22.79	18.07	4.17	21.55	19.99	15.95	4.17
DUC2001	3.46	19.39	37.39	15.58	24.81	23.70	23.66	13.46
Krapivin	4.31	13.59	11.80	2.50	15.88	22.43	10.62	2.14
NUS	5.12	9.53	16.17	2.84	26.77	24.70	17.12	1.90

Table 4: The average recall of predicted KPs with different phrase lengths (PL) on all six benchmarks, from EmbedRank(BERT) and MDERank(BERT).

It is notable that MDERank particularly outperforms baselines on long-document datasets, verifying that MDERank could mitigate the weakness of performance degradation on long documents from PD methods. We further investigate effects of document length in Section 5.4. Absolute and relative sampling for KPEBERT achieve comparable performance on the 6 benchmarks with absolute sampling gaining a very small margin. Relative sampling performs better on NUS but is worse on Inspec and SemEval2017. We plan to continue exploring sampling approaches in future work, to reduce dependency on θ and improve KPEBERT.

5.4 Analyses

Effects of Document Length Section 5.3 demonstrates the superior performance of MDERank especially on long documents. We conduct two experiments to further analyze effects of document length on the performance of PD methods and MDERank. We choose EmbedRank(BERT) to represent PD methods. In the first experiment, both approaches use BERT for embedding and we truncate a document into the first 128, 256, 512 words. As shown in Table 5, F_1 for EmbedRank(BERT) drops drastically as the document length increases from 128 to 512, reflecting the

Method	**Doc Len**	**F_1@5**	**F_1@10**	**F_1@15**
EmbedRank(BERT)	128	8.76	14.75	16.28
	256	5.86	10.19	12.90
	512	3.75	6.34	8.11
MDERank(BERT)	128	12.86	16.06	16.67
	256	14.45	16.01	16.64
	512	15.24	18.33	17.95

Table 5: Effects of document lengths (the first 128, 256, 512 words of a document) on the KPE performance on the NUS dataset from EmbedRank(BERT) and MDERank(BERT).

Method	**Pooling**	**Layer**	**DUC2001**		
			F1@5	**F1@10**	**F1@15**
EmbedRank(BERT)	AvgPooling	3	16.19	21.21	22.12
		6	10.76	15.33	17.63
		12	10.41	15.15	17.69
	MaxPooling	3	6.97	11.04	12.27
		6	7.12	10.93	13.13
		12	8.12	11.62	13.58
MDERank(BERT)	AvgPooling	3	12.00	16.45	19.08
		6	12.40	17.07	19.02
		12	13.00	17.93	19.45
	MaxPooling	3	11.06	16.16	18.01
		6	11.06	15.91	17.98
		12	13.05	17.31	19.13

Table 6: KPE performance on DUC2001 from EmbedRank(BERT) and MDERank(BERT) using different BERT layers for embedding and pooling methods. AvgPooling and MaxPooling are employed on the output of a specific layer to produce document embeddings.

weakness of EmbedRank(BERT) that the increased document length exacerbates discrepancy between sequence lengths of the document and KP candidates and mismatches between their embeddings, which degrades the KPE performance. In contrast, the performance of MDERank(BERT) improves steadily with increased document lengths, demonstrating the robustness of MDERank to document lengths and its capability to improve KPE from more context in longer documents.

In the second experiment, we investigate effects of document length beyond 512 on EmbedRank and MDERank. To accommodate documents longer than 512, we choose BigBird (Zaheer et al., 2020) as the embedding model. BigBird replaces the full self-attention in Transformer with sparse attentions of global, local, and random attentions, reducing the quadratic complexity to sequence length from Transformer to linear. In order to select valid datasets for this evaluation, we count the average percentage of gold label KPs appearing in the first m words in a document on the three longest datasets, DUC2001, NUS, and Krapivin. We observe that the first 500 words nearly cover 90% gold KPs in DUC2001, whereas 50% gold KPs in Krapivin are in the first 2500 words, and 50% gold KPs in NUS are in the first 2000 words. Therefore, we drop DUC2001 and use NUS and Krapivin for the second experiment. We keep the first 2500 and 2000 words for documents in Krapivin and NUS, respectively. Table 7 shows that on NUS, when increasing the document length from 512 to 2000, MDERank(BigBird) outperforms MDERank(BERT) by 2.38 F_1@15. On Krapivin, when increasing the document length from 512 to 2500, MDERank(BigBird) also improves MDERank(BERT) by 0.12 F_1@15. In contrast, the performance of EmbedRank degrades dramatically with longer context, since more context introduces more candidates into ranking and also worsens the discrepancy between lengths of document and phrases, which in turn greatly reduces the accuracy of similarity comparison.

Effects of Encoder Layers and Pooling Methods The findings in (Jawahar et al., 2019; Kim et al., 2020; Rogers et al., 2020) show that BERT captures a rich hierarchy of linguistic information, with surface features in lower layers, syntactic features in middle layers, and semantic features in higher layers. We conduct experiments to understand the effects on MDERank and EmbedRank when using different BERT layers for embedding. We choose the third, the sixth, and the last layer from BERT-Base. We study the interactions between encoder layers and different Pooling methods. As shown in Table 6, for both AvgPooling and MaxPooling, F_1 from MDERank(BERT) shows a steady gain to the increase of layers. On the contrary, with AvgPooling, F_1 from EmbedRank(BERT) drastically drops as the layers rises from 3 to 12, probably due to that the lower BERT layer provides more rough and generic representations, which may alleviate mismatch in similarity comparison for Phrase-Document methods. We test the average F1@5, F1@10, F1@15 with the configuration for EmbedRank(BERT) that yields best results on DUC2001, i.e., AvgPooling and layer 3, on all 6 datasets and the results are 3.7, 1.8 and 1.6 absolute lower than MDERank(BERT). Compared to AvgPooling, MaxPooling produces weaker document embedding, which severely degrades the performance of EmbedRank and slightly degrades performance of MDERank. On the other hand, MaxPooling probably reduces differences in embeddings

Method	**NUS** (512)			**NUS** (2000)			**Krapivin** (512)			**Krapivin** (2500)		
	F$_1$@5	F$_1$@10	F$_1$@15	F$_1$@5	F$_1$@10	F$_1$@15	F$_1$@5	F$_1$@10	F$_1$@15	F$_1$@5	F$_1$@10	F$_1$@15
EmbedRank(BERT)	3.75	6.34	8.11	–	–	–	4.05	6.60	7.84	–	–	–
EmbedRank(BigBird)	2.56	5.16	7.11	1.08	1.36	2.20	3.24	5.14	6.31	1.05	1.93	2.28
MDERank(BERT)	15.24	18.33	17.95	–	–	–	11.78	12.93	12.58	–	–	–
MDERank(BigBird)	15.42	17.68	17.81	15.36	19.56	20.33	11.62	11.99	11.70	11.33	12.71	12.70

Table 7: KPE performance from EmbedRank and MDERank using BERT and BigBird for embedding. 512, 2000, 2500 in the parentheses represent the number of words kept for each document in datasets. The results for NUS(2000) and Krapivin (2500) are missing for EmbedRank(BERT) and MDERank(BERT) due to limitation on input sequence length from BERT.

F$_1$@K	θ	**Dataset**						
		Inspec	**SemEval2017**	**SemEval2010**	**DUC2001**	**Krapivin**	**NUS**	**AVG**
5	TextRank	28.93	21.34	11.46	13.30	7.85	7.57	15.08
	YAKE	28.06	21.63	12.95	22.51	12.91	14.11	18.70
10	TextRank	38.13	32.71	17.23	19.15	10.47	10.59	21.38
	YAKE	35.80	32.23	17.95	26.97	14.36	17.72	24.17
15	TextRank	39.49	37.95	19.89	22.11	11.40	12.83	23.95
	YAKE	37.43	37.52	20.69	26.28	13.58	17.95	25.58

Table 8: The KPE performance (F$_1$@K) from MDERank(KPEBERT) with KPEBERT pre-trained using YAKE and TextRank as θ for producing pseudo labels, respectively. **AVG** is the average F1@K on all six benchmarks

across layers, hence performance of EmbedRank becomes stable across layers with MaxPooling.

For both pooling methods, MDERank using the last BERT layer achieves the best results, demonstrating that MDERank can fully benefit from stronger contextualized semantic representations.

Effects of the Choice of θ on KPEBERT We also investigate the effects of choosing different unsupervised KPE methods as θ for generating pseudo labels for KPEBERT pre-training. When balancing the extraction speed and KPE quality, TextRank is another choice for θ besides YAKE. As shown in Table 3, YAKE performs better than TextRank on long-document datasets but worse on short-document datasets. After replacing YAKE with TextRank as θ for producing pseudo labels and training KPEBERT, the KPE results of the respective MDERank(KPEBERT) with absolute sampling are shown in Table 8. We observe that MDERank(KPEBERT) using YAKE as θ significantly outperforms MDERank(KPEBERT) using TextRank as θ, on both short-document datasets and long-document datasets (except worse on Inspec and comparable on SemEval2017). Although on average YAKE performs worse than TextRank on the six benchmarks, the better performance from YAKE on long documents coupled with its stable performance may be a crucial factor when choosing θ for pre-training KPEBERT. Results in Table 3 shows that MDERank(KPEBERT) with YAKE for pseudo labeling yields superior performance on both short and long documents. In other words, KPEBERT benefits from the stable performance from YAKE on long documents for pseudo labeling while exhibiting robustness to the relatively low performance on short documents from YAKE.

6 Conclusion

We propose a novel embedding-based unsupervised KPE approach, MDERank, to improve reliability of similarity match compared to previous embedding-based methods. We also propose a novel self-supervised learning method and develop a KPE-oriented PLM, KPEBERT. Experiments demonstrate MDERank outperforms SOTA on diverse datasets and further benefits from KPEBERT. Analyses further verify the robustness of MDERank to different lengths of keyphrases and documents, and that MDERank benefits from longer context and stronger embedding models. Future work includes improving KPEBERT for MDERank by optimizing sampling strategies and pre-training methods.

Appendices

A Effects of Masking Methods on MDERank

Given occurrences of a candidate KP c_i in a document d as $[p_1, p_2, \ldots, p_t]$, we study several methods to mask these occurrences and generate the masked document $d_M^{c_i}$, considering the potential bias e.g., frequency, sequence length, and nested phrases.

Mask Once The *Mask Once* method only masks the first occurrence of a candidate. This strategy eliminates the bias towards high frequency candidate KPs. However, it may prefer longer candidate KPs (i.e., candidate KPs that consist of more subwords) with the same argument shown in Section 1. MDERank may benefit from this masking strategy on datasets with annotation bias towards long keyphrases.

Mask Highest The *Mask Highest* method considers the collection of $d_M^{c_i}$s obtained by masking each occurrence of a candidate phrase c_i once in the document, and select the one that has the *smallest* cosine similarity with the embeddings of d. This method considers a balance of impacts from sequence length and frequency of candidate phrases.

Mask Subset One issue in KPE is that there may be heavy nesting among candidate KPs. For example, “support vector machine” may result in nested candidates such as “support vector machine”, “support vector”, “vector machine”, and even “machine”. Neither *Mask All* nor *Mask Once* strategy addresses this issue and hence the nested KPs may take up a large proportion in the final results, drastically damaging the diversity. We design the *Mask Subset* method to alleviate impact of nested candidate KPs. Firstly, all candidates are ranked by their phrase length in a descending order. Secondly, when generating a masked document for each candidate in order, *Mask Subset* records the positions of masked words and requires that each candidate could only be masked with words not in the recorded positions.

The KPE results from MDERank(BERT) using these masking strategies are shown in Table 9. The masking variants do not bring remarkable improvement compared with the results from Mask All, and Mask Once and Mask Highest perform even worse on the long-document datasets. This is because masking only one occurrence of a candidate will not emphasize the change of semantics significantly, especially on long documents. Mask subset could partially address the diversity problem by reducing the number of nested candidates selected by MDERank. Figure 3 shows a comparison on diversity between *Mask Subset* and other methods, where the evaluation metric for diversity is defined in Equation 4. The Phrase-Document method refers to EmbedRank(BERT). We could see from Figure 3 that MDERank with Mask Subset indeed boosts the diversity over Mask All and even exceeds gold labels on several datasets.

$$Diveristy(d) = \frac{t_u}{t_n} * 100 \tag{4}$$

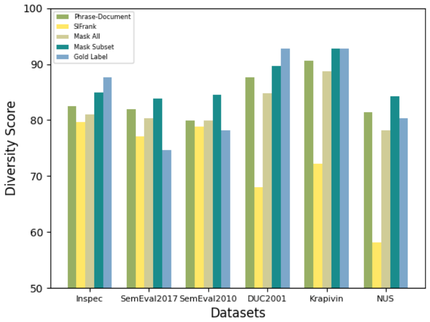

Figure 3: Diversity scores from different methods on various datasets. A higher bar indicates a better diversity. The diversity of gold keyphrases are in blue and on the right.

B Impact of Similarity Measure

The common similarity measures include Cosine and Euclidean distance. However, the choice of similarity measure does not matter for MDERank performance. We conduct experiments to investigate the impact of the similarity measure on the performance of MDERank, and the results are shown in Table 10. We observe that Cosine and Euclidean similarity measure are not a salient factor for the ranking results for both EmbedRank(BERT) and MDERank(BERT).

Abstract

Probing is popular to analyze whether linguistic information can be captured by a well-trained deep neural model, but it is hard to answer how the change of the encoded linguistic information will affect task performance. To this end, we study the dynamic relationship between the encoded linguistic information and task performance from the viewpoint of Pareto Optimality. Its key idea is to obtain a set of models which are Pareto-optimal in terms of both objectives. From this viewpoint, we propose a method to optimize the Pareto-optimal models by formalizing it as a multi-objective optimization problem. We conduct experiments on two popular NLP tasks, *i.e.*, machine translation and language modeling, and investigate the relationship between several kinds of linguistic information and task performances. Experimental results demonstrate that the proposed method is better than a baseline method. Our empirical findings suggest that some syntactic information is helpful for NLP tasks whereas encoding more syntactic information does not necessarily lead to better performance, because the model architecture is also an important factor.

1 Introduction

Recent years have witnessed great success of deep neural networks for natural language processing tasks, such as language modeling (Zaremba et al., 2014; Merity et al., 2018) and Neural Machine Translation (Bahdanau et al., 2015; Vaswani et al., 2017). The excellent task performance they achieved spiked the interest in interpreting their underlying mechanism. Since linguistic knowledge is crucial in natural languages, an emerging body of literature uses *probes* (Conneau et al., 2018; Alt et al., 2020; Saleh et al., 2020; Cao et al., 2021) to investigate whether a standard model trained towards better task performance also captures the linguistic information. From the perspective of information theory, Voita and Titov (2020) and Pimentel et al. (2020b) show that probes can be used to estimate the amount of linguistic information captured by a fixed model.

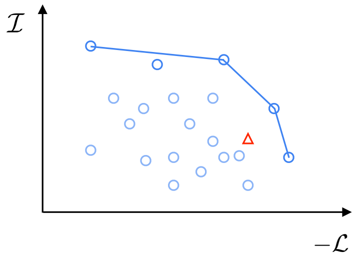

Figure 1: Illustration of Pareto frontier by a toy example. Triangle (△) corresponds to the standard checkpoint with best performance and each circle (◯) corresponds to a sampled checkpoint. The y-axis indicates the linguistic information $\mathcal{I}$ encoded by the model, and x-axis indicates the negative loss value $-\mathcal{L}$.

However, the above probing only extracts linguistic information from a fixed standard model, which helps little to understand the relationship between the task performance and linguistic information encoded by the model. For example, under their methodology, it is difficult to answer the following two questions. First, would adding linguistic information be beneficial for an NLP model; second, is it harmful when this linguistic information is reduced. Therefore, it is still an open and intriguing question to reveal how task performance changes with respect to different amounts of linguistic information.

To this end, this paper proposes a novel viewpoint to study the relationship between task performance and the amount of linguistic information, inspired by the criterion of Pareto Optimality which is widely used in economics (Greenwald and Stiglitz, 1986). Our main idea is to obtain Pareto-optimal models on a test set in terms of both linguistic information and task performance and then visualize their relationship along with these

optimal models. By comparing a standard model with these optimal models, it is clear to answer the question that whether adding the encoded information is helpful to improve the task performance over the standard model , as illustrated in Figure 1, where the points on the line are Pareto-optimal and the red triangle denotes the standard model with best performance.

Nevertheless, it is typically intractable to obtain the Pareto-optimal models according to both dimensions on test data. To address the challenge, we propose a principled method to approximately optimize the Pareto-optimal models on the training data which can be expected to generalise well on test sets according to statistical learning theory (Vapnik, 1999). Formally, the approach can be regarded as a multi-objective optimization problem: during the learning procedure, it optimizes two objectives, *i.e.*, the task performance and extracted linguistic information. In addition, we develop a computationally efficient algorithm to address the optimization problem. By inspecting the trend of those Pareto-optimal points, the relationship between task performance and linguistic information can be clearly illustrated. Back to our questions, we also consider two instances within the proposed methodology: one aims to maximize the amount of linguistic information (*i.e.*, adding) while the other tries to minimize it (*i.e.*, reducing).

We conduct experiments on two popular NLP tasks, i.e., machine translation and language modeling, and choose three different linguistic properties, including two syntactic properties (Part-of-Speech and dependency labels) and one phonetic property. We investigate the relationship between NMT performance and each syntactic information, and the relationship between LM performance and phonetic information. For machine translation, we use LSTM, *i.e.*, RNN-search (Bahdanau et al., 2015), and Transformer (Vaswani et al., 2017) as the main model architectures, and conduct our experiments on En ⇒ De and Zh ⇒ En tasks. For language modeling, we employ the LSTM model and conduct experiments on the Penn Treebank dataset. The experimental results show that: i) syntactic information encoded by NMT models is important for MT task and reducing it leads to sharply decreased performance; ii) the standard NMT model obtained by maximum likelihood estimation (MLE) is Pareto-optimal for Transformer but it is not the case for LSTM based NMT; iii) reducing the phonetic information encoded by LM models only makes task performance drop slightly.

In summary, our contributions are three-fold:

1. We make an initial attempt to study the relationship between encoded linguistic information and task performance, *i.e.*, how the change of linguistic information affects the performance of models.
2. We propose a new viewpoint from Pareto Optimality as well as a principled approach which is formulated as a multi-objective optimization problem, to visualize the relationship.
3. Our experimental results show that encoding more linguistic information is not necessary to yield better task performance depending on the specific model architecture.

2 Related Work

Probe With the impressive performance of Neural Network models for NLP tasks (Sutskever et al., 2014; Luong et al., 2015; Vaswani et al., 2017; Devlin et al., 2019; Xu et al., 2020), people are becoming interested in understanding neural models (Ding et al., 2017; Li et al., 2019, 2020). One popular interpretation method is probe (Conneau et al., 2018), also known as auxiliary prediction (Adi et al., 2017) and diagnostic classification (Hupkes et al., 2018), which aims to understand how neural models work and what information they have encoded and used. From the perspective of information theory, Voita and Titov (2020) and Pimentel et al. (2020b) show that probes can be used to estimate the amount of linguistic information captured by a model. However, recent research studies point out that probes fail to demonstrate whether the information is used by models. For example, Hewitt and Liang (2019) show that the probe can also achieve high accuracy in predicting randomly generated tags, which is useless for the task. And Ravichander et al. (2021) present that the representations encode the linguistic properties even if they are invariant and not required for the task. Instead of studying the encoded linguistic information by training a probe for fixed representations, in this work we study how the amount change of linguistic information affects the performance of NLP tasks.

Information Removal Information removal is crucial in the area of transfer learning (Ganin and Lempitsky, 2015; Tzeng et al., 2017; Long et al., 2018) and fairness learning (Xie et al., 2017; Elazar and Goldberg, 2018), where people want to remove domain information or bias from learned representations. One popular method is Adversarial Learning (Goodfellow et al., 2014; Ganin and Lempitsky, 2015), which trains a classifier to predict the properties of representations, *e.g.*, domain information or gender bias, while the feature extractor tries to fool the classifier. In this work, when using our method to reduce the linguistic information in the representations, we find that our multi-objective loss function is the same form as adversarial learning, which provides the theoretical guarantee for using adversarial learning to find the Pareto-optimal solutions to a multi-objective problem.

Recently, Elazar et al. (2020) also propose to study the role of linguistic properties with the idea of information removal (Ravfogel et al., 2020). However, the representations got by their method may not be Pareto-optimal, because it only minimizes the mutual information, but ignores the objective of task performance. On the contrary, our proposed method optimizes towards both objectives, thus our results can be used to visualize the relationship between linguistic properties and task performance.

Pareto Optimality The idea of Pareto Optimality (Mas-Colell et al., 1995) is an important criterion in economics, where the goal is to characterize situations where no variable can be better off without making at least one variable worse off. It has been also widely used in the area of sociology and game theory (Beckman et al., 2002; Chinchuluun et al., 2008). In addition, in artificial intelligence Martínez et al. (2020) use Pareto optimality to solve group fairness problem and Duh et al. (2012) proposed to optimize an MT system on multiple metrics based on the theory of Pareto optimality. In particular, Pimentel et al. (2020a) propose a variant of probing on the hidden representation of deep models and they consider Pareto optimality in terms of both objectives similar to our work. Comparing with their work, one difference is the choice of objectives. Another significant difference is that they optimize probing model in a conventional fashion, and thus are unable to study the relationship between linguistic information and task performance.

3 Visualizing Relationship via Pareto Optimality

We consider the relationship between linguistic information and task performance for two popular tasks in NLP, i.e., machine translation and language modeling. Let $\boldsymbol{x} = \{x_1, x_2, ..., x_N\}$ be a sentence and $\boldsymbol{s} = \{s_1, s_2, ..., s_N\}$ be the labels of the linguistic property of $\boldsymbol{x}$, where s_i is the label for x_i, e.g., POS tag. On both tasks, a deep model typically encodes $\boldsymbol{x}$ into a hidden representation $\boldsymbol{h}$ with a sub-network E parameterized by θ_e: $\boldsymbol{h} = E(\boldsymbol{x})$, and then uses another sub-network D parameterized by θ_d to map $\boldsymbol{h}$ into an output.

3.1 Background

$\boldsymbol{h}$ and Loss in NMT An NMT architecture aims to output a target sentence $\boldsymbol{y} = \{y_1, y_2, ..., y_M\}$ for a given source sentence $\boldsymbol{x}$ according to $P(\boldsymbol{y} \mid \boldsymbol{x}; \theta)$ (Zaremba et al., 2014; Vaswani et al., 2017), where θ indicates a set of parameters of a sequence-to-sequence neural network, which contains an encoder E and a decoder D. We define $\boldsymbol{h}$ as the output of the encoder. To train θ, the MLE loss is usually minimized on a training dataset. For NMT, the loss is defined as following:

$$L_\theta(\boldsymbol{x}, \boldsymbol{y}) = -\sum_{j=1}^{M} \log P(y_j | \boldsymbol{x}, \boldsymbol{y}_{<j}; \theta) \quad (1)$$

In our experiments, we consider two models, namely the LSTM (Bahdanau et al., 2015) and Transformer (Vaswani et al., 2017).

$\boldsymbol{h}$ and Loss in LM For language modeling task, a deep model typically generates a token x_j based on $\boldsymbol{x}_{<j}$ according to $P(x_j|\boldsymbol{x}_{<j}; \theta)$. Here the sub-networks E is set as one hidden layer to encode $\boldsymbol{x}_{<j}$ into $\boldsymbol{h}_{<j}$ and D is set as the sub-network to generate x_j on top of $\boldsymbol{h}_{<j}$. The parameter θ is optimized by the following MLE loss:

$$L_\theta(\boldsymbol{x}) = -\sum_{j=1}^{N} \log P(x_j|\boldsymbol{x}_{<j}; \theta).$$

To make notations consistent for both NMT and LM, in the rest of this paper, we follow the form of Eq. (1) and re-write the $L_\theta(\boldsymbol{x})$ in LM as $L_\theta(\boldsymbol{x}, \boldsymbol{y})$, where $\boldsymbol{y}$ is a shifted version of $\boldsymbol{x}$, i.e., $\boldsymbol{y} = \{x_2, \cdots, x_N\}$.

Encoded Information Let $\mathrm{I}(\boldsymbol{h}, \boldsymbol{s})$ denote the linguistic information in the representation $\boldsymbol{h}$, *i.e.*, the mutual information between $\boldsymbol{h}$ and the linguistic label $\boldsymbol{s}$. Since the probability $p(\boldsymbol{h}, \boldsymbol{s})$ is unknown, it is intractable to compute $\mathrm{I}(\boldsymbol{h}, \boldsymbol{s})$. Following Pimentel et al. (2020b), we approximately estimate

$\mathrm{I}(\boldsymbol{h}, \boldsymbol{s})$ by using a probing model q as follows:

$$\begin{aligned} \mathrm{I}(\boldsymbol{h}, \boldsymbol{s}) &= H(\boldsymbol{s}) - H(\boldsymbol{s}|\boldsymbol{h}) \\ &\approx \mathrm{H}(\boldsymbol{s}) - \min_{\theta_q} L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s}) \\ &= \mathrm{H}(\boldsymbol{s}) + \min_{\theta_q} \sum_i \log q(s_i|\boldsymbol{h}; \theta_q) \end{aligned} \tag{2}$$

where $H(\boldsymbol{s})$ is the entropy of linguistic labels, $H(\boldsymbol{s}|\boldsymbol{h})$ is the ideal cross entropy, and $L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})$ is the cross-entropy loss of the probe model q parameterized by θ_q.

Theory of Pareto Optimality Pareto optimality (Mas-Colell et al., 1995) is essentially involved in the multi-objective optimization problem. Suppose that we have K different objectives M_k to evaluate a parameter θ', *i.e.*,

$$\arg\max_{\theta'}[M_1(\theta'); M_2(\theta'); ...; M_K(\theta')]. \tag{3}$$

There are two important concepts in Pareto optimality as follows:

Definition 1. *Pareto Optimal: A parameter* θ^* *is Pareto-optimal iff for any* θ'*, the condition always holds that,* $\forall i = 1, ..., k,\ M_i(\theta^*) \geq M_i(\theta')$ *and* $\exists j$ *such that* $M_j(\theta^*) > M_j(\theta')$.

Definition 2. *Pareto Frontier: The set of all Pareto-optimal parameters is called the Pareto frontier.*

3.2 Viewpoint via Pareto Optimality

Motivation Suppose θ is a given model parameter, $L(\theta)$ is its task performance on a test set, and $I(\theta)$ is the amount of linguistic information encoded in its hidden representation. Conventionally, if one can figure out a function f such that $I = f(L)$ for any θ, it is trivial to study their relationship by visualizing f. Unfortunately, for some complicated situations as illustrated in Figure 1, there does not exist such a function to represent the relationship between two variables due to a large number of many-to-many correspondences.

Our Viewpoint Pareto Optimality, a well-known criterion in economics (Mas-Colell et al., 1995), is widely used to analyze the relationship among multiple variables in a complicated environment (Chinchuluun et al., 2008). In our context, it is also a powerful tool to reveal the relationship between the encoded linguistic information and task performance. Taking the Pareto Frontier in Figure 1 as an example, since the capacity of a model is fixed and linguistic information may compete with other kinds of information, capturing more linguistic information may reduce the amount of information from other sources that are also helpful for the model. Nevertheless, if increasing the amount of linguistic information constantly leads to performance gain, i.e., linguistic information is complimentary to translation, only one Pareto Optimal point would exist on the top right corner.

Therefore, in this paper, we propose to study the relationship between $I(\theta)$ and $L(\theta)$ from the viewpoint of Pareto Optimality. Our key idea is to take into account only Pareto-optimal models rather than all models like the conventional method. Thanks to the definition of Pareto optimality, there are no many-to-many correspondences between two variables along the Pareto frontier. Hence their relationship can be visualized by the trend of these frontier points, as shown in Figure 1. Taking Figure 1 as an example, to answer the questions mentioned before, we can see that adding more information is possible to increase the task performance comparing with a standard model. According to this viewpoint, the core challenge is how to obtain a set of models which are Pareto optimality on a test dataset.

It is natural to employ a *heuristic* method to approximately obtain the Pareto-optimal models as following. We can first randomly select a number of checkpoints during the standard training and probe each checkpoint by optimizing its corresponding probing model q, as shown in Eq (2). Second, we can record the task performances and the amounts of linguistic information of the selected models on a test set. Finally, we can find the Pareto-optimal points and obtain the Pareto frontier. However, when using this method in our experiments, we find the amounts of encoded linguistic information for all checkpoints are similar and the the task performances of those checkpoints are worse than the optimal model. Hence, in the next section, a new method will be presented to approximately derive the Pareto-optimal models.

4 Methodology

4.1 Multi-Objective Optimization

To study the relationship between linguistic information and task performance, our goal is to obtain a set of models θ which are Pareto optimal on test data in terms of both objectives. Inspired by statistical learning theory (Vapnik, 1999), we propose an approach by optimizing the Pareto-optimal models towards both objectives on a given training dataset, which are expected to generalize well on unseen test data, i.e., these models are Pareto optimal on unseen test data. Formally, Our approach can be formulated as the following multi-objective optimization problem:

$$\arg\min_{\theta}[L_\theta(\boldsymbol{x}, \boldsymbol{y}); -\mathrm{I}(\boldsymbol{h}, \boldsymbol{s})] \qquad (4)$$

where minimizing $L_\theta(\boldsymbol{x}, \boldsymbol{y})$ aims to promote the task performance and maximizing $\mathrm{I}(\boldsymbol{h}, \boldsymbol{s})$ encourages a model to encode more linguistic information in the representation. Once we obtain a set of Pareto-optimal models, we can observe how increasing the encoded linguistic information affects the variance of task performance.

To further study how reducing the encoded linguistic information affects task performance, we optimize a similar multi-objective problem:

$$\arg\min_{\theta}[L_\theta(\boldsymbol{x}, \boldsymbol{y}); \mathrm{I}(\boldsymbol{h}, \boldsymbol{s})] \qquad (5)$$

The only difference between Eq. (4) and Eq. (5) is that the former maximizes $\mathrm{I}(\boldsymbol{h}, \boldsymbol{s})$ while the latter minimizes $\mathrm{I}(\boldsymbol{h}, \boldsymbol{s})$.

Since $H(\boldsymbol{s})$ is a constant term, we can plug Eq. (2) into the above two equations and obtain the following reduced multi-objective problems:

$$\arg\min_{\theta}[L_\theta(\boldsymbol{x}, \boldsymbol{y}); \min_{\theta_q} L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})] \qquad (6)$$

$$\arg\min_{\theta}[L_\theta(\boldsymbol{x}, \boldsymbol{y}); -\min_{\theta_q} L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})] \qquad (7)$$

Notice that in the above equations, $\min_{\theta_q} L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})$ resembles a conventional probing if $\boldsymbol{h}$ is a fixed representation. However, unlike the standard probing applied on top of a fixed $\boldsymbol{h}$ determined by the standard model, here $\boldsymbol{h}$ is the representation obtained from a encoder E parameterized by θ_e. It is also worth noting that the Pareto frontiers obtained from the Eq. (6) and (7) are independent, although they have a similar measurement, because the Pareto Optimal is only valid for the same objective.

4.2 Optimization Algorithm

To solve the above multi-objective problems, we leverage the linear-combination method to find a set of solutions, and then filter the non-Pareto-optimal points from the set to get the Pareto frontier. The details of our algorithm are shown below.

Optimization Process Since the detailed optimization method for Eq. (6) is similar to that for Eq. (7), in the following we take Eq. (6) as an example to describe the optimization method. Inspired by (Duh et al., 2012), we employ a two-step strategy for optimization to find the Pareto frontier to address the multi-objective problems.

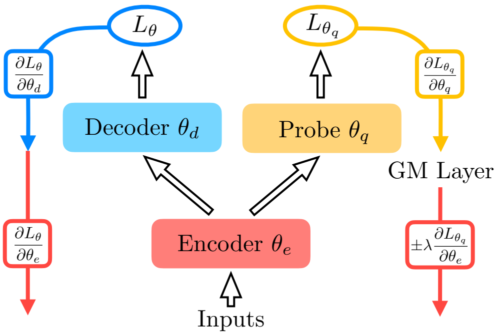

Figure 2: Overview of our multi-objective optimization method, where $L_y = L_\theta(\boldsymbol{x}, \boldsymbol{y})$ and $L_{\theta_q} = L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})$. In the back propagation, the GM Layer multiplies the gradient by $\pm\lambda$, i.e., λ for Eq. (6) and $-\lambda$ for Eq. (7).

In the first step, we adopt an method to find the Pareto-optimal solutions to the problem. There are several different methods to solve the problem, such as linear-combination, PMO (Duh et al., 2012) and APStar (Martínez et al., 2020). In this work, we adopt the linear-combination method because of its simplicity. Specifically, we select a coefficient set $\{\lambda_k \mid \lambda_k > 0\}$ and minimize the following interpolating function for each coefficient λ_k: [1]

$$\arg\min_{\theta}\left(L_\theta(\boldsymbol{x}, \boldsymbol{y}) + \lambda_k \min_{\theta_q} L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})\right) \qquad (8)$$

Notice that the first term of the loss function $L_\theta(\boldsymbol{x}, \boldsymbol{y})$ is the function of both encoder parameters θ_e and decoder parameters θ_d, while the second term $\min_{\theta_q} L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})$ is only the function of θ_e. Therefore, when minimizing Eq.(8), we apply a Gradient-Multiple (GM) Layer on the representations before inputting it into the probe model. As shown in Fig. 2, in the forward propagation, the GM Layer acts as an identity transform, while in the backward propagation, the GM Layer multiples the gradient by $\pm\lambda$ and passes it to the preceding layers. Note that when the multiplier is $-\lambda$, the GM Layer is the same as Gradient Reversal Layer (Ganin and Lempitsky, 2015).

Suppose $\{\theta_k^* \mid \theta_k^* > 0\}$ is the minimized solution set for Eq. (8). In the second step, to get more accurate solutions, we filter the non-Pareto-optimal points of the solution set obtained by $\{\theta_k^* \mid \theta_k^* > 0\}$. Finally, we get the Pareto frontier to the multi-objective problem according to the definition of Pareto optimality.

---

[1] Eq. (8) is similar to the loss of standard multiple task learning (MTL) (Dong et al., 2015; Lee et al., 2020), $\arg\min_{\theta,\theta_q}\left(L_\theta(\boldsymbol{x}, \boldsymbol{y}) \pm \lambda_k L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})\right)$. However, the solutions to the loss are weaker than our solutions according to Pareto optimality, and it can not remove linguistic information

Algorithm 1 Optimization Algorithm

```
Input: $\Lambda = \{\lambda_k\}$, learning rate $\eta$

16:     end if
17: end for
```

Detailed Algorithm The overall optimization algorithm regarding to Eq. (6) is shown in Algorithm 1. Theoretically, when minimizing Eq. (8), in every step updating θ, we should retrain the probe model θ_q to minimize $L_{\theta_q}(\boldsymbol{h}, \boldsymbol{s})$ in for many steps, in order to estimate $\mathrm{H}(\boldsymbol{s}|\boldsymbol{h})$ precisely. However, this is time-consuming and inefficient. Instead, after updating θ, we update θ_q only by one step (see line 7 Algorithm 1). Empirically, we find that optimization in this way has been very effective.

In addition, as is mentioned by Elazar and Goldberg (2018), information leakage may occur when minimizing the mutual information. Therefore, after the training process is finished, we fix the deep model and retrain another probe model to estimate $\mathrm{H}(\boldsymbol{s}|\boldsymbol{h})$ more precisely (line 9 in Algorithm 1). When maximizing the mutual information, we find there is no difference between $\mathrm{H}(\boldsymbol{s}|\boldsymbol{h})$ estimated by jointly trained or retrained probe models.

5 Experimental Settings

5.1 Dataset

We conduct experiments on both machine translation and language modeling tasks. For machine translation, we conduct the experiments on En ⇒ De and Zh ⇒ En translation tasks. For En ⇒ De task, we use WMT14 corpus which contains 4M sentence pairs. For Zh ⇒ En task, we use LDC corpus which consists of 1.25M sentence pairs, and we choose NIST02 as our validation set, and NIST06 as our test set. For language modeling task, we use Penn Treebank[2] dataset. We preprocess our data using byte-pair encoding (Sennrich et al., 2016) and keep all tokens in the vocabulary. For machine translation, we use case-insensitive 4-gram BLEU score (Papineni et al., 2002) to measure the task performance, which is proved to be positively correlated well with the MLE loss (**?**); For language modeling, we directly use the MLE loss to evaluate the task performance.

5.2 Linguistic Properties

For machine translation, we study part-of-speech (POS) and dependency labels in this work. Since there are no gold labels for the MT datasets, we use Stanza toolkit[3] (Qi et al., 2020) to annotate source sentences and use the pseudo labels for running our algorithm, following Sennrich and Haddow (2016); Li et al. (2018). We clean the labels and remove the sentences that fail to be parsed by Stanza from the dataset. To study whether all kinds of linguistic information are critical for neural models, we also investigate the phonetic information on the language modeling task. More precisely, the probing model needs to predict the first character of the International Phonetic Alphabet of each word.[4] We get the labels with the open source toolkit English-to-IPA[5]. We use mutual information $\mathrm{I}(\boldsymbol{h}, \boldsymbol{s}) = \mathrm{H}(\boldsymbol{s}) - \mathrm{H}(\boldsymbol{s}|\boldsymbol{h})$ to evaluate the amount of information in the representations. Since $\mathrm{H}(\boldsymbol{s})$ is a constant, we only compare $\mathrm{H}(\boldsymbol{s}|\boldsymbol{h})$ in the experiments. Note that $\mathrm{H}(\boldsymbol{s}|\boldsymbol{h})$ is estimated by our probe model q.

5.3 Implementation Details

All of our models are implemented with Fairseq[6] (Ott et al., 2019). For NMT experiments, our LSTM model consists of a bi-directional 2-layer encoder with 256 hidden units, and a 2-layer decoder

---

in our preliminary experiments.

[2] `https://deepai.org/dataset/penn-treebank`

[3] `https://github.com/stanfordnlp/stanza`

[4] For example, given the input sentence "This dog is so cute", the probing model is asked to predict "ð d ɪ s k".

[5] `https://github.com/mphilli/English-to-IPA`

[6] `https://github.com/pytorch/fairseq`

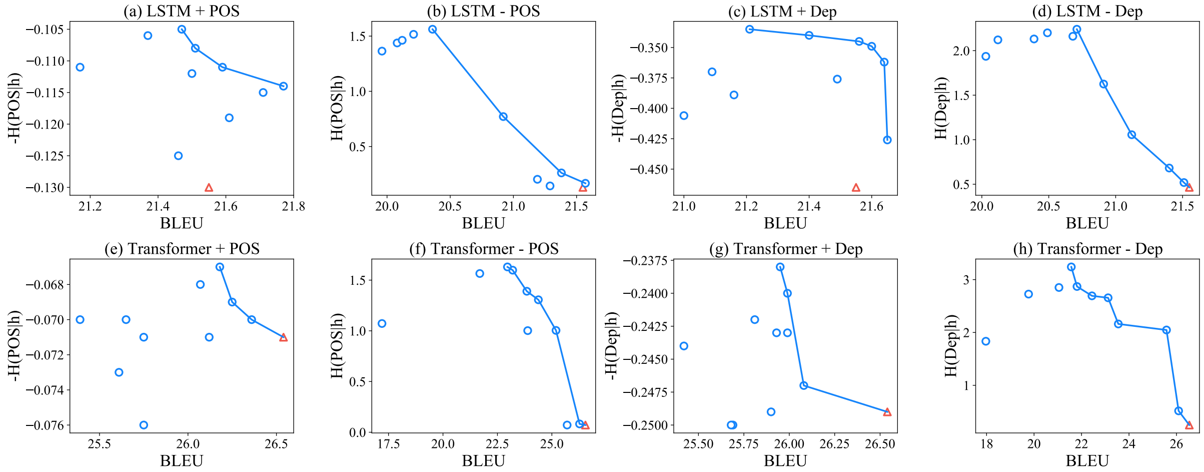

Figure 3: Experiments on WMT14 corpus. Triangle (△) denotes the model trained by minimizing MLE loss, circle (◯) denotes the models obtained by our method, and the models on the line (—) denotes the Pareto frontier.

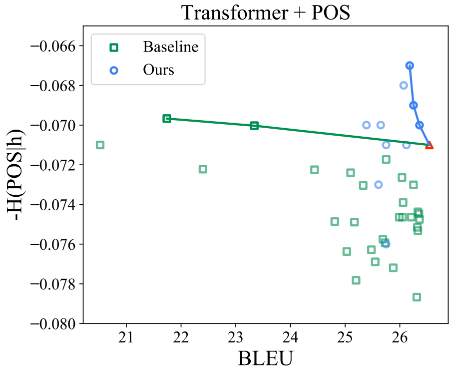

Figure 4: Comparison with baseline method. Triangle (△) denotes the standard model by minimizing MLE loss. The green line and blue line are frontiers got from baseline method and our method respectively.

with 512 hidden units, and the probe model is a 2-layer MLP with 512 hidden units. Our Transformer model consists of a 6-layer encoder and a 6-layer decoder, whose hyper-parameters are the same as the base model in (Vaswani et al., 2017), and the probe model is a 6-layer transformer encoder. For LM experiments, our model is a 2-layer LSTM with 256 hidden states, and the probe model is a 2-layer MLP with 256 hidden states. More training details about our models are shown in appendix A.

6 Experiment Results

In the following experiments, "**Model + Property**", e.g., "Transformer+Pos", which is corresponding to Eq. 4 and studies how adding the linguistic properties information affects the task performance. Instead, "**Model - Property**", e.g., "Transformer-Pos", which is corresponding to Eq. 5 and studies how removing the linguistic properties information affects the task performance. It is worth noting that merging the two frontiers of **+ Property** and **- Property** together would lead to trivial results, because Pareto Optimal points of the **+ Property** are more likely to dominate. However, we think the frontier of **- Property** is helpful for answering the question that whether reducing the encoded linguistic information would affect the model performance. Therefore, we plot the Pareto frontiers for the two objectives independently.

6.1 Soundness of Methodology

The heuristic method mentioned before can be considered as a simple and straightforward baseline method to measure the relationship. To set up this baseline, we firstly save some checkpoints every 1,000 steps when training a standard model. Second, we randomly sample 30 checkpoints for probing and plot a scatter diagram in terms of BLEU and encoded linguistic information.

As shown in Figure 4, we compare our proposed method with the heuristic method in the setting of "Transformer+Pos". Comparing with the baseline method, the frontier obtained from our method is better: for each model explored by baseline, there exists at least one model explored by our method whose two objectives, i.e., encoded linguistic information and BLEU score, are larger. The main reason is that the objective of baseline method only considers the task performance and most checkpoints contain similar encoded linguistic information. Therefore, the models optimized by our multi-objective method is more close to the globally Pareto-optimal points [7], making the

---

[7] It is worth mentioning that there are no algorithms to guarantee globally Pareto-optimal solutions in our scenario

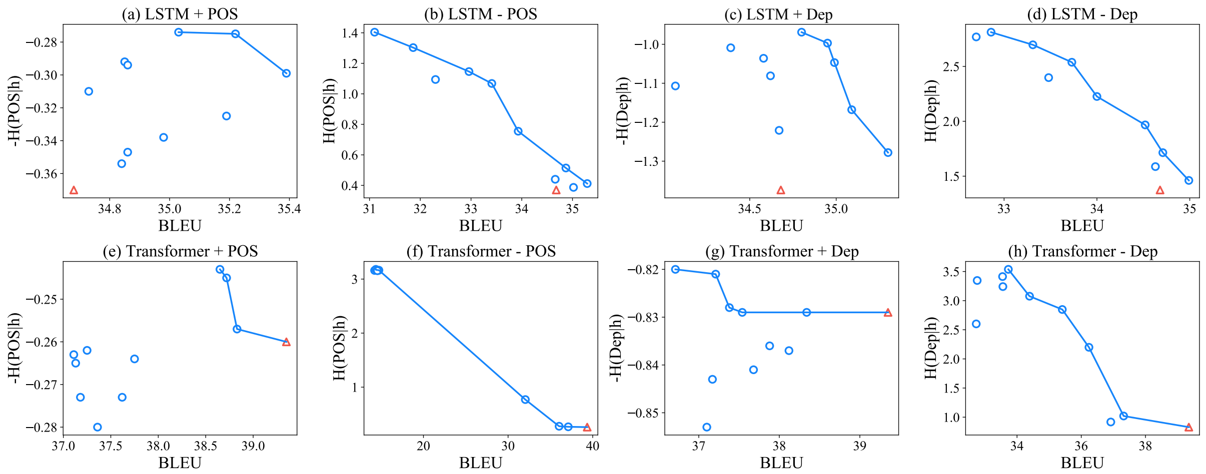

Figure 5: Experimental results on LDC corpus. The format is the same as Fig. 3

revealed relationship between encoded linguistic information and task performance more reliable. Therefore, in the next subsection, our proposed method will be used to visualize the relationship between encoded linguistic information and task performance for neural models.

6.2 Visualization Results

Results on NMT The results of machine translation on the WMT dataset are shown in Figure 3. For LSTM based NMT, we observe that the standard model, i.e., the △ in Figure 3, is not in the Pareto frontier in Figure 3 (a,c). In other words, when adding linguistic information into the LSTM model, it is possible to obtain a model which contains more POS or DEP information and meanwhile leads to better BLEU score than the standard model by standard training. In contrast, for Transformer based NMT, the standard model is in the Pareto frontier, as shown in Figure 3 (e,g). This finding provides an explanation to the fact in NMT: many efforts (Luong et al., 2016; Nădejde et al., 2017; Bastings et al., 2017; Hashimoto and Tsuruoka, 2017; Eriguchi et al., 2017) have been devoted to improve the LSTM based NMT architecture by explicitly modeling linguistic properties, but few have been done on Transformer based NMT (McDonald and Chiang, 2021; Currey and Heafield, 2019). In addition, when removing the linguistic information from LSTM or Transformer, the standard model is very close to the lower right of Pareto frontier, or even at the frontier, as shown in Figure 3 (b,d,f,h). This result shows that removing linguistic information always hurts the performance of NMT models for both LSTM and Transformer, indicating that encoding POS and DEP information is important for NMT task. Similar trends are observed on the LDC datasets, as shown in Figure 5. More details about the effect of randomness on our approach are shown in appendix B.

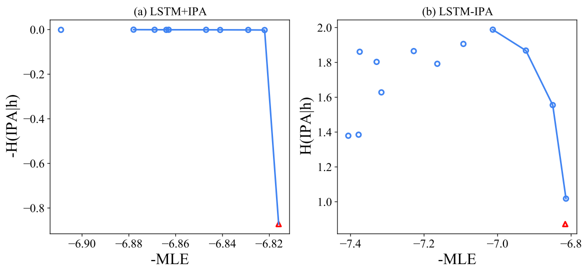

Figure 6: Experimental results on the PTB dataset.

Results on LM Above experiments have shown that both syntactic information are important for NMT models, and then a natural question is whether all kinds of linguistic information are important for neural models. To answer this question, we propose to investigate the influence of phonetic information on a language model. Figure 6 depicts the relationship between encoded phonetic information and task performance for an LSTM based language model. In Figure 6 (a), we find that the performances of Pareto-optimal models drop slightly when forcing an LSTM model to encode more phonetic information. Besides, as the Pareto-frontier shown in Figure 6 (b), removing phonetic information from an LSTM model only leads to a slight change in performance. These experiments demonstrate that the encoded phonetic information may be not that critical for an LSTM based language model. This finding suggest that

---

on the training data. Although the globally Pareto-optimal solutions are unknown, our solutions are definitely more close to them than the solutions by baseline.

not all kinds of linguistic information are crucial for LSTM based LM and it is not promising to further improve language modeling with phonetic information.

7 Conclusion

This paper aims to study the relationship between linguistic information and the task performance and proposes a new viewpoint inspired by the criterion of Pareto Optimality. We formulate this goal as a multi-objective problem and present an effective method to address the problem by leveraging the theory of Pareto optimality. We conduct experiments on both MT and LM tasks and study their performance with respect to linguistic information sources. Experimental results show that the presented approach is more plausible than a baseline method in the sense that it explores better models in terms of both encoded linguistic information and task performance. In addition, we obtain some valuable findings as follows: i) syntactic information encoded by NMT models is important for MT task and reducing it leads to sharply decreased performance; ii) the standard NMT model obtained by minimizing MLE loss is Pareto-optimal for Transformer but it is not the case for LSTM based NMT; iii) reducing the phonetic information encoded by LM models only leads to slight performance drop.

21.49	0.01847	0.108	0
21.52	0.00060	0.1123	0

Table 1: Experiment results from LSTM + POS setting. Specifically, “mean” and “var” denotes the mean and the variance over the window.

A Training Details

On the WMT14 corpus, training one LSTM model with 4 V100 GPUs costs 5 hours, and training one Transformer with 8 V100 GPUs costs 8 hours. On LDC corpus, training one LSTM model with 4 V100 GPUs costs 3 hours, and training one Transformer with 8 V100 GPUs costs 3 hours. On the PTB dataset, training LSTM model with 1 V100 GPU costs 6 minutes.

When running our algorithm, we empirically observe that when λ is below 0.01, the optimized models show little difference comparing with the standard model, and when λ is larger than 0.1, the proposed algorithm becomes unstable and can't converge to Pareto-optimal solutions well. Therefore, we take ten values from 0.1 to 0.01 at equal intervals as λ in Eq. 8, and train ten models with different λ for each condition respectively. Then we plot all the models and the Pareto frontier of these models in the experiments.

B Effects of Randomness

Following the method from Chen et al. (2018), we check if randomness will affect our experimental results. Specifically, we select a window of size 3 around the best checkpoint model and report the mean and variance over the selected window. The results are shown in Table 1. Because repeating experiments under all the settings are too extensive, we only randomly select 4 models from LSTM + POS settings. As shown in the table, all the variances are small, and the variances of the entropy even achieve 0. This suggests that the random disturbance of our experiments are small and thus our results are reliable.

Efficient Argument Structure Extraction with Transfer Learning and Active Learning

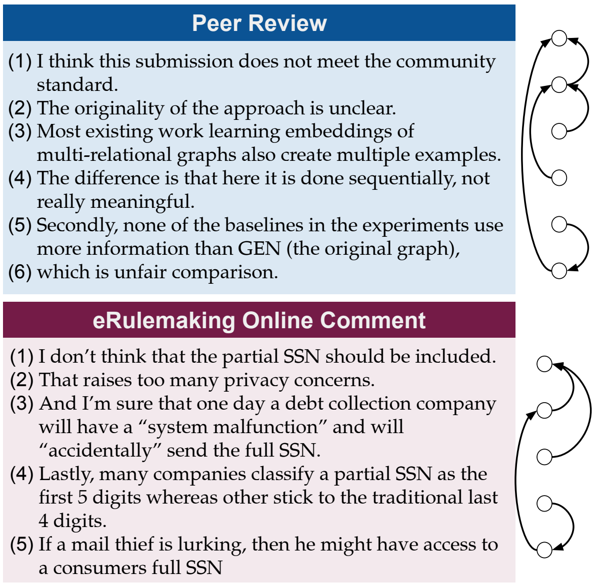
Abstract

The automation of extracting argument structures faces a pair of challenges on (1) encoding long-term contexts to facilitate comprehensive understanding, and (2) improving data efficiency since constructing high-quality argument structures is time-consuming. In this work, we propose a novel context-aware Transformer-based argument structure prediction model which, on five different domains, significantly outperforms models that rely on features or only encode limited contexts. To tackle the difficulty of data annotation, we examine two complementary methods: (i) *transfer learning* to leverage existing annotated data to boost model performance in a new target domain, and (ii) *active learning* to strategically identify a small amount of samples for annotation. We further propose model-independent sample acquisition strategies, which can be generalized to diverse domains. With extensive experiments, we show that our simple-yet-effective acquisition strategies yield competitive results against three strong comparisons. Combined with transfer learning, substantial F1 score boost (5-25) can be further achieved during the early iterations of active learning across domains.

1 Introduction

Identifying and understanding the argumentative discourse structure in text has been a critical task in argument mining (Peldszus and Stede, 2013; Cabrio and Villata, 2018; Lawrence and Reed, 2019; Li et al., 2020). It plays an important role of discovering the central theses and reasoning process across a wide spectrum of domains, from formal text such as legal documents (Palau and Moens, 2009; Lippi and Torroni, 2016; Poudyal et al., 2020) and scientific literature (Mayer et al., 2020; Fergadis et al., 2021; Al Khatib et al., 2021), to online posts and discussions (Cardie et al., 2008; Boltužić and Šnajder, 2014; Park and Cardie, 2014; Habernal and Gurevych, 2017; Hua and Wang, 2017). Here we focus on automatic **argumentative relation prediction**—given any proposition in a document, predict the existence and polarity (support or attack) of relation from any other proposition within a specified context window. One major challenge resides in capturing *long-term dependencies*. As illustrated in Fig. 1, propositions with an argumentative relation are often separated by a large text span, requiring the understanding of a longer context (Nguyen and Litman, 2016; Opitz and Frank, 2019).



Peer Review

(1) I think this submission does not meet the community standard.
(2) The originality of the approach is unclear.
(3) Most existing work learning embeddings of multi-relational graphs also create multiple examples.
(4) The difference is that here it is done sequentially, not really meaningful.
(5) Secondly, none of the baselines in the experiments use more information than GEN (the original graph),
(6) which is unfair comparison.

eRulemaking Online Comment

(1) I don't think that the partial SSN should be included.
(2) That raises too many privacy concerns.
(3) And I'm sure that one day a debt collection company will have a "system malfunction" and will "accidentally" send the full SSN.
(4) Lastly, many companies classify a partial SSN as the first 5 digits whereas other stick to the traditional last 4 digits.
(5) If a mail thief is lurking, then he might have access to a consumers full SSN

Figure 1: Excerpts of arguments in peer reviews and online comments. On the right, argumentative structure is labeled as support relations among propositions. Despite differences in topics and vocabularies, we see similar structural patterns with long-term dependencies, motivating learning transferable representations across domains.

Existing methods for this important task are often time-consuming, as they require at least three steps (Nguyen and Litman, 2016; Stab and Gurevych, 2017; Niculae et al., 2017; Mayer et al., 2020): (1) acquiring high-quality labels from do-

Findings of the Association for Computational Linguistics: ACL 2022, pages 423 - 437
May 22-27, 2022 ©2022 Association for Computational Linguistics

main experts, (2) manually designing customized features to address long dependencies and encode task-specific language, and (3) model training. To exacerbate the challenge, the resulting models are hardly generalizable to new domains.

Consequently, our main goal is to design an *easy-to-use* framework that can facilitate researchers and practitioners to build argument structure extraction models for *new domains rapidly* and *accurately*. To this end, we first propose a novel *context-aware* argument relation prediction model, which can be directly fine-tuned from pre-trained Transformers (Vaswani et al., 2017; Liu et al., 2019). For a given proposition, the model encodes a broad context of neighboring propositions in the same document, and predicts whether each of them supports, attacks, or has no relation to the original one. By contrast, prior work only encodes pairwise propositions while ignoring contexts (Mayer et al., 2020).

Moreover, while training on a large labeled corpus has become the *de facto* method for neural models, labeling argument structures is a laborious process even for experienced annotators with domain knowledge (Green, 2014; Saint-Dizier, 2018; Lippi and Torroni, 2016). Our second goal is to investigate *efficient model training*, by using fewer samples for a new domain. We study the following two complementary techniques: (i) **Transfer learning** (TL) adapts models trained on existing annotated data in a different domain, or leverages unlabeled in-domain data for better representation learning. (ii) **Active learning** (AL) strategically selects *samples in the new domain* based on a sample acquisition strategy with the goal of optimizing training performance. This process is often done in multiple rounds within a given budget (Settles, 2009). As pointed out by Lowell et al. (2019), model-specific selection methods may not generalize across successor models and domains. We thus design model-independent strategies to encourage the inclusion of *unseen words*, and sentences with *discourse markers*. Both are easy to implement and incur little computation cost. We compare them with popular methods based on uncertainty (Lewis and Gale, 1994; Houlsby et al., 2011) and sample diversity (Sener and Savarese, 2018).

For experiments, we release **AMPERE++**[1], the first dataset in the peer review domain labeled with argument relations. Our annotation process involves over 10 months of training and multi-round sessions with experienced annotators, finally yielding $3,636$ relations over 400 reviews originally collected in our prior work (Hua et al., 2019). It has the highest overall relation density and the most attack relations, compared to prior datasets (Table 1). We also evaluate on four other datasets covering diverse topics, including Essays (Stab and Gurevych, 2017), AbstRCT (Mayer et al., 2020) for biomedical paper abstracts, ECHR (Poudyal et al., 2020) for case-law documents, and the Cornell eRulemaking Corpus (CDCP) (Park and Cardie, 2018) for online comments on public policies. Our second data contribution comprises three large collections of unlabeled samples tailored for self-supervised pretraining for the first three domains.

Drawing from extensive experiment results, we make the following observations: (1) Our proposed model, which can encode longer contexts, yields better argument relation prediction results than comparisons or variants that operate over limited contexts (§6.1). (2) TL substantially improves performance for target domains when less labeled data is available. For example, for ECHR and CDCP, using AMPERE++ as the source domain, with only half of the target domain training data, the model achieves better F1 scores than non-transferred model trained over the entire training set (§6.2). This also highlights the value of our AMPERE++ data. (3) Among AL methods, our newly proposed model-independent acquisition strategies yield competitive results against comparisons that require significantly more computations (§6.3). (4) TL further improves all AL setups and narrows the gaps among strategies (§6.3).

2 Related Work

Argument Structure Extraction. Analyzing argumentation in natural language text has seen rapid growth (Lippi and Torroni, 2016; Cabrio and Villata, 2018; Lawrence and Reed, 2019), yet the most challenging aspect of it is to extract the structures among diverse argument components. Conceptually, the structure extraction model needs to address two subtasks: (1) determining which propositions are targeted (head detection), and (2) identifying the argumentative relations towards the head propositions. Early work (Peldszus and Stede, 2013, 2015) takes inspiration from discourse parsing. While practically argument relations can be dis-

---

[1] Data and code are available at `https://xinyuhua.github.io/Resources/acl22/`.

persed across the text, contrary to assumptions in common discourse theory (Mann and Thompson, 1988; Webber et al., 2019). More recent work considers all pairwise combinations of propositions (Stab and Gurevych, 2014; Niculae et al., 2017; Mayer et al., 2020), which incurs expensive computations for long documents. Our model encodes a sequence of propositions and extract their labels in one forward pass, leading to much reduced training and inference complexity while allowing access to more contexts.

Transfer Learning for Structured Prediction. Collecting human annotations for structured tasks is costly, especially when discourse-level understanding and domain expertise are required (Mieskes and Stiegelmayr, 2018; Schulz et al., 2019; Poudyal et al., 2020). It is thus desirable to reuse existing labels from a similar task, and transfer learning (TL) is often employed. It can be divided into two broad categories (Pan and Yang, 2009): (1) *Transductive* approaches adapt models learned from a labeled source domain to a different target domain over the same task, and have shown promising results for discourse (Kishimoto et al., 2020) and argument (Chakrabarty et al., 2019; Accuosto and Saggion, 2019) related tasks. (2) *Inductive* methods aim to leverage unlabeled data, usually in the same domain as the target domain, and have gained popularity with the pre-training and fine-tuning paradigm using Transformer models (Devlin et al., 2019; Gururangan et al., 2020). We study both types in this work, with a particular focus on transductive approaches where the effect of different source domains are compared.

Active Learning (AL) has been explored in many NLP problems including named entity recognition (Tomanek and Hahn, 2009; Shen et al., 2018), text classification (Tong and Koller, 2001; Hoi et al., 2006), and semantic parsing (Iyer et al., 2017; Duong et al., 2018). Unlike the traditional supervised setting where training data is sampled beforehand, AL allows the learning system to actively select samples to maximize the performance, subject to an annotation budget (Settles, 2009; Aggarwal et al., 2014). Common AL strategies are either based on model uncertainty (Houlsby et al., 2011; Yuan et al., 2020), or promoting the diversity in sample distribution (Bodó et al., 2011; Sener and Savarese, 2018). However, both paradigms require coupling sampled data with a specific learned model, which may cause subpar performance by a successor model (Lowell et al., 2019). We propose model-independent acquisition strategies that are faster to train and do not rely on any model.

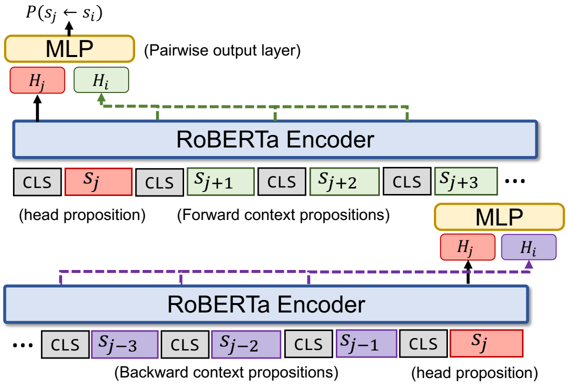


Figure 2: Our context-aware argument relation prediction model. For each head proposition $\boldsymbol{s}_j$, we encode both the backward (purple) and forward (green) contexts. H_j, the last layer states, represents proposition $\boldsymbol{s}_j$. H_i, where i can be $j \pm 1, j \pm 2, \ldots, j \pm L$ (L is the window size), is concatenated with H_j and fed into the pairwise output layer, to yield the probability of $\boldsymbol{s}_j \leftarrow \boldsymbol{s}_i$.

3 Argument Relation Prediction Model

Task Formulation. Given a document that is segmented into a list of propositions, our task is to predict the existence of a `support` or `attack` link $\boldsymbol{s}_j \leftarrow \boldsymbol{s}_i$ between propositions $\boldsymbol{s}_i$ and $\boldsymbol{s}_j$. Here the targeted proposition $\boldsymbol{s}_j$ is the *head*, and $\boldsymbol{s}_i$ is the *tail*. Our end-to-end model considers all proposition pairs. We also consider a simplified setting, where head propositions are given a priori.

A Context-aware Model. Fig. 2 depicts our model: It is built on top of the RoBERTa encoder (Liu et al., 2019) which reads in a sequence of tokens. It contains stacked layers with bidirectional multi-headed self-attentions. Different from prior work that only encodes single propositions, given a head proposition $\boldsymbol{s}_j$, we concatenate it with its surrounding context, including the L propositions before and after it. Propositions are separated by `[CLS]` tokens. We use their last layer's states, denoted as H_j, to represent $\boldsymbol{s}_j$. Other propositions within the window defined by L then become candidates for tail propositions.

After encoding, each tail candidate representation H_i is concatenated with the head representation H_j to form the input to the output layer, with the final prediction formulated as:

$$P(y_r|\boldsymbol{s}_j, \boldsymbol{s}_i) = \text{softmax}(\tanh([H_j; H_i] \cdot \boldsymbol{W}_1) \cdot \boldsymbol{W}_2) \quad (1)$$

where y_r corresponds to three classes: `support`, `attack`, and `no-rel` if there is no link. $\boldsymbol{W}_1$ and $\boldsymbol{W}_2$ are trainable parameters. Dropout (Srivastava et al., 2014) is added between layers.

Training objective is cross-entropy loss over the labels of pairwise propositions within the context window. Our simplified setting reduces the prediction complexity from $\mathcal{O}(n^2)$ (Mayer et al., 2020) to $\mathcal{O}(nL)$, with n being the proposition count.

4 Active Learning Strategies

One major goal of this work is to explore AL solutions that can reduce the amount of samples for annotation, since labeling such a dataset can be the most laborious part of argument structure understanding. We consider a pool-based AL scenario (Settles, 2009), where labels for the training set $\mathcal{U}$ are assumed to be unavailable initially. The learning procedure is carried out in T iterations. In the t-th iteration, b samples are selected using a given acquisition strategy. These samples are labeled and added into the labeled pool to comprise $\mathcal{D}_t$, on which a model $\mathcal{M}_t$ is then trained.

4.1 Comparison Methods

For baselines, we consider **RANDOM-PROP**, which samples b propositions from the unlabeled training set with uniform distribution. Its variant, **RANDOM-CTX**, instead samples at the context level — i.e., for a given head, its entire forward or backward context of L propositions are sampled as a whole, until the total number of propositions reaches b.

The **MAX-ENTROPY** (Lewis and Gale, 1994; Joshi et al., 2009) method selects the most uncertain samples, based on the entropy score $\mathcal{H}(\cdot)$ using the model trained in the previous iteration:

$$\mathcal{H}(y_r|\boldsymbol{s}_j, \boldsymbol{s}_i) = -\sum_r P(y_r|\boldsymbol{s}_j, \boldsymbol{s}_i) \log P(y_r|\boldsymbol{s}_j, \boldsymbol{s}_i) \quad (2)$$

where $P(y_r|\boldsymbol{s}_j, \boldsymbol{s}_i)$ is the predicted probability of a relation label (Eq. 1).

Bayesian Active Learning by Disagreement (**BALD**) (Houlsby et al., 2011) is another common approach to exploit the uncertainty of unlabeled data by applying dropout at test time for multiple runs over the same sample, and picks ones with higher disagreement:

$$\arg\max_{\boldsymbol{s}_i} \mathcal{H}(y_r|\boldsymbol{s}_j, \boldsymbol{s}_i) - \mathbb{E}_\theta[\mathcal{H}(y_r|\boldsymbol{s}_j, \boldsymbol{s}_i, \theta)] \quad (3)$$

Uncertainty-based methods are at risk of selecting "outliers" or alike samples (Settles, 2009). To encourage diversity of the selected samples, we consider **CORESET** (Sener and Savarese, 2018), which enlarges differences among samples and achieves competitive performance in many vision tasks. At a high level, each sample is represented as a vector, e.g., we use the proposition representation H_i. A random set of b samples are selected for labeling in the first iteration. In each subsequent iteration t, data points in the labeled pool $\mathcal{D}_{t-1}$ are treated as cluster centers, and the sample with the greatest L_2 distance from its nearest cluster center is selected. This process is repeated b times to build the new labeled pool $\mathcal{D}_t$.

4.2 Model-independent Acquisition Methods

One risk in AL is that samples selected by a model might not be useful for future models (Lowell et al., 2019). This motivates our design of *model-independent* acquisition methods. Our first method, **NOVEL-VOCAB**, promotes propositions with more unseen words. Assuming the frequency of a word w in the labeled pool is $\mathcal{V}(w)$, the novelty score for an unlabeled sample $\boldsymbol{s}_i$ is computed as:

$$\text{novelty-score}(\boldsymbol{s}_i) = \sum_{w_t \in \boldsymbol{s}_i} \frac{f_{i,t}}{(1 + \mathcal{V}(w_t))} \quad (4)$$

where $f_{i,t}$ is the frequency of word w_t in sample $\boldsymbol{s}_i$. Samples with the highest novelty scores are selected for labeling. If a proposition has a high word overlap with samples in the labeled pool, the denominator $\mathcal{V}(w_t)$ will be high, and this sample is less likely to be chosen.

Our second method, **DISC-MARKER**, aims to select more relation links by matching any of the following 18 prominent discourse markers from PDTB manual (Webber et al., 2019) (matching statistics are in Appendix A.1).[2] For comparison, we also show a complementary approach **NO-DISC-MARKER**, which samples propositions *without* any of those discourse markers.

because	therefore	however
although	though	nevertheless
nonetheless	thus	hence
consequently	for this reason	due to
in particular	particularly	specifically
in fact	actually	but

---

[2] When matched sentences exceed selection budget, we randomly sample with equal probabilities.

Density	21.8%	13.8%	20.0%	11.7%	21.0%

Table 1: Statistics of five datasets, including our AMPERE++ data with newly annotated relations on AMPERE (Hua et al., 2019). We report the total numbers of documents (# Doc.), tokens (# Tok.), propositions (# Prop.), support (# Supp.) and attack (# Att.) relations, unique head propositions (# Head), and relation density as the percentage of propositions that are supported or attacked by at least one proposition.

5 Datasets and Domains

We experiment with five datasets from distinct domains, with key statistics listed in Table 1. Below we outline data collection and annotation, notable preprocessing steps, and data splits.

Domain 1: Peer Reviews (New Annotation). We first annotate argument relations on AMPERE (Hua et al., 2019), which consists of 400 ICLR 2018 paper reviews collected from OpenReview. Each review has been annotated with segmented propositions and corresponding types (i.e., *evaluation*, *request*, *fact*, *reference*, and *quote*). We augment this dataset by labeling the support and attack relations among the propositions. This new dataset is called **AMPERE++**.

We hire three proficient English speakers to annotate the entire dataset in multiple rounds. During annotation, they are displayed with the propositions along with their types. We impose two constraints. (1) Each proposition can only support or attack at most one other proposition. (2) Factual propositions (*fact*, *reference*, *quote*) cannot be supported or attacked by subjective ones (*evaluation*, *request*). Similar rules are used by Park and Cardie (2018). We include detailed guidelines in Appendix B. For quality control and disagreement resolution, the annotators are joined by a fourth judge after each round, where they discuss samples with different labels to reach agreement.

The resulting dataset contains 3,636 relations from 400 reviews with a substantial inter-annotator agreement score of 0.654 (Fleiss' κ). Following our prior work (Hua et al., 2019), we use 300 reviews for training, 20 for validation, and 80 for test. We also collect 42k reviews from OpenReview for ICLR 2019-2021, UAI 2018, and NeurIPS 2013-2020, which are used in the self-supervised learning experiments for improving representation learning.

Domain 2: Essays. Our second dataset is based on the essays curated by Stab and Gurevych (2017) from `essaysforum.com`. Argumentative propositions are identified at the sub-sentence level and labeled as "*premise*", "*claim*", or "*major claim*". Support and attack relations are annotated from a premise to a claim or to another premise. The link cannot cross paragraph boundaries, highlighting the dataset's focus on relations close by.

We split the original training set into 282 essays for training and 40 for validation. The remaining 80 are reserved for test. Similarly, we also download 26K essays from the same online forum for self-supervised representation learning.

Domain 3: Biomedical Paper Abstracts. Next, we use the **AbstRCT** corpus (Mayer et al., 2020), which contains 700 paper abstracts retrieved from PubMed.[3] The primary subjects are Randomized Controlled Trials of diseases. Notably, AbstRCT has much fewer propositions and relations than the previous two datasets, due to the factual nature of paper abstracts.

Following Mayer et al. (2020), we use 350 abstracts for training, 50 for validation, and 300 for test. We employ the 133K unlabeled abstracts released by Cohan et al. (2018) for self-supervision.

Domain 4: Legal Documents. Legal texts are studied in the early work of argument mining (Palau and Moens, 2009; Lippi and Torroni, 2016). We choose the **ECHR** corpus (Poudyal et al., 2020), containing 42 recently-annotated case-law documents of the European Court of Human Rights. The authors define an argument structure as a list of premises and a conclusion. We consider each premise as linked to the corresponding conclusion. The dataset is split into 27 documents for training, 7 for validation, and 8 for test.

Domain 5: Online User Comments. Finally, we include the Cornell eRulemaking Corpus (Park and Cardie, 2018), extracted from an online forum where the public argues for or against proposed rules. The 731 annotated comments are mostly related to the Consumer Debt Collection Practices

---

[3] `https://pubmed.ncbi.nlm.nih.gov/`

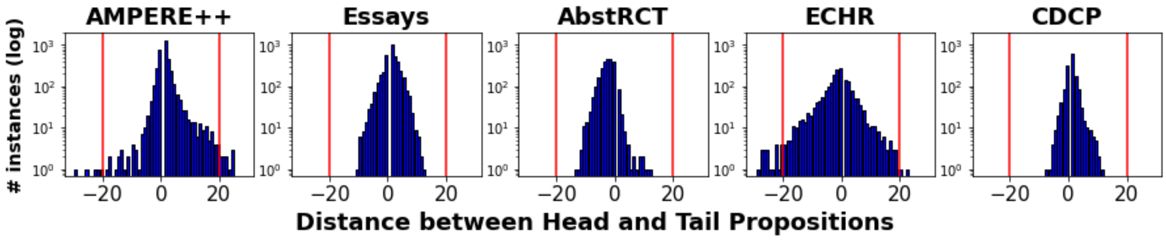

Figure 3: Distribution of distance (measured by number of propositions) between head-tail pairs across five domains. Positive values indicate that the tail appears after the head in the document, and vice versa.

rule (**CDCP**), and is annotated with support relations only. We adopt the original splits: 501 for training, 80 for validation, and 150 for test. On average, there are less than two relation links per comment, and only 21% of the propositions are supported.

Head-tail Distance Distribution. Recall that our context-aware model only encodes context propositions up to a fixed window size. Although this setup neglects some relation links, we show in Fig. 3 that a large enough window size (e.g., 20) is sufficient to cover all (Essays, CDCP, AbstRCT) or over 98% (AMPERE++, ECHR) of all relations.

Fig. 3 further highlights domain-specific patterns. AMPERE++ and CDCP are skewed to the right, indicating reviewers and online users tend to put their claims upfront with supporting arguments appearing later. On the contrary, paper abstracts (AbstRCT) usually describe premises first and then draw conclusions. Essays and ECHR have more balanced distributions between both directions.

Proposition Length and Label Distribution. Due to differences in argument schemes, proposition length varies considerably across domains. AbstRCT has the longest propositions with an average of 45 tokens. Consequently, the actual encoder input may contain less than 20 propositions due to the maximum token limit. Under our context-aware encoding, the ratio of positive samples (`support` or `attack`) is boosted to 29% because they are less likely to be truncated due to the relative proximity to head propositions (Fig. 3). The other four domains have similar positive ratios, ranging from 6% (AMPERE++) to 17% (CDCP).

Existing relation prediction methods (Stab and Gurevych, 2017; Niculae et al., 2017; Mayer et al., 2020) label all pairwise propositions within the same document, leading to much lower positive ratios, especially for ECHR where documents are long. In §6.1 we show that such unbalanced distribution poses difficulties for traditional methods.

6 Experiments and Results

In this section, we design experiments to answer the following questions. (1) To which degree is the context-aware model better at identifying argumentative relations (§6.1)? (2) How much improvement can transfer learning (TL) make when different source domains are considered for a target domain (§6.2)? (3) Does unlabeled in-domain data help downstream tasks using self-supervised pretraining and inductive transfer learning (§6.2)? (4) How do active learning (AL) strategies perform on relation prediction and whether combining transfer learning leads to further performance boost (§6.3)?

Evaluation is based on macro-F1 scores as done in prior work (Stab and Gurevych, 2017; Niculae et al., 2017). For tasks without attack labels (ECHR and CDCP), the macro average is calculated over `support` and `no-rel` only, otherwise it is averaged over three classes. Each setup is run five times with different random seeds, and the average scores on test sets are reported.

Implementation of our models is based on the Transformer (Wolf et al., 2020). Our encoder is RoBERTa-base (Liu et al., 2019), which has 12 layers with a hidden size of 768. We apply dropout (Srivastava et al., 2014) with a probability of 0.1 for the output MLP layer. We use the Adam optimizer (Kingma and Ba, 2015) with 16 sequences per batch. We hypertune our proposed argument relation prediction model with different number of maximum training epochs $\{5, 10, 15\}$, warmup steps $\{0, 1000, 5000\}$, learning rate $\{1\text{e-}5, 1\text{e-}6, 5\text{e-}5\}$, and scheduler $\{\texttt{constant}, \texttt{linear}\}$. The best validation result is achieved with 15 epochs, 5000 warmup steps, 1e-5 as learning rate, and the `constant` scheduler. We use this configuration for all model training experiments.

	AMPERE++	Essays	AbstRCT	ECHR	CDCP
SVM-linear	24.82	28.69	33.60	21.18	29.01
SVM-RBF	26.38	31.68	32.65	21.36	30.34

$L = 10$	75.69	69.41	59.27	67.51	69.47
$L = 20$	**77.64**	71.30	63.62	**70.82**	**70.37**
OURS (end-to-end)					
$L = 20$	74.34	67.68	63.73	61.35	63.13

Table 2: F1 scores for argument relation prediction. Each entry is averaged over five runs with different random seeds. The best result for each dataset is **bolded**. Our context-aware model outperforms both baselines except for AbstRCT. The difference between *head given* and *end-to-end* is close, suggesting that the key challenge for structure extraction lies in relation prediction. Our model performance improves when larger window size L is used.

6.1 Supervised Learning Results

We first evaluate our model with the standard supervised learning over the full training set using varying window sizes. We assume the heads are given at both training and inference, except for the end-to-end setting.

Comparisons. We implement an **SVM** with features adapted from Table 10 of Stab and Gurevych (2017), except for features specific to the essays domain (e.g., whether a proposition is in the introduction). We experiment with both linear and radial-basis function (RBF) kernels, with regularization coefficients tuned on validation. More details can be found in Appendix A.2.

SEQPAIR is based on the sequence pair classification setup (Devlin et al., 2019) using the pretrained RoBERTa. Each pair of head and tail is concatenated and segmented with the `[SEP]` token. The `[CLS]` token is prepended to the beginning of the sequence and used for classification. This setup resembles the model in Mayer et al. (2020).

We further compare with two dataset-specific **BENCHMARK** models: Stab and Gurevych (2017) use a rich set of features tailored for essays to train SVMs, and Niculae et al. (2017) employ structured SVMs on CDCP.

Results. As shown in Table 2, our context-aware model outperforms the comparisons except for Essays and AbstRCT. The feature-rich SVM marginally outperforms our model, though the features are not generalizable to new domains. As mentioned in §5, AbstRCT has much higher positive ratio than other domains. This indicates that our model is more robust against unbalanced training data than the pairwise approach.

The performance drop for end-to-end models are marginal in most cases, underscoring relation prediction as the key challenge for structure extraction, which the simplified setup has to tackle as well.

6.2 Transfer Learning Results

Results in the previous section show large performance discrepancies among different domains. For instance, domains with few labeled samples, such as AbstRCT and CDCP, lead to worse performance. Moreover, annotating argument structures for some domains is even more involved, e.g., Poudyal et al. (2020) hired three lawyers to annotate ECHR legal documents. We hypothesize that basic reasoning skills for understanding argument structures can be shared across domains, thus we study transfer learning, a well-suited technique that leverages existing data with similar task labels (*transductive*) or unlabeled data of the same target domain (*inductive*). Concretely, we present thorough experiments of TL over all transfer pairs, where the model is first trained on the source domain and fine-tuned on the target domain.

Transductive TL. The upper half of Table 3 shows that *three out of four models transferred from AMPERE++ achieve better performance than their supervised learning counterparts in Table 2*. In particular, we observe more than 5 F1 points gains on ECHR and CDCP, which contain the least amount of labeled samples. However, when transferred from the four other datasets, performance occasionally drops. This can be due to the distinct language style and argumentative structure (AbstRCT), the source domain size (CDCP, ECHR), or the model's failure to learn good representations due to over-reliance on discourse markers (Essays). Overall, *AMPERE++ consistently benefits diverse domains for argument structure understanding, demonstrating its usage for future research.*

Inductive TL. Motivated by recent findings (Beltagy et al., 2019; Lee et al., 2020; Gururangan et al., 2020) that self-supervised pre-training over specific domains significantly improves downstream tasks, we also consider the *inductive* transfer learning setup with the following two objectives: (1) masked language

	AMPERE++	Essays	AbstRCT	ECHR	CDCP
SRC → TGT (Transductive TL)					
AMPERE++	–	73.84	63.42	**76.50**	**75.93**
Essays	77.93	–	60.62	68.72	74.11

AMPERE++	–	**74.90**	62.34	–	–
Essays	76.69	–	62.38	–	–
AbstRCT	**79.52**	73.09	–	–	–

Table 3: Results for transfer learning. First column denotes the source domain, the rest are target domains. The best result per column is in **bold**. Transfer learning that outperforms the in-domain training setup (Table 2, second last row) is highlighted in green. Notably, using AMPERE++ as the source domain yields better performance than the standard supervised setting. Overall, self-supervised pre-training can further benefit transductive transfer learning.

model (**MLM**) prediction, which randomly selects 15% of the input tokens for prediction as done in Devlin et al. (2019); (2) **context-aware sentence perturbation** (**Context-Pert**), which packs each document into a sequence of sentences segmented by the `[CLS]` token, 20% of which are replaced by random sentences from other documents, another 20% shuffled within the same document, and the rest unchanged. The pre-training objective is to predict the perturbation type of each sentence. Results are in the middle part of Table 3, where MLM pre-training benefits all three domains. Context-Pert improves AMPERE++ even more, but negatively affects the other two domains.

Combining Inductive and Transductive TL. Moreover, we showcase that *adding self-supervised learning as an extra pre-training step for transductive TL further boosts performance.* From the lower half of Table 3, the pre-trained model uniformly improves over the standard transductive TL. Notably, *using target domain for pre-training leads to better results than using the source domain data.* This implies that better representation learning for target domain language is more effective than a stronger source domain model.

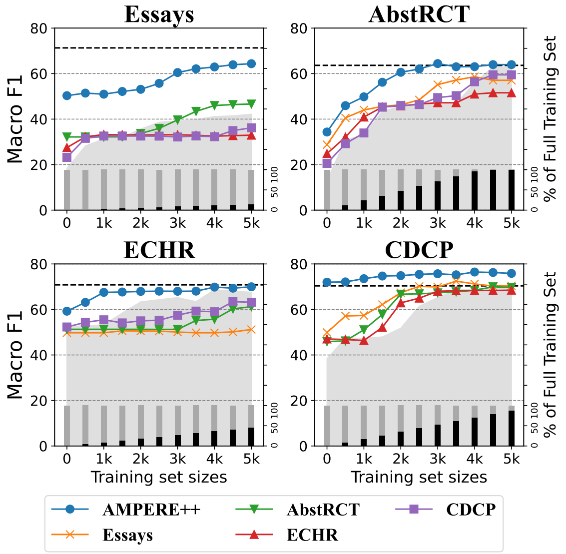

Figure 4: Macro F1 scores with limited training data. We sample training set from 0 to 5,000 samples, in an increment of 500. Bottom bars indicate the percentage of such subsets over the full training set. Scatter plots represent the transfer learning results from different source domains, with those from non-TL settings marked as shaded areas. Horizontal dashed lines represent the performance using the full training set. Models using AMPERE++ as the source domain consistently yield better F1 scores than others and non-TL models.

Effectiveness of TL in Low-Resource Setting. To quantitatively demonstrate how TL benefits low-resource target domains, we control the size of training data and conduct transductive TL for each domain. Fig. 4 plots the trends where training data varies from 0 to 5,000, incremented by 500. *Among all datasets, AMPERE++ yields the best transfer learning results as the source domain: Using less than half of the target training set, it allows to approach or exceed the fully trained models.* For other datasets, we observe mixed results when they are used as the source. In general, TL brings more improvements when less training data is used.

6.3 Active Learning Results

Comparisons of Acquisition Strategies. Fig. 5 plots the F1 scores for all strategies as discussed in §4 across 10 AL iterations. As expected, the performance gradually improves with more labeled data. The three model-based methods: **MAX-ENTROPY**, **BALD**, and **CORESET** generally attain better performance, suggesting the efficacy of common AL methods on argument relation understanding. The model-independent strategies yield competitive results. In particular, **DISC-MARKER** proves to be

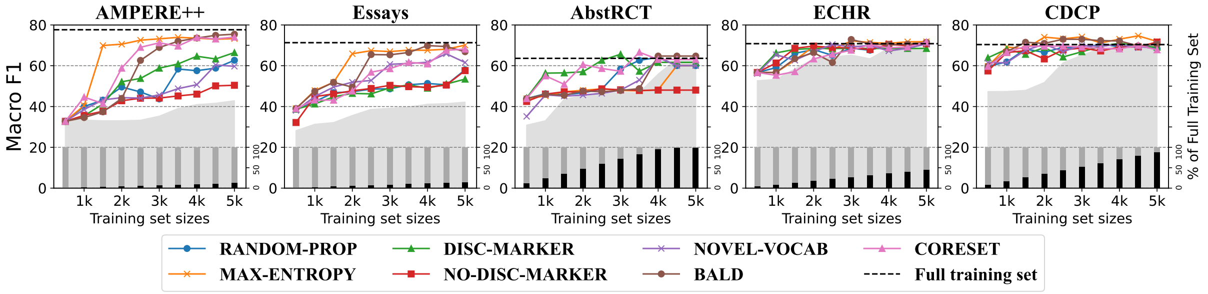

Figure 5: Active learning results using different acquisition methods in 10 iterations. Shaded areas stand for the **RANDOM-CTX** performance, which aligns with that in Figure 4. We show performance for three model-independent strategies, **DISC-MARKER**, **NOVEL-VOCAB**, **NO-DISC-MARKER**, alongside three strong comparisons. The model-independent strategies yields significantly better results than random sampling. On AbstRCT, ECHR, and CDCP, **DISC-MARKER** achieves better or competitive performance than **MAX-ENTROPY** and **BALD**. To better visualize the performance difference, rescaled plots for ECHR and CDCP are in Appendix A.3.

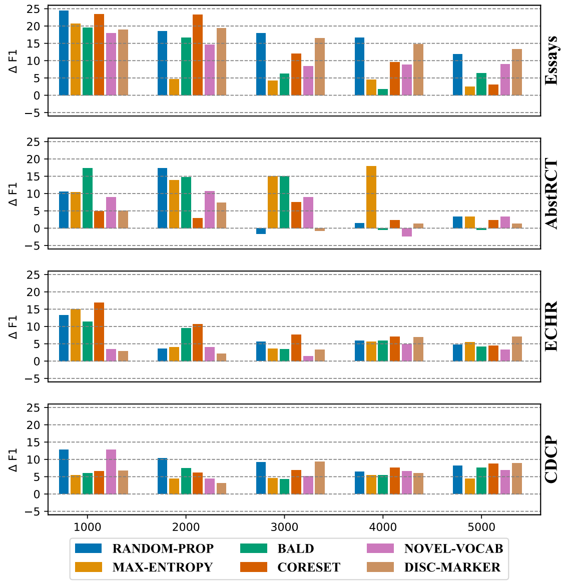

Figure 6: Improvements of macro F1 scores by adding TL to each AL strategy. AMPERE++ is used as the source domain for TL. We observe consistent gains across the board except for AbstRCT when the training samples are close to full. Generally, the improvements decline when more training samples are included.

a good selection heuristics for AMPERE++ and AbstRCT. Its relatively low scores on Essays is likely due to the abundance of discourse markers in this domain, so that random sampling would have similar effects. By contrast, avoiding discourse markers (**NO-DISC-MARKER**) tends to hurt performance. Notably, *without relying on any trained model, task-specific acquisition strategies can be effective for labeling argument relations.*

Warm-start Active Learning. Finally, we investigate the added benefits of transfer learning for major active learning systems. In each AL iteration, we warm-start the model with checkpoints trained from AMPERE++, and calculate the difference of F1 scores from the non-TL counterpart. Fig. 6 shows the results for five of the ten iterations. We observe improvements across the board, especially with small training data size. For AbstRCT, the TL warm-start either makes no difference or slightly hurts performance after 3,000 samples are available, whereas the **MAX-ENTROPY** method constantly benefits from warm-starting. Our findings suggest that TL is an effective add-on for early stage AL, benefiting different strategies uniformly.

7 Conclusion

We present a simple yet effective framework for argument structure extraction, based on a context-aware Transformer model that outperforms strong comparisons on five distinct domains, including our newly annotated dataset on peer reviews. We further investigate two complementary frameworks based on transfer learning and active learning to tackle the data scarcity issue. Based on our extensive experiments, transfer learning from our newly annotated AMPERE++ dataset and self-supervised pre-training consistently yield better performance. Our model-independent strategies approach popular model-based active learning methods.

A Model and General Details

A.1 Discourse Markers

In §4.2 of the main paper we introduce a **DISC-MARKER** based acquisition method for active learning. The matching statistics of the 18 discourse markers are shown in Fig. 8. We break down the count based on whether a proposition is the `head` or `tail` of any relation. As expected, certain discourse markers such as “because”, “but”, and “due to” likely indicate a `tail` proposition, whereas “therefore”, “thus” tend to be found in `head` propositions.

A.2 SVM Comparison

In Table 4, we describe the full feature set used in the SVM comparison model in § 6.1 of the main paper. These features are adapted from Table 10 of Stab and Gurevych (2014). The indicators are from their Table B.1 in the Appendix.

For hyper-parameter search, we tune the regularization coefficient C over values $\{0.1, 0.5, 1.0, 10.0\}$. The best performing model (macro-F1) on validation set is used for evaluation.

Group	Description
Lexical	Binary lemmatized unigram of the head and tail propositions (top 500 frequent ones are considered)
Syntactic	Binary POS features of head and tail propoisitions
Structural	Number of tokens of head and tail; Number of propositions between source and tail; head presents before tail; tail presents before head
Indicator	Indicator type present in head or tail; indicator type present between head and tail
ShNo	Shared nouns between head and tail propositions (number and binary)

Table 4: Features used for SVM model.

A.3 Active Learning Results

In Fig. 5, we compare active learning methods over five datasets on the same 0-80 scale. Results of different strategies fall in tight ranges for ECHR and CDCP. For better visualization, we show the same figure on a 50–80 scale in Fig. 7.

B AMPERE++ Annotation

To annotate argument relations over the AMPERE (Hua et al., 2019) dataset, we hire three proficient English speakers who are US-based college students. The first author serve as the judge to resolve disagreements.The detailed guidelines are shown in Table 6. Throughout the annotation, we identify difficult cases and summarize representative ones in Table 5.

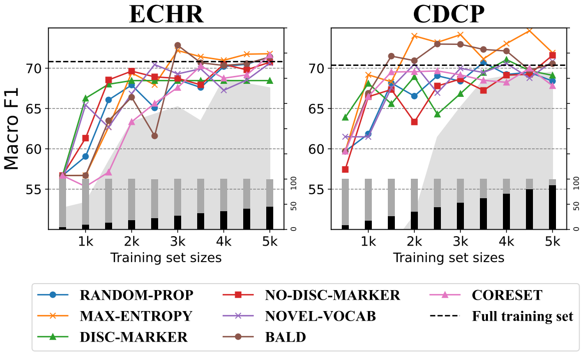

Figure 7: Active learning results for ECHR and CDCP on 50–80 scale. The scores are the same as the rightmost two plots in Figure 5.

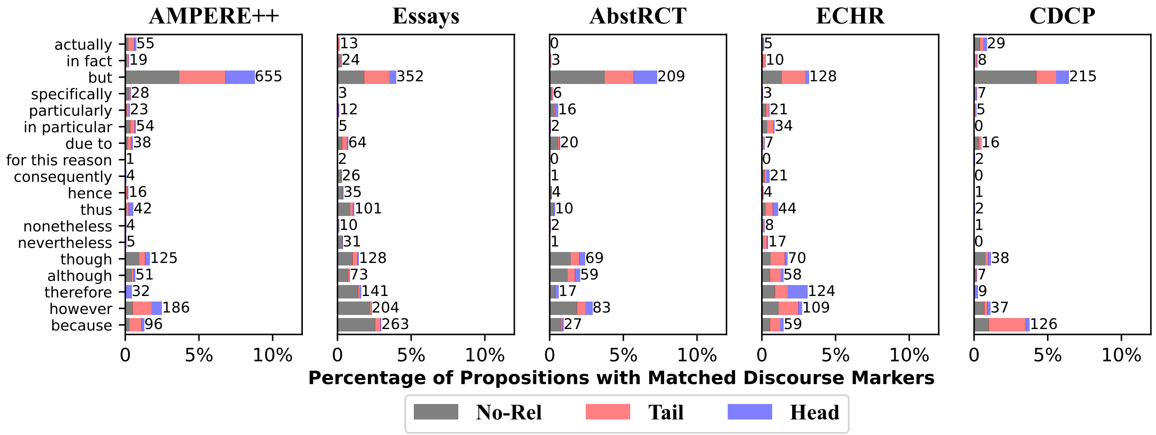

Figure 8: The distribution of matched discourse markers in each dataset. We indicate the raw count next to each bar. Propositions that are `tail` or `head` of any relation are highlighted in colors. Overall, about 10–20% of the propositions contain at least one discourse marker. Certain discourse markers correlate well with the existence of argument relations. For instance, "because", "due to", "however" are more likely to be found in `tail`; "therefore", "thus" tend to appear in `head`.

Tail	Only macro-average F-scores are reported.
Head	Please present micro-average scores as well
Label	`support`
Tail	Fig 3: This could really be drawn considerably better
Head	Make the dots bigger and their colors more distinct.
Label	`support`
Tail	Fig 4. right looks like a reward signal.
Head	but is labelled Proportion correct.
Label	`attack`
Tail	This idea is not novel
Head	In the first part of the paper (Section 2) the authors propose to use the optimal transport distance . . . as the objective for GAN optimization.
Label	`attack`
Tail	Then, the difference is crystal clear.
Head	The difference between Figure 1, 4, and 6 could be clarified.
Label	`no-rel`
Tail	The discussion following Corollary 1 suggests that $\sum_i \hat{v}_{T,i}^{1/2}$ might be much smaller than d G_∞.
Head	but we should always expect it to be at least a constant,
Label	`no-rel`

Table 5: Representative challenging examples during argument relation annotation on AMPERE++.

General Instruction
In the following studies, you will read a total of 400 peer reviews collected from the ICLR-2018 conference. The annotation is carried out in 20 rounds. In each round, you will independently annotate 20 reviews and upload to the server. All annotators will meet and discuss the disagreements. Another judge will resolve the cases and add it to the pool of samples for future reference.

Annotation Schema
Each review document is already segmented into chunks of argumentative discourse units (ADU), which is the basis for relation annotation. Prior work has provided labels for types of these ADUs:

EVALUATION: Subjective statements, often containing qualitative judgement.
REQUEST: Statements requesting a course of action.
FACT: Objective information of the paper or commonsense knowledge.
REFERENCE: Citations or URLS.
QUOTE: Quoations from the paper.
NON-ARG: Non-argumentative statements.

Please first read the entire review. Then, from the beginning of the document, start annotating support and attack relations. We consider a support relation holds from proposition `A` to proposition `B` if and only if the validity of `B` can be undermined without `A`, or `A` presents concrete examples to generalize `B`. For example, "*It is unclear which hacks are the method generally.*" is supported by "*Because the method is only evaluated in one environment.*".

We consider an attack relation holds from proposition `A` to proposition `B` if and only if `A` contrasts or questions `B`'s stance. For example, "*The authors mentioned that the grammar in general is not context free.*" is attacked by "*But the grammar is clearly context-free.*"

Both the support and attack relations can be implicit or explicit. Explicit relations are indicated by discourse markers, whereas implicit relations require inference from the context. For example, "*In particular, how does the variational posterior change as a result of the hierarchical prior?*" implicitly supports "*It's not clear as to why this approach is beneficial*". Because the question instantiates the "unclear" claim regarding the approach.

Special Cases
Please enforce the following constraints:

1. The factual propositions (i.e., FACT, REFERENCE, QUOTE) cannot be supported by any subjective propositions (i.e., EVALUATION, REQUEST).
2. One proposition can support or attack at most one proposition.
3. Chain support does not need to be explicitly annotated. For instance, if `A` supports `B`, `B` supports `C`, then `A` supports `C` does not need annotation.

Table 6: Argumentative relation annotation guideline for AMPERE++.

Plug-and-Play Adaptation for Continuously-updated QA

Abstract

Language models (LMs) have shown great potential as implicit knowledge bases (KBs). And for their practical use, knowledge in LMs need to be updated periodically. However, existing tasks to assess LMs' efficacy as KBs do not adequately consider multiple large-scale updates. To this end, we first propose a novel task—Continuously-updated QA (CuQA)—in which multiple large-scale updates are made to LMs, and the performance is measured with respect to the success in adding and updating knowledge while retaining existing knowledge. We then present LMs with plug-in modules that effectively handle the updates. Experiments conducted on zsRE QA and NQ datasets show that our method outperforms existing approaches. We find that our method is 4x more effective in terms of updates/forgets ratio, compared to a fine-tuning baseline.

1 Introduction

LM-as-KB is a new paradigm in which pre-trained language models (LMs) are used as implicit knowledge bases (KBs) (Petroni et al., 2019). This is made possible by LMs' impressive ability to memorize factual knowledge (Heinzerling and Inui, 2021; Brown et al., 2020). Recently, two tasks have been used to assess such ability: LAMA, a knowledge probing benchmark, challenges LMs to fill in masked words over relational knowledge (Petroni et al., 2019); and closed-book QA (CBQA) examines whether LMs can correctly answer natural language questions (Roberts et al., 2020).

For practical usage, LM-as-KB requires that LMs are updated periodically to stay current with the ever-evolving world. Thus, LMs' ability to update knowledge should also be evaluated. To this end, we present **Continuously-updated QA (CuQA)**, which tests the ability to continuously inject knowledge to update (or **target knowledge**), while retaining existing knowledge (or **source knowledge**). Specifically, we consider multiple large-scale knowledge updates (8k to 60k) covering two scenarios: injecting new knowledge (Scenario 1 in Figure 1) and updating existing knowledge (Scenario 2 in Figure 1) .

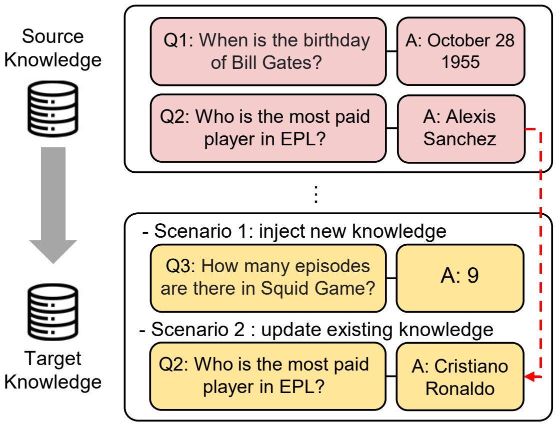

Figure 1: Examples of CuQA showcasing two scenarios.

Our goal is to organize the implicit storage of knowledge, to add target knowledge (*yellow box* in Figure 1) and anchor to select target knowledge. A simple approach is to train updated LMs from scratch; however, this is far too expensive considering the parameter sizes of recent LMs, such as 175B for GPT-3 (Brown et al., 2020) and about 11B for T5 (Raffel et al., 2020). There has also been related work for the two scenarios. For Scenario 1, a method for continual learning can be adopted, constraining the distance between parameters before and after fine-tuning (Chen et al., 2020). However, this approach still suffers from so-called catastrophic forgetting, where the LMs fail to retain large amounts of source knowledge. For Scenario 2, one may consider knowledge editing methods, where we see reasonable performances for a single knowledge edit while retaining the rest (De Cao et al., 2021; Mitchell et al., 2021). However, this line of work does not perform well when multiple

---

Findings of the Association for Computational Linguistics: ACL 2022, pages 438 - 447
May 22-27, 2022

edits are accumulated, *e.g.*, only 67% of 125 edits were updated, as reported in (Mitchell et al., 2021).

We propose to efficiently extend LMs with plug-and-play modules that store target knowledge. More specifically, we adopt a parameter-expansion method in which the LM storing existing knowledge is extended with plug-in feed-forward modules storing updated knowledge. Depending on the input, the LM selectively uses either the original LM or a plug-in module. We stress that, by keeping the original LM intact, we retain (a) not only source knowledge, (b) but also those outdated from updates (*red arrow* in Figure 1). (a) is important to avoid catastrophic forgetting, while (b) is useful when updates need to be reverted due to ethical concerns—for example, there can be malicious attempts to override facts.

We evaluate our approach on zsRE (Levy et al., 2017) and Natural Questions (Kwiatkowski et al., 2019) to showcase successful updates of new knowledge and retention of existing knowledge. We measure the accuracies on both previous and updated knowledge and find that ours show x4 higher updates/forgets ratio, compared to fine-tuning. We also release our code and dataset.[1]

Our key contributions are as follows:

- We present CuQA, a novel task to assess LMs' ability to continuously inject knowledge to update.
- We propose a new methodology, plug-and-play adaptation, to continually learn new knowledge while better retaining existing knowledge.

2 Related Work

The relevant research can be categorized into three groups: Knowledge Editing, Continual Learning, and Adaptation. In Table 1, we compare these with our method.

Method	Forgetting less?	Scales to a large set?	Conflict with old facts?
(a) Editing	✓	✗	✓
(b) CL	✓	✓	✗
(c) Adaptation	✗	✓	✗
Our Method	✓	✓	✓

Table 1: Conceptual comparison of existing approaches.

Editing Implicit Knowledge In Table 1(a), knowledge editing methods (De Cao et al., 2021; Mitchell et al., 2021; Dai et al., 2021) aim to efficiently edit model's parameters on examples that have conflicts with old facts, while preserving the outputs of untargeted examples. Instead of directly updating gradients by fine-tuning, these methods transform the gradients for new edit parameters. As representative methods for knowledge editing, KnowledgeEditor (KE) (De Cao et al., 2021) using LSTM produces gate vectors, then the gated sum of gradients is updated into the model, while MEND (Mitchell et al., 2021) uses simple MLP layers and residual connections for the same purpose. Although these methods succeeded in updating the target examples less forgetting, their target scenario is a single edit, such that the cumulative effect of multiple edits does not reflect well, which disqualifies its use for our target task of update large-scale data (8K$\sim$60K). As reported in (Mitchell et al., 2021), MEND successfully updates only 67% of edits when applying 125 edits, while our finding was consistent when none of the 125 edits was applied in our evaluation.[2] In addition, for editing previous knowledge, KE and MEND simulate knowledge updates, by generating synthetic knowledge from LM. Such generations may not be realistic data and also give unfair advantages to LM-based methods, while we use actual up-to-date knowledge as new data, which were annotated on recent corpus (Zhang and Choi, 2021).

Continual Learning (CL) for NLP For our task, we can adopt CL methods, learning a new task while preserving the accuracy on previous tasks. Kirkpatrick et al. (2017) proposed Elastic Weight Consolidation, alleviating catastrophic forgetting. This method regularizes learning on a new task, by constraining the parameters trained on the previous task. For NLP tasks, RecAdam (Chen et al., 2020) uses the regularization and annealing technique, which is a CL baseline in our experiment. While CL approaches focusing on forgetting do not consider conflicts between old and new knowledge, our work deals with such a realistic scenario. Additionally, previous work (Dhingra et al., 2021) proposed benchmarks for probing temporal language models, asking "Fill-in-the-Blank (FIB)" questions. Meanwhile, FIB questions are limited to evaluate masked language models, such as BERT and RoBERTa. We extend to evaluate arbitrary questions for a knowledge-intensive task; closed-

book QA, which can evaluate generative LMs with broader applicability, to include T5 and GPT.

Task-aware Adaptation for Transformers Recent works (Hu et al., 2021; Wang et al., 2020; Lin et al., 2020) study LM adaptation to new labeled data in a new domain, which has a different data distribution from that at pretraining. These works show performance improvements on downstream tasks in the new domain, while fine-tuning a small number of parameters. However, these adaptation methods do not consider sequential training, and overwrite the new data into the parameters that store previous knowledge. In our experiment, it is observed that the adaptation methods are rapidly forgetting previously seen data, while performing well on new knowledge.

3 A Continuously-updated QA Task

Task Description In this section, we propose Continuously-updated QA (CuQA), a new continual learning task for knowledge updates in LMs based on closed-book QA (CBQA) (Roberts et al., 2020). In CBQA, LMs answer factual questions with the implicit knowledge stored in the model, without any external context (*i.e.*, in contrast to open-domain QA), so that LMs are required to adequately update their parameters to the target knowledge. In our CuQA, LMs learn source (original) knowledge first, then update them with target (new) knowledge without source knowledge access. For the above setting, source knowledge (to be retained) and target knowledge (to be added) in CuQA do not have any overlap of QA pairs (or paraphrases) for any given fact.

Specifically, we denote a factual pair of question and answer as (q, a), source knowledge as $\mathcal{K}_s$, and target as $\mathcal{K}_t$. We first build an initial model θ^{old} pre-trained on source knowledge $\mathcal{K}_s$. Then, we inject target knowledge $\mathcal{K}_t$ into the pre-trained model and obtain the infused model θ^{new}. Our goal is to memorize $\mathcal{K}_t$ on model θ^{new}, with less forgetting $\mathcal{K}_s$. If knowledge in $\mathcal{K}_t$ conflicts one in $\mathcal{K}_s$, the model is required to adjust its parameters by reflecting the target knowledge. Note that multiple target knowledge can be sequentially updated to the model (see details in Section 4).

Research Questions CuQA is designed to address the following research questions:

- RQ1: Can the method learn target knowledge while retaining source knowledge?
- RQ2: How does sequentially learning multiple target knowledge affect the performance?
- RQ3: How does the size of each target knowledge affect the performance?

Metric For evaluation, we measure the success of updates, retaining of source knowledge, and generality using exact match (EM) scores. Additionally, we measure the ratio of forgets to updates.

- **Accuracy on $\mathcal{K}_t$** : we evaluate how much model θ^{new} **successfully updates** examples in $\mathcal{K}_t$.
- **Accuracy on $\mathcal{K}_s$**: how much model θ^{new} **forgets** examples in $\mathcal{K}_s$. This indicates performance degradation, when replacing θ^{old} with θ^{new}.
- **Accuracy on $\mathcal{P}_s$, $\mathcal{P}_t$**: how well model θ^{new} **generalizes** on semantically equivalent questions (or paraphrases).
- **F/U Ratio** (# of forgets/# of updates): how many examples in $\mathcal{K}_s$ are forgotten per an update of one example in $\mathcal{K}_t$. (# of forgets) is equal to the difference of correct prediction cases in $\mathcal{K}_s$, between θ^{old} and θ^{new}.

4 Method

In this section, we describe baseline approaches (Section 4.1), and introduce our proposed method for plug-and-play adaptation (Section 4.2).

4.1 Baseline Approaches

We establish three baseline for (a), (b), and (c), in Table 1. Since we found that a knowledge editing approach is outperformed by fine-tuning, we exclude it as baselines, and add fine-tuning instead.

Fine-tuning on target knowledge As a naive baseline, we start with the previous work (Roberts et al., 2020) for CBQA, by fine-tuning T5 (Raffel et al., 2020) with encoder-decoder structure. This baseline is to fine-tune the pre-trained model θ^{old} on facts in $\mathcal{K}_t$ to minimize the loss:

$$\mathcal{L}_{FT} = \sum_{(q,a)\in\mathcal{K}_t} L((q,a);\theta) \qquad (1)$$

where L refers to a seq2seq loss. This baseline is expected to optimize accuracy on target knowledge $\mathcal{K}_t$, thus increases the distance between the before- (θ^{old}) and after-parameters (θ^{new}) resulting in the risk of forgetting. For other baselines and our method, we adopt the same transformer: T5 as backbone network.

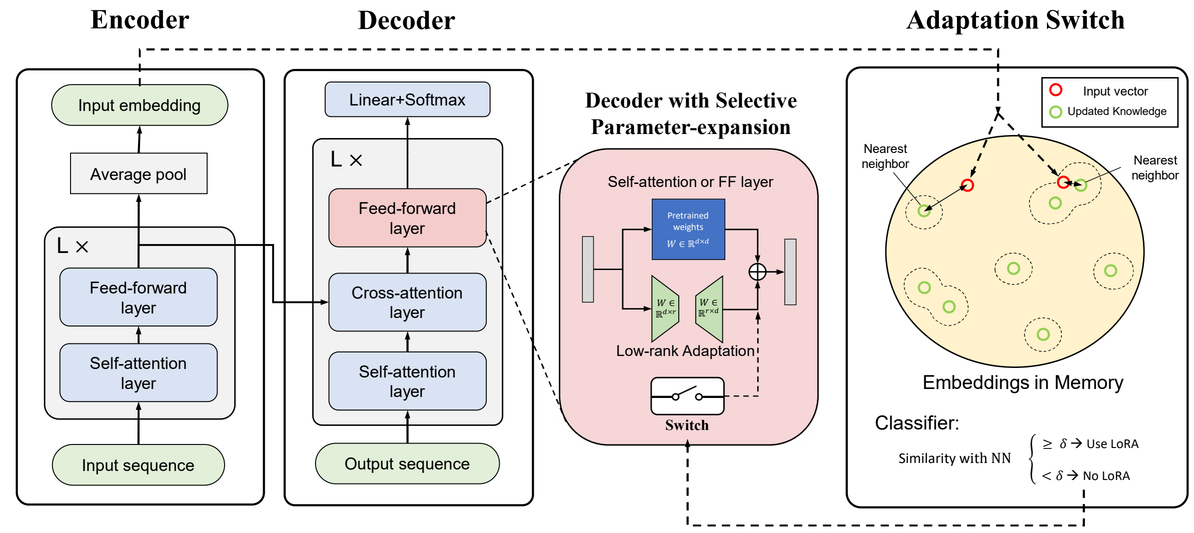

Figure 2: An overview of our proposed architecture.

Regularized fine-tuning for CL We adopt RecAdam (Chen et al., 2020) aiming to reduce the forgetting risk by adding a constraint to minimize the distance between θ^{old} and θ^{new} as follow:

$$\mathcal{R} = \|(\theta - \theta^{old})\|_p \tag{2}$$

where $\|\cdot\|_p$ indicates L_p norm. In addition, RecAdam uses an annealing technique, controlling the ratio between $\mathcal{R}$ and the fine-tuning loss (Eq. (1)) as follows:

$$\mathcal{L}_{total} = \lambda(t)\mathcal{L}_{FT} + (1 - \lambda(t))\mathcal{R}, \tag{3}$$

$$\lambda(t) = \frac{1}{1 + \exp(-k \cdot (t - t_0))} \tag{4}$$

where k and t_0 are hyper-parameters.

Adapters for knowledge updates For adaptation approaches, we implement two parameter-expansion methods: K-adapter (Wang et al., 2020) and LoRA (Hu et al., 2021). The approaches freeze the parameters θ^{old} in pre-trained LM and augment additional new parameters $\tilde{\theta}$ in the LM to train target knowledge as following:

$$\mathcal{L}_{adap} = \sum_{(q,a)\in\mathcal{K}_t} L((q, a); \theta^{old}, \tilde{\theta}). \tag{5}$$

For $\tilde{\theta}$, K-adapter (Wang et al., 2020) uses augmented self-attention layers, while LoRA (Hu et al., 2021) utilizes extra low-rank matrices.

4.2 Our Method

Motivated by the intuition of regularization to preserve source knowledge and that of adapters to inject target knowledge into new parameters, we show their strengths can be combined for our task. At the inference phase, our method selectively uses the plug-in modules to keep source knowledge intact, while tasks requiring target knowledge will be redirected to new plug-in modules.

Specifically, our distinction is augmenting function f (in an original LM) with function g, representing source and target knowledge respectively. The function f is a single layer in transformer trained on source knowledge $\mathcal{K}_s$, and g is an augmented function with new parameters for $\mathcal{K}_t$. Existing work, such as LoRA, can be interpreted by adding the two functions:

$$h = f(x) + g(x) \tag{6}$$

where f is one-linear layer in self-attention or feed-forward layers. That is, $f(x) = W_0x$, where $W_0 \in \mathrm{R}^{d\times k}$ denotes the pre-trained and fixed parameters. LoRA uses low-rank matrices as $g(x)$, *i.e.*, $g(x) = BAx$, where $B \in \mathrm{R}^{d\times r}$, $A \in \mathrm{R}^{r\times k}$, and $r \ll min(d, k)$. The low-rank matrices A and B are trainable parameters for updating target knowledge. The new layer with the additional matrices is denoted as follows:

$$h = W_0x + BAx = (W_0 + BA)x \tag{7}$$

However, the above add-aggregation has a limitation, as $g(x)$ can affect the model's outputs, and increase the distance between hidden states in θ^{old} and θ^{new}, which causes a forgetting problem.

Our key distinction is adding a selector, that is selectively activated for q requiring the use of plug-in module g, as follows:

$$h = f(x) + \sigma(q) \cdot g(x) \tag{8}$$

where $\sigma(q)$ is 1 or 0 depending on query q. While there can be various ways to train the selector in a sophisticated way, supervised either directly, or indirectly in an end-to-end manner, we show a simple unsupervised selector is already sufficient to show gains. Specifically, our selector is a key-value lookup where the key is m_i and value is g. At inference time, when given query q is based on facts in $\mathcal{K}_t$, we activate the augmented g for generating its output. If q is not from $\mathcal{K}_t$, we use only the original model θ^{old} for generation. To classify whether the input is from $\mathcal{K}_t$ or not, we build explicit memory with embeddings of $\mathcal{K}_t$ and leverage the distance with nearest neighbor (NN) in the memory.

Let $\mathcal{M} \in \mathrm{R}^{N \times d}$ be memory embeddings that stores embeddings of input questions in $\mathcal{K}_t$, where N is the total number of examples in $\mathcal{K}_t$. As shown in Figure 2, question embedding can be extracted from the encoder, by averaging the hidden states of input sequence. In T5 model with encoder-decoder, this averaging method is known to be effective on semantic textual similarity, as in (Ni et al., 2021). Given question q, cosine similarity with NN is calculated as follows:

$$s_q = \max_i(\mathrm{sim}(m_i, q)), \;\; m_i \in \mathcal{M} \tag{9}$$

where sim indicates cosine similarity. Based on s_q, if the score is greater than or equal to threshold δ, we assume q is from target knowledge $\mathcal{K}_t$. We build a indicator function as follows:

$$\sigma(q) = \begin{cases} 1 & \text{if } \; s_q \geq \delta, \\ 0 & \text{if } \; s_q < \delta. \end{cases} \tag{10}$$

In other words, $s_q \geq \delta$ indicates that input q is semantically similar with one fact in $\mathcal{K}_t$. At that time, our model is augmented with g that stores new and updated knowledge.

Meanwhile, as shown in Figure 2, we apply the selective use of parameters to only a decoder in a transformer architecture, not a encoder. The switch σ depends on query embedding q, and the embedding q is extracted from T5 encoder. If we apply the switch σ to hidden states in T5 encoder, this causes a recursion relation, or inefficient computations. By augmenting g for the decoder, embedding q is not changing during updating target knowledge, and depends on only pre-trained θ^{old}.

General case of multiple knowledge updates Our new perspective has another benefit of naturally generalizing to sequential (>2) sources. Assume that there are multiple target knowledge to be sequentially updated, *i.e.*, $\mathcal{K}_t^1, \mathcal{K}_t^2, ..., \mathcal{K}_t^M$. We build multiple functions g_k and memories $\mathcal{M}_k$ (where $k = 1, ...M$), according to each target knowledge. The new function considering the multiple knowledge is denoted as follows:

$$h = f(x) + \sum_{k=1}^{M} \sigma_k(q) \cdot g_k(x) \tag{11}$$

During training j-th target $\mathcal{K}_t^j$, the switch $\sigma_k(q)$ is activated where $1 \leq k \leq j$. At inference time, our selector extracts top1-NN fact m^*, which is closest to a query q. If m^* is in $\mathcal{M}_k$, the switch $\sigma_j(q)$ is activated where $1 \leq j \leq k$, as follows:

$$m^* = \underset{m}{\mathrm{argmax}}(\mathrm{sim}(m, q)), \;\; m \in \mathcal{M}_{1:M} \tag{12}$$

If the NN fact m^* is in $\mathcal{M}_j$, we estimate that its implicit knowledge is stored in the accumulated function $\sum_{k=1}^{j} g_k(x)$. That is, when m^* is in $\mathcal{M}_j$, the activation is decided as follows:

$$\sigma_k(q) = \begin{cases} 1 & \text{if } \; s_q \geq \delta \; \text{ and } \; 1 \leq k \leq j, \\ 0 & \text{if } \; s_q < \delta. \end{cases} \tag{13}$$

An alternative adapter We can replace LoRA with K-adapter (Wang et al., 2020). In K-adapter, f is a transformer layer (denoted as TRM(x)), and g is multiple transformer layers with two projection layers (denoted as KIA(x))). That is, $f(x) =$ TRM(x), consisting of one self-attention & two feed-forward layers. In the original paper (Wang et al., 2020), $g(x)$ consists of multiple transformer layers and up&down projection layers. For K-adapter, we set a simple version with only a single transformer layer, as follows:

$$h = \mathrm{TRM}(x) + \mathrm{KIA}(x) \tag{14}$$

where the parameters in TRM are fixed and that in KIA is trainable on target knowledge.

5 Experiment

In this section, we demonstrate the effectiveness of our approach on CuQA.

Datasets We evaluate our method on the following closed-book QA datasets:

(1) **Zero-shot Relation Extraction (zsRE)**: Levy et al. (2017) build relation-specific QA pairs, and De Cao et al. (2021) utilize this dataset for a closed-book QA task. This set provides question paraphrases based on the same fact and answer. We split this set into two groups ($\mathcal{K}_s$ and $\mathcal{K}_t$) that do not share the same facts. To validate generalization, we build held-out sets ($\mathcal{P}_s$ and $\mathcal{P}_t$) that are not used in training process. For this, we sample one QA pair among paraphrases based the same fact as $\mathcal{P}$.

(2) **Natural Questions (NQ) + SituatedQA**: Kwiatkowski et al. (2019) build NQ – a large-scale QA dataset based on user queries. We consider NQ as source knowledge $\mathcal{K}_s$ except outdated facts based on SituatedQA. Zhang and Choi (2021) proposed SituatedQA identifying temporal- and geographical-dependent questions on a subset of NQ. We use the temporal-dependent QA pairs as $\mathcal{K}_t$, which are annotated based on 2021 dump of Wikipedia. For $\mathcal{P}_s$ and $\mathcal{P}_t$, as both NQ and SituatedQA do not provide paraphrases, we follow (De Cao et al., 2021) using back-translation for generating paraphrases.

Implementation For T5 model, we use a large version with total 770M parameters. In our experiment, we assume that the old model θ^{old} storing source knowledge is available. For NQ, we used the open-source pre-trained model[3] as the model θ^{old}. For zsRE, we load and train T5 model[4] on source knowledge. For training, we set batch size 64 on 4 RTX3090 GPUs, and used Adam (Kingma and Ba, 2015) optimizer with learning rate 4e-4. For development set, we sample each 1K from $\mathcal{K}_s$, $\mathcal{K}_t$, and select the maximum harmonic mean of their accuracies as a best model. As a hyper-parameter, we search δ in a range of [0,1] with 0.05 step size, and found the best value (δ=0.9) based on development set. As embedding memory $\mathcal{M}$, we used additional parameters: 60M for zsRE and 8.5M for NQ. The size of the memories can be reduced by several techniques, such as random projection (Luan et al., 2020) and binary encoding (Yamada et al., 2021), which is left out of our focus.

Comparison with baselines We compare our method with baselines, as mentioned in Section 3.2; Fine-tuning (B-I), RecAdam (B-II), LoRA (B-III), and K-adapter (B-IV). When re-implementing K-adapter, we do not freeze the parameters of decoder, unlike in the original paper (Wang et al., 2020), because the performance is not changing when freezing. We train each model until 80 epochs and select a best model by the harmonic mean of source/target knowledge in development set.

	The total # of examples			
	$\mathcal{K}_s$	$\mathcal{P}_s$	$\mathcal{K}_t$	$\mathcal{P}_t$
zsRE (Large)	60K	24K	60K	24K
zsRE (Medium)	60K	24K	30K	12K
zsRE (Small)	60K	24K	15K	6K
NQ + SituatedQA	59K	32K	8.3K	1.6K

Table 2: Statistics of datasets.

5.1 R1: Comparing Ours with Baselines

Table 3 shows our main experimental results on two CBQA datasets. First, the model θ^{old} memorizes the source knowledge $\mathcal{K}_s$ well and generalizes on the paraphrase set $\mathcal{P}_s$ as well, showing high accuracy on both datasets. After training on $\mathcal{K}_t$, all models perform well on $\mathcal{K}_t$ and $\mathcal{P}_t$. These results indicate that these models are at least appropriate for memorizing training data in the current task.

Meanwhile, while acquiring $\mathcal{K}_t$, the models show variant results on $\mathcal{K}_s$ and $\mathcal{P}_s$, which have the different ability of retaining previous knowledge against forgetting. In Fine-tuning (B-I), its performances on source knowledge $\mathcal{K}_s$ and $\mathcal{P}_s$ decrease as training epochs (see Figure 3). RecAdam (B-II) alleviates the forgetting problem of fine-tuning, but the performance gains are marginal on two datasets. K-adapter (B-III) shows the strong performance on $\mathcal{K}_s$ with less forgetting, however, does not perform well on $\mathcal{P}_s$ and $\mathcal{P}_t$ showing low generalization. Because LoRA (B-IV) has the fewest trainable parameters, its forgetting is more aggravated, showing the worst performance on $\mathcal{K}_s$ and $\mathcal{P}_s$ in both zsRE and NQ. Ours with either K-adapter or LoRA shows the best performance on $\mathcal{K}_s$ and $\mathcal{K}_t$. In terms of the F/U ratio, our method also shows the lowest loss when updating one new example. Figure 3 shows how the performance of each model changes over training epochs, on the development set.

Ablation study In an ablation study, we test which component has the higher impact on memorizing implicit knowledge, on paraphrase set $\mathcal{P}_s$ and $\mathcal{P}_t$. In our method with LoRA, the function f in Eq. (8) can be applied to any pro-

jection layer in transformers. While the original work (Hu et al., 2021) applies to query- and value-matrices (W_Q, W_V) in self-attention, we consider feed-forward layers (W_{FF}), as well as self-attention. In addition, we observe how does the performance vary when the number of parameters increases by controlling rank r. In Table 4, we empirically found applying feed-forward layers is more effective than query and value projection, especially on target knowledge $\mathcal{P}_t$. These results indicate that memorizing factual knowledge is more relevant with a feed-forward module, which is consistent with the views in (Sukhbaatar et al., 2019; Geva et al., 2020).

5.2 R2: Accumulating over Multiple $\mathcal{K}_t$

To evaluate the scalability of our method on multiple $\mathcal{K}_t$ (>2), we assume multiple updates (five-phase) with smaller amount of examples, by splitting target knowledge $\mathcal{K}_t$ in zsRE (Large, 60K), into four sets, from $\mathcal{K}_t^1$ to $\mathcal{K}_t^4$ (each 15K). In this experiment, we train models during 40 epochs/phase. To generalize for LoRA baseline, we aggregate multiple g_k by addition, by activating all the switches at inference, *i.e.*, $\sigma_{1:M}(x) = 1$ in Eq. (13). This setting assumes that this baseline cannot leverage our selector to organize the storage of implicit knowledge. Figure 4 shows the performances of Fine-tuning, LoRA, and Ours, over training epochs. In fine-tuning, the accuracy on source knowledge keeps dropping during the whole training process. In LoRA, multiple updating deteriorates memorizing target knowledge stored in adapters, faster than source knowledge stored in the original parameters. This indicates that the fewer parameters, the faster the forgetting. In contrast, our method consistently outperforms the baselines, by retaining five knowledge, with forgetting less. To summarize these results, sequential updates aggravate forgetting of the fine-tuning method, which can be overcome through the selective use of adapters.

5.3 R3: Over varying Size of $\mathcal{K}_t$

As the size of target knowledge increases, it makes LMs suffer from more forgetting, increasing the

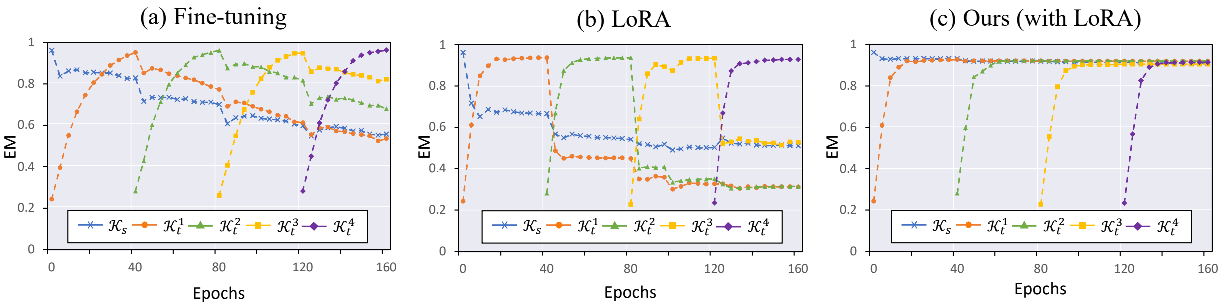

Figure 4: The accuracies on multiple knowledge sources (K=5) over training epochs for zsRE.

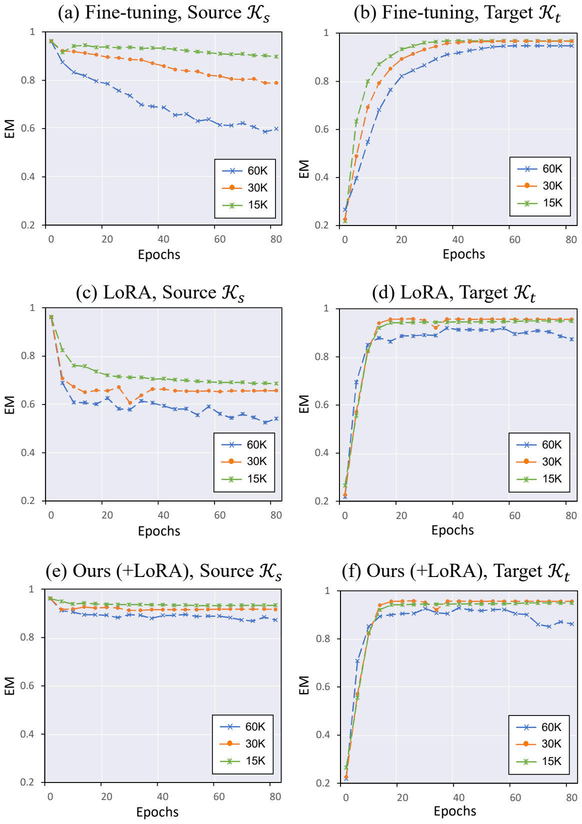

Figure 5: Accuracies over varying size of zsRE.

distance between before- and after-parameters. In this section, we observe how does the performance of each model vary as different sizes of $\mathcal{K}_t$. Figure 5 shows the the accuracies of zsRE datasets (Large-60K, Medium-30K, Small-15K), over training epochs. On source knowledge $\mathcal{K}_s$, the performance of fine-tuning and LoRA keeps dropping, and the accuracy drops are proportional to the size of target knowledge. Meanwhile, our method with LoRA consistently maintains high performance, which is not sensitive to training epochs. On target knowledge $\mathcal{K}_t$, the performances of three models reach high accuracy. However, our method on Large zsRE shows unstable performance at the end of training, which may need to use early stopping.

		Ground-truth

		Source	Target
Selector Prediction	Source	95.3	35.1
	Target	70.8 (0.0)	91.7 (97.4)

Table 6: The accuracies of Ours/Retrieval in four cases.

5.4 Analysis of Selector

In Table 5, we show the distribution of selector's predictions and the ground-truths, in our experiment on zsRE (Large). Nearest Neighbor-based selector successfully classifies 88.9% of examples, while 11.1% failed. In our method, if the selector classifies an input as target knowledge, the plug-in g is activated. Instead of the use of g, we can retrieve answers aligned with questions in $\mathcal{M}$, not generate them. We compare our generation with the retrieval in each case of Table 5. Table 6 shows the accuracy of predicting the answers, where the numbers in each cell indicate EM of our generation (retrieval: in parentheses). If an example in source knowledge is incorrectly classified as target, there is no relevant fact in $\mathcal{M}$, thus the accuracy in this case is zero. In contrast to Retrieval, our generative method is robust in this case, achieving 70.8% EM, because ours with g learned the source knowledge.

6 Conclusion

This paper studies how to accumulate new knowledge to LMs that stores existing knowledge. We propose a simple yet effective method to update target knowledge into new parameters, preventing from forgetting source knowledge. On two datasets: zsRE and NQ, our empirical results show that our proposed method can improve existing approaches for continual learning or task adaptation.

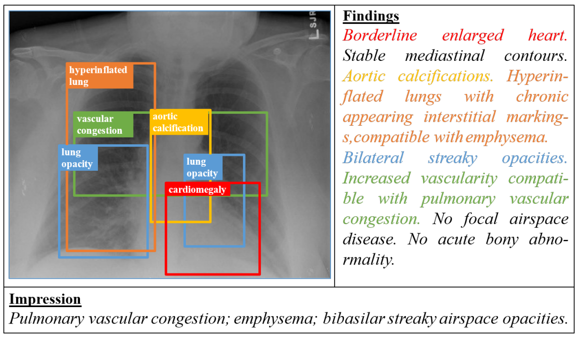
Abstract

Medical images are widely used in clinical decision-making, where writing radiology reports is a potential application that can be enhanced by automatic solutions to alleviate physicians' workload. In general, radiology report generation is an image-text task, where cross-modal mappings between images and texts play an important role in generating high-quality reports. Although previous studies attempt to facilitate the alignment via the co-attention mechanism under supervised settings, they suffer from lacking valid and accurate correspondences due to no annotation of such alignment. In this paper, we propose an approach with reinforcement learning (RL) over a cross-modal memory (CMM) to better align visual and textual features for radiology report generation. In detail, a shared memory is used to record the mappings between visual and textual information, and the proposed reinforced algorithm is performed to learn the signal from the reports to guide the cross-modal alignment even though such reports are not directly related to how images and texts are mapped. Experimental results on two English radiology report datasets, i.e., IU X-Ray and MIMIC-CXR, show the effectiveness of our approach, where the state-of-the-art results are achieved. We further conduct human evaluation and case study which confirm the validity of the reinforced algorithm in our approach.[1]

1 Introduction

Radiology report generation aims to automatically generate a free-text description from a specific clinical radiograph (e.g., chest X-ray), which can significantly alleviate the burden of radiologists and thus improve the quality and standardization of health care. With the advantages of its applications, radiology report generation has become an interesting research topic attracted in both artificial intelligence and clinical medicine. Recently, to generate more accurate reports, approaches based on deep learning techniques are adapted to this task and have achieved great success (Jing et al., 2018; Li et al., 2018; Liu et al., 2019).



Findings

Borderline enlarged heart. Stable mediastinal contours. Aortic calcifications. Hyperinflated lungs with chronic appearing interstitial markings,compatible with emphysema. Bilateral streaky opacities. Increased vascularity compatible with pulmonary vascular congestion. No focal airspace disease. No acute bony abnormality.

Impression

Pulmonary vascular congestion; emphysema; bibasilar streaky airspace opacities.

Figure 1: A chest X-ray image with its report, where aligned visual and textual features are linked by colors.

To effectively perform radiology report generation, most existing studies adopted conventional encoder-decoder architectures with convolutional neural networks (CNN) as the encoder and recurrent neural networks (e.g., LSTM (Hochreiter and Schmidhuber, 1997), GRU (Cho et al., 2014)) or non-recurrent neural networks (e.g., Transformer (Vaswani et al., 2017)) as the decoder. Considering that there is alignment between radiographs and their corresponding doctor-written reports (such as the mappings demonstrated in Figure 1 where visual and textual features representing the same content are highlighted in the same color), the ability of a model to learn such alignment is the key to achieve outstanding performance. To model the alignment information, Jing et al. (2018) proposed a co-attention mechanism to explicitly learn the linking between visual features in the radiographs and the semantic information in the corresponding doctor-written text reports, where the model is trained to generate text sequences via maximum likelihood estimation (MLE). However, one chal-

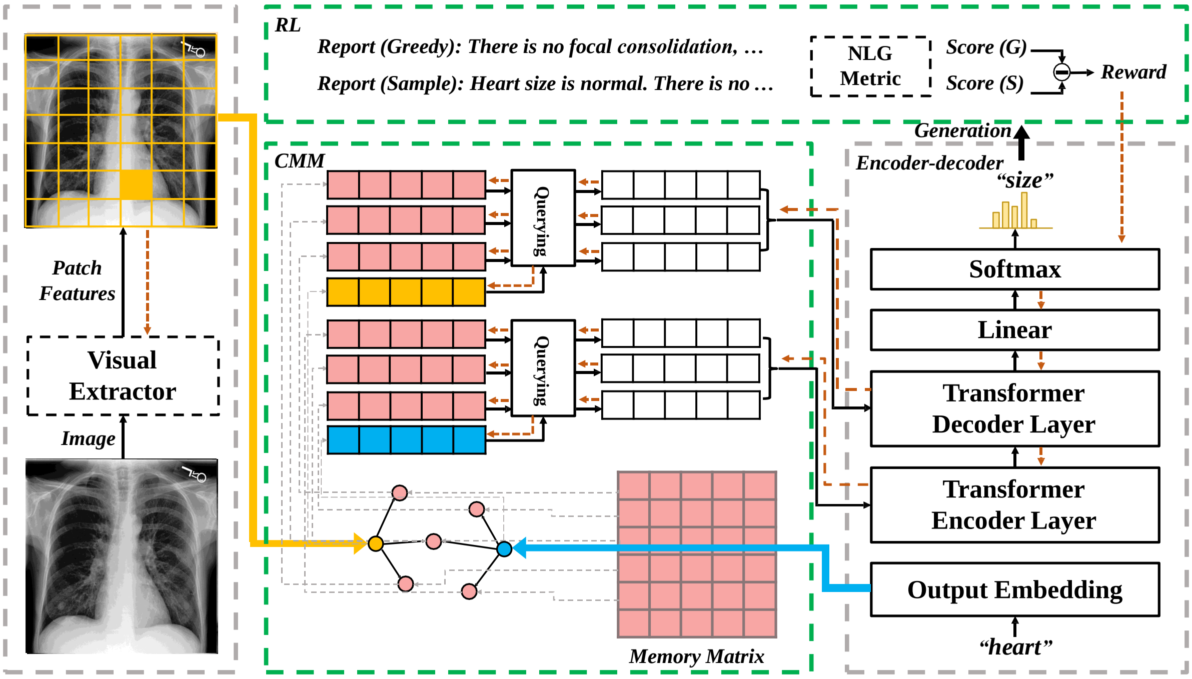

Figure 2: The overall architecture of our proposed approach, where the visual extractor, encoder, and decoder are shown in gray dash boxes with the details omitted. The CMM and reward computation process of RL are illustrated in green dash boxes, and the orange dash arrows indicate back-propagation of gradients from training the model. The orange, blue, and red nodes in CMM denote the vector representations of visual features, textual features, and memories, respectively.

lenge to learn the alignment is that there is no annotated alignment for such research to perform supervised learning to accurately map cross-modal information, so that normal learning procedure may not fit this scenario. To address this challenge, reinforcement learning (RL) is a potential solution, because it is able to guide the learning process of the cross-modal alignment with appropriate supervision from carefully designed rewards. Although there are studies following this paradigm by using RL to perform report generation, they focused on other aspects of this task rather than facilitating the mappings for cross-modal information. For example, Li et al. (2018) designed sentence- and word-level rewards to guide the model to choose to either retrieve a template sentence or generate a new sentence, and Jing et al. (2019) ultilized multi-agent RL to capture the imbalanced distribution between abnormality and normality. Therefore, RL on cross-modal alignment is expected to be studied and has the potential for further improvements.

In this paper, we propose to enhance radiology report generation via reinforced cross-modal alignment to alleviate the requirement of annotated supervision while facilitate the interactions across modalities (i.e., images and texts). In detail, our approach is based on Chen et al. (2021b), where a cross-modal memory (CMM) module is used to stores the cross-modal information that bridges the visual and textual features. Based on CMM, the proposed RL algorithm is applied to leverage the signals from natural language generation (NLG) metrics, i.e., BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011) and ROUGE (Lin, 2004), to guide the cross-modal mappings so as to better matching features from images and texts as well as have a direct target of learning outcome for report generation. Experimental results confirm the validity of our approach, which outperforms strong baselines and achieves the state-of-the-art performance on two widely used benchmark datasets, i.e., IU X-Ray (Demner-Fushman et al., 2016) and MIMIC-CXR (Johnson et al., 2019). Moreover, we perform human evaluation and case study to further illustrate the validity of the proposed RL in our approach.

2 The Proposed Approach

Following previous studies (Jing et al., 2018; Li et al., 2018; Liu et al., 2019; Chen et al., 2021b), we treat radiology report generation as a sequence-to-sequence task, where the source sequence are patch features $\mathbf{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_s, ..., \mathbf{x}_S\}$ from an input image, where $\mathbf{x}_s \in \mathbb{R}^d$ is extracted by visual extractors, and the target sequence $\mathbf{Y} = \{y_1, y_2, ..., y_t, ..., y_T\}$ is the corresponding report to the image, with $y_t \in \mathbb{V}$ being generated tokens, T the length of the report and $\mathbb{V}$ the vocabulary of all possible tokens. On the top of the general sequence-to-sequence paradigm, we add CMM which allows the proposed RL to take the signal from $\mathbf{Y}$ and use it to guide cross-modal mappings for $\mathbf{X}$ and $\mathbf{Y}$. An overview of our proposed approach is presented in Figure 2, where the details for different parts are illustrated as follows.

2.1 The Overall Generation Pipeline

In general, our model is composed of three major components, i.e., the visual extractor, the CMM, and the encoder-decoder part, where the CMM is dynamically integrated into the encoding and decoding process. The high-level descriptions of the three components are explained below.

Visual Extractor The visual features $\mathbf{X}$ of a radiology image $\mathbf{I}$ are extracted by pre-trained convolutional neural networks (CNN), such as VGG (Simonyan and Zisserman, 2015) or ResNet (He et al., 2016). Normally, an image is decomposed into regions with equal size (i.e., patches), and the extracted features from patches are then expanded into a sequence by simply concatenating all features from each row in a row-by-row manner, where the process is formulated by

$$\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_s, ..., \mathbf{x}_S\} = f_v(\mathbf{I}) \qquad (1)$$

with $f_v(\cdot)$ representing the visual extractor. Then the result is used as the source sequence for all subsequent modules.

Cross-modal Memory Memories are widely used to model the associations between different types of features through the mapping of keys and values and its effectiveness in doing so is demonstrated in many previous natural language processing studies (Miller et al., 2016; Xu et al., 2019; Tian et al., 2020; Cornia et al., 2020; Nie et al., 2020; Wu et al., 2021; Chen et al., 2021a). Therefore, we use CMM, which is based on Chen et al. (2021b), to record potentially shared information of visual and textual features in the memory so that the entire learning process is able to explicitly map corresponding parts in images and texts within a unified representation space. Formally, given a source sequence $\mathbf{X} = \{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_s, ..., \mathbf{x}_S\}$ from an image, we feed it to the CMM module to obtain the memory correspondences $\{\mathbf{r}_{\mathbf{x}_1}, \mathbf{r}_{\mathbf{x}_2}, ..., \mathbf{r}_{\mathbf{x}_s}, ..., \mathbf{r}_{\mathbf{x}_S}\}$ for the visual features. Similarly, the given the generated text sequence $\{y_1, y_2, ..., y_{t-1}\}$ for $\mathbf{I}$ with embedding $\{\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_{t-1}\}$ is also fed to CMM to form memory correspondences for textual features $\{\mathbf{r}_{\mathbf{y}_1}, \mathbf{r}_{\mathbf{y}_2}, ..., \mathbf{r}_{\mathbf{y}_{t-1}}\}$.

Encoder-Decoder The encoder-decoder in our model is built upon standard Transformer. In detail, the encoding process is formulated as

$$\{\mathbf{z}_1, \mathbf{z}_2..., \mathbf{z}_S\} = f_e(\mathbf{r}_{\mathbf{x}_1}, \mathbf{r}_{\mathbf{x}_2}, ..., \mathbf{r}_{\mathbf{x}_S}) \qquad (2)$$

where $f_e(\cdot)$ is the encoder. With the encoded results, the decoding process is formulated by

$$y_t = f_d(\mathbf{z}_1, \mathbf{z}_2, ..., \mathbf{z}_S, \mathbf{r}_{\mathbf{y}_1}, \mathbf{r}_{\mathbf{y}_2}, ..., \mathbf{r}_{\mathbf{y}_{t-1}}) \qquad (3)$$

where $f_d(\cdot)$ is the decoder and y_t the generated token at the current time step.

2.2 Cross-modal Memory

In our approach, CMM serves as an intermediate medium to connect the visual and textual features and thus allows the model to automatically learn the cross-modal mappings without relying on gold annotated alignments. Specifically, CMM contains a memory matrix[2] $\mathbf{M} = [\mathbf{m}_1, ..., \mathbf{m}_i, ..., \mathbf{m}_\mathcal{N}]$ that consists of $\mathcal{N}$ memory vectors ($\mathbf{m}_i$ is the i-th memory vector) to align the visual and textual features. It applies multi-thread[3] alignments to the visual features (i.e., $\mathbf{x_s}$), the textual features (i.e., $\mathbf{y}_t$), and the memory vectors (i.e., $\mathbf{m_i}$), where the alignments in all threads follow the same procedure.

In detail, in each thread, it firstly maps $\mathbf{x_s}$, $\mathbf{y}_t$, and $\mathbf{m_i}$ to the alignment space $\mathbf{x}'_s$, $\mathbf{y}'_t$, $\mathbf{k}_i$ through three trainable matrices (i.e., $\mathbf{W}_x$, $\mathbf{W}_y$, and $\mathbf{W}_k$), respectively, which is formally represented by

$$\mathbf{x}'_s = \mathbf{x}_s\mathbf{W}_x,\ \mathbf{y}'_t \ = \mathbf{y}_t\mathbf{W}_y,\ \mathbf{k}_i = \mathbf{m}_i\mathbf{W}_k \quad (4)$$

Next, for each visual feature (i.e., $\mathbf{x}'_s$), CMM computes the distances (denoted by $d_{s,i}$) between $\mathbf{x}'_s$ all memory vectors (i.e., $\mathbf{k}_i$) in the alignment space by $d_{s,i} = \mathbf{x}'_s \cdot \mathbf{k}_i$ and extracts the closest $\mathcal{K}$ memory vectors (i.e., keys in the memories) which are denoted as $[\mathbf{k}_{s,1}, \cdots, \mathbf{k}_{s,j}, \cdots, \mathbf{k}_{s,\mathcal{K}}]$. Then, CMM finds the corresponding memory vectors $\mathbf{m}_{s,j}$ of the keys $\mathbf{k}_{s,j}$ in the memory matrix and uses a trainable matrix $\mathbf{W}_v$ to map $\mathbf{m}_{s,j}$ to its corresponding value vectors ($\mathbf{v}_{s,j}$) through $\mathbf{v}_{s,j} = \mathbf{m}_{s,j} \cdot \mathbf{W}_v$

---

[2] One way to obtain the memory matrix $\mathbf{M}$ is to randomly initialize it and then update it during the training process.

[3] Thread number can be arbitrarily set in experiments.

Afterwards, we compute the weighted sum of the value vectors and obtain the output $\mathbf{r}_{\mathbf{x}_s}$ for $\mathbf{x}_s$ by

$$\mathbf{r}_{\mathbf{x}_s} = \Sigma_{j=1}^{\mathcal{K}} w_{s,j} \mathbf{v}_{s,j} \tag{5}$$

where the weight $w_{s,j}$ is computed through

$$w_{s,j} = \frac{\exp(\mathbf{x}'_s \cdot \mathbf{k}_{s,j})}{\Sigma_{j=1}^{\mathcal{K}} \exp(\mathbf{x}'_s \cdot \mathbf{k}_{s,j})} \tag{6}$$

The same procedure is applied to the textual features and obtain the output $\mathbf{r}_{\mathbf{y}_t}$ for $\mathbf{y}_t$. Finally, CMM concatenates the output $\mathbf{r}_{\mathbf{x}_s}$ and $\mathbf{r}_{\mathbf{y}_t}$ from all threads and feeds them to the encoder-decoder structure in our model.

2.3 Reinforced Cross-modal Alignment

Although CMM provides a "soft" mechanism to facilitate the linking between visual and textual features, there is still no annotated alignment to guide an accurate learning process, which is a common problem exists in previous work (Jing et al., 2018). To address this problem, we propose to use RL to provide appropriate supervision from NLG evaluation metrics to search for better mappings between features from different modalities. In doing so, we treat the genration model as the **agent** that interacts with an external **environment** (visual and textual features). Therefore, all parameters of our approach, θ, define a **policy** p_θ that results in an **action** (i.e., the prediction of the next word). Upon generating the end-of-sequence (EOS) token, the agent uses a **reward** r based on evaluation metrics, e.g., BLEU, METEOR and ROUGE, etc., where the reward r_t for the action at step t is the improvement on the evaluation metric by generating the the next word y_t, which is formally expressed by

$$r_t = r(\mathbf{Y}_t) - r(\mathbf{Y}_{t-1}) \tag{7}$$

where $\mathbf{Y}_t = \{y_1, y_2, ..., y_t\}$ and $\mathbf{Y}_{t-1} = \{y_1, y_2, ..., y_{t-1}\}$. Therefore, the entire reward R of generating $\mathbf{Y} = \{y_1, y_2, ..., y_t, ..., y_T\}$ is the sum of r_t:

$$R = \sum_{t=1}^{T} r(\mathbf{Y}_t) - r(\mathbf{Y}_{t-1}) = r(\mathbf{Y}) \tag{8}$$

Then the model is trained to maximize the expected reward $\mathbb{E}_{\mathbf{Y}\sim p_\theta}\left[r\left(\mathbf{Y}\right)\right]$ from the generated report $\mathbf{Y}$ via a sampling strategy (e.g., sampling by probabilities). Based on $\mathbb{E}_{\mathbf{Y}\sim p_\theta}\left[r\left(\mathbf{Y}\right)\right]$, the loss of our entire approach is defined as

$$L(\theta) = -\mathbb{E}_{\mathbf{Y}\sim p_\theta}\left[r\left(\mathbf{Y}\right)\right] \tag{9}$$

with the gradient of $L(\theta)$ for θ computed using the REINFORCE algorithm (Williams, 1992) via

$$\nabla_\theta L(\theta) = -\mathbb{E}_{\mathbf{Y}\sim p_\theta}\left[r\left(\mathbf{Y}\right) \nabla_\theta \log p_\theta\left(\mathbf{Y}\right)\right] \tag{10}$$

Then, we approximate the expectation (i.e., the expected gradient) through a single Monte-Carlo sample $\mathbf{Y}$ from p_θ:

$$\nabla_\theta L(\theta) \approx -r\left(\mathbf{Y}\right) \nabla_\theta \log p_\theta\left(\mathbf{Y}\right) \tag{11}$$

However, the gradient estimated from the above process is of high variance. To maintain the stability of the RL, we follow Rennie et al. (2017a) to reduce such variance by introducing a reference reward b.[4] Therefore, Eq. (10) is formalized as

$$\nabla_\theta L(\theta) = -\mathbb{E}_{\mathbf{Y}\sim p_\theta}\left[(r\left(\mathbf{Y}\right) - b) \nabla_\theta \log p_\theta\left(\mathbf{Y}\right)\right] \tag{12}$$

with the expected gradient approximated by

$$\nabla_\theta L(\theta) \approx -\left(r\left(\mathbf{Y}\right) - b\right) \nabla_\theta \log p_\theta\left(\mathbf{Y}\right) \tag{13}$$

Note that, in our approach, b is obtained by computing the NLG metric (e.g., BLEU-4) of the generated report using greedy sampling during inferencing at the training stage. As a result, any actions (i.e., result in some generated $\mathbf{Y}$) that returns higher $r\left(\mathbf{Y}\right)$ than b drives the following learning process to take as more such actions as possible.

3 Experiment Settings

3.1 Datasets

In our experiments, we use two conventional benchmark datasets, i.e., IU X-RAY (Demner-Fushman et al., 2016)[5] from Indiana University and MIMIC-CXR (Johnson et al., 2019)[6] from the Beth Israel Deaconess Medical Center. The IU X-RAY is a

---

[4] b is normally a constant (i.e., a reference reward value) obtained from higher rewards by sampling all possible actions. Note that the introduction of b does not change the expected gradient (Eq. (10)), proved by

$$\begin{aligned}\mathbb{E}_{\mathbf{Y}\sim p_\theta}\left[b\nabla_\theta \log p_\theta\left(\mathbf{Y}\right)\right] &= b\sum_{\mathbf{Y}} \nabla_\theta p_\theta\left(\mathbf{Y}\right) \\ &= b\nabla_\theta \sum_{\mathbf{Y}} p_\theta\left(\mathbf{Y}\right) \\ &= b\nabla_\theta 1 \\ &= 0\end{aligned}$$

LR (encoder-decoder)	5e-5, **1e-4**, 3e-4, 5e-4

Table 2: The hyper-parameters tested in tuning our models, where LR (visual extractor) and LR (encoder-decoder) represent the learning rates for the visual extractor and the encoder-decoder. The bold values illustrate the best hyper-parameter configuration for both IU X-Ray and MIMIC-CXR.

relatively small dataset with 7,470 chest X-ray images and 3,955 corresponding reports; the MIMIC-CXR is the largest public radiography dataset with 473,057 chest X-ray images and 206,563 reports.

Following the experiment settings from previous studies (Li et al., 2018; Jing et al., 2019; Chen et al., 2020), we exclude the samples without reports for both datasets. For IU X-Ray, we use the same split (i.e., 70%/10%/20% for train/validation/test set) as that in Li et al. (2018) and for MIMIC-CXR we adopt its official split. Table 1 show the statistics of all datasets in terms of the numbers of images, reports, patients and the average length of reports with respect to train/validation/test sets.

3.2 Baseline and Evaluation Metrics

To examine our proposed model, we use three baselines for comparison in our experiments. The first, namely **Base**, is the backbone encoder-decoder used in our full model, i.e., a three-layer Transformer model with 8 heads and 512 hidden units without other extensions. The second, namely **Base+RL** is the Transformer model with the same architecture of **Base**, where reinforcement learning is applied to training the model.[7] The third, namely **Base+CMM**, is the Transformer model with the same backbone architecture of **Base** and CMM, without RL.

For evaluation, we follow Chen et al. (2020) to evaluate the above models by two types of metrics, namely, conventional natural language generation (NLG) metrics and clinical efficacy (CE) metrics[8]. The NLG metrics[9] include BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011) and ROUGE-L (Lin, 2004). For CE metrics, the CheXpert (Irvin et al., 2019)[10] is applied to label the generated reports and compare the results with ground truths in 14 different categories related to thoracic diseases and support devices. We use precision, recall, and F1 scores to evaluate model performance for CE metrics.

3.3 Implementation Details

To ensure consistency with previous studies (Li et al., 2018; Chen et al., 2020), we use two images for each patient as the input for report generation on IU X-Ray and one image for MIMIC-CXR. For visual extractor, we adopt the ResNet101 (He et al., 2016) pretrained on ImageNet (Deng et al., 2009) to extract patch features with 512 dimensions for each feature. For the encoder-decoder backbone, considering the quality of text representation significantly determines the model performance (Radford et al., 2018; Song and Shi, 2018; Lewis et al., 2020; Song et al., 2021), we use Transformer (Vaswani et al., 2017), which has demonstrated its superior in modeling text in many natural language processing tasks, as the encoder-decoder and randomly initialize its parameters. For the memory matrix in CMM, its dimension and the number of memory vectors $\mathcal{N}$ are set to 512 and 2048, respectively, with random initialization. In addition, the thread number and the $\mathcal{K}$ in CMM are set to 8 and 32, respectively. We train our model using MLE for 30 epochs to regularize the action space before the RL is applied. Afterwards, we start RL using the Adam optimizer (Kingma and Ba, 2015). Table 2 reports the hyper-parameters tested in tuning our models for the two datasets. For each dataset, we try all combinations of the hyper-parameters and use the one achieving the highest BLEU-4 on the validation sets of IU X-Ray and MIMIC-CXR. For example, the best performing learning rates of

---

[7] This baseline verifies the effectiveness of reinforcement learning on the same structure of **Base** without CMM.

[8] Note that CE metrics only apply to MIMIC-CXR because the labeling schema of CheXpert is designed for MIMIC-CXR, which is different from that of IU X-Ray.

Table 3: NLG and CE evaluations of different models on the test sets of IU X-Ray and MIMIC-CXR datasets. BL-n denotes BLEU score using up to 4-grams; MTR and RG-L denote METEOR and ROUGE-L, respectively. The average improvement over all NLG metrics compared to Base is also presented in the "Avg. Δ" column.

the visual extractor and other parameters are set to 5×10^{-5} and 1×10^{-4}, respectively, and we decay them by 0.8 per epoch for all datasets.

4 Results and Analysis

4.1 Overall Results

The experimental results of different models on the two benchmark datasets are reported in Table 3 where Base, Base+CMM, and Base+RL represent the aforementioned baselines and Base+CMM+RL represents our full model.

There are several observations. First, all models with CMM consistently outperform Base and Base+RL on both datasets with respect to all NLG metrics, which confirms the advantage of incorporating cross-modal memory into Transformer-based models. Second, the comparison between models with and without RL (i.e., Base vs. Base+RL and Base+CMM vs. Base+CMM+RL) on different metrics confirms the effectiveness of using RL to train such generation model, where models with RL outperforms the ones without RL on all evaluation metrics. This observation indicates that RL has its superiority to map essential features from images and texts with distant (even irrelevant) signals (i.e., NLG metrics) so as to produce better radiology reports. Third, in particular, our full model Base+CMM+RL outperforms all other models by a large margin on both datasets with respect to all metrics, although the other baselines have already achieved outstanding performance, which indicates the effectiveness of the design of reinforced cross-modal alignment. This observation further confirms that, under the RL setting, CMM is able to better search for the cross-modal alignment in the memory representation space without explicit supervision and provides a more accurate feature correspondence in generating high-quality reports.

4.2 Comparison with Previous Studies

We further compare our full model (i.e. Base+CMM+RL) with existing studies on the same datasets, and report the results (in terms of NLG and CE metrics) in Table 4. It is observed that our approach outperforms all previous studies. Particularly, compared with previous studies that also use RL (e.g., Hrgr and Cmas-RL), our approach focuses on using RL to leverage the signals from NLG metrics so as to update the whole model, whereas their approaches focus on using RL to improve the decision-making of sentence template utilization and abnormality detection. In addition, compared with Chen et al. (2021b) that uses memory-based approach to align cross-modal information, our approach is able to outperform their approach with the help of the proposed RL mechanism, which demonstrates the effectiveness of our approach to further enhance the cross-modal modeling. Furthermore, the overall comparison indicates that it is of great potential in exploiting informative patterns among images and their texts for report generation without requiring any external resources, while previous studies (e.g., CoAtt and Hrgr) rely on extra information (e.g., private datasets for visual extractor pretraining) for this task.

4.3 Human Evaluation

We employ human evaluation to further evaluate the effect of different modules (i.e., CMM and RL) in our proposed model. In detail, we randomly select 100 chest X-ray images and their ground truth reports from the test set of MIMIC-CXR, as

Data	Model	NLG Metrics						CE Metrics

Table 4: Comparisons of our proposed models (i.e., CMM+RL) with previous studies on the test sets of IU X-Ray and MIMIC-CXR with respect to NLG and CE metrics. Herein, ‡ marks the results that are directed cited from their paper and ◇ represents the results of our runs with their released codes.

Model	Cor.	Flu.	Cov.	Avg.
Base	5.0	13.0	8.0	8.7
+rl	9.0	23.0	15.0	15.7
+cmm	21.0	30.0	20.0	23.7
+cmm+rl	**65.0**	**34.0**	**57.0**	**52.0**

Table 5: The results of human evaluation for different models. Cor., Flu. and Cov. are abbreviations of correctness, language fluency, and content coverage, respectively, with Avg. denoting the average of them.

well as the reports generated from the baselines and our model. Five human experts who are familiar with radiology are asked to choose the best reports among the generated and the ground truth reports. Following Li et al. (2018), the assessment criterion used in our experiments include correctness, language fluency, and content coverage. The results are reported in Table 5. Overall, Base+cmm+rl outperforms all baselines with a more satisfying result from humans in terms of all the criterion. In particular, Base+cmm+rl significantly outperforms other baselines on correctness and coverage, which further confirms that the reinforced cross-modal alignment helps our approach generate more accurate and comprehensive reports.

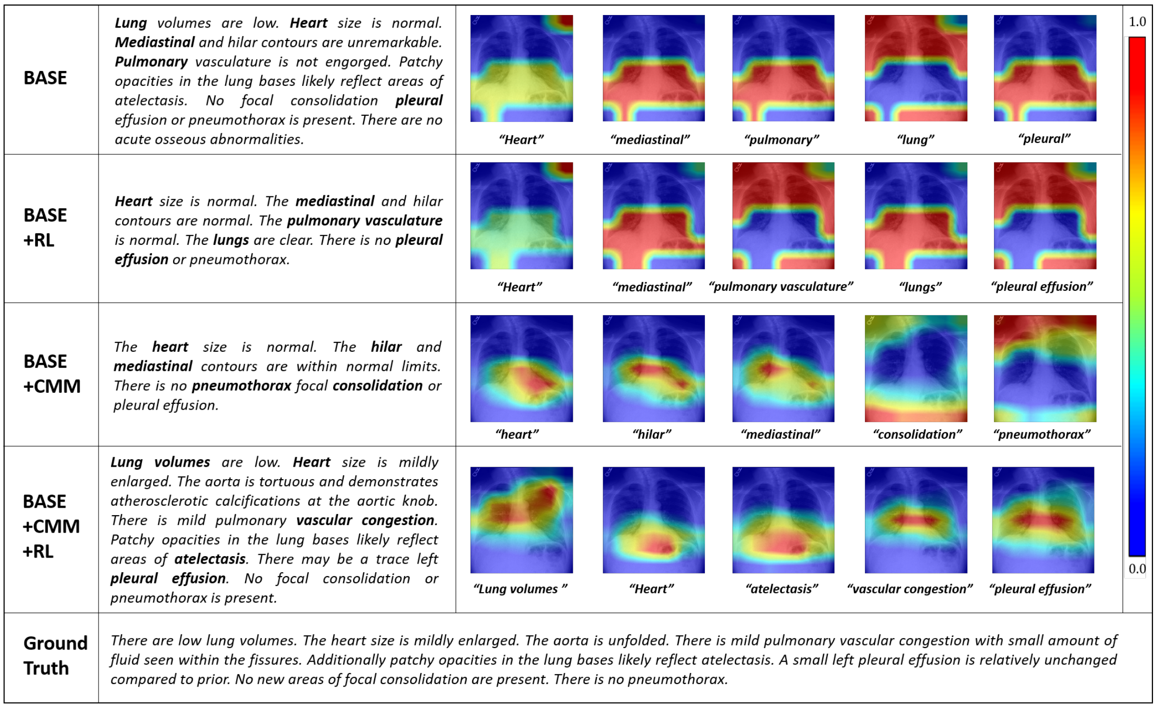
4.4 Case Study

To further investigate the effect of our model, we perform a case study on the generated reports from different models (i.e., Base, Base+rl, Base+cmm, and Base+cmm+rl) with an example input chest X-ray image chosen from the test set of MIMIC-CXR. Figure 3 shows the example image with its ground-truth report, and the generation outputs from different models. For each model, we also demonstrate the mappings between regions of the image and words/phrases in the generated text, where the intensity[11] of the mappings is illustrated on the images with different colors.

The observations are drawn from two different aspects. First, Base+cmm and Base+cmm+rl is able to generate descriptions aligned with the ground-truth, which confirms the effectiveness of CMM. For example, for the medical findings in the ground-truth reports (i.e., "*low lung volumes*", "*heart size is mildly enlarged*", "*atelectasis*", and "*vascular congestion*"), Base+cmm and Base+cmm+rl covers many key words in the findings (e.g., "*low lung volumes*", "*heart size*", "*atelectasis*" and "*vascular congestion*") in the gen-

---

[11] The intensity is measured by the attention scores extracted by the first layer of the decoder.



BASE	***Lung*** *volumes are low.* ***Heart*** *size is normal.* ***Mediastinal*** *and hilar contours are unremarkable.* ***Pulmonary*** *vasculature is not engorged. Patchy opacities in the lung bases likely reflect areas of atelectasis. No focal consolidation* ***pleural*** *effusion or pneumothorax is present. There are no acute osseous abnormalities.*
BASE +RL	***Heart*** *size is normal. The* ***mediastinal*** *and hilar contours are normal. The* ***pulmonary vasculature*** *is normal. The* ***lungs*** *are clear. There is no* ***pleural effusion*** *or pneumothorax.*
BASE +CMM	*The* ***heart*** *size is normal. The* ***hilar*** *and* ***mediastinal*** *contours are within normal limits. There is no* ***pneumothorax*** *focal* ***consolidation*** *or pleural effusion.*
BASE +CMM +RL	***Lung volumes*** *are low.* ***Heart*** *size is mildly enlarged. The aorta is tortuous and demonstrates atherosclerotic calcifications at the aortic knob. There is mild pulmonary* ***vascular congestion****. Patchy opacities in the lung bases likely reflect areas of* ***atelectasis****. There may be a trace left* ***pleural effusion****. No focal consolidation or pneumothorax is present.*
Ground Truth	*There are low lung volumes. The heart size is mildly enlarged. The aorta is unfolded. There is mild pulmonary vascular congestion with small amount of fluid seen within the fissures. Additionally patchy opacities in the lung bases likely reflect atelectasis. A small left pleural effusion is relatively unchanged compared to prior. No new areas of focal consolidation are present. There is no pneumothorax.*

Figure 3: Visualizations of image-text mappings between particular regions (indicated by colored weights) of a chest X-ray image and words/phrases from its reports generated by BASE, BASE+RL, BASE+CMM, , and BASE+CMM+RL, respectively. The color spectrum indicates the value of weight in the range of [0, 1].

erated reports whereas BASE can cover few of them. Second, the validity of RL in aligning the cross-modal features can be observed from the fact that BASE+CMM+RL is able to generate relatively more accurate reports (e.g. "*Heart size is mildly enlarged*") than BASE+CMM (e.g. "*Heart size is normal*") because the former obtains better visual-textual mappings. For example, the abnormality (i.e., "*pleural effusion*") presented in chest X-ray image is covered by the generated report from BASE+CMM+RL and the corresponding region on the image is precisely associated with to the texts.

5 Related Work

The task that is the most relevant to ours is image captioning, which aims to generation text captions that describe the content of the given images (Vinyals et al., 2015; Xu et al., 2015; Anderson et al., 2018; Wang et al., 2019). Being one of its applications and extensions to the medical domain, radiology report generation aims to depicting radiology images with professional texts (Liu et al., 2019; Huang et al., 2019; Miura et al., 2020; Zhang et al., 2020; Alfarghaly et al., 2021; Nooralahzadeh et al., 2021; Najdenkoska et al., 2021; Wang et al., 2021). In general, existing approaches for radiology report generation were mainly designed and proposed to better align images and texts or to exploit highly-patternized features of texts. For example, Jing et al. (2018) proposed a co-attention mechanism to simultaneously explore visual and semantic information with a multi-task learning framework; Li et al. (2018) introduced a template database to incorporate patternized information; Chen et al. (2020) improved generation process by applying a memory-driven Transformer to model patternized information; Chen et al. (2021b) proposes memory-based module to model the cross-modal information. In addition, there are studies that use RL to perform report generation (e.g., Jing et al. (2019) utilized multi-agent RL to capture the imbalanced distribution between abnormality and normality), but their focus is not to utilize RL for text and image alignment. Compared to previous studies, our model offers an effective alternative for radiology reports generation, where a soft intermediate layer with RL is provided to facilitate the mappings between visual and textual features, which allows one to produce more accurate descriptions for radiology images.

6 Conclusion

In this paper, we propose an RL approach based on CMM to better align visual and textual features for radiology report generation. In detail, a shared memory is used to store the cross-modal information and RL is applied to leverage the signals from NLG metrics to guide cross-modal mappings so as to better link features from images and texts. The experimental results on two benchmark datasets (i.e., IU X-Ray and MIMIC-XCR) demonstrate the effectiveness of our model, which achieves the state-of-the-art performance on both datasets. Human evaluation and the case study further confirm that our approach is able to generate high-quality reports with meaningful image-text alignment.

Abstract

Deep learning has demonstrated performance advantages in a wide range of natural language processing tasks, including neural machine translation (NMT). Transformer NMT models are typically strengthened by deeper encoder layers, but deepening their decoder layers usually results in failure. In this paper, we first identify the cause of the failure of the deep decoder in the Transformer model. Inspired by this discovery, we then propose approaches to improving it, with respect to model structure and model training, to make the deep decoder practical in NMT. Specifically, with respect to model structure, we propose a cross-attention drop mechanism to allow the decoder layers to perform their own different roles, to reduce the difficulty of deep-decoder learning. For model training, we propose a collapse reducing training approach to improve the stability and effectiveness of deep-decoder training. We experimentally evaluated our proposed Transformer NMT model structure modification and novel training methods on several popular machine translation benchmarks. The results showed that deepening the NMT model by increasing the number of decoder layers successfully prevented the deepened decoder from degrading to an unconditional language model. In contrast to prior work on deepening an NMT model on the encoder, our method can deepen the model on both the encoder and decoder at the same time, resulting in a deeper model and improved performance.

1 Introduction

With the help of the deep neural network, the feature extraction capability of models has been substantially enhanced (Schmidhuber, 2015; LeCun et al., 2015). Deep neural network models are also popular for natural language processing (NLP) tasks. The most typical deep neural network model in NLP is based on the convolutional neural network (CNN) (Gehring et al., 2017) and Transformer (Vaswani et al., 2017) structures, and the deep pretrained Transformer language model has begun to dominate NLP. The deep neural network model has also attracted substantial interest in neural machine translation (NMT), for both theoretical research (Wang et al., 2019; Li et al., 2020a, 2021a; Kong et al., 2021) and competition evaluation (Zhang et al., 2020; Wu et al., 2020b,a; Meng et al., 2020). Because it has been demonstrated that deep neural network models can benefit from an enriched representation, deep NMT models also show advantages with respect to translation performance (Wu et al., 2019; Wei et al., 2020).
