Introduction

Welcome to SemEval-2019!

The Semantic Evaluation (SemEval) series of workshops focuses on the evaluation and comparison of systems that can analyse diverse semantic phenomena in text with the aim of extending the current state of the art in semantic analysis and creating high quality annotated datasets in a range of increasingly challenging problems in natural language semantics. SemEval provides an exciting forum for researchers to propose challenging research problems in semantics and to build systems/techniques to address such research problems.

SemEval-2019 is the thirteenth workshop in the series of International Workshops on Semantic Evaluation. The first three workshops, SensEval-1 (1998), SensEval-2 (2001), and SensEval-3 (2004), focused on word sense disambiguation, each time growing in the number of languages offered, in the number of tasks, and also in the number of participating teams. In 2007, the workshop was renamed to SemEval, and the subsequent SemEval workshops evolved to include semantic analysis tasks beyond word sense disambiguation. In 2012, SemEval turned into a yearly event. It currently runs every year, but on a two-year cycle, i.e., the tasks for SemEval 2019 were proposed in 2018.

SemEval-2019 was co-located with the 17th Annual Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies (NAACL HLT 2019) in Minneapolis, Minnesota, USA. It included the following 11 shared tasks organized in five tracks:

- Frame Semantics and Semantic Parsing
  - Task 1: Cross-lingual Semantic Parsing with UCCA
  - Task 2: Unsupervised Lexical Semantic Frame Induction
- Opinion, Emotion and Abusive Language Detection
  - Task 3: EmoContext: Contextual Emotion Detection in Text
  - Task 4: Hyperpartisan News Detection
  - Task 5: HatEval: Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter
  - Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media
- Fact vs. Fiction
  - Task 7: RumourEval 2019: Determining Rumour Veracity and Support for Rumours
  - Task 8: Fact Checking in Community Question Answering Forums
- Information Extraction and Question Answering
  - Task 9: Suggestion Mining from Online Reviews and Forums
  - Task 10: Math Question Answering
- NLP for Scientific Applications
  - Task 12: Toponym Resolution in Scientific Papers

This volume contains both Task Description papers that describe each of the above tasks, and System Description papers that present the systems that participated in these tasks. A total of 11 task description papers and 220 system description papers are included in this volume.

We are grateful to all task organizers as well as to the large number of participants whose enthusiastic participation has made SemEval once again a successful event. We are thankful to the task organizers who also served as area chairs, and to task organizers and participants who reviewed paper submissions. These proceedings have greatly benefited from their detailed and thoughtful feedback. We also thank the NAACL HLT 2019 conference organizers for their support. Finally, we most gratefully acknowledge the support of our sponsors: the ACL Special Interest Group on the Lexicon (SIGLEX) and Microsoft.

Invited Speaker:

Samuel R. Bowman, New York University

Invited Talk: Task-Independent Sentence Understanding

Samuel R. Bowman
New York University

Abstract

This talk deals with the goal of task-independent language understanding: building machine learning models that can learn to do most of the hard work of language understanding before they see a single example of the language understanding task they're meant to solve, in service of making the best of modern NLP systems both better and more data-efficient. I'll survey the (dramatic!) progress that the NLP research community has made toward this goal in the last year. In particular, I'll dwell on GLUE—an open-ended shared task competition that measures progress toward this goal for sentence understanding tasks—and I'll preview a few recent and forthcoming analysis papers that attempt to offer a bit of perspective on this recent progress.

Biography

I have been on the faculty at NYU since 2016, when I finished my PhD with Chris Manning and Chris Potts at Stanford. At NYU, I'm a core member of the new school-level Data Science unit, which focuses on machine learning, and a co-PI of the CILVR machine learning lab. My research focuses on data, evaluation techniques, and modeling techniques for sentence understanding in natural language processing, and on applications of machine learning to scientific questions in linguistic syntax and semantics. I am an area chair for *SEM 2018, ICLR 2019, and NAACL 2019; I organized a twenty-three person team at JSALT 2018; and I earned a 2015 EMNLP Best Resource Paper Award and a 2017 Google Faculty Research Award.

Abstract

We present the SemEval 2019 shared task on Universal Conceptual Cognitive Annotation (UCCA) parsing in English, German and French, and discuss the participating systems and results. UCCA is a cross-linguistically applicable framework for semantic representation, which builds on extensive typological work and supports rapid annotation. UCCA poses a challenge for existing parsing techniques, as it exhibits reentrancy (resulting in DAG structures), discontinuous structures and non-terminal nodes corresponding to complex semantic units. The shared task has yielded improvements over the state-of-the-art baseline in all languages and settings. Full results can be found in the task's website https://competitions.codalab.org/competitions/19160.

1 Overview

Semantic representation is receiving growing attention in NLP in the past few years, and many proposals for semantic schemes have recently been put forth. Examples include Abstract Meaning Representation (AMR; Banarescu et al., 2013), Broad-coverage Semantic Dependencies (SDP; Oepen et al., 2016), Universal Decompositional Semantics (UDS; White et al., 2016), Parallel Meaning Bank (Abzianidze et al., 2017), and Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013). These advances in semantic representation, along with corresponding advances in semantic parsing, can potentially benefit essentially all text understanding tasks, and have already demonstrated applicability to a variety of tasks, including summarization (Liu et al., 2015; Dohare and Karnick, 2017), paraphrase detection (Issa et al., 2018), and semantic evaluation (using UCCA; see below). In this shared task, we focus on UCCA parsing in multiple languages.

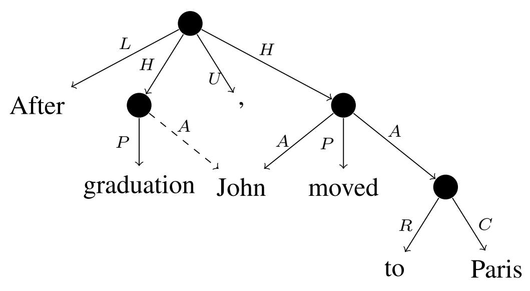

Figure 1: An example UCCA graph.

One of our goals is to benefit semantic parsing in languages with less annotated resources by making use of data from more resource-rich languages. We refer to this approach as *cross-lingual* parsing, while other works (Zhang et al., 2017, 2018) define cross-lingual parsing as the task of parsing text in one language to meaning representation in another language.

In addition to its potential applicative value, work on semantic parsing poses interesting algorithmic and modeling challenges, which are often different from those tackled in syntactic parsing, including reentrancy (e.g., for sharing arguments across predicates), and the modeling of the interface with lexical semantics.

UCCA is a cross-linguistically applicable semantic representation scheme, building on the established Basic Linguistic Theory typological framework (Dixon, 2010b,a, 2012). It has demonstrated applicability to multiple languages, including English, French and German, and pilot annotation projects were conducted on a few languages more. UCCA structures have been shown to be well-preserved in translation (Sulem et al., 2015), and to support rapid annotation by non-experts, assisted by an accessible annotation interface (Abend et al., 2017).[1] UCCA has already shown applicative value for text simplifica-

[1] https://github.com/omriabnd/UCCA-App

		Scene Elements
P	**Process**	The main relation of a Scene that evolves in time (usually an action or movement).
S	**State**	The main relation of a Scene that does not evolve in time.
A	**Participant**	Scene participant (including locations, abstract entities and Scenes serving as arguments).
D	**Adverbial**	A secondary relation in a Scene.
		Elements of Non-Scene Units
C	**Center**	Necessary for the conceptualization of the parent unit.
E	**Elaborator**	A non-Scene relation applying to a single Center.
N	**Connector**	A non-Scene relation applying to two or more Centers, highlighting a common feature.
R	**Relator**	All other types of non-Scene relations: (1) Rs that relate a C to some super-ordinate relation, and (2) Rs that relate two Cs pertaining to different aspects of the parent unit.
		Inter-Scene Relations
H	**Parallel Scene**	A Scene linked to other Scenes by regular linkage (e.g., temporal, logical, purposive).
L	**Linker**	A relation between two or more Hs (e.g., "when", "if", "in order to").
G	**Ground**	A relation between the speech event and the uttered Scene (e.g., "surprisingly").
		Other
F	**Function**	Does not introduce a relation or participant. Required by some structural pattern.

Table 1: The complete set of categories in UCCA's foundational layer.

tion (Sulem et al., 2018b), as well as for defining semantic evaluation measures for text-to-text generation tasks, including machine translation (Birch et al., 2016), text simplification (Sulem et al., 2018a) and grammatical error correction (Choshen and Abend, 2018).

The shared task defines a number of tracks, based on the different corpora and the availability of external resources (see §5). It received submissions from eight research groups around the world. In all settings at least one of the submitted systems improved over the state-of-the-art TUPA parser (Hershcovich et al., 2017, 2018), used as a baseline.

2 Task Definition

UCCA represents the semantics of linguistic utterances as directed acyclic graphs (DAGs), where terminal (childless) nodes correspond to the text tokens, and non-terminal nodes to semantic units that participate in some super-ordinate relation. Edges are labeled, indicating the role of a child in the relation the parent represents. Nodes and edges belong to one of several *layers*, each corresponding to a "module" of semantic distinctions.

UCCA's *foundational layer* covers the predicate-argument structure evoked by predicates of all grammatical categories (verbal, nominal, adjectival and others), the inter-relations between them, and other major linguistic phenomena such as semantic heads and multi-word expressions. It is the only layer for which annotated corpora exist at the moment, and is thus the target of this shared task. The layer's basic notion is the *Scene*, describing a state, action, movement or some other relation that evolves in time. Each Scene contains one main relation (marked as either a Process or a State), as well as one or more Participants. For example, the sentence "After graduation, John moved to Paris" (Figure 1) contains two Scenes, whose main relations are "graduation" and "moved". "John" is a Participant in both Scenes, while "Paris" only in the latter. Further categories account for inter-Scene relations and the internal structure of complex arguments and relations (e.g., coordination and multi-word expressions). Table 1 provides a concise description of the categories used by the UCCA foundational layer.

UCCA distinguishes *primary* edges, corresponding to explicit relations, from *remote* edges (appear dashed in Figure 1) that allow for a unit to participate in several super-ordinate relations. Primary edges form a tree in each layer, whereas remote edges enable reentrancy, forming a DAG.

UCCA graphs may contain *implicit* units with no correspondent in the text. Figure 2 shows the annotation for the sentence "A similar technique is almost impossible to apply to other crops, such as cotton, soybeans and rice."[2] It includes a single Scene, whose main relation is "apply", a secondary relation "almost impossible", as well as two complex arguments: "a similar technique" and the coordinated argument "such as cotton, soybeans, and rice." In addition, the Scene includes an implicit argument, which represents the agent of the "apply" relation.

While parsing technology is well-established

[2]The same example was used by Oepen et al. (2015) to compare different semantic dependency schemes.

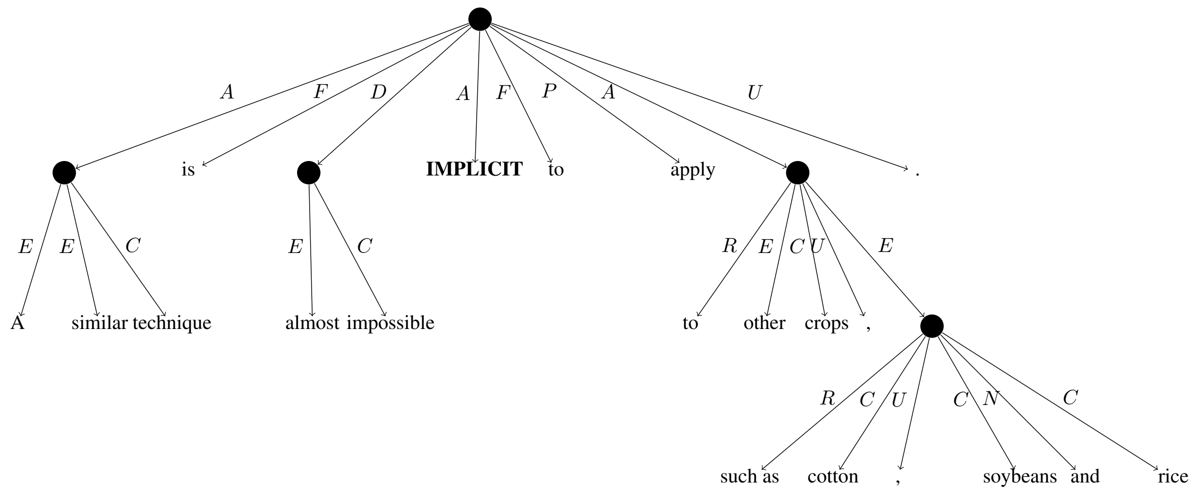

Figure 2: UCCA example with an implicit unit.

for syntactic parsing, UCCA has several formal properties that distinguish it from syntactic representations, mostly UCCA's tendency to abstract away from syntactic detail that do not affect argument structure. For instance, consider the following examples where the concept of a Scene has a different rationale from the syntactic concept of a clause. First, non-verbal predicates in UCCA are represented like verbal ones, such as when they appear in copula clauses or noun phrases. Indeed, in Figure 1, "graduation" and "moved" are considered separate Scenes, despite appearing in the same clause. Second, in the same example, "John" is marked as a (remote) Participant in the graduation Scene, despite not being explicitly mentioned. Third, consider the possessive construction in "John's trip home". While in UCCA "trip" evokes a Scene in which "John" is a Participant, a syntactic scheme would analyze this phrase similarly to "John's shoes".

The differences in the challenges posed by syntactic parsing and UCCA parsing, and more generally by semantic parsing, motivate the development of targeted parsing technology to tackle it.

3 Data & Resources

All UCCA corpora are freely available.[3] For English, we use v1.2.3 of the Wikipedia UCCA corpus (*Wiki*), v1.2.2 of the UCCA *Twenty Thousand Leagues Under the Sea* English-French parallel corpus (*20K*), which includes UCCA manual annotation for the first five chapters in French and English, and v1.0.1 of the UCCA German *Twenty Thousand Leagues Under the Sea* corpus, which includes the entire book in German. For consistent annotation, we replace any Time and Quantifier labels with Adverbial and Elaborator in these data sets. The resulting training, development[4] and test sets[5] are publicly available, and the splits are given in Table 2. Statistics on various structural properties are given in Table 3.

The corpora were manually annotated according to v1.2 of the UCCA guidelines,[6] and reviewed by a second annotator. All data was passed through automatic validation and normalization scripts.[7] The goal of validation is to rule out cases that are inconsistent with the UCCA annotation guidelines. For example, a Scene, defined by the presence of a Process or a State, should include at least one Participant.

Due to the small amount of annotated data available for French, we only provided a minimal training set of 15 sentences, in addition to the development and test set. Systems for French were expected to pursue semi-supervised approaches, such as cross-lingual learning or structure projection, leveraging the parallel nature of the corpus, or to rely on datasets for related formalisms, such as Universal Dependencies (Nivre et al., 2016). The full unannotated 20K Leagues corpus in English and French was released as well, in order to facilitate pursuing cross-lingual approaches.

Datasets were released in an XML format, including tokenized text automatically pre-

Table 3: Statistics of the corpora used for the shared task.

processed using spaCy (see §5), and gold-standard UCCA annotation for the train and development sets.[8] To facilitate the use of existing NLP tools, we also released the data in SDP, AMR, CoNLL-U and plain text formats.

4 TUPA: The Baseline Parser

We use the TUPA parser, the only parser for UCCA at the time the task was announced, as a baseline (Hershcovich et al., 2017, 2018). TUPA is a transition-based DAG parser based on a BiLSTM-based classifier.[9] TUPA in itself has been found superior to a number of conversion-based parsers that use existing parsers for other formalisms to parse UCCA by constructing a two-way conversion protocol between the formalisms. It can thus be regarded as a strong baseline for system submissions to the shared task.

5 Evaluation

Tracks. Participants in the task were evaluated in four settings:

1. English in-domain setting, using the Wiki corpus.
2. English out-of-domain setting, using the Wiki corpus as training and development data, and 20K Leagues as test data.
3. German in-domain setting, using the 20K Leagues corpus.
4. French setting with no training data, using the 20K Leagues as development and test data.

In order to allow both even ground comparison between systems and using hitherto untried resources, we held both an **open** and a **closed** track for submissions in the English and German settings. Closed track submissions were only allowed to use the gold-standard UCCA annotation distributed for the task in the target language, and were limited in their use of additional resources. Concretely, the only additional data they were allowed to use is that used by TUPA, which consists of automatic annotations provided by spaCy:[10] POS tags, syntactic dependency relations, and named entity types and spans. In addition, the closed track only allowed the use of word embeddings provided by fastText (Bojanowski et al., 2017)[11] for all languages.

Systems in the open track, on the other hand, were allowed to use any additional resource, such as UCCA annotation in other languages, dictionaries or datasets for other tasks, provided that they make sure not to use any additional gold standard annotation over the same text used in the UCCA

[8] https://github.com/UniversalConceptualCognitiveAnnotation/docs/blob/master/FORMAT.md

[9] https://github.com/huji-nlp/tupa

[10] http://spacy.io

[11] http://fasttext.cc

corpora.[12] In both tracks, we required that submitted systems are not trained on the development data. We only held an open track for French, due to the paucity of training data. The four settings and two tracks result in a total of 7 competitions.

Scoring. The following scores an output graph $G_1 = (V_1, E_1)$ against a gold one, $G_2 = (V_2, E_2)$, over the same sequence of terminals (tokens) W. For a node v in V_1 or V_2, define $yield(v) \subseteq W$ as is its set of terminal descendants. A pair of edges $(v_1, u_1) \in E_1$ and $(v_2, u_2) \in E_2$ with labels (categories) ℓ_1, ℓ_2 is *matching* if $yield(u_1) = yield(u_2)$ and $\ell_1 = \ell_2$. Labeled precision and recall are defined by dividing the number of matching edges in G_1 and G_2 by $|E_1|$ and $|E_2|$, respectively. F_1 is their harmonic mean:

$$2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

Unlabeled precision, recall and F_1 are the same, but without requiring that $\ell_1 = \ell_2$ for the edges to match. We evaluate these measures for primary and remote edges separately. For a more fine-grained evaluation, we additionally report precision, recall and F_1 on edges of each category.[13]

6 Participating Systems

We received a total of eight submissions to the different tracks: *MaskParse@Deskiñ* (Marzinotto et al., 2019) from Orange Labs and Aix-Marseille University, *HLT@SUDA* (Jiang et al., 2019) from Soochow University, *TüPa* (Pütz and Glocker, 2019) from the University of Tübingen, *UC Davis* (Yu and Sagae, 2019) from the University of California, Davis , *GCN-Sem* (Taslimipoor et al., 2019) from the University of Wolverhampton, *CUNY-PekingU* (Lyu et al., 2019) from the City University of New York and Peking University, *DANGNT@UIT.VNU-HCM* (Nguyen and Tran, 2019) from the University of Information Technology VNU-HCM, and *XLangMo* from Zhejiang University. Some of the teams participated in more than one track and two systems (*HLT@SUDA* and *CUNY-PekingU*) participated in all the tracks.

In terms of parsing approaches, the task was quite varied. *HLT@SUDA* converted UCCA graphs to constituency trees and trained a constituency parser and a recovery mechanism of remote edges in a multi-task framework. *MaskParse@Deskiñ* used a bidirectional GRU tagger with a masking mechanism. *Tüpa* and *XLangMo* used a transition-based approach. *UC Davis* used an encoder-decoder architecture. *GCN-SEM* uses a BiLSTM model to predict Semantic Dependency Parsing tags, when the syntactic dependency tree is given in the input. *CUNY-PKU* is based on an ensemble that includes different variations of the TUPA parser. *DANGNT@UIT.VNU-HCM* converted syntactic dependency trees to UCCA graphs.

Different systems handled remote edges differently. *DANGNT@UIT.VNU-HCM* and *GCN-SEM* ignored remote edges. *UC Davis* used a different BiLSTM for remote edges. *HLT@SUDA* marked remote edges when converting the graph to a constituency tree and trained a classification model for their recovery. *MaskParse@Deskiñ* handles remote edges by detecting arguments that are outside of the parent's node span using a detection threshold on the output probabilities.

In terms of using the data, all teams but one used the UCCA XML format, two used the CoNLL-U format, which is derived by a lossy conversion process, and only one team found the other data formats helpful. One of the teams (*MaskParse@Deskiñ*) built a new training data adapted to their model by repeating each sentence N times, N being the number of non-terminal nodes in the UCCA graphs. Three of the teams adapted the baseline TUPA parser, or parts of it to form their parser, namely *TüPa*, *CUNY-PekingU* and *XLangMo*; *HLT@SUDA* used a constituency parser (Stern et al., 2017) as a component in their model; *DANGNT@UIT.VNU-HCM* is a rule-based system over the Stanford Parser, and the rest are newly constructed parsers.

All teams found it useful to use external resources beyond those provided by the Shared Task. Four submissions used external embeddings, MUSE (Conneau et al., 2017) in the case of *MaskParse@Deskiñ* and *XLangMo*, ELMo (Peters et al., 2018) in the case of *TüPa*,[14] and BERT (Devlin et al., 2018) in the case of *HLT@SUDA*.

[12]We are not aware of any such annotation, but include this restriction for completeness.

[13]The official evaluation script providing both coarse-grained and fine-grained scores can be found in `https://github.com/huji-nlp/ucca/blob/master/scripts/evaluate_standard.py`.

Table 4: Official F1-scores for each system in each track. Prim.: primary edges, Rem.: remote edges.

Other resources included additional unlabeled data (*TüPa* and *CUNY-PekingU*), a list of multi-word expressions (*MaskParse@Deskiñ*), and the Stanford parser in the case of *DANGNT@UIT.VNU-HCM*. Only *CUNY-PKU* used the *20K* unlabeled parallel data in English and French.

A common trend for many of the systems was the use of cross-lingual projection or transfer (*MaskParse@Deskiñ*, *HLT@SUDA*, *TüPa*, *GCN-Sem*, *CUNY-PKU* and *XLangMo*). This was necessary for French, and was found helpful for German as well (*CUNY-PKU*).

7 Results

Table 4 shows the labeled and unlabeled F1 for primary and remote edges, for each system in each track. Overall F1 (All) is the F1 calculated over both primary and remote edges. Full results are available online.[15]

Figure 3 shows the fine-grained evaluation by labeled F1 per UCCA category, for each system in each track. While Ground edges were uniformly difficult to parse due to their sparsity in the training data, Relators were the easiest for all systems, as they are both common and predictable. The Process/State distinction proved challenging, and most main relations were identified as the more common Process category. The winning system in most tracks (HLT@SUDA) performed better on almost all categories. Its largest advantage was on Parallel Scenes and Linkers, showing was especially successful at identifying Scene boundaries relative to the other systems, which requires a good understanding of syntax.

8 Discussion

The *HLT@SUDA* system participated in all the tracks, obtaining the first place in the six English and German tracks and the second place in the French open track. The system is based on the conversion of UCCA graphs into constituency trees, marking remote and discontinuous edges for recovery. The classification-based recovery of the remote edges is performed simultaneously with the constituency parsing in a multi-task learning framework. This work, which further connects between semantic and syntactic parsing, proposes a recovery mechanism that can be applied to other grammatical formalisms, enabling the conversion of a given formalism to another one for parsing. The idea of this system is inspired by the pseudo non-projective dependency parsing approach proposed by Nivre and Nilsson (2005).

The *MaskParse@Deskiñ* system only participated to the French open track, focusing on cross-lingual parsing. The system uses a semantic tagger, implemented with a bidirectional GRU and a masking mechanism to recursively extract the inner semantic structures in the graph. Multilingual word embeddings are also used. Using the English and German training data as well as the small French trial data for training, the parser ranked fourth in the French open track with a labeled F1 score of 65.4%, suggesting that this new model could be useful for low-resource languages.

The *Tüpa* system takes a transition-based approach, building on the TUPA transition system and oracle, but modifies its feature representations. Specifically, instead of representing the parser configuration using LSTMs over the partially parsed graph, stack and buffer, they use feed-

forward networks with ELMo contextualized embeddings. The stack and buffer are represented by the top three items on them. For the partially parsed graph, they extract the rightmost and leftmost parents and children of the respective items, and represent them by the ELMo embedding of their form, the embedding of their dependency heads (for terminals, for non-terminals this is replaced with a learned embedding) and the embeddings of all terminal children. Results are generally on-par with the TUPA baseline, and surpass it from the out-of-domain English setting. This suggests that the TUPA architecture may be simplified, without compromising performance.

The *UC Davis* system participated only in the English closed track, where they achieved the second highest score, on par with TUPA. The proposed parser has an encoder-decoder architecture, where the encoder is a simple BiLSTM encoder for each span of words. The decoder iteratively and greedily traverses the sentence, and attempts to predict span boundaries. The basic algorithm yields an unlabeled contiguous phrase-based tree, but additional modules predict the labels of the spans, discontiguous units (by joining together spans from the contiguous tree under a new node), and remote edges. The work is inspired by Kitaev and Klein (2018), who used similar methods for constituency parsing.

The *GCN-SEM* system uses a BiLSTM encoder, and predicts bi-lexical semantic dependencies (in the SDP format) using word, token and syntactic dependency parses. The latter is incorporated into the network with a graph convolutional network (GCN). The team participated in the English and German closed tracks, and were not among the highest-ranking teams. However, scores on the UCCA test sets converted to the bi-lexical CoNLL-U format were rather high, implying that the lossy conversion could be much of the reason.

The *CUNY-PKU* system was based on an ensemble. The ensemble included variations of TUPA parser, namely the MLP and BiLSTM models (Hershcovich et al., 2017) and the BiLSTM model with an additional MLP. The system also proposes a way to aggregate the ensemble going through CKY parsing and accounting for remotes and discontinuous spans. The team participated in all tracks, including additional information in the open domain, notably synthetic data based on automatically translating annotated texts. Their system ranks first in the French open track.

The *DANGNT@UIT.VNU-HCM* system participated only in the English Wiki open and closed tracks. The system is based on graph transformations from dependency trees into UCCA, using heuristics to create non-terminal nodes and map the dependency relations to UCCA categories. The manual rules were developed based on the training and development data. As the system converts trees to trees and does not add reentrancies, it does not produce remote edges. While the results are not among the highest-ranking in the task, the primary labeled F1 score of 71.1% in the English open track shows that a rule-based system on top of a leading dependency parser (the Stanford parser) can obtain reasonable results for this task.

9 Conclusion

The task has yielded substantial improvements to UCCA parsing in all settings. Given that the best reported results were achieved with different parsing and learning approaches than the baseline model TUPA (which has been the only available parser for UCCA), the task opens a variety of paths for future improvement. Cross-lingual transfer, which capitalizes on UCCA's tendency to be preserved in translation, was employed by a number of systems and has proven remarkably effective. Indeed, the high scores obtained for French parsing in a low-resource setting suggest that high quality UCCA parsing can be straightforwardly extended to additional languages, with only a minimal amount of manual labor.

Moreover, given the conceptual similarity between the different semantic representations (Abend and Rappoport, 2017), it is likely the parsers developed for the shared task will directly contribute to the development of other semantic parsing technology. Such a contribution is facilitated by the available conversion scripts available between UCCA and other formats.

Acknowledgments

We are deeply grateful to Dotan Dvir and the UCCA annotation team for their diligent work on the corpora used in this shared task.

Abstract

This paper describes a simple UCCA semantic graph parsing approach. The key idea is to convert a UCCA semantic graph into a constituent tree, in which extra labels are deliberately designed to mark remote edges and discontinuous nodes for future recovery. In this way, we can make use of existing syntactic parsing techniques. Based on the data statistics, we recover discontinuous nodes directly according to the output labels of the constituent parser and use a biaffine classification model to recover the more complex remote edges. The classification model and the constituent parser are simultaneously trained under the multi-task learning framework. We use the multilingual BERT as extra features in the open tracks. Our system ranks the first place in the six English/German closed/open tracks among seven participating systems. For the seventh cross-lingual track, where there is little training data for French, we propose a language embedding approach to utilize English and German training data, and our result ranks the second place.

1 Introduction

Universal Conceptual Cognitive Annotation (UCCA) is a multi-layer linguistic framework for semantic annotation proposed by Abend and Rappoport (2013). Figure 1 shows an example sentence and its UCCA graph. Words are represented as terminal nodes. Circles denote non-terminal nodes, and the semantic relation

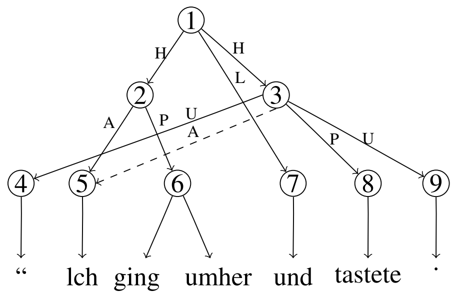

Figure 1: A UCCA graph example from the German data. The English translation is “ I went around and groped . We assign a number to each non-terminal node to facilitate illustration.

between two non-terminal nodes is represented by the label on the edge. One node may have multiple parents, among which one is annotated as the primary parent, marked by solid line edges, and others as remote parents, marked by dashed line edges. The primary edges form a tree structure, whereas the remote edges enable reentrancy, forming directed acyclic graphs (DAGs).[1] The second feature of UCCA is the existence of nodes with discontinuous leaves, known as discontinuity. For example, node 3 in Figure 1 is discontinuous because some terminal nodes it spans are not its descendants.

Hershcovich et al. (2017) first propose a transition-based UCCA Parser, which is used as the baseline in the closed tracks of this shared task. Based on the recent progress on transition-based parsing techniques, they propose a novel set of transition actions to handle both discontinuous and remote nodes and design useful features based on bidirectional LSTMs. Hershcovich et al. (2018) then extend their previous approach and propose to utilize the annotated data with other

[*]Corresponding author, hlt.suda.edu.cn/zhenghua

[1]The full UCCA scheme also has implicit and linkage relations, which are overlooked in the community so far.

semantic formalisms such as abstract meaning representation (AMR), universal dependencies (UD), and bilexical Semantic Dependencies (SDP), via multi-task learning, which is used as the baseline in the open tracks.

In this paper, we present a simple UCCA semantic graph parsing approach by treating UCCA semantic graph parsing as constituent parsing. We first convert a UCCA semantic graph into a constituent tree by removing discontinuous and remote phenomena. Extra labels encodings are deliberately designed to annotate the conversion process and to recover discontinuous and remote structures. We heuristically recover discontinuous nodes according to the output labels of the constituent parser, since most discontinuous nodes share the same pattern according to the data statistics. As for the more complex remote edges, we use a biaffine classification model for their recovery. We directly employ the graph-based constituent parser of Stern et al. (2017) and jointly train the parser and the biaffine classification model via multi-task learning (MTL). For the open tracks, we use the publicly available multilingual BERT as extra features. Our system ranks the first place in the six English/German closed/open tracks among seven participating systems. For the seventh cross-lingual track, where there is little training data for French, we propose a language embedding approach to utilize English and German training data, and our result ranks the second place.

2 The Main Approach

Our key idea is to convert UCCA graphs into constituent trees by removing discontinuous and remote edges and using extra labels for their future recovery. Our idea is inspired by the pseudo non-projective dependency parsing approach propose by Nivre and Nilsson (2005).

2.1 Graph-to-Tree Conversion

Given a UCCA graph as depicted in Figure 1, we produce a constituent tree shown in Figure 2 based on our algorithm described as follows.

1) Removal of remote edges. For nodes that have multiple parent nodes, we remove all remote edges and only keep the primary edge. To facilitate future recovery, we concatenate an extra "remote" to the label of the primary edge, indicating that the corresponding node has other remote relations. We can see that the label of the child node 5 becomes "A-remote" after conversion in Figure 1 and 2.

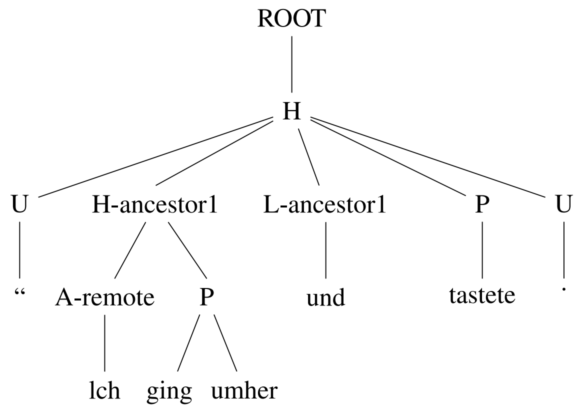

Figure 2: Constituent tree converted from UCCA gragh.

	train	dev	total	percent(%)
ancestor 1	1460	149	1609	91.3
ancestor 2	96	19	115	6.5
ancestor 3	21	0	21	1.2
discontinuous	16	2	18	1.0

Table 1: Distribution of discontinuous structures in the English-Wiki data, which is similar in the German data.

2) Handling discontinuous nodes. We call node 3 in Figure 1 a discontinuous node because the terminal nodes (also words or leaves) it spans are not continuous ("lch ging umher und" are not its descendants). Since mainstream constituent parsers cannot handle discontinuity, we try to remove discontinuous structures by moving specific edges in the following procedure.

Given a discontinuous node $A = 3$, we first process the leftmost non-descendant node $B = “lch''$. We go upwards along the edges until we find a node $C = 2$, whose father is either the lowest common ancestor (LCA) of $A = 3$ and $B = “lch''$ or another discontinuous node. We denote the father of $C = 2$ as $D = 1$.

Then we move $C = 2$ to be the child of $A = 3$, and concatenate the original edge label with an extra string (among "ancestor 1/2/3/..." and "discontinuous") for future recovery, where the number represents the number of edges between

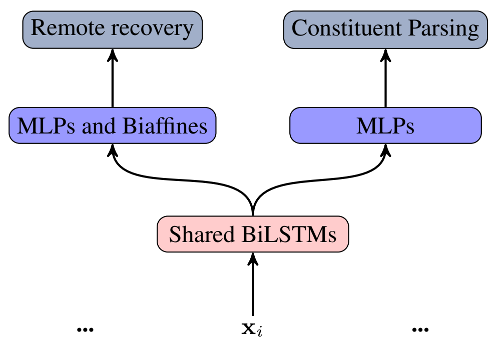

Figure 3: The framework of MTL.

the ancestor $D = 1$ and $A = 3$.

After reorganizing the graph, we then restart and perform the same operations again until there is no discontinuity.

Table 1 shows the statistics of the discontinuous structures in the English-Wiki data. We can see that D is mostly likely the LCA of A and B, and there is only one edge between D and A in more than 90% cases.

Considering the skewed distribution, we only keep "ancestor 1" after graph-to-tree conversion, and treat others as continuous structures for simplicity.

3) Pushing labels from edges into nodes. Since the labels are usually annotated in the nodes instead of edges in constituent trees, we push all labels from edges to the child nodes. We label the top node as "ROOT".

2.2 Constituent Parsing

We directly adopt the minimal span-based parser of Stern et al. (2017). Given an input sentence $\mathbf{s} = w_1...w_n$, each word w_i is mapped into a dense vector $\mathbf{x}_i$ via lookup operations.

$$\mathbf{x}_i = \mathbf{e}_{w_i} \oplus \mathbf{e}_{t_i} \oplus ...$$

where $\mathbf{e}_{w_i}$ is the word embedding and $\mathbf{e}_{t_i}$ is the part-of-speech tag embedding. To make use of other auto-generated linguistic features, provided with the datasets, we also include the embeddings of the named entity tags and the dependency labels, but find limited performance gains.

Then, the parser employs two cascaded bidirectional LSTM layers as the encoder, and use the top-layer outputs as the word representations.

Afterwards, the parser represents each span $w_i...w_j$ as

$$\mathbf{r}_{i,j} = (\mathbf{f}_j - \mathbf{f}_i) \oplus (\mathbf{b}_i - \mathbf{b}_j)$$

where $\mathbf{f}_i$ and $\mathbf{b}_i$ are the output vectors of the top-layer forward and backward LSTMs.

The span representations are then fed into MLPs to compute the scores of span splitting and labeling. For inference, the parser performs greedy top-down searching to build a parse tree.

2.3 Remote Edge Recovery

We borrow the idea of the state-of-the-art biaffine dependency parsing (Dozat and Manning, 2017) and build our remote edge recovery model. The model shares the same inputs and LSTM encoder as the constituent parser under the MTL framework (Collobert and Weston, 2008). For each remote node, marked by "-remote" in the constituent tree, we consider all other non-terminal nodes as its candidate remote parents. Given a remote node A and another non-terminal node B, we first represent them as the span representations. $\mathbf{r}_{i,j}$ and $\mathbf{r}_{i',j'}$, where i, i', j, j' are the start and end word indices governed by the two nodes. Please kindly note that B may be a discontinuous node.

Following Dozat and Manning (2017), we apply two separate MLPs to the remote and candidate parent nodes respectively, producing $\mathbf{r}^{\texttt{child}}_{i,j}$ and $\mathbf{r}^{\texttt{parent}}_{i',j'}$.

Finally, we compute a labeling score vector via a biaffine operation.

$$\mathbf{s}(A \leftarrow B) = \begin{bmatrix} \mathbf{r}^{\texttt{child}}_{i,j} \\ 1 \end{bmatrix}^{\mathrm{T}} \mathbf{W}\mathbf{r}^{\texttt{parent}}_{i',j'} \quad (1)$$

where the dimension of the labeling score vector is the number of the label set, including a "NOT-PARENT" label.

Training loss. We accumulate the standard cross-entropy losses of all remote and non-terminal node pairs. The parsing loss and the remote edge classification loss are added in the MTL framework.

2.4 Use of BERT

For the open tracks, we use the contextualized word representations produced by BERT (Devlin et al., 2018) as extra input features.[2] Following previous works, we use the weighted summation of the last four transformer layers and then multiply a task-specific weight parameter following (Peters et al., 2018).

[2]We use the multilingual cased BERT from https://github.com/google-research/bert.

3 Cross-lingual Parsing

Because of little training data for French, we borrow the treebank embedding approach of Stymne et al. (2018) for exploiting multiple heterogeneous treebanks for the same language, and propose a language embedding approach to utilize English and German training data. The training datasets of the three languages are merged to train a single UCCA parsing model. The only modification is to concatenate each word position with an extra language embedding (of dimension 50), i.e. $\mathbf{x}_i \oplus \mathbf{e}_{lang=en/de/fr}$ to indicate which language this training sentence comes from. In this way, we expect the model can fully utilize all training data since most parameters are shared except the three language embedding vectors, and learn the language differences as well.

4 Experiments

Except BERT, all the data we use, including the linguistic features and word embeddings, are provided by the shared task organizer (Hershcovich et al., 2019). We also adopt the averaged F1 score as the main evaluation metrics returned by the official evaluation scripts (Hershcovich et al., 2019).

We train each model for at most 100 iterations, and early stop training if the peak performance does not increase in 10 consecutive iterations.

Table 2 shows the results on the dev data. We have experimented with different settings to gain insights on the contributions of different components. For the single-language models, it is clear that using pre-trained word embeddings outperforms using randomly initialized word embeddings by more than 1% F1 score on both English and German. Finetuning the pre-trained word embeddings leads to consistent yet slight performance improvement. In the open tracks, replacing word embedding with the BERT representation is also useful on English (2.8% increase) and German (1.2% increase). Concatenating pre-trained word embeddings with BERT outputs leads is also beneficial.

For the multilingual models, using randomly initialized word embeddings is better than pre-trained word embeddings, which is contradictory to the single-language results. We suspect this is due to that the pre-trained word embeddings are independently trained for different languages and would lie in different semantic spaces without proper aligning. Using the BERT outputs is tremendously helpful, boosting the F1 score by more than 10%. We do not report the results on English and German for brevity since little improvement is observed for them.

5 Final Results

Table 3 lists our final results on the test data. Our system ranks the first place in six tracks (English/German closed/open) and the second place in the French open track. Note that we submitted a wrong result for the French open track during the evaluation phase by setting the wrong index of language, which leads to about 2% drop of averaged F1 score (0.752). Please refer to (Hershcovich et al., 2019) for the complete results and comparisons.

6 Conclusions

In this paper, we describe our system submitted to SemEval 2019 Task 1. We design a simple UCCA semantic graph parsing approach by making full use of the recent advance in syntactic parsing community. The key idea is to convert UCCA graphs into constituent trees. The graph recovery

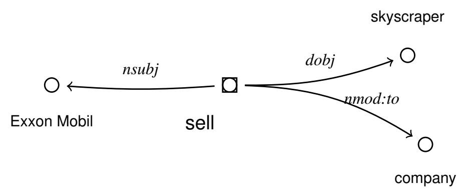
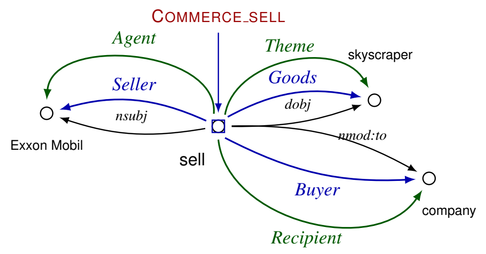
Abstract

This paper presents Unsupervised Lexical Frame Induction, Task 2 of the International Workshop on Semantic Evaluation in 2019. Given a set of prespecified syntactic forms in context, the task requires that verbs and their arguments be clustered to resemble semantic frame structures. Results are useful in identifying polysemous words, i.e., those whose frame structures are not easily distinguished, as well as discerning semantic relations of the arguments. Evaluation of unsupervised frame induction methods fell into two tracks: Task A) *Verb Clustering* based on FrameNet 1.7; and B) *Argument Clustering*, with B.1) based on FrameNet's core frame elements, and B.2) on VerbNet 3.2 semantic roles. The shared task attracted nine teams, of whom three reported promising results. This paper describes the task and its data, reports on methods and resources that these systems used, and offers a comparison to human annotation.



(a) Input: subcategorization frames.



(b) Output: Semantic Frame Tagging using labels learned by Unsupervised methods.

Figure 1: Given semantically unlabeled structures (1a), annotate the input with semantic information learned via unsupervised methods (1b).

1 Introduction

SemEval 2019 Task 2 focused on the unsupervised semantic labeling of a set of prespecified (semantically) unlabeled structures (Figure 1). Unsupervised learning methods analyze these structures (Figure 1a) to augment them with semantic labels (Figure 1b). The shape of the manually labeled input frames is constrained to an *acyclic* connected tree of lexical items (words and multi-word units) of maximum depth 1, where just one root governs several arguments. The task used Berkeley FrameNet (FN) (Ruppenhofer et al., 2016) and Q. Zadeh and Petruck (2019), guidelines for this task, to determine the arguments and label them with semantic information.

We compared the proposed system results for unsupervised semantic tagging with that of human annotated (or, gold-standard) data in three different subtasks (Figure 2). To evaluate the systems, we computed distributional similarities between their generated unsupervised labeled data and human annotated reference data. For computing similarities we used general purpose numeral methods of text clustering, in particular BCUBED F-SCORE (Bagga and Baldwin, 1998) as the single figure of merit to rank the systems.

The most important result of the shared task is the creation of a benchmark for a future complex task. This benchmark includes a moderately sized, manually annotated set of frames, where only the verbs of each were included, along with their *core frame elements* (which uniquely define a frame as Ruppenhofer et al. describe). To complement FN's core frame elements that have highly specific meanings, the benchmark also includes the annotated argument structures of the verbs based on the generic semantic roles proposed for verb classes in VerbNet 3.2 (Kipper et al., 2000; Palmer et al., 2017). The benchmark comes with simplified annotation guidelines and a modular annotation system with browsing and editing capabilities.[1] Complementing the benchmarking are several state-of-the-art competing baselines, from the participants, that serve as a point of departure for improvements in the future.[2]

The rest of this paper is organized as follows: Section 2 contextualizes this task; Section 3 offers a detailed task-description; Section 4 describes the data; Section 5 introduces the evaluation metrics and baselines; Section 6 characterizes the participating systems and unsupervised methods that participants used; Section 7 provides evaluation scores and additional insight about the data; and Section 8 presents concluding remarks.

2 Background

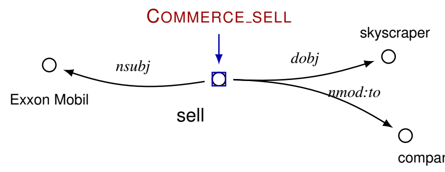
Frame Semantics (Fillmore, 1976) and other theories (Gamerschlag et al., 2014) that adopt typed feature structures for representing knowledge and linguistic structures have developed in parallel over several decades in theoretical linguistic studies about the syntax–semantics interface, as well as in empirical corpus-driven applications in natural language processing. Building repositories of (lexical) semantic frames is a core component in all of these efforts. In formal studies, lexical semantic frame knowledge bases instantiate foundational theories with tangible examples, e.g., to provide supporting evidence for the theory. Practically, frame semantic repositories play a pivotal role in natural language understanding and semantic parsing, both as inspiration for a representation format and for training data-driven machine learning systems, which is required for tasks such as information extraction, question-answering, text summarization, among others.

However, manually developing frame semantic databases and annotating corpus-derived illustrative examples to support analyses of frames are resource-intensive tasks. The most well-known frame semantic (lexical) resource is FrameNet (Ruppenhofer et al., 2016), which only covers a (relatively) small set of the vocabulary of contemporary English. While NLP research has integrated FrameNet data into semantic parsing, e.g., Swayamdipta et al. (2018), these methods cannot extend beyond previously seen training labels, tagging out-of-domain semantics as *unknown* at best. This limitation does not hinder unsupervised methods, which will port and extend the coverage of semantic parsers, a common challenge in semantic parsing (Hartmann et al., 2017).

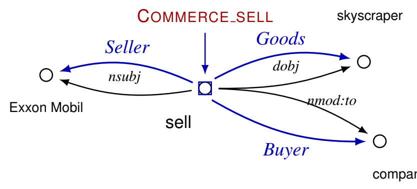
Unsupervised frame induction methods can serve as an assistive semantic analytic tool, to build language resources and facilitate linguistic studies. Since the focus is usually to build language resources, most systems (Pennacchiotti et al. (2008); Green et al. (2004)) have used a lexical semantic resource like WordNet (Miller, 1995) to extend coverage of a resource like FrameNet. Some methods, e.g., Modi et al. (2012) and Kallmeyer et al. (2018), tried to extract FrameNet-like resources automatically without additional semantic information. Others (Ustalov et al. (2018); Materna (2012)) addressed frame induction only for verbs with two arguments.

Lastly, unsupervised frame induction methods can also facilitate linguistic investigations by capturing information about the reciprocal relationships between statistical features and linguistic or extra-linguistic observations (e.g., Reisinger et al. (2015)). This task aimed to benchmark a class of such unsupervised frame induction methods.

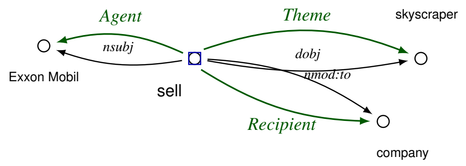
3 Task Description



(a) **Task A** - Identifying Semantic Frames: Unsupervised learned labels evaluated against FN's lexical units



(b) **Task B.1** - Full Frame Semantic Tagging: Unsupervised labels evaluated against FN's frames



(c) **Task B.2** – Case Role Labeling: Unsupervised labels evaluated against generic semantic roles (VerbNet)

Figure 2: Subtasks of SemEval 2019 Task 2.

[1] http://sfa.phil.hhu.de/.

[2] See https://competitions.codalab.org/competitions/19159 for accessing the task's language resources, tools, and further technical details.

The ambitious goal of this task was the unsupervised induction of frame semantic structures from tokenized and morphosyntacally labeled text corpora. We sought to achieve this goal by building an evaluation benchmark for three tasks. **Task A** dealt with unsupervised labeling of verb lemmas with their frame meaning. **Task B** involved unsupervised argument role labeling, where **B.1** benchmarked unsupervised labeling of frame-specific frame elements (FEs) based on FN, and **B.2** benchmarked unsupervised role labeling of arguments in Case Grammar terms (Fillmore, 1968) and against a set of generic semantic roles, taken primarily from VerbNet.

The task was unsupervised in that it forbade the use of any explicit semantic annotation (only permitting morphosyntactic annotation). Instead, we encouraged the use of unsupervised representation learning methods (e.g., word embeddings, brown clusters) to obtain semantic information. Hence, systems learn and assign semantic labels to test records without appealing to any explicit training labels. For development purposes, developers received a small labeled development set.

3.1 Task A: Clustering Verbs

The goal of this task was to identify verbs that evoke the same frame. The task involved labeling verb uses in context to resemble their categorization based on Frame Semantics (Figure 2a). Here, we used FN 1.7 as the reference for frame definitions. Hence, the task constituted the unsupervised induction of FN's lexical units, where a lexical unit (LU) is a pairing of a lemma and a frame. For example, we expected that the LUs *auction*.v, *retail*.v, *sell*.v, etc., which evoke the typed situation of COMMERCE_SELL, be labeled with the same unsupervised tag.[3]

The task resembles word sense induction in that it assigns a class (or sense) label to a verb. In word sense induction (WSI), labels are determined and evaluated on word forms (lemma + part-of-speech e.g., *sell.v* or *auction.n*). WSI evaluations assume that the inventory of senses (set S_is) for different word forms f is devised independently. For instance, assuming f_1 is labeled with the set of senses S_1 and f_2 with S_2, then $S_1 \cap S_2 \neq \phi$ only if $f_1 = f_2$; and, if $f_1 \neq f_2$ then $S_1 \cap S_2 = \phi$ (as in other SemEval benchmarks, including Agirre and Soroa (2007); Manandhar et al. (2010); Jurgens and Klapaftis (2013); Navigli and Vannella (2013)). For instance, in WSI evaluations based on OntoNotes (Hovy et al., 2006), six different labels from S_{sell} are assigned to the lemma $sell$.v, and one label s' is assigned to $auction$.v, knowing that $s' \notin S_{sell}$. Typically, lexical semantic relationships among members of S_is (e.g., synonymy, antonymy) are then analyzed independently of WSI (e.g., Lenci and Benotto (2012); Girju et al. (2007); McCarthy and Navigli (2007)). In contrast, this task assumes that the sense inventory is defined independent of word forms.

This task involves uncovering mapping between word forms f and members of S such that different word forms (i.e., $f_i \neq f_j$) can be mapped to the same meaning (label), and the same meaning (label) can be mapped to several word forms. We defined S with respect to FrameNet and assumed that its typed-situation frames are units of meaning. So, COMMERCE_SELL captures the meaning associated with both $sell$.v and $auction$.v., as well as other selling-related words. Hence, in some sense, Task A goes beyond the ordinary WSI task as it also demands identifying (unspecified) lexical semantic relationships between verbs.

3.2 Task B.1: Unsupervised Frame Semantic Argument Labeling

Taking the frames as primary and defining roles relative to each frame, the aim of Task B.1 was to cluster prespecified verb-headed argument structures according to the principles of Frame Semantics, where FrameNet served as the reference for evaluation. This task amounted to unsupervised labeling of frames and core FEs (Figure 2b). Because FrameNet defines FEs frame-specifically, Task B.1 entails Task A.

Given a set of semantically-unlabelled arguments as input (e.g., Figure 1a), the root nodes (i.e., verbs) are clustered and assigned to a set of unsupervised frame labels π_i ($1 \leq i \leq n$, where n is the number of latent frames). Then, the arguments are labeled with semantic role labels (FEs) interpreted locally given the frame. That is, for any pair of π_x and π_y, the set of assigned roles R_x to arguments under π_x are assumed to be independent from R_y labels for π_y ($R_x \cap R_y = \phi$).

3.3 Task B.2: Unsupervised Case Role Labeling

We defined Subtask B.2 in parallel to Subtask B.1 and involved an idea from Case Grammar. The ar-

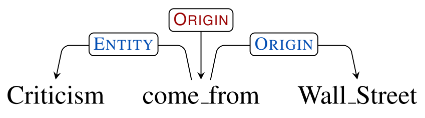
[3]Dark red small caps indicate FN frames.

guments of a verb in a set of prespecified subcategorization frames were clustered according to a common set of generic semantic roles (Figure 2c). Here, the task assumed that semantic roles are universal and generic (e.g., Agent, Patient). Their configuration determines the argument structure of verb-headed phrases. We evaluated this unsupervised labeling of arguments with semantic roles independently of the class, sense, and word form of a verb. We compared the role labels against a set of semantic roles from VerbNet 3.2 (Kipper et al., 2000). Given a verb instance, no guarantee exists that input argument structures for B.2 and B.1 would be the same.

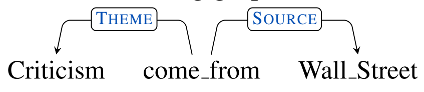
4 Evaluation Dataset

The dataset consists of manual annotations for verb-headed frame structures anchored in tokenized sentences. These frame structures were manually annotated using the guidelines for this task (Q. Zadeh and Petruck, 2019). For example, as already illustrated, the verb *come_from*.v is annotated in terms of FN's ORIGIN frame and its *core* FEs, as Example 1 shows.

(1) Criticism of futures COMES FROM Wall Street.



Also, using the set of 32 generic semantic role labels in VerbNet 3.2 and two additional roles, COGNIZER and CONTENT, we annotated arguments of the verb as the following graphic shows.



We assumed unique identifiers for sentences, e.g., #s1 for Example 1. The evaluation record for *come_from*.v (Task A) appears below, where #s1 4_5 specifies the position of the verb in the sentence (Example 1).

A [#s1 4_5 come_from.ORIGIN]

Similarly, for Task B.1 and Task B.2, respectively, the evaluation records are as follows here.

B.1 [#s1 4_5 come_from.ORIGIN Criticism-:-1-:-ENTITY Wall_Street-:-6_7-:-ORIGIN]

B.2 [#s1 4_5 come_from.NA Criticism-:-1-:-THEME Wall_Street-:-6_7-:-SOURCE]

We stripped off the manually asserted labels from the records and passed them to systems for assigning unsupervised labels. Evidently, later a scorer program (Section 5) compared system-generated labels with the manually assigned labels.

4.1 Data Sampling

We sampled data from the *Wall Street Journal* (WSJ) corpus of the Penn Treebank. Kallmeyer et al. (2018) provided frame annotations similar to those in this task for a portion of WSJ sentences, using SemLink (Bonial et al., 2013) and EngVallex (Cinková et al., 2014) to generate frame semantic annotations semi-automatically. That work was based on FrameNet and the Prague Dependency Treebank (PSD) (Hajič et al., 2012) from the Broad-coverage Semantic Dependency resource (Oepen et al., 2016). We started by annotating a portion of the records in Kallmeyer et al. (2018), and later deviated from this subset to create a more representative sample of the overall diversity and distribution of verbs in the WSJ corpus using a stratified random sampling method.

4.2 Guidelines

The annotation guidelines for this task were slightly different from those of FrameNet and various semantic dependency treebanks. In contrast to FN, which annotates a full span of text as an argument filler, or PropBank, which annotates syntactic constituents of arguments of verbs (Palmer et al., 2005), we identified the text spans and only annotated a single word or a multi-word unit (MWU), i.e., the semantic head of the span, like annotations in Oepen et al. (2016) and Abstract Meaning Representation (Banarescu et al., 2013). To illustrate, in Example 1, FN would annotate *Criticism of futures* as filling the FE ENTITY. We only annotated *Criticism*, understanding it as the LU that evokes JUDGMENT_COMMUNICATION, which in turn represents the meaning of the whole text span. Thus, we assumed that another frame f_a fills an argument of a frame. We annotated only the main content word(s) that evoke(s) f_a; these main words are the *semantic heads*.[4]

Multi-word unit semantic heads (e.g., named entities, word form combinations) are annotated as if a single word form, such as *Wall Street* (# 1), excluding modifiers. In contrast to semantic depen-

[4]The annotation guidelines (Q. Zadeh and Petruck, 2019) discuss decisions about marking semantic heads and the complex situations resulting from it for argument annotation.

dency structures (e.g., DELPH-IN MRS-Derived Semantic Dependencies, Enju PredicateArgument Structures, and Tectogramatical Representation in PSD (Oepen et al., 2016)), we did not commit to the underlying syntactic structure of the sentence since we were not obliged to relabel only syntactic structures. Rather, we annotated words and MWUs if the frame analysis permitted doing so.[5]

4.3 Annotation Procedure

We annotated the data in a modular manner and in a semi-controlled environment using an annotation system developed for this purpose. The procedure consisted of four steps: 1) Reading and Comprehension; 2) Choosing a Frame; 3) Annotating Arguments; and 4) Rating, Commenting, or Revising. We tracked and logged all changes in the data as well as annotator interaction with the annotation system upon starting to annotate. The tool measured the time that annotators spent on each record and each annotation step, as well as how annotators moved between steps.

In Step 1, annotators viewed a sentence with one highlighted verb, as in Example 2.

(2) Criticism of futures **COMES** from Wall Street.

The goal of this step was understanding the meaning of the verb and its semantic function, and identifying semantic heads of arguments and their associated words or MWUs. To continue, an annotator must confirm the understanding of the verb's meaning of the verb, and can identify its semantic arguments. Without confirmation, an annotator would terminate the annotation process for that input sentence and go to the next one.

If confirmed, Step 2 required the annotator to choose the frame that the verb evoked. This step may have included annotating multi-word phrasal verbs, e.g., COMES+FROM (Example 2). The annotation system assisted by providing a list of likely frames for the verb, including a LU lookup function (as in FN), an extended set of LUs derived via statistical methods, and previously logged annotations. After reviewing the definitions of the proposed frames, annotators chose one, or annotated the verb form with a different existing FN frame. Otherwise, the annotator terminated the process and the record moved to the list of "skipped items".

The annotation of arguments, Step 3, required that annotators label the core FEs of the chosen frame by first identifying their semantic head, which first may have required marking MWUs, e.g., Wall+Street in Example 3, below.

(3) Criticism of futures **comes from** Wall Street.

The tool lists the core FEs and their definitions, and checks the integrity of record annotations to ensure that each core FE is annotated only once. In parallel, annotators add the verb's subcategorization frame and its semantic role. We did not annotate null instantiated FEs (but FN does). During step 3, annotators could go back to the previous step and change their choice of frame type.

For Step 4, annotators rated their annotation, stating their opinion on how well the annotated instance fit FrameNet's definition and how it compared to other annotated instances. In a sense, annotators measured their confidence in the assigned labels. They did so by selecting a number on a scale from 1 to 5, with 1 not confident at all and 5 the most confident, i.e., the annotation fit perfectly to the chosen FrameNet frame, its definition, and examples. Annotators had the option to add free text comments on each record.

The annotation procedure was rarely straightforward. Given the interdependence of Steps 2 and 3, annotators usually moved back and forth between them. In Step 2 an annotator might believe that a target verb did not belong in any existing FN frame. Likewise, annotators could terminate the annotation process even upon reaching the last step.

4.3.1 Quality Control

At least two annotators verified all annotation used in the evaluation. A main annotator annotated all records in the dataset; two other annotators verified or disputed those annotations. If annotators could not reach an agreement, we removed the record from the SemEval dataset.

A full analysis of annotator disagreement goes beyond the scope of this work. While the source of annotator disagreement may seem trivial and simple (e.g., only one annotator understood the sentence correctly), we believe that some sentences may have more than one interpretation, all of which are plausible. Like the disagreement resulting from incorrect frame assignment, deciding what frame a verb evokes may be challenging; and resolving the dilemma is not always simple. Choosing between two related frames (e.g.,

[5]Q. Zadeh and Petruck describe the issues in detail.

BUILDING vs. INTENTIONALLY_CREATE, related via Inheritance in FN), or identifying metaphorical and non-metaphorical uses of a verb requires subtle and sophisticated understanding of the semantics of the language, and of Frame Semantics. At times, disagreements pointed to more complex linguistic issues that remain in debate, e.g., choosing the semantic head of a syntactically complex argument, treating quantifiers, conjunctions, etc.

4.4 Summary statistics

Table 1 shows a statistical summary of the annotation task. The **SemEval** column reports the statistics for the final set of records, i.e., gold records with double-agreement between annotators, and which we used to evaluate the systems. **Total** reports the statistics of all analyzed records, from which we chose our **SemEval** data. **Skipped** and **InProg** show the statistics for discarded records and records without a final decision, respectively. **Dev** shows the statistics for the development set.

Each of the rows reports a value of a component of the data or annotator interaction with the data. **Records** indicates the number of annotated verbs and their arguments. **Sentences** and **Tokens** indicate the size of the sub-corpus of the annotated records. **VF** is the number of distinct verb lemmas (273), mapped to the number of distinct frames that the **Frames-Type** row shows (149) (Figure 3 in Appendix A.1 plots their frequency distribution.) **FElements** reports the number of annotated FEs categorized under the number of FE types shown in the **FE-Type** row. **Sem-Arg** shows the number of annotated verb arguments with VerbNet-like semantic roles, classified into 32 of 41 possible semantic role categories. **Multi-word** lists the number of annotated MWUs

	SemEval	Total	Skipped	InProg	Dev
Records	4,620	5,637	301	716	594
Sentences	3,346	3,803	294	675	582
Tokens	90,460	102,067	8,329	19,151	15198
Verb-Forms	273	373	93	210	35
Frame-Type	149	234	75	185	37
#FEs	9,510	11,269	373	1,386	1,128
FE-Type	198	270	64	197	62
Sem-Arg	9,466	11,215	370	1,379	1,079
Multi-word	2,366	2,773	61	346	368
Confidence	3.30	3.2	2.41	2.5	3.34
Time	539h	742h	25h	177h	19h
Total-Move	68,784	83,753	1,903	13,066	4,406

Table 1: Annotation and Data Statistical Summary

Confidence reports the average of annotator-assigned confidence scores for annotations per record. Although interpreting this measure demands more work, the averages appear to be as expected. Specifically, **SemEval** is higher in value than both **InProg** and **Skipped**, facts that we associate with double agreement and the choice reviewing process. Still, many records with high confidence scores remained as **InProg** given the lack of double agreement. Table 5 (Appendix A.1) lists the top 10 frames annotated with their respective highest and lowest confidence ratings averaged by their frequency in **SemEval**.

The last two rows of Table 1 are meta-data on the annotation process. **Time** reports the total time annotators spent in active annotation, engaged in the steps described above (742 hours), excluding the reviewing process (Section 4.3.1) and including the time to annotate MWUs. **Total-Move** is the total number of logical moves for frame annotation between annotators and the annotation system, i.e., logged changes in the process of frame and core FE annotation. This number excludes annotation of verb subcategorization with generic semantic roles.[6]

In **SemEval**, annotated frames had an average of 2.15 arguments, requiring a minimum of five logical moves to annotate (MWU-less sentences). However, on average, each **SemEval** record required 14.8 moves. This number is even higher for **InProg** (18.2); we believe that it indicates the complexity of the annotation task. Table 4 (Appendix A.1) further details annotator activity, with time spent and moves per annotation step. As expected, frame annotation of verbs (Step 2), was the most time consuming part of the task.

4.5 Development Dataset

Shared task participants received a development set consisting of 600 records from a total of 4,620 records, where Table 4 shows the statistics. The development set contained gold annotations for all three subtasks.

5 Evaluation Metrics

For all subtasks, as figure of merit, here we report the performance of participating systems with measures for evaluating text clustering techniques, including the classic measures of Purity (PU), inverse-Purity (IPU), and their harmonic mean (PIF) (Steinbach et al., 2000), as well as the harmonic mean for BCubed precision and recall (i.e.,

[6]With the exception of a few verbs, annotators rarely changed the annotation system's rule-based suggestions of VerbNet semantic roles.

BcP, BcR, and BcF, respectively) (Bagga and Baldwin, 1998).

To compute these measures for the pairing of reference-labeled data and unsupervised-labeled data (with each having an exact set of annotated items), we built a contingency table T with rows for gold labels and columns for unsupervised system labels. We filled the table with the number of intersecting items, as done in cross-tabulation of results in classification tasks to compute precision and recall. For Task A (Section 3), T tracks the unsupervised system labels and the gold reference labels assigned to verbs. For Task B.1, we labeled the rows and columns of T with tuples (l_v, l_a), where l_v labels the frame evoking verb and l_a labels the FE filler. For Task B.2, the rows and columns in T track the unsupervised system labels and the gold reference labels (generic semantic roles) assigned to arguments.

These performance measures reflect a notion of similarity between the distribution of unsupervised labels and that of the gold reference labels, given certain criteria. Specifically, they define the notions of consistency and completeness of automatically generated clusters based on the evaluation data. Each method measures consistency and completeness in its own way, and alone may lack sufficient information for a clear understanding and analysis of system performance (Amigó et al., 2009). But, as the *single metric for system ranking*, we used the BcF measure, given its satisfactory behavior in certain situations. Note that we modeled the task and its evaluation as hard clustering, where a record receives only one label, without overlap in any generated category of items.

5.1 Baselines

Similar to other clustering tasks, we use baselines of random, all-in-one-cluster (AIn1), and one-cluster-per-instance (1CpI). Additionally, we adapted the baseline of *the most frequent sense* in WSI for these tasks by introducing the one-cluster-per-head (1CpH) baseline in Task A, and one-cluster-per-syntactic-category (1CpG) for verb argument clustering in Task B.2.[7] For Task B.1, we built a baseline, 1CpGH for labeling verbs with their lemmas (as in 1CpH) and FEs with grammatical relation to their heads (as in 1CpG). We included two more labels lcmpx and rcmpx for frame fillers with no direct syntactic relation to the head verb, if occurring left of or right of the verb, respectively.

Both 1CpH and 1CpG (and their combination for Task B.1) are hard to beat because of the long-tailed distribution of the frequency of our test data. E.g., most verbs frequently instantiate one particular frame and rarely other ones. Similarly, a particular role (FE) frequently is filled by words that have a particular grammatical relation to its governing verb; e.g., most subjects of most verb forms receive the agent label in their subcategorization frame (or, an agent-like element in their Frame Semantics representations). Evidently the chosen labels for grammatical relations influences 1CpG and 1CpHG scores. Values reported later (specifically, Tables 6 and 2) could be improved by employing heuristics, e.g., relabeling enhanced dependencies using a few rules.

We also employed one unsupervised and a second supervised system baselines. For the unsupervised one, we trained the system with data from Kallmeyer et al. (2018). For the supervised one, we used OPEN-SESAME, a state-of-the-art supervised FrameNet tagger (Swayamdipta et al., 2018). After converting its output to the format of the present task, we evaluated it similar to other systems. Both systems were trained out-of-the-box with no additional tuning.

6 System Descriptions

We received submissions from nine teams (13 participants). Only three chose to submit system description papers. Arefyev et al. (2019) provided a solution for Task A and Task B.2, using both sets of these results to address Task B.1. Task A used language models and Hearst-like patterns to tune and obtain contextualized vector representations for the verbs in the test set. A hierarchical agglomerative clustering method followed, where hyperparameters were set with labeled and unlabeled records from the development and test sets. Task B.2 employed a logistic regression trained over the development set to identify only the most frequent labels. The classifier was based on features obtained from a language model and hand-crafted rules. Using logistic regression and training this algorithm with the development set remains an issue of concern, given the intended unsupervised scenario. While we objected to using the development set to train a supervised system for this

[7]We use syntactic dependencies of the Enhanced Universal Dependencies formalism (Schuster and Manning, 2016).

subtask, we still report its scores. The differences between its results and those of the other systems may be informative. Still, we considered Arefyev et al.'s results for Task B only complementarily, not to rank the systems.

Anwar et al. (2019) proposed a method that was similar to that of Arefyev et al. (2019). Arefyev et al. used contextualized word embeddings from the BERT language modeling tool Devlin et al. (2018), whereas Anwar et al. used pre-trained embeddings. They merged the outputs of Tasks A and B.2 for Task B.1. Task A used agglomerative clustering of vectors with concatenated verb representation vectors and vectors that represent usage context. Task B.2 employed hand crafted features, a method to encode syntactic information, and again an agglomerative clustering method.

Ribeiro et al. (2019) also reported results for all subtasks using similar techniques to those reported in the other two submitted papers. Ribeiro et al. (2019) used the bidirectional neural language model BERT, which Arefyev et al. (2019) also used. Task A employed contextualized word representations proposed in (Ustalov et al., 2018), and Biemann's clustering algorithm (Biemann, 2006). Compared to the two other systems, Ribeiro et al. (2019) exploited input structures, weighted them, and used them elegantly in its algorithm. With the same method but different hyper-parameters for B.2 along with combining results from Task A, Ribeiro et al. (2019) offered a solution to B.1.

7 Results and Data Analysis

Table 2 reports the BcF scores for system submissions along with a baseline for each task.[8] As the table shows, each system performs best only in one of the tasks. We report Arefyev et al.'s submission for Tasks B.1 and B.2 only to show the benefit of using a small amount of training data and a supervised method together with a clustering algorithm, provided that such training data is available. As readers know, finding the optimal (actual) number of clusters is an open research area. Participants knew the number of clusters: whereas Arefyev et al. and Anwar et al. used this information, Ribeiro et al. opted for a statistical method tuned with data that we provided.

The baseline systems, the unsupervised method of Kallmeyer et al. (2018) performed the worst

System	BcF	BcF	BcF
Arefyev et al.	**70.70**	~~63.12~~	~~64.09~~
Anwar et al.	68.10	**49.49**	42.1
Ribeiro et al.	65.32	42.75	**45.65**
BASELINE	65.35	45.79	39.03
	Task A	B.1	B.2

Table 2: Summary of Results. The BASELINE for Task A is 1CPH, and for B.1 and B.2 is 1CPHG. Best results appear in bold face; discarded results are crossed out. Table 6 lists all other baselines.

of all systems regarding BcF. This result is not surprising since that work did not effectively handle MWUs in the test, where only the head of the MWU was kept. However, the output of Open-SESAME, and its low BcF was indeed surprising.

We fed Open-SESAME the sentences from the test set; it identified approximately 5k frames. However, the overlap with the test set was only 1,216 records (identification problem in Open-SESAME). These 1,216 records exhibit a mismatch between 536 of the arguments and their respective target verbs. We ignored the system's extra or incorrectly generated arguments, and replaced the missing items with those of the 1CPHG baseline records. We then used the resulting records for evaluation against the task's gold data as did the task's participants. As Table 3 shows, the unsupervised method outperforms the supervised system for all tasks by a wide margin, i.e.,the unsupervised label set can carry more information than does the supervised label set.

	BcP	BcR	BcF
Task A	84.52	44.67	58.45
Task B.1	81.04	31.6	45.47
Task B.2	34.26	36.56	35.37

Table 3: Open-SESAME Performance

We compared results for confidence measure that annotators assigned to records. First, we split the evaluation records according to their assigned confidence value into five subsets E_i, $1 \leq i \leq 5$, such that subset E_1 contained only records with confidence value 1, E_2 contained only record with confidence value 2, etc.. Then we evaluated system outputs on each subset E_i and logged that BcF. Later, we performed this evaluation cumulatively using subsets E_i's by adding records from all E_js to E_i where $i < j$. Interpreting the obtained values requires careful attention (e.g., changes in the prior probabilities of gold clusters and their

[8]The full list of baselines and performance measures appear in Table 6 of the Appendix.

cardinality must be taken into account), overall, we observed a similar trend for all systems: as expected, namely a positive correlation between the confidence value and BCF. Thus, what human annotators usually found hard to annotate, automatic systems also found hard to cluster. (The reverse relation does not hold). Or, pessimistically, the level of noise in annotation increases as their associated confidence decreases. (Table 7 in Appendix A.2 details the results.)

Finally, we wanted to identify the frames that machines found difficult to cluster. To estimate difficulty we used the differences in BCF under the following conditions. We repeated the evaluation process $1 \leq i \leq n$ times (where n is the number of gold labels for a task) for each system. In each iteration i, we removed all data items of a gold category i. We measured and noted the resulting BCF in the given iteration; we deduced the score from the system performance over the entire gold set. To cancel frequency effects, we normalized the differences by the number of gold data instances. We removed all records annotated as COMMERCE_SELL from the evaluation set E to form E'. We computed the BCF of the systems over E' ($E' \subset E$), and measured $d = E_{\mathrm{BCF}} - E'_{\mathrm{BCF}}$. We interpreted a positive difference as an easy to cluster gold category i, and a negative difference as a hard to cluster gold category i.

The heat maps in Table 8 and Table 9 show a summary of the results for Task A and Task B.2, respectively. All systems performed similarly for approximately 30% of the gold classes. Comparing differences across systems and the baselines of 1CPH and 1CPG reveals (possibly) interesting information. Thus, for example, in Task A, most systems found COMMERCE_SELL hard and COMMERCE_BUY easy to cluster. Interestingly, a set of six verbs evokes each frame: *buy, purchase, buy_back, buy_up, buy_out, buy_into* for COMMERCE_BUY; and *sell, retail, auction, place, deal, resell* for COMMERCE_SELL. From these two sets of verbs, three are polysemous: *buy* in the former, and *place* and *deal* in the latter. Does the morphology of the verbs (e.g., *buy-back*, *resell*) make one easy to cluster? Alternatively, are other factors at play, such as the number of verb instances? How these factors might influence the proposed naive BCF-difference model is an open question.

8 Concluding Remarks

We have presented the SemEval 2019 task on unsupervised lexical frame induction. We described the task in detail, provided a summary of methods that participants developed, and compared the results. Although much room for improvement of the task remains, we consider it a step forward. It employed a well-motivated typology of lexical frames to distinguish lexical frame induction tasks. The evaluation data derived from annotations of a well-known resource, namely a portion of WSJ sentences, perhaps the most annotated corpus of English. These features provide opportunities for future investigation, in particular in studies related to reciprocal relations between syntactic and lexical semantic frame structures.

One reason to promote using unsupervised methods is their inherent flexibility to embrace unknown data. These methods have a high margin of tolerance for *noise*, and perform better than supervised method with insufficient training data. For unsupervised data, obtaining or generating training data is easier than doing so with supervised methods because they simply do not require annotation. For example, all participant systems could collect similar unlabeled training data from only syntactically annotated corpora to generate more unlabeled records. Ultimately, such methods can achieve respectable performance, and produce clusters which are both more informative than the unlabeled input and supervised categories (under certain situations). As shown, unsupervised methods can even outperform a state-of-the-art Frame Semantics parser by a wide margin (Section 7), while a very large gap remains for improvements in future work.

A Appendices

A.1 Appendix I: Annotation Process

A.1.1 Time and Moves per Annotation Step

Table 4 shows the amount of effort to develop the SemEval dataset in terms of time and moves that the annotation system recorded. (See Sections 4.3, 4.4).

Annotator Activity	**Time**	**Moves**
Reading and Comprehension	78	4,795
Choosing a Frame	177	9,737
Annotating Arguments	81	19,510
Rating, Revising, Commenting	115	25,793
Multi-word Unit Annotation	89	8,949
Total	539	68,784

Table 4: Total hours and number of moves for each annotation step for the 4,620 record dataset.

A.1.2 Plot of frequency of annotated frames

Figure 3 plots the frequency distribution of the annotated frames in the gold data (**SemEval**).

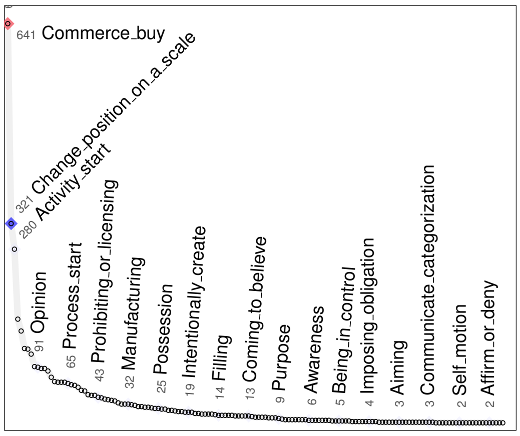

Figure 3: Frequency Distribution of Annotated Frames

A.1.3 Some Frames and their Averaged Confidence

Table 5 lists FN frames annotated with the highest and lowest confidence. Table 4 details hours spent to derive the evaluation data set. Section 4.3 discusses both tables. The full list of annotations in human readable form is available to browse and comment on at http://corpora.phil.hhu.de/fi/frames.html.

A.2 Appendix II: Statistical Summary of Evaluation and System Submissions

A.2.1 Unabridged Results Table

Table 6 extends Table 2. Section 5 defines the abbreviations. A horizontal line separates participating systems and the baselines.

A.2.2 Confidence Measures and BCF Performance

Table 7 shows system BCF scores for confidence. The table shows changes in the BCF of systems when altering the evaluation set based on the assigned confidence for an annotated record. (See Section 7 for an explanation).

Frame Type	**#VF**	**#Rec**	**Conf**

Abstract

We describe our solutions for semantic frame and role induction subtasks of SemEval 2019 Task 2. Our approaches got the highest scores, and the solution for the frame induction problem officially took the first place. The main contributions of this paper are related to the semantic frame induction problem. We propose a combined approach that employs two different types of vector representations: dense representations from hidden layers of a masked language model, and sparse representations based on substitutes for the target word in the context. The first one better groups synonyms, the second one is better at disambiguating homonyms. Extending the context to include nearby sentences improves the results in both cases. New Hearst-like patterns for verbs are introduced that prove to be effective for frame induction. Finally, we propose an approach to selecting the number of clusters in agglomerative clustering.

1 Introduction

Semeval-2019 Task 2 consisted of three subtasks, this paper presents solutions to all three which were all performing better than other submitted approaches. The first solution officially took the first place in the competition, the other two used tuning on the development set provided by the organizers, which was then interpreted as using additional corpora.

Semantic Frame Induction (Subtask A) is the task of grouping target word occurrences in a text corpus according to their frame (meaning and semantic arguments structure). Target words are usually verbs, nouns, and adjectives (these have argument structure; however in the shared task dataset only verbs were present). For instance, the verbs *rise, fall* and *climb* in the sentences *The dollar is rising, which makes Russian economy unstable* and *The dollar fell 1% in September after climbing 2% in August* should be clustered together, while the verb *climb* in sentences like *People climb mountains* should be clustered separately. For the sake of brevity, occurrences of different words sharing the same frame will be called synonyms, and occurrences of the same word belonging to different frames will be called homonyms. This may violate the traditional meaning of these terms. For instance, *fall* and *rise* are not considered synonyms in the classical sense. Semantic Role Induction refers to finding realizations of semantic arguments in text and relating them to corresponding semantic frame slots. Generic role induction (subtask B.2) requires a small number of frame-independent roles like *Agent, Patient, Theme*, etc. Frame-specific role induction (subtask B.1) allows labeling arguments of each frame independently from other frames. For instance, *Microsoft* in *Microsoft bought Github* and *Google* in *Google opened new offices* should be labeled as the same role in B.2 but may be labeled differently in B.1. For further details please refer to QasemiZadeh et al. (2019).

In this paper, we focused mainly on the Frame Induction subtask. The main contributions for this subtask are the following. A combined approach to semantic frame induction is introduced, which clusters dense representations obtained from hidden layers of a masked LM first and sparse bag-of-words representations of possible substitutes for a word in context afterward. This approach resulted in better clustering of both synonyms and homonyms[1]. New Hearst-like patterns designed specifically for verbs were used and they proved to be beneficial for Semantic Frame Induction. Also, a simple but effective semi-supervised approach to selecting the number of clusters for agglomerative clustering was proposed. Finally, we proposed ex-

[1]GRANNy in the team name stands for General Relation Acquisition with Neural Networks

tending context with neighboring sentences which have shown consistent improvements for both of our representations. For solving subtask B.2 we used a semi-supervised approach of training logistic regression over features that were partly designed and partly learned in an unsupervised fashion. To ensure the best performance on verbs that were not present in training data (the majority of examples in the test) we used cross-validation with a lexical split, to select optimal features and hyperparameters. For solving subtask B.1 we trivially reused labels from B.2

2 Related Work

This section describes previous work which our approach is based on. Word Sense Induction (WSI) is the task of clustering occurrences of an ambiguous word according to their meaning which is similar to Frame Induction. One of the major differences from Frame Induction is that WSI doesn't require grouping together different words with similar meanings, however, we adopt some ideas from WSI in this work. Instead of graph or vector representation of word co-occurrence information traditionally used to solve WSI task, Baskaya et al. (2013) proposed exploiting n-gram language model (LM) to generate possible substitutes for an ambiguous word in a particular context. Their approach was one of the best in SemEval-2013 WSI shared task (Jurgens and Klapaftis, 2013). Struyanskiy and Arefyev (2018) proposed pretraining SOTA neural machine translation model built from Transformer blocks (Vaswani et al., 2017) to restore target words hidden from its input (replaced with a special token CENTERWORD). After pretraining, they exploited both predicted output embeddings to represent ambiguous words and attention weights to better weigh relevant context words in word2vec weighted average representation. A combination of these representations achieved SOTA results on one of the datasets from RUSSE'2018 Word Sense Induction for the Russian language shared task (Panchenko et al., 2018). Amrami and Goldberg (2018) develop ideas from Baskaya et al. (2013) exploiting neural bidirectional LM ELMO (Peters et al., 2018) instead of n-gram LM for generating substitutes. To improve results further they propose using dynamic symmetric patterns "T and _", "_ and T" (here "T" stands for the target word and "_" for the position at which we collect LM predictions). For instance, to represent the word *orange* in *He wears an orange shirt* instead of predicting what comes after *wears* in *He wears* they predict what comes after *and* in *He wears orange and* (similarly, for backward LM they predict what comes before *and* in *and orange shirt*). This provides more information to the LM because we don't hide the ambiguous word and forces it to produce its co-hyponyms instead of all possible continuations given a one-sided context. Other important contributions include lemmatizing substitutes to remove grammatical bias from representations (which was especially important for verbs) and using IDF weights to penalize frequent substitutes, which are probably worse for discriminating between senses. They achieve SOTA results on the SemEval-2013 WSI dataset.

Devlin et al. (2018) proposed BERT (Bidirectional Encoder Representations from Transformers). Like the model from Struyanskiy and Arefyev (2018), BERT is a deep NN built from Transformer blocks and pretrained on the task of restoring words hidden from its input (replaced with a special token [MASK], hence they named it masked LM). However they used much deeper models, pretrained them on much more data and predicted hidden words at each timestep rather than generating them as an output sequence. Also additional next sentence prediction task was used to pretrain the model for sentence pairs classification (like paraphrase detection and NLI). BERT has shown better results than previous SOTA models on a wide spectrum of natural language processing tasks.

3 Semantic Frame Induction

In this section, we describe our approaches to building vector representations of an occurrence of the target word (which is always a verb in the SemEval-2019 Frame Induction task dataset). The first approach exploits dense vector representations of the target word in a context obtained from hidden layers of BERT model. Another approach builds sparse TF-IDF BOW vectors from substitutes generated for the target word by BERT masked LM. We found that each model has its own downsides when used with non-trainable distance functions like cosine and Euclidean, and with traditional clustering algorithms like agglomerative clustering, DBScan, and affinity propagation. The first approach didn't discriminate different senses of the same verb, the second one had problems with clustering together similar senses of different verbs. In preliminary experiments, we tried fixing the first problem by learning a distance function instead of using a fixed one, but this didn't help, presumably due to a very small amount of labeled data provided and restrictions on using additional labeled data. So our best performing algorithm is two-stage: it groups examples to a relatively small number of large clusters using the first representation (merging synonyms together while not taking into consideration homonyms) and then splits each of them into smaller clusters using the second representation (disambiguating homonyms). Finally, we describe our approach to clustering these vector representations and propose a technique for selecting the appropriate number of clusters.

3.1 BERT Hidden Representations

In the preliminary experiments, we compared dense representations from different layers of two BERT models pretrained on English texts: bert-base-uncased and bert-large-uncased with 3x more weights. While being significantly slower, the large model didn't show better clustering results for the development set, so we stuck to the base model. Presumably, fine-tuning the large model to the final task could reveal its superiority, but this would require much more labeled data that was provided. Interestingly, a weighted average of word2vec embeddings for context words proposed for WSI in Arefyev et al. (2018) showed similar results, which also supports the hypothesis that distance functions like cosine or Euclidean are not appropriate for BERT hidden representations. BERT-base consists of 12 Transformer blocks with 12 attention heads each, hidden state dimensionality is 768. It was pre-trained on lowercased texts split into subword units. Hyperparameters were selected on the development set, the best results were achieved using outputs of the layer 6 at timestep when the first subword of the verb was fed in. Also, better results were achieved when input texts were lemmatized. This can be explained by the large grammatical bias of LMs also noticed by Amrami and Goldberg (2018): it is much easier to correctly predict grammatical attributes like number, gender, tense from contexts, so it is more beneficial to assign higher probabilities to all verbs with correct tense than to all verbs with correct meaning when losses like cross-entropy are used, which results in large distance between occurrences of the same verb in the same meaning, but in different tenses.

3.2 Substitutes Representations

We adopt ideas from Amrami and Goldberg (2018) for our second approach to Frame Induction, with several important differences. First, we propose new patterns which are more suitable for verbs. Secondly, we use BERT, which proved to be better than ELMO for generating substitutes in our series of preliminary experiments. This is likely due to the fact that BERT takes into account the whole context in all of its layers, unlike bidirectional LM in ELMO, which consists of two independently trained language models, one using only right context, and another only left context. Lastly, we do hard clustering instead of soft clustering required for SemEval-2013 WSI, hence we do not sample from distributions predicted by LM, but instead, take the topmost probable substitutes. We found this approach works better than one doing soft clustering and then selecting the most probable cluster for each example.

To generate substitutes, a masked LM based on the bert-base-uncased model was utilized. It is likely that the large model could generate better substitutes, but we left it for future work. Non-lemmatized lowercased text was passed through all the layers of the model. We didn't add biases of the last linear layer to obtain less frequent but more contextually suitable subwords. We took K most probable substitutes to represent each example (K=40 was selected on the development set), lemmatized them to get rid of grammatical bias, and then built TF-IDF bag-of-words vectors. To improve results we employ symmetric patterns. Symmetric patterns were first proposed in Hearst (1992) and then used in many cases, including Widdows and Dorow (2002), Panchenko et al. (2012), Schwartz et al. (2015), to extract lexical relations like hyponymy, hypernymy, co-hyponymy, etc. from texts, and to augment lexical resources. However, we were not aware of any Hearst-like patterns designed specifically for verbs. Along with "T and _" pattern and trivial "T" and "_" patterns we proposed and experimented with "T and then _", "T and will _" and "T and then will _" patterns. We suppose that the meaning of a verb is better described not by its hypernyms or co-hyponyms (which are traditionally extracted for nouns using patterns like "_ such as T" or "T and _") but rather by preceding and following events which are better extracted by the proposed patterns. "T and then _" pattern has shown the best results both for the development and the test sets. For instance, to generate substitutes for the verb *build* in *They are building phones* we pass *They are building and then* [MASK] *phones* and collect predictions at the masked timestep. We found that among others, substitutes like *export, distribute, ship* are generated for *Manufacturing* frame and *establish, open, close* for *Building* frame of the verb *build* allowing to discriminate between them. See Appendix A for examples.

3.3 Clustering

We experimented with K-means, DBScan, Affinity Propagation and Agglomerative clustering algorithms implemented in the scikit-learn (Pedregosa et al., 2011) and found agglomerative clustering to achieve the best results. To select hyperparameters of Agglomerative clustering for dense representations (number of clusters and distance functions between points and clusters) we used a simple yet effective semi-supervised approach: merge the development and test sets (labeled and unlabeled respectively) and perform grid search for hyperparameters that provide clustering with optimal value of the target metric (BCubed-f1 in our case) on the labeled subset. Almost always optimal results were obtained using cosine distance for points and average linkage for clusters (average distance between elements).

3.4 Combined Approach

Our best performing submission was made of a combination of techniques described above. At phase 1, we clustered dense representations using proposed semi-supervised agglomerative clustering. At phase 2, we split each cluster separately using sparse representations and conventional agglomerative clustering with cosine distance and average linkage (selected on the development set). We didn't use the semi-supervised tuning again because at that stage most clusters didn't contain labeled examples. During the blind evaluation period, we simply split each cluster into two (this method is denoted as **Combined** below). In the post-evaluation period, we experimented with more sophisticated approaches. Finally, our best results (denoted as *Combined2*) were obtained when the number of clusters at phase 2 was selected using silhouette score and small clusters (with less than 20 examples) or clusters with different target verbs were left intact. Also, during the post-evaluation period, we tried extending the context with nearby sentences (sentences with adjacent IDs in the Penn Treebank corpus). This allowed us to incorporate more information about the preceding and following events, which resulted in improved performance of both representations. In **Combined2** we passed a large context of maximum 7 sentences to the left and to the right for dense, and smaller context of 2 sentences on both sides for sparse representations (selected on the development set).

3.5 Dataset and Experiments

Due to limitations imposed by the task, we restricted ourselves to only using labeled data provided by the organizers. For the majority of our experiments, we used the development set that consisted of 600 examples of 35 verbs clustered into 41 frames. There are many examples of synonymy in this dataset but not so many of homonymy. Almost all ambiguous verbs have less than 5 examples for all frames except their most frequent frame, hence we used only verbs *join* and *believe* (54/9 and 12/8 examples of their first/second most frequent frame respectively) to select hyperparameters likely resulting in a suboptimal performance on the test.

For internal evaluation of different representations and hyperparameters selection, we used the following procedure: the development set or its subset was clustered many times using agglomerative clustering with all feasible hyperparameter values, and maximum BCubed-f1 value (maxB3f1) was taken as a score for the representation. This allowed us to compare clusterability of different representations while avoiding problems of selecting the number of clusters and other hyperparameters. Of course, there is a possibility that other clustering algorithms might perform better with different representations, however, we didn't see improvements from using other clustering algorithms and stick to agglomerative clustering. Table 1 shows maxB3f1 for the whole development set and for all examples of several homonyms. Evidently, dense representations are significantly better when clustering the whole development set, while sparse representations with

Table 3: Subtask-A, effect of pattern and context size

an appropriate pattern are better for disambiguating homonyms.

We denote the proportion of synonyms sharing common cluster as recall for synonyms and the proportion of homonyms put in separate clusters as recall for homonyms. Figure 1 shows both metrics depending on the number of clusters for agglomerative clustering of the whole development set. It is evident that until a relatively large number of clusters (30) almost all synonyms are correctly clustered together when using dense representations, yet homonyms are clustered together as well, which gives almost 1.0 recall for synonyms and nearly 0.0 recall for homonyms. MaxB3f1 of approximately 0.94 is achieved at around 25-28 clusters (depending on the context size) where synonyms are still clustered almost perfectly. At the same time, sparse representations split homonyms into different clusters even at very small numbers of clusters, but simultaneously split synonyms also, achieving lower maxB3f1 of 0.91 in a wider range of 25-40 clusters. To solve this problem, our final solution clusters dense representations first and then splits large clusters containing examples of the same verb (to prevent splitting synonyms) into a small number of clusters to improve recall for homonyms.

Table 2 compares results on the test set. Verb baseline assigns the first token of the verb to each example as its cluster id. It overestimates the real number of clusters in the test (149), giving the highest precision but very low recall because synonyms are never clustered together. Dense representation with semi-supervised agglomerative clustering slightly underestimates the number of clusters in the test set (similarly to the development set) resulting in the highest recall due to merged synonyms. The combined approach splits some clusters hurting BCubed-recall a bit but increasing BCubed-precision, even more, resulting in better BCubed-f1. The last row shows that selecting the number of clusters which maximizes silhouette score (unsupervised approach) instead of BCubed-f1 of the labeled subset results in much worse results, hence our semi-supervised approach is beneficial. Finally, we noticed that the largest cluster had all the examples of both *sell* and *buy*, which were among the most frequent verbs in the test set. In FrameNet, they are assigned to *Commerce_sell* and *Commerce_buy* frames respectively which is a questionable solution since these are just different ways to put into words the same type of event with the same participants (something like commercial-transfer-of-property). We simply moved all examples of the verb *sell* into a separate cluster which gave significant improvement in BCubed-f1. However, this result is out of competition due to the manual postprocessing. Yet, our best result without manual postprocessing is still ranked first.

In Table 3 we report the results of clustering the test set depending on the pattern and the context size used to build sparse representations at phase 2. In addition to standard metrics, we report maxB3F1 which excludes the effect of a suboptimal number of clusters selected on the comparison results. Our proposed pattern seems to give small but consistent improvement as well as context extension. The context of 1-3 sentences on both sides is a reasonable choice for sparse representations.

4 Semantic Role Induction

After looking at examples from the development set we decided that the subtask B.2 (generic semantic role induction) could be solved much more effectively using a classifier than any kind of clustering because generic roles look more like a high-level linguistic abstraction than something naturally occurring in texts. We used the development set to trained logistic regression on top of representations extracted from BERT and several hand-crafted features. BERT was pretrained in unsupervised fashion on large corpora and this results in much better generalization of our semi-supervised approach compared to a logistic regression trained only on hand-crafted features (see ablation analysis below). To select hyperparameters we used cross-validation with lexical split (i.e. there were no common verbs in train and test subsets for each fold) to ensure the best performance on new verbs not seen during training. This approach was rejected as using an additional labeled corpora to train a supervised component. However we hardly see how the development set provided by the organizers can be considered as additional.

4.1 Model Description and Results

We trained a logistic regression classifier for the 14 most frequent semantic roles in the development set. Following recommendations of Devlin et al. (2018) we used outputs from the last four layers of BERT as features. These outputs were taken for two timesteps at which the target argument and its corresponding verb were fed. To be exact, we found the first subword of the verb (for instance, *buy* for *buy out*) and the last subword for the argument (*Union* for *European Union*) performing best. Additionally we used several hand-designed features. Table 4 shows our submission results. Also, we display results when using only BERT and only hand-designed features suggesting that both of them contribute positively

Method	#cl	PuIpuF1	B3P	B3R	B3F1

Logistic regression	14	**77.47**	**56.21**	**74.41**	**64.04**
w/o designed feats.	14	76.93	54.71	73.55	62.75
w/o BERT feats.	13	65.08	41.90	55.01	47.57

Table 4: Subtask-B.2, results on test

to the results but BERT features are much more important. For additional details regarding hand-designed features and ablation analysis please refer to Appendix B. We didn't experiment with subtask B.1 due to the lack of time, instead we used labels predicted for subtask B.2 which resulted in 64.43 / 73.11 BCubed-F1 / PuIpu-F1 compared to 45.79 / 57.99 of the best performing baseline.

5 Conclusions

We show how neural language models can be effectively used for unsupervised inference of semantic structures. To improve the result of semantic frame induction we used a combined approach that utilizes two different vector representations, and adjusted our clustering algorithm accordingly. The design stemmed from our analysis of problems in use of neural language models for the purpose of semantic frame induction; the experiments showed that issues may be strongly related to how the models treat such linguistic phenomena as synonymy and homonymy. Designing a system that addresses this problem directly allowed us to improve the result significantly. We think that our result could be additionally improved by finding better parameters and/or model combinations. We also think that further research in this direction could lead to neural language models that explicitly address various linguistic phenomena by design, for even better inference of semantic properties.

Acknowledgments

Table 6: Subtask-B.2, ablations on test set.

A Examples of generated substitutes

To show how substitutes can disambiguate homonyms we generated substitutes for examples of two most frequent frames for several verbs. For each verb we excluded rare substitutes with $P(subs|frame_i) < 0.4$ for both frames. Then we sorted the rest according to the probability ratio $\frac{P(subs|frame_1)}{P(subs|frame_2)+1e-6}$. Table 5 shows substitutes with the largest and the smallest ratio (most discriminating substitutes).

B Features and ablation analysis for Generic Semantic Role Induction subtask

We used the following hand-crafted features: an indicator that the argument is to the left of the verb and an indicator that the particle *by* is between them; categorical features for the output syntactic relation of the argument, the last relation in the path between the argument and the verb, the part of speech of the first word of the argument, the number of words and the number of words starting with a capital letter in the argument. All these features were concatenated, categorical features were encoded with one-hot vectors. In the preliminary experiments we noticed that hand-crafted features performed well by themselves but didn't improve results when concatenated with BERT outputs; this was resolved by multiplying the features by 10 (we attribute the effect to very high dimensionality of BERT outputs compared to hand-crafted features, which requires harmonizing the variance each of them adds to the scalar product in the logistic regression). We tried multiplying each feature by its own constant determined analytically from its dimensionality, but this worsened the results, so we left it for the future work.

Table 6 shows results for subtask B.2 after removing features from input representation or using different BERT layers instead of the last four. For ablation analysis, we selected L2-regularization strength using cross-validation with a lexical split after removing each feature while leaving all other hyperparameters intact. The features with largest contribution to the result are (from most to least important) BERT output at the argument, at the verb, the last relation in the path from the argument to the verb, the indicator that the particle *by* is between them (which was designed to fix errors due to passive voice) and the indicator that the argument is to the left of the verb. All other features' contributions (not shown) are small. Remarkably, removing all BERT features gives very large decrease in performance (-18 B3F1) while removing only outputs at the argument/verb gives only moderate decrease (-5.5/-3.5 B3F1) which can be explained by deeply bidirectional nature of BERT resulting in some information about both the verb and the argument present in each of these outputs. Finally, we tried using other BERT layers instead of the last four (layers 8-11) and found that intermediate layers perform best. For instance, layer 8 can replace the last four layers with very little decrease in performance, while the last two layers (10, 11) concatenated perform noticeably worse but much better than the first layers.

SemEval-2019 Task 3: EmoContext Contextual Emotion Detection in Text

Ankush Chatterjee, Kedhar Nath Narahari, Meghana Joshi and Puneet Agrawal
Microsoft, India

Abstract

In this paper, we present the SemEval-2019 Task 3 - EmoContext: Contextual Emotion Detection in Text. Lack of facial expressions and voice modulations make detecting emotions in text a challenging problem. For instance, as humans, on reading "*Why don't you ever text me!*" we can either interpret it as a sad or angry emotion and the same ambiguity exists for machines. However, the context of dialogue can prove helpful in detection of the emotion. In this task, given a textual dialogue i.e. an utterance along with two previous turns of context, the goal was to infer the underlying emotion of the utterance by choosing from four emotion classes - *Happy*, *Sad*, *Angry* and *Others*. To facilitate the participation in this task, textual dialogues from user interaction with a conversational agent were taken and annotated for emotion classes after several data processing steps. A training data set of 30160 dialogues, and two evaluation data sets, Test1 and Test2, containing 2755 and 5509 dialogues respectively were released to the participants. A total of 311 teams made submissions to this task. The final leader-board was evaluated on Test2 data set, and the highest ranked submission achieved 79.59 micro-averaged F1 score. Our analysis of systems submitted to the task indicate that Bi-directional LSTM was the most common choice of neural architecture used, and most of the systems had the best performance for the *Sad* emotion class, and the worst for the *Happy* emotion class.

1 Introduction

Emotions are basic human traits and have been studied by researchers in the fields of psychology, sociology, medicine, computer science etc. for several years. Some of the prominent work in understanding and categorizing emotions include Ekman's six class categorization (Ekman, 1992) and Plutchik's "Wheel of Emotion" (Plutchik and Kellerman, 1986) which suggested eight primary bipolar emotions . In recent times, several Artificial Intelligence (AI) agents like Siri, Cortana, Alexa have emerged and they primarily focus on providing users with assistance on specific tasks such as booking tickets or scheduling meetings etc. However, we believe that for machines and humans to develop a deeper partnership, an Intelligence Quotient (IQ) is not enough. These agents need to also possess an Emotional Quotient (EQ). Social conversational agents like Mitsuku[1] or Ruuh [2] (Damani et al., 2018) are experimental agents designed to have human-like persona, and possess a deeper sense of EQ; understanding and expressing emotions is an inherent aspect of these agents.
Detecting emotions in textual dialogues is a challenging problem in absence of facial expressions and voice modulations. Moreover, we observed that context of ongoing dialogue can completely change the emotion for an utterance as compared to perceived emotion when the utterance is evaluated standalone. Table 1 presents few such examples. Note that, in the first example *"I started crying"* will be perceived as '*Sad*' by a majority, however considering it in context, it turns out to be a '*Happy*' emotion. Similarly, in the second example, the last turn *"Try to do that once"* is very likely to be perceived as '*Others*', however again, a majority will judge it as '*Angry*' with the given context.

Naturally, considering context to estimate emotion of a text utterance becomes even more important for aforementioned scenarios of digital assistants and conversational agents, because of their text-based conversational interface. This task was

User Turn-1	Conversational Agent Turn-1	User Turn-2	True Class
I just qualified for the Nabard internship	WOOT! Thats great news. Congratulations!	I started crying	Happy
How dare you to slap my child	If you spoil my car, I will do that to you too	Just try to do that once	Angry
I was hurt by u more	You didn't mean it.	say u love me	Sad

Table 1: Examples showing influence of context in determining emotion of last utterance.

designed to invite research interest in the area of emotion detection in text. More details about the task can be found on our web page[3]. The evaluation data set served as a benchmark to compare various techniques and the task received attention from a wide range of researchers from industry as well as academia. We believe continued interest in this field will be beneficial towards making the AI-agents more human-like.

2 Related Work

Researchers have achieved good results on image based emotion recognition (Wang et al., 2018), (Zhang et al., 2016) as well as voice based emotion recognition (Pierre-Yves, 2003). Techniques have been proposed to detect emotions in spoken dialog systems (Liscombe et al., 2005). However, classifying textual dialogues based on emotions is relatively new research area. Emotion-detection algorithms for text can be largely bucketized into following two categories:

(a) *Hand-crafted Feature Engineering Based Approaches:* - Many methods exploit the usage of keywords in a sentence with explicit emotional/affect value (Balahur et al., 2011), (Strapparava and Mihalcea, 2008), (Sykora et al., 2013). To that end, several lexical resources have been created, such as WordNet-Affect (Strapparava et al., 2004) and SentiWordNet (Esuli and Sebastiani, 2007). Part-of-Speech taggers like the Stanford POS tagger are also used to exploit the structure of keywords in a sentence. These pattern/dictionary based approaches, although attaining high precision scores, suffer from low recall.

Hasan et al. (2014), Purver and Battersby (2012), Suttles and Ide (2013) and Wang et al. (2012) have also harnessed cues from emoticons and hashtags. Other methods rely on extracting statistical features such as presence of frequent n-grams, negation, punctuation, emoticons, hashtags to form representations of sentences which are then used as input by classifiers such as Decision Trees, SVMs among others to predict the output (Alm et al., 2005), (Balabantaray et al., 2012), (Davidov et al., 2010), (Kunneman et al., 2014), (Yan and Turtle, 2016). However, all of these methods require extensive feature engineering and they often do not achieve high recall due to diverse ways of representing emotions. For example, the following utterance, *"Trust me! I am never gonna order again"*, contains no affective words despite conveying an emotion of anger or frustration perhaps.

(b) *Deep Learning Based Approaches:* - Deep Neural networks have enjoyed considerable success in varied tasks in text, speech and image domains. Variations of Recurrent Neural Networks, such as Long Short Term Memory networks (LSTM) (Hochreiter and Schmidhuber, 1997) and Bidirectional LSTM (BiLSTM) (Schuster and Paliwal, 1997) have been effective in modeling sequential information. Also, Convolutional Neural Networks (CNN) (Krizhevsky et al., 2012) have been a popular choice in the image domain. Their introduction to the text domain has proven their ability to decipher abstract concepts from raw signals (Kim, 2014).
Recently, approaches which employ Deep Learning for emotion detection in text have been proposed. Zahiri and Choi (2017) predicts emotion in a TV show transcript. Abdul-Mageed and Ungar (2017) and Köper et al. (2017) tries to understand emotions of tweets. Li et al. (2017) learns to detect emotions on user comments in Chinese language. Felbo et al. (2017) learns representation based on emoticons, and uses it for emotion detection. A further detailed analysis of various approaches have been provided by Chatterjee et al. (2019). It is worth noting that textual dialogues are informal and laden with misspellings which pose serious challenges for automatic emotion detection approaches. Prior to this task, to the best of our knowledge, the methods proposed by Mundra

[3]Task webpage: humanizing-ai.com/emocontext.html

et al. (2017) and Chatterjee et al. (2019) are some of the few methods that tackled the problem of emotion detection in English textual dialogues.

3 Task Details

Problem Definition: *In a textual dialogue, given an utterance along with its two previous turns of context, classify the emotion of the utterance as one of the following classes: Happy, Sad, Angry or Others.*

The motivation for restricting the number of emotion classes stems from the popularity of these emotions in conversational data. The task proceeded in two phases. A training corpus, Train, of 30160 dialogues was provided at the beginning of Phase 1. The evaluation in this phase was done on an evaluation data set, Test1, comprising of 2755 dialogues. The labels for Test1 were made public five weeks before the end of Phase 1, allowing participants time and data to improve their models. The final evaluation was carried out in Phase 2 on a evaluation data set, Test2, which comprised of 5509 dialogues. It is important to note that while the maximum number of submissions a participant could make in Phase 1 was 20 per day, it was reduced to 10 per day during Phase 2.

4 Data Collection

A data set of textual dialogues was released to facilitate participation in this task. Several data processing steps were performed to create the final set of textual dialogues which are further explained in this section.

4.1 Dialogue Collection and Processing

A dialogue mined from the user's interaction with agent is defined as a tuple of 3 values - User Turn-1 (Utterance of the user), Conversational Agent Turn-1 (Response by the agent), User Turn-2 (User utterance as response to agent).
To begin with, user interactions with the agent over a period of one year were considered and over 2 million dialogues were randomly sampled. These dialogues further went through the processing and data cleaning as described in further subsections.

4.1.1 Offensive filtering

All the dialogues were passed through a filtering layer to remove offensive and sensitive content such as adult information, politically sensitive topics, or ethnic-religious content, or other potentially contentious material, such as inappropriate references to violence, crime and illegal substances etc. Several lexicons and human judgments were used to achieve this filtering.

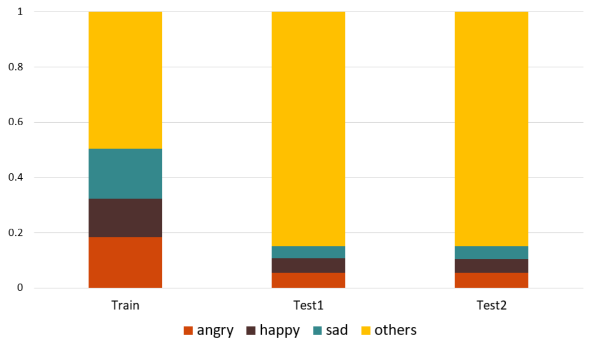

Figure 1: Comparison of class distribution in Training vs Evaluation data sets.

Emotion	Happy	Sad	Angry	Others	#
Train	4243	5463	5506	14948	30160
Test1	142	125	150	2338	2755
Test2	284	250	298	4677	5509

Table 2: Emotion label count across classes in Train, Test1 and Test2 data sets.

4.1.2 PII filtering

Personally Identifiable Information (PII) identifies the unique identity of a given user. This includes personal data like names, phone numbers, email Ids, among others. Dialogues containing any PII content were removed using hand crafted rules and via human judgments.

4.1.3 Language filtering

Given that the agent was available for users across geographies, the dialogues contained multiple languages and users employed code-mixed language as well. We used language detectors as well as user modeling to identify the language in the dialogues and filter non-English dialogues from the data set.

4.2 Training Data Set Creation

In the collected textual dialogues the emotion classes were not frequently expressed and hence directly annotating a random sample of textual dialogues results in very low volume of textual dialogues with emotion class. This problem was tackled by Gupta et al. (2017) and we used similar heuristics and strategies to ensure a higher ratio of

textual dialogues with emotion classes. This exercise was primarily conducted to reduce the cost of human judgments and is further explained below. We started with a small set (approximately 300) of annotated dialogues per emotion class obtained by showing a randomly selected sample to human judges. Using a variation of the model described by Palangi et al. (2016), we created embedding for these annotated dialogues. Potentially similar dialogues were further identified from the entire pool of dialogues using a threshold-based cosine similarity and these dialogues form our candidate set for each emotion class. Various heuristics like presence of opposite emoticons (example ":'(" in a potential candidate set for *Happy* emotion class), sentiment analysis, length of utterances etc. are used to further prune the candidate set in certain cases. The candidate set is then shown to human judges to determine if they belong to an emotion class. Using this method, we cut down the amount of human judgments required by five times as compared to showing a random sample of dialogues and then choosing dialogues with emotion class from them.
Data belonging to class "*Others*" is collected by randomly selecting dialogues from our pool of dialogues and were human labelled to discard any dialogues with emotion class such as *Happy*, *Sad* or *Angry*.
Figure 1 shows the distribution of different classes in training data set.

4.3 Evaluation Data Set Creation

Unlike training data set where we intentionally over sampled dialogues from emotion classes to help participants with a larger volume of data with emotion classes, we maintained the natural distribution of emotion classes in evaluation data sets. We randomly sampled and annotated two evaluation sets, Test1 and Test2, of size 2755 and 5509 respectively. Detailed distribution of emotion classes in these sets is described in Table 2.

4.4 Emotion Class Labeling

For this specific task of emotion class labelling, 50 human judges were trained. Given a dialogue, i.e an utterance with two previous turns as context, a judge was asked to annotate the utterance as belonging to one of the following four classes: *Happy*, *Angry*, *Sad* or *Others*. All dialogues were judged by 7 human judges and a majority consensus was taken as the final class label. Fleiss' Kappa score (Shrout and Fleiss, 1979) of 0.58 was observed on training data set and of 0.59 on evaluation data set. Such a Kappa score indicates the existence of multiple perspectives about the underlying emotion of a conversation.

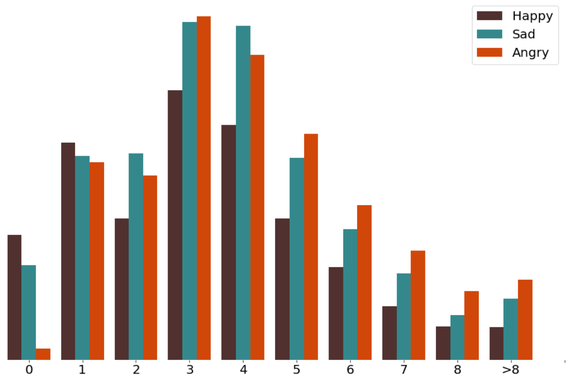

Figure 2: Comparison of word count of utterances per emotion class. Emoticons were removed for this calculation, as a result of which the leftmost bin of 0 word count can be seen as well.

5 Data Analysis

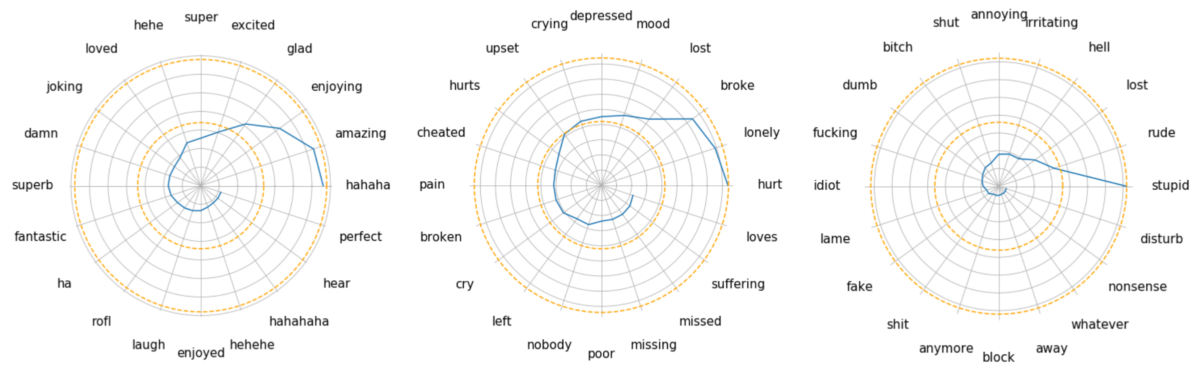
In this section we analyze the utterance in the dialogue that was judged by human judges for emotion classes.

5.1 Word Count

Figure 2 shows the distribution of the word count of utterances per emotion class. We observed that users tend to repeat emoticons several times. Hence emoticons were removed from utterances for this calculation, as a result of which the utterances which had only emoticons are clubbed in the leftmost bin with utterance of length 0. It can be observed that happiness is often expressed through emoticons and hence happy emotion class has highest count under the bin of 0 word count. Also, happiness is often expressed in fewer words as compared to other emotions can be observed from the graph. Another point to note is that angry emotion class is often expressed using more words as compared to other emotion classes.

5.2 Top Unigrams

Figure 3 shows the most frequent unigrams per emotion class in our data set. Note that emoticons are not considered as unigrams for this analysis. The length of the radius in the spiral graph denotes the frequency of the unigram in all the utterances belonging to that particular emotion class. In order



(a) Happy (b) Sad (c) Angry

Figure 3: Most frequent unigrams per emotion class in our data set. The length of the radius in the spiral graph denotes the frequency of the unigram in all the utterances for a emotion class. Only those unigrams which are not in the top 500 list of most frequent unigrams of the “Others” class have been considered.

Happy	😂	😁	😀	😄	😄
Sad	😭	😞	😢	💔	😔
Angry	😡	😠	😒	😑	😤

Table 3: Top five emoticons per emotion class.

to avoid neutral words like “my”, “what”, “sure” from showing up in the analysis, we consider only those unigrams which are not in the top 500 list of most frequent unigrams of the “Others” class.

5.3 Top Emoticons

Emoticons are frequently used in textual dialogues, as was observed by Gupta et al. (2017), who found 21% of textual dialogues to contain emoticons. Table 3 shows the top emoticons observed in utterances per emotion class. While most emoticons align with our expectations of the most frequent emoticons, it is interesting to note the frequent use of broken-heart emoticon to express sad emotion.

6 Evaluation Metric

Evaluation was carried out using the micro-averaged F1 score ($F1_\mu$) for the three emotion classes - *Happy*, *Sad* and *Angry* on the submissions made with predicted class of each sample in the evaluation data set. To be precise, we define the metric as following:

$$P_\mu = \frac{\Sigma TP_i}{\Sigma(TP_i + FP_i)} \forall i \epsilon \{Happy, Sad, Angry\}$$

$$R_\mu = \frac{\Sigma TP_i}{\Sigma(TP_i + FN_i)} \forall i \epsilon \{Happy, Sad, Angry\}$$

$$F1_\mu = 2 \cdot \frac{P_\mu \cdot R_\mu}{P_\mu + R_\mu}$$

where TP_i is the number of samples of class i which are correctly predicted, FN_i and FP_i are the counts of *Type-I and Type-II errors* [4] respectively for the samples of class i.

Our final metric $F1_\mu$ is calculated as the harmonic mean of P_μ and R_μ.

7 Baseline Model

To encourage and assist participants in making their first submission, we provided a starter kit, which consisted of scripts for training a naive baseline model. The script also enabled participants to cross-validate their model and create a submission file. This section explains the baseline model in detail.

7.1 Data Processing

Minimal data pre-processing steps were provided. These included replacing certain repeated punctuation marks with their single instances, lower casing, removing extra space and tokenization. For example, “I am so happy!!” was converted to “i am so happy !”.

7.2 Model Architecture

We modeled the task of detecting emotions as a multi-class classification problem where given a dialogue, the model outputs probabilities of it belonging to four output classes - *Happy*, *Sad*, *Angry* and *Others*. The three turns are concatenated using a special <*eos*> token. The concatenated input is passed into a pre-trained word embedding

Table 4: Input representations used by top systems.

layer, which projects the words into continuous vector representations. We used 100 dimensional GloVe embeddings (Pennington et al., 2014) for this purpose. The embeddings are processed by an LSTM layer, which produces a 128 dimensional representation of the sentence. This representation is then mapped to a 4 dimensional output vector which outputs probabilities per emotion class using a fully connected neural network. The architecture of the model was kept deliberately simple and was intended to serve as a starting point for participants. The baseline model achieved a $F1_\mu$ score of 0.5861 on the final leader board and most teams were able to beat the baseline model. Further details on the model and its comparison with other systems can be seen in Table 5.

8 Systems and Results

As mentioned earlier in section 3, the task was conducted in two phases. The first phase saw a participation from 311 teams and 164 teams participated in the second phase. In this section, we briefly describe the top systems [5], followed by observations across systems regarding the techniques used and their performance across different emotion classes.

[5]The top 2 systems - *Leo1020* and *Mfzszgs* did not submit system description papers, and hence have been omitted from discussion in this Section.

8.1 Top Systems

Due to the overwhelming number of participants, we cannot describe all systems. We describe the main features of the top few systems ranked according to their final performance.

- **NELEC** uses a combination of lexical features such as word and character grams, along with additional signals like emotional intensity, valence-arousal-dominance scores. In addition, they use adult, offensive and sentiment classifiers' scores from neural models. Using these features, the authors trained a Light-GBM tree (Ke et al., 2017), which achieves better performance than their deep-learning based architecture.

- **SymantoResearch** explores different deep-learning based architectures, some of them employing multi-task learning to better classify *Others* class vs. emotion classes. By ensembling such architectures with fine-tuned BERT (Devlin et al., 2018) and USE (Cer et al., 2018) models, the authors are able to distinguish three emotions (*Sad*, *Happy*, *Angry*) and separate them from the rest (*Others*) more accurately.

- **ANA** uses an ensemble of fine tuned BERT model and Hierarchical LSTMs, where the semantic and emotional content of text is encoded via GloVe, ELMo (Peters et al., 2018)

Table 5: Performance comparison of top 15 teams on leaderboard.

and DeepMoji (Felbo et al., 2017) embeddings, following which a contextual LSTM encodes the entire dialogue for prediction.

- **CAiRE_HKUST** experiments with combinations of feature based models and end-to-end neural models. The feature based models use various pre-trained word embeddings and emotional embeddings, combining them with Logistic Regression and XGBoost (Chen and Guestrin, 2016). For the end-to-end neural models, the authors found the performance of hierarchical models, which take sequential nature of dialogue into account, to be better.

- **SNU_IDS** proposes several methods for alleviating the problems caused by difference in class distributions between training data and test data. The authors also present a semi-hierarchical neural architecture combining character and word embeddings that effectively encodes an utterance in context of the previous utterances.

- **THU-HCSI** is composed of three CNN-based neural network models trained for different base tasks - four-emotion classification, *Angry-Happy-Sad* classification and *Others-or-not* classification respectively. The authors use multiple steps of voting to combine the predictions of these base classifiers, resulting in a more accurate and robust model performance.

- **Figure Eight** uses an ensemble of transfer learning models for capturing the representations of the utterances. Using sophisticated fine-tuning techniques described in ULMFiT (Howard and Ruder, 2018), the authors observe that transfer learning using pre-trained language models outperforms models trained from scratch.

8.2 Miscellaneous Observations

From the system description papers of the top 15 teams, we observed that BiLSTMs/LSTMs were the most frequently used neural models. GRU (Chung et al., 2014) and CNN models were used by a few teams, and some variations of attention mechanism were employed by most of the teams to enhance performance of their models. Transfer learning using BERT, ELMo, ULMFit was a popular choice among top teams, and almost all the teams used an ensemble of their best models to create the final model.

	F1$_\mu$
Max	0.7959
Min	0.0143
Mean	0.6599
Median	0.694
1st Quartile	0.637
3rd Quartile	0.7317
Std. Dev.	0.1264

Table 6: Performance statistics of all participants.

Table 4 shows the embeddings used by the top 5 teams. It can be observed that GloVe was used most frequently. BERT and ELMo were the most popular choice for transfer learning. NTUA-SLP embeddings (Baziotis et al., 2018) were used as well to leverage its affective information. Participant teams tried various ways to encode the emotional content expressed by emoticons, and Deepmoji and Emoji2Vec (Eisner et al., 2016) were utilized in this regard. A good number of teams used the "ekphrasis" package (Baziotis et al., 2017) for tokenization, word normalization and word segmentation.

8.3 Performance across Emotion Classes

Table 5 displays the detailed performance of the top 15[6] participant teams. Upon inspection, it can be observed that the performance of the systems on the *Happy* class was not as good as the other emotion classes for the evaluation set. We believe, this is largely due to the natural ambiguity existing between neutral and happy utterances. For example, a greeting like "*Happy Morning*" can be thought of as expressing a happy emotion by some, while being judged to be neutral by others. We also observed that most systems performed best for the *Sad* emotion class. Table 6 provides some basic statistics on the results obtained by the whole set of participants.

9 Conclusion

A total of 311 teams made submissions to the task. The final leader-board was evaluated on Test2 data set, and the highest ranked submission achieved 79.59 $F1_\mu$ score. Our analysis of systems submitted to the task indicate that Bi-directional LSTM was the most common choice of network architecture used by participants, and most systems had best performance for *Sad* emotion class, and worst for *Happy* emotion class. A large number of teams have participated in the task but only 46 teams submitted their final system description papers; in fact, the top 2 teams in Phase 2 did not submit their system description paper. It was also observed that the ranking of various systems across both the phases varied significantly. In this task, we released the evaluation set without labels to participants, in future tasks it might be useful to also experiment with system submissions such that the entire evaluation set is never seen, with or without labels to the participants during the evaluation phase in a bid to have completely blind evaluation.

[6]Final rankings of all participating systems can be consulted via the CodaLab website of our task: https://competitions.codalab.org/competitions/19790

ANA at SemEval-2019 Task 3: Contextual Emotion detection in Conversations through hierarchical LSTMs and BERT

Chenyang Huang, Amine Trabelsi, Osmar R. Zaïane
Department of Computing Science, University of Alberta
{chuang8,atrabels,zaiane}@ualberta.ca

Abstract

This paper describes the system submitted by ANA Team for the SemEval-2019 Task 3: EmoContext. We propose a novel Hierarchical LSTMs for Contextual Emotion Detection (HRLCE) model. It classifies the emotion of an utterance given its conversational context. The results show that, in this task, our HRCLE outperforms the most recent state-of-the-art text classification framework: BERT. We combine the results generated by BERT and HRCLE to achieve an overall score of 0.7709 which ranked 5th on the final leader board of the competition among 165 Teams.

1 Introduction

Social media has been a fertile environment for the expression of opinion and emotions via text. The manifestation of this expression differs from traditional or conventional opinion communication in text (e.g., essays). It is usually short (e.g. Twitter), containing new forms of constructs, including emojis, hashtags or slang words, etc. This constitutes a new challenge for the NLP community. Most of the studies in the literature focused on the detection of sentiments (i.e. positive, negative or neutral) (Mohammad and Turney, 2013).

Recently, emotion classification from social media text started receiving more attention (Yaddolahi et al., 2017; Mohammad et al., 2018). Emotions have been extensively studied in psychology (Ekman, 1992; Plutchik, 2001). Their automatic detection may reveal important information in social online environments, like online customer service. In such cases, a user is conversing with an automatic chatbot. Empowering the chatbot with the ability to detect the user's emotion is a step forward towards the construction of an emotionally intelligence agent. Giving the detected emotion, an emotionally intelligent agent would generate an empathetic response. Although its potential convenience, detecting emotion in textual conversation has seen limited attention so far. One of the main challenges is that one users utterance may be insufficient to recognize the emotion (Huang et al., 2018). The need to consider the context of the conversion is essential in this case, even for human, specifically given the lack of voice modulation and facial expressions. The usage of figurative language, like sarcasm, and the class size's imbalance adds up to this problematic (Chatterjee et al., 2019a).

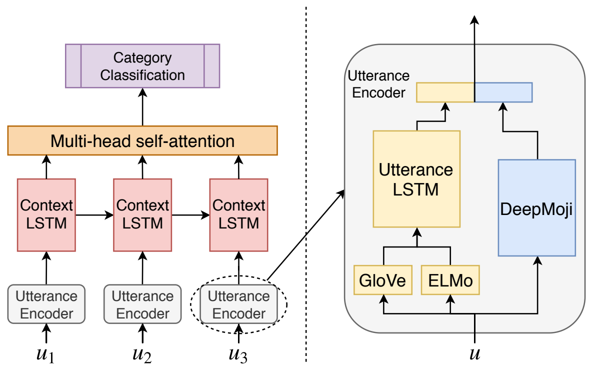

Figure 1: An illustration of the HRLCE model

In this paper, we describe our model, which was proposed for the SemEval 2019-Task 3 competition: Contextual Emotion Detection in Text (EmoContext). The competition consists in classifying the emotion of an utterance given its conversational context. More formally, given a textual user utterance along with 2 turns of context in a conversation, the task is to classify the emotion of user utterance as Happy, Sad, Angry or Others (Chatterjee et al., 2019b). The conversations are extracted from Twitter.

We propose an ensemble approach composed of two deep learning models, the *Hierarchical LSTMs for Contextual Emotion Detection* (HRLCE) model and the BERT model (Devlin et al., 2018). The BERT is a pre-trained language model that has shown great success in many NLP classification tasks. Our main contribution consists in devising the HRLCE model.

Figure 1 illustrates the main components of the HRLCE model. We examine a transfer learning approach with several pre-trained models in order to encode each user utterance semantically and emotionally at the word-level. The proposed model uses Hierarchical LSTMs (Sordoni et al., 2015) followed by a multi-head self attention mechanism (Vaswani et al., 2017) for a contextual encoding at the utterances level.

The model evaluation on the competition's test set resulted in a 0.7709 harmonic mean of the macro-F1 scores across the categories *Happy*, *Angry*, and *Sad*. This result ranked 5th in the final leader board of the competition among 142 teams with a score above the organizers' baseline.

2 Overview

2.1 Embeddings for semantics and emotion

We use different kinds of embeddings that have been deemed effective in the literature in capturing not only the syntactic or semantic information of the words, but also their emotional content. We breifly describe them in this section.

GloVe, (Pennington et al., 2014) is a widely used pre-trained vector representation that captures fine-grained syntactic and semantic regularities. It has shown great success in word similarity tasks and Named Entity Recognition benchmarks.

ELMo, or Embeddings from Language Models, (Peters et al., 2018) are deep contextualized word representations. These representations enclose a polysemy encoding, i.e., they capture the variation in the meaning of a word depending on its context. The representations are learned functions of the input, pre-trained with deep bi-directional LSTM model. It has been shown to work well in practice on multiple language understanding tasks like question answering, entailment and sentiment analysis. In this work, our objective is to detect emotion accurately giving the context. Hence, employing such contextual embedding can be crucial.

DeepMoji (Felbo et al., 2017) is a pre-trained model containing rich representations of emotional content. It has been pre-trained on the task of predicting the emoji contained in the text using Bi-directional LSTM layers combined with an attention layer. A distant supervision approach was deployed to collect a massive (1.2 billion Tweets) dataset with diverse set of noisy emoji labels on which DeepMoji is pre-trained. This led to state-of-the art performance when fine-tuning DeepMoji on a range of target tasks related to sentiment, emotion and sarcasm.

2.2 Hierarchical RNN for context

One of the building component of our proposed model (see Figure 1) is the Hierarchical or Context recurrent encoder-decoder (HRED) (Sordoni et al., 2015). HRED architecture is used for encoding dialogue context in the task of multi-turn dialogue generation task (Serban et al., 2016). It has been proven to be effective in capturing the context information of dialogue exchanges. It contains two types of recurrent neural net (RNN) units: *encoder* RNN which maps each utterance to an utterance vector; *context* RNN which further processes the utterance vectors. HRED is expected to produce a better representation of the context in dialogues because the *context* RNN allows the model to represent the information exchanges between the two speakers.

2.3 BERT

BERT, the Bidirectional Encoder Representations for Transformers, (Devlin et al., 2018) is a pre-trained model producing context representations that can be very convenient and effective. BERT representations can be fine-tuned to many downstream NLP tasks by adding just one additional output layer for the target task, eliminating the need for engineering a specific architecture for a task. Using this setting, it has advanced the state-of-the-art performances in 11 NLP tasks. Using BERT in this work has slightly improved the final result, when we combine it with our HRLCE in an ensemble setting.

2.4 Importance Weighting

Importance Weighting (Sugiyama and Kawanabe, 2012) is used when label distributions between the training and test sets are generally different, which is the case of the competition datasets (Table 2). It corresponds to weighting the samples according to their importance when calculating the loss.

A supervised deep learning model can be regarded as a parameterized function $f(\boldsymbol{x}; \boldsymbol{\theta})$. The backpropagation learning algorithm through a differentiable loss is a method of *empirical risk minimization* (ERM). Denote $(\boldsymbol{x}_i^{tr}, y_i^{tr})$, $i \in [1 \dots n_{tr}]$

are pairs of training samples, testing samples are $(\boldsymbol{x}^{te}, y^{te})$, $i \in [1 \dots n_{te}]$.

The ratio $P(\boldsymbol{x})^{te}/P(\boldsymbol{x})^{tr}$ is referred as the *importance* of a sample $\boldsymbol{x}$. When the label distribution of training data and testing data are different: $P(\boldsymbol{x}^{te}) \neq P(\boldsymbol{x}^{tr})$, the training of the model $f_{\boldsymbol{\theta}}$ is then called under *covariate shift*. In such situation, the parameter $\hat{\boldsymbol{\theta}}$ should be estimated through *importance-weighted ERM*:

$$\arg\min_{\boldsymbol{\theta}} \Big[\frac{1}{n_{tr}} \sum_{i=1}^{n_{tr}} \frac{P(\boldsymbol{x}^{te})}{P(\boldsymbol{x}^{tr})} \text{loss}(y_i^{tr}, f(\boldsymbol{x}_i^{tr}; \boldsymbol{\theta}))\Big]. \tag{1}$$

3 Models

Denote the input $\boldsymbol{x} = [u_1, u_2, u_3]$, where u_i is the ith penultimate utterance in the dialogue. y is the emotion expressed in u_3 while giving u_1 and u_2 as context.

To justify the effectiveness of the modules in HRLCE, we propose two baseline models: SA-LSTM (SL) and SA-LSTM-DeepMoji (SLD). The SL model is part of the SLD model, while the later one composes the utterance encoder of our HRLCE. Therefore, we illustrate the models consecutively in Sections 3.1, 3.2, and 3.3.

3.1 SA-LSTM (SL)

Let $\boldsymbol{x}$ be the concatenation of u_1 ,u_2, and u_3. Hereby, $\boldsymbol{x} = [x_1, x_2, \cdots, x_n]$, where x_i is the ith word in the combined sequence. Denote the pre-trained GloVe model as G. As GloVe model can be directly used by looking up the word x_i, we can use $G(x_i)$ to represent its output. On the contrary, ELMo embedding is not just dependent on the word x_i, but on all the words of the input sequence. When taking as input the entire sequence $\boldsymbol{x}$, n vectors can be extracted from the pre-trained ElMo model. Denote the vectors as $\boldsymbol{E} = [E_1, E_2, \cdots, E_n]$. E_i contains both contextual and semantic information of word x_i. We use a two-layer bidirectional LSTM as the encoder of the sequence $\boldsymbol{x}$. For simplicity, we denote it as $LSTM^e$. In order to better represent the information of x_i, we use the concatenation of $G(x_i)$ and E_i as the feature embedding of x_i. Therefore, we have the following recurrent progress:

$$h_t^e = LSTM^e([G(x_t); E_t], h_{t-1}^e). \tag{2}$$

h_t^e is the hidden state of encoder LSTM at time step t, and $h_0^e = \mathbf{0}$. Let $\boldsymbol{h}_{\boldsymbol{x}}^e = [h_t^e, h_t^e, \cdots, h_t^e]$ be the n hidden states of encoder given the input $\boldsymbol{x}$. Self-attention mechanism has been proven to be effective in helping RNN dealing with dependency problems (Lin et al., 2017). We use the multi-head version of the self-attention (Vaswani et al., 2017) and set the number of channels for each head as 1. Denote the self-attention module as SA, it takes as input all the hidden states of the LSTM and summarizes them into a single vector. This process is represented as $h_{\boldsymbol{x}}^{sa} = SA(\boldsymbol{h}_{\boldsymbol{x}}^e)$. To predict the model, we append a fully connected (FC) layer to project $h_{\boldsymbol{x}}^{sa}$ on to the space of emotions. Denote the FC layer as $output$. Let $o_{\boldsymbol{x}}^{SL} = output(h_{\boldsymbol{x}}^{sa})$, then the estimated label of $\boldsymbol{x}$ is the $\arg\max_i(o_{\boldsymbol{x}}^{SL})$, where i is ith value in the vector $o_{\boldsymbol{x}}^{SL}$.

	F1	Happy	Angry	Sad	Harm. Mean
SL	Dev	0.6430	0.7530	0.7180	0.7016
	Test	0.6400	0.7190	0.7300	0.6939
SLD	Dev	0.6470	0.7610	0.7360	0.7112
	Test	0.6350	0.7180	0.7360	0.6934
HRLCE	Dev	0.7460	0.7590	0.8100	**0.7706**
	Test	0.7220	0.766	0.8180	**0.7666**
BERT	Dev	0.7138	0.7736	0.8106	0.7638
	Test	0.7151	0.7654	0.8157	0.7631

Table 1: Macro-F1 scores and its harmonic means of the four models

3.2 SA-LSTM-DeepMoji (SLD)

SLD is the combination of SA and DeepMoji. An SLD model without the output layer is in fact the utterance encoder of the proposed HRLCE, which is illustrated in the right side of Figure 1. Denote the DeepMoji model as D, when taking as input $\boldsymbol{x}$, the output is represented as $h_{\boldsymbol{x}}^d = D(\boldsymbol{x})$. We concatenate $h_{\boldsymbol{x}}^d$ and $h_{\boldsymbol{x}}^{sa}$ as the feature representation of sequence of $\boldsymbol{x}$. Same as SL, an FC layer is added in order to predict the label: $o_{\boldsymbol{x}}^{SLD} = output([h_{\boldsymbol{x}}^{sa}; h_{\boldsymbol{x}}^d])$.

3.3 HRLCE

Unlike SL and SLD, the input of HRLCE is not the concatenation of u_1, u_2, and u_3.

Following the annotation in Section 3.1 and 3.2, an utterance u_i is firstly encoded as $h_{u_i}^{sa}$ and $h_{u_i}^d$. We use another two layer bidirectional LSTM as the context RNN, denoted as $LSTM^c$. Its hidden states are iterated through:

$$h_t^c = LSTM^c([h_{u_t}^{sa}; h_{u_t}^d], h_{t-1}^c), \tag{3}$$

where $h_0^c = \mathbf{0}$. The three hidden states $\boldsymbol{h^c} = [h_1^c, h_2^c, h_3^c]$, are fed as the input to a self-attention layer. The resulting vector $SA(\boldsymbol{h^c})$ is also projected to the label space by an FC layer.

3.4 BERT

BERT (Section 2.3) can take as input either a single sentence or a pair of sentences. A "sentence" here corresponds to any arbitrary span of contiguous words. In this work, in order to fine-tune BERT, we concatenate utterances u_1 and u_2 to constitute the first sentence of the pair. u_3 is the second sentence of the pair. The reason behind such setting is that we assume that the target emotion y is directly related to u_3, while u_1 and u_2 are providing additional context information. This forces the model to consider u_3 differently.

4 Experiment

4.1 Data preprocessing

From the training data we notice that emojis are playing an important role in expressing emotions. We first use *ekphrasis* package (Baziotis et al., 2017) to clean up the utterances. *ekphrasis* corrects misspellings, handles textual emotions (e.g. ':)))'), and normalizes tokens (hashtags, numbers, user mentions etc.). In order to keep the semantic meanings of the emojis, we use the *emojis* package[1] to first convert them into their textual aliases and then replace the ":" and "_" with spaces.

4.2 Environment and hyper-parameters

We use PyTorch 1.0 for the deep learning framework, and our code in Python 3.6 can be accessed in GitHub[2]. For fair comparisons, we use the same parameter settings for the common modules that are shared by the SL, SLD, and HRLCE. The dimension of *encoder* LSTM is set to 1500 per direction; the dimension of *context* LSTM is set to 800 per direction. We use Adam optimizer with initial learning rate as 5e-4 and a decay ratio of 0.2 after each epoch. The parameters of DeepMoji are set to trainable. We use *BERT-Large* pre-trained model which contains 24 layers.

	happy	angry	sad	others	size
Train	14.07%	18.26%	18.11%	49.56%	30160
Dev	5.15%	5.44%	4.54%	84.86%	2755
Test	4.28%	5.57%	4.45%	85.70%	5509

Table 2: Label distribution of train, dev, and test set

[1]https://pypi.org/project/emoji/

[2]https://github.com/chenyangh/SemEval2019Task3

According to the description in (CodaLab, 2019), the label distribution for *dev* and *test* sets are roughly 4% for each of the emotions. However, from the *dev* set (Table 2) we know that the proportions of each of the emotion categories are better described as %5 each, thereby we use %5 as the empirical estimation of distribution $P(\boldsymbol{x}^{te})$. We did not use the exact proportion of *dev* set as the estimation to prevent the overfitting towards *dev* set. The sample distribution of the *train* set is used as $P(\boldsymbol{x}^{tr})$. We use *Cross Entropy* loss for all the aforementioned models, and the loss of the training samples are weighted according to Eq. 1.

4.3 Results and analysis

We run 9-fold cross validation on the training set. Each iteration, 1 fold is used to prevent the models from overfitting while the remaining folds are used for training. Therefore, every model is trained 9 times to ensure stability. The inferences over *dev* and *test* sets are performed on each iteration. We use the majority voting strategy to merge the results from the 9 iterations. The results are shown in Table 1. It shows that the proposed HRLCE model performs the best. The performance of SLD and SL are very close to each other, on the *dev* set, SLD performs better than SL but they have almost the same overall scores on the *test* set. The Macro-F1 scores of each emotion category are very different from each other: the classification accuracy for emotion *Sad* is the highest in most of the cases, while the emotion *Happy* is the least accurately classified by all the models. We also noticed that the performance on the *dev* set is generally slightly better than that on the *test* set.

5 Conclusions

Considering the competitive results generated by BERT, we combined BERT and our proposed model in an ensemble and obtained 0.7709 on the final test leaderboard. From a confusion matrix of our final submission, we notice that there are barely miss-classifications among the three categories (*Angry, Sad*, and *Happy*). For example, the emotion Sad is rarely miss-classified as "Happy" or "Angry". Most of the errors correspond to classifying the emotional utterances in the *Others* category. We think, as future improvement, the models need to first focus on the binary classification "Others" versus "Not-Others", then the "Not-Others" are classified in their respective emotion.

Abstract

The paper describes the organization of the SemEval 2019 Task 5 about the detection of hate speech against immigrants and women in Spanish and English messages extracted from Twitter. The task is organized in two related classification subtasks: a main binary subtask for detecting the presence of hate speech, and a finer-grained one devoted to identifying further features in hateful contents such as the aggressive attitude and the target harassed, to distinguish if the incitement is against an individual rather than a group. HatEval has been one of the most popular tasks in SemEval-2019 with a total of 108 submitted runs for Subtask A and 70 runs for Subtask B, from a total of 74 different teams. Data provided for the task are described by showing how they have been collected and annotated. Moreover, the paper provides an analysis and discussion about the participant systems and the results they achieved in both subtasks.

1 Introduction

Hate Speech (HS) is commonly defined as any communication that disparages a person or a group on the basis of some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristics (Nockleby, 2000). Given the huge amount of user-generated contents on the Web, and in particular on social media, the problem of detecting, and therefore possibly contrasting the HS diffusion, is becoming fundamental, for instance for fighting against misogyny and xenophobia.
Some key aspects feature online HS, such as virality, or presumed anonymity, which distinguish it from offline communication and make it potentially also more dangerous and hurtful. Often hate speech fosters discrimination against particular categories and undermines equality, an everlasting issue for each civil society. Among the mainly targeted categories there are immigrants and women. For the first target, especially raised by refugee crisis and political changes occurred in the last few years, several governments and policy makers are currently trying to address it, making especially interesting the development of tools for the identification and monitoring such kind of hate (Bosco et al., 2017). For the second one instead, hate against the female gender is a long-time and well-known form of discrimination (Manne, 2017). Both these forms of hate content impact on the development of society and may be confronted by developing tools that automatically detect them.

A large number of academic events and shared tasks for different languages (i.e. English, Spanish, Italian, German, Mexican-Spanish, Hindi) took place in the very recent past which are centered on HS and related topics, thus reflecting the interest by the NLP community. Let us mention the first and second edition of the *Workshop on Abusive Language*[1] (Waseem et al., 2017), the *First Workshop on Trolling, Aggression and Cyberbullying* (Kumar et al., 2018), that also included a shared task on aggression identification, the tracks on *Automatic Misogyny Identification* (AMI) (Fersini et al., 2018b) and on *Authorship and Aggressiveness Analysis* (MEX-A3T) (Carmona et al., 2018) proposed at the 2018 edition of IberEval[2], the GermEval Shared Task on the *Identification of Offensive Language* (Wiegand et al.,

Minneapolis, Minnesota, USA, June 6–7, 2019. ©2019 Association for Computational Linguistics

2018), and finally the *Automatic Misogyny Identification task* (AMI) (Fersini et al., 2018a) and the *Hate Speech Detection task* (HaSpeeDe) (Bosco et al., 2018) at EVALITA 2018[3] for investigating respectively misogyny and HS in Italian.

HatEval consists in detecting hateful contents in social media texts, specifically in Twitter's posts, against two targets: immigrants and women. Moreover, the task implements a multilingual perspective where data for two widespread languages, English and Spanish, are provided for training and testing participant systems.
The motivations for organizing HatEval go beyond the advancement of the state of the art for HS detection for each of the involved languages and targets. The variety of targets of hate and languages provides a unique comparative setting, both with respect to the amount of data collected and annotated applying the same scheme, and with respect to the results achieved by participants training their systems on those data. Such comparative setting may help in shedding new light on the linguistic and communication behaviour against these targets, paving the way for the integration of HS detection tools in several application contexts. Moreover, the participation of a very large amount of research groups in this task (see Section 4) has improved the possibility of in-depth investigation of the involved phenomena.

The paper is organized as follows. In the next section, the datasets released to the participants for training and testing the systems are described. Section 3 presents the two subtasks and the measures we exploited in the evaluation. Section 4 reports on approaches and results of the participant systems. In Section 5, a preliminary analysis of common errors in top-ranked systems is proposed. Section 6 concludes the paper.

2 Data

The data have been collected using different gathering strategies. For what concerns the time frame, tweets have been mainly collected in the time span from July to September 2018, with the exception of data with target women. Indeed, the most part of the training set of tweets against women has been derived from an earlier collection carried out in the context of two previous challenges on misogyny identification (Fersini et al., 2018a,b). Different approaches were employed

	Training		**Test**	
Label	**Imm.**	**Women**	**Imm.**	**Women**
Hateful	39.76	44.44	42.00	42.00
Non-Hateful	60.24	55.56	58.00	58.00
Individual Target	5.89	64.94	3.33	80.63
Generic Target	94.11	35.06	96.67	19.37
Aggressive	55.08	30.06	59.84	34.44
Non-Aggressive	44.92	69.94	40.16	65.56

Table 1: Distribution percentages across sets and categories for English data. The percentages for the target and aggressiveness categories are computed on the total number of hateful tweets.

	Training		**Test**	
Label	**Imm.**	**Women**	**Imm.**	**Women**
Hateful	41.93	41.38	40.50	42.00
Non-Hateful	58.07	58.62	59.50	58.00
Individual Target	13.72	87.58	32.10	94.94
Generic Target	86.28	12.42	67.90	5.06
Aggressive	68.58	87.58	50.31	92.56
Non-Aggressive	31.42	12.42	46.69	7.44

Table 2: Distribution percentages across sets and categories for Spanish data. The percentages for the target and aggressiveness categories are computed on the total number of hateful tweets.

to collect tweets: (1) monitoring potential victims of hate accounts, (2) downloading the history of identified haters and (3) filtering Twitter streams with keywords, i.e. words, hashtags and stems. Regarding the keyword-driven approach, we employed both neutral keywords (in line with the collection strategy applied in Sanguinetti et al. (2018)), derogatory words against the targets, and highly polarized hashtags, in order to collect a corpus for reflecting also on the subtle but important differences between HS, offensiveness (Wiegand et al., 2018) and stance (Taulé et al., 2017). The keywords that occur more frequently in the collected tweets are: *migrant*, *refugee*, *#buildthatwall*, *bitch*, *hoe*, *women* for English, and *inmigra-*, *arabe*, *sudaca*, *puta*, *callate*, *perra* for Spanish[4].

The entire HatEval dataset is composed of 19,600 tweets, 13,000 for English and 6,600 for Spanish. They are distributed across the targets as follows: 9,091 about immigrants and 10,509 about women (see also Tables 1 for English and 2 for Spanish). Figures 1 and 2 show the distribution of the labels in the training and development set data according to the different targets of hate (woman and immigrants, respectively).

[3]http://evalita.org

[4]The complete set of keywords exploited is available here: https://github.com/msang/hateval/blob/master/keyword_set.md

2.1 Annotation

The data are released after the annotation process, which involved non-trained contributors on the crowdsourcing platform *Figure Eight* (F8)[5]. The annotation scheme applied to the HatEval data is a simplified merge of schemes already applied in the development of corpora for HS detection and misogyny by the organizers (Fersini et al., 2018a,b; Bosco et al., 2018), also in the context of funded projects with focus on the tasks topics[6] (Sanguinetti et al., 2018; Poletto et al., 2017). It includes the following categories:

- **HS** - a binary value indicating if HS is occurring against one of the given targets (women or immigrants): 1 if occurs, 0 if not.
- **Target Range** - if HS occurs (i.e. the value for the feature HS is 1), a binary value indicating if the target is a generic group of people (0) or a specific individual (1).
- **Aggressiveness** - if HS occurs (i.e. the value for the feature HS is 1), a binary value indicating if the tweeter is aggressive (1) or not (0).

We gave the annotators a series of guidelines in English and Spanish, including the definition for hate speech against the two targets considered, the aggressiveness's definition and a list of examples[7]. As requested by the platform, we provided a restricted set of "correct" answers to test the reliability of the annotators. We required to collect at least three independent judgments for each tweet. We adopted the default F8 settings for assigning the majority label (relative majority). The F8 reported average confidence (i.e., a measure combining inter-rater agreement and reliability of the contributor) on the English dataset for the fields HS, TR, AG is 0.83, 0.70 and 0.73 respectively, while for the Spanish dataset is 0.89, 0.47 and 0.47. The use of crowdsourcing has been successfully already experimented in several tasks and in HS detection too, both for English (Davidson et al., 2017) and other languages (Sanguinetti et al., 2018). However, stimulated by the discussion in (Basile et al., 2018), we decided to apply a similar methodology by adding two more expert annotations to all the crowd-annotated data, provided by native or near-native speakers of British English and Castilian Spanish, having a long experience in annotating data for the specific task's subject. We assigned the final label for this data based on majority voting from *crowd*, *expert1*, and *expert2*. This does not erase the contribution of the crowd, but hopefully maximises consistency with the guidelines in order to provide a solid evaluation benchmark for this task.

For data release and distribution each post has been identified by a newly generated index which substitutes the original Twitter's IDs.

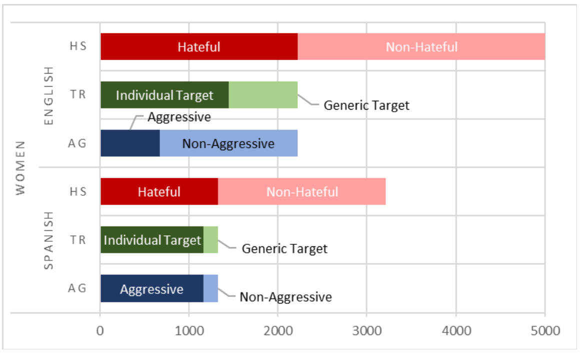

Figure 1: Distribution of the annotated categories in English and Spanish training and development set for the target women.

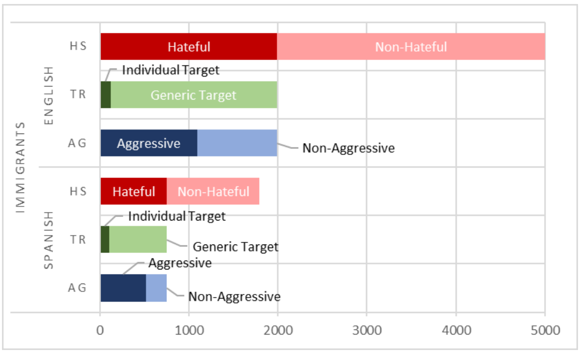

Figure 2: Distribution of the annotated categories in English and Spanish training and development set for the target immigrants.

2.2 Training, Development and Test Data

Data for training and development were released according to the distribution described in Figures 1 and 2 across languages (Spanish and English) and targets (women and immigrants). For what concerns Spanish, the training and development set includes 5,000 tweets, (3,209 for the target women and 1,991 for immigrants), while for English it in-

[5] http://www.figure-eight.com/

[6] http://hatespeech.di.unito.it/ihateprejudice.html.

[7] Annotation guidelines provided are accessible here: https://github.com/msang/hateval/blob/master/annotation_guidelines.md.

cludes 10,000 tweets (5,000 for each target). For a cross-language perspective see Figures 1 and 2. It can be also observed that the distribution across categories is pivoting around the main task category, HS, while the other ones more freely vary. Indeed, in order to provide a more balanced distribution of the HS and non-HS categories in the dataset released for Subtask A, we altered the natural distribution: both in the training and test set, hateful tweets are over-represented with respect to the distribution observed in the data we collected from Twitter[8]. Instead, the distribution of the other categories which are relevant for Subtask B is not constrained, and naturally follows from the selection of tweets for representing the classes relevant for the main Subtask A.

As far as the test set is concerned, 3,000 tweets have been annotated for English, half with target women and half immigrants, and 1,600 for Spanish distributed with the same proportion across the targets of hate: 1,260 hateful tweets and 1,740 non-hateful tweets for English, 660 hateful tweets and 940 non-hateful tweets for Spanish.

According to the schema described above, the format of an annotated tweet in the training and development set has the following pattern:

ID, Tweet-text, HS, TR, AG

where ID is a progressive number denoting the tweet within the dataset, Tweet-text is the given text of the tweet, while the other parts of the pattern, given in the training data and to be predicted in the test set, are: Hate Speech [HS] (1 or 0), Target Range [TR] (0 for group or 1 for individual), and Aggressiveness [AG] (0 or 1). Data included in the test instead only include ID and Tweet-text, the annotation of HS, TR and AG to be provided by participants according to the subtask.
An example of annotation is the following:

7, lol, chop her head off and rape the bitch https://t.co/ZB8CosmSD8, 1, 1, 1

which has been considered by the annotators as hateful, against an individual target, and aggressive. The latter category is not necessarily associated to HS, as shown in the following example, where a hateful content is expressed against a generic group of people in terms of disrespect and misogynistic stereotypes rather than using an aggressive language:

11, WOW can't believe all these women riding the subway today? Shouldn't these bitches be making sandwiches LOL #ihatefemales.., 1, 0, 0

3 Task Description

The task is articulated around two related subtasks. The first consists of a basic detection of HS, where participants are asked to mark the presence of hateful content. In the second subtask instead fine-grained features of hateful contents are investigated in order to understand how existing approaches may deal with the identification of especially dangerous forms of hate, i.e., those where the incitement is against an individual rather than against a group of people, and where an aggressive behaviour of the author can be identified as a prominent feature of the expression of hate. The participants will be asked in this latter subtask to identify if the target of hate is a single human or a group of persons, and if the message author intends to be aggressive, harmful, or even to incite, in various forms, to violent acts against the target (see e.g. (Sanguinetti et al., 2018)).

3.1 Subtask A - Hate Speech Detection against immigrants and women

Subtask A is a two-class (or binary) classification task where the system has to predict whether a tweet in English or in Spanish with a given target (women or immigrants) contains HS or not. The following sentences present examples of a hateful and non-hateful tweet where the targets are women.

[hateful]

[id: 32411] Cállate @[redacted] y la gran puta madre que te repario. Que le diste a la poltica...nada. Basura.
Shut up @[redacted] you motherfucker. What did you do for politics... nothing. Trash.[9]

[non-hateful]

[id: 33033] @[redacted] This is inhumane 😔 Karma is a bitch she ll get around these brainless heartless assholes!

[8]The whole original annotated dataset was very skewed towards the non-HS class (only about 10% of the annotated data contained hate speech).

[9]The target of the misogynistic hate here is Victoria Donda Prez, an Argentinian woman, human rights activist and member of the Argentine National Congress (mentioned in the at-mention of the original tweet).

3.2 Subtask B - Aggressive behaviour and Target Classification

Next, in Subtask B systems are asked to classify hateful tweets (e.g., tweets where HS against our targets has been identified) regarding both aggressive attitude and the target harassed. On one hand, the kind of target must be classified, and the task is binary:

- *Individual*: the text includes hateful messages purposely sent to a specific target.
- *Generic*: it refers to hateful messages posted to many potential receivers.

[**Individual**]:

> [id: 4723] @[redacted] Come on box I show you my cock darling

[**Generic**]:

> [id: 5823] Women are equal and deserve respect. Just kidding, they should suck my dick.

On the other hand, the aggressive behaviour has to be identified, then we propose a two-class classification task also for this feature. A tweet must be classified as aggressive or not:

[**Aggressive**]

> [id:1890] Sick barstewards! This is what happens when we put up the refugees welcome signs! They not only rape our wives or girlfriends, our daughters but our ruddy mothers too!! https://t.co/XAYLr6FjNk

[**Non-Aggressive**]

> [id: 945] @EmmanuelMacron Hello?? Stop groping my nation.Schneider: current migrant crisis represents a plan orchestrated and prepared for a long time by international powers to radically alter Christian and national identity of European peoples.http

3.3 Evaluation Measures and Baseline

The evaluation of the results considers different strategies and metrics for Subtasks A and B in order to allow more fine-grained scores.

Subtask A. Systems will be evaluated using standard evaluation metrics, including Accuracy, Precision, Recall and macro-averaged F_1-score.

In order to provide a measure that is independent on the class size, the submissions will be ranked by macro-averaged F_1-score, computed as described in (Özgür et al., 2005). The metrics will be computed as follows:

$$Accuracy = \frac{\textit{number of correctly predicted instances}}{\textit{total number of instances}} \quad (1)$$

$$Precision = \frac{\textit{number of correctly predicted instances}}{\textit{number of predicted labels}} \quad (2)$$

$$Recall = \frac{\textit{number of correctly predicted labels}}{\textit{number labels in the gold standard}} \quad (3)$$

$$F_1\text{-score} = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (4)$$

Subtask B. The evaluation of systems participating to Subtask B will be based on two criteria: (1) partial match and (2) exact match. Regarding the partial match, each dimension to be predicted (HS , TR and AG) will be evaluated independently from the others using standard evaluation metrics, including accuracy, precision, recall and macro-averaged F_1-score. We will report to the participants all the measures and a summary of the performance in terms of macro-averaged F_1-score, computed as follows:

$$F_1\text{-score} = \frac{F_1(HS) + F_1(AG) + F_1(TR)}{3} \quad (5)$$

Concerning the exact match, all the dimensions to be predicted will be jointly considered computing the Exact Match Ratio (Kazawa et al., 2005). Given the multi-label dataset consisting of n multi-label samples (x_i, Y_i), where x_i denotes the i-th instance and Y_i represents the corresponding set of labels to be predicted (HS $\in \{0,1\}$, TR $\in \{0,1\}$ and AG $\in \{0,1\}$), the Exact Match Ratio (EMR) will be computed as follows:

$$EMR = \frac{1}{n}\sum_{i=1}^{n} I(Y_i, Z_i) \quad (6)$$

where Z_i denotes the set of labels predicted for the i-th instance and I is the indicator function. The submissions will be ranked by EMR. This choice is motivated by the willingness to capture the difficulty of modeling the entire phenomenon, and therefore to identify the most dangerous behaviours against the targets.

Baselines. In order to provide a benchmark for the comparison of the submitted systems, we considered two different baselines. The first one (*MFC baseline*) is a trivial model that assigns the most frequent label, estimated on the training set, to all the instances in the test set. The second one (*SVC baseline*) is a linear Support Vector Machine (SVM) based on a TF-IDF representation, where the hyper-parameters are the default values set by the scikit-learn Python library (Pedregosa et al., 2011).

4 Participant Systems and Results

HatEval has been one of the most popular tasks in SemEval-2019 with a total of 108 submitted runs for Subtask A and 70 runs for Subtask B. We received submission from 74 different teams, of which 22 teams participated to all the subtasks for the two languages[10].

Besides traditional Machine Learning approaches, it has been observed that more than half of the participants investigated Deep Learning models. In particular, most of the systems adopted models known to be particularly suitable for dealing with texts, from Recurrent Neural Networks to recently proposed language models (Sabour et al., 2017; Cer et al., 2018). Consequently, external resources such as pre-trained Word Embeddings on tweets have been widely adopted as input features. Only a few works deepen the linguistic features analysis, probably due to the high expectations on the ability of Deep Learning models to extract high-level features. Most of the submitted systems adopted traditional preprocessing techniques, such as tokenization, lowercase, stopwords, URLs and punctuation removal. Some participants investigated Twitter-driven preprocessing procedures such as hashtag segmentation, slang conversion in correct English and emoji translation into words. It is worth mentioning that the construction of customized hate lexicons derived by the detection of language patterns in the training set has been preferred to the use of external hate lexicons expressing a more universal knowledge about the hate speech phenomenon, additionally demonstrating the need of developing more advanced approaches for detecting hate speech towards women and immigrants.

[10]The evaluation results are published here: https://docs.google.com/spreadsheets/d/1wSFKh1hvwwQIoY8_XBVkhjxacDmwXFpkshYzLx4bw-0/

4.1 Subtask A - Hate Speech Detection against immigrants and women

We received 69 submissions to the English Subtask A, of which 49% and 96% outperformed the SVC and MFC baseline respectively, in terms of macro-averaged F_1-score. Among the five best performing teams, only the team of *Panaetius*, which obtained the second position (0.571), has not provided a description of their system. The higher macro-averaged F_1-score (0.651) has been obtained by the Fermi team. They trained a SVM model with RBF kernel only on the provided data, exploiting sentence embeddings from Google's Universal Sentence Encoder (Cer et al., 2018) as features. Both the third, fourth and fifth ranked teams employ Neural Network models and, more specifically, Convolutional Neural Networks (CNNs) and Long Short Term Memory networks (LSTMs). In particular, the third position has been obtained by the *YNU_DYX* team, which system achieved 0.535 macro-averaged F_1-score by training a stacked Bidirectional Gated Recurrent Units (BiGRUs) (Cho et al., 2014) exploiting fastText word embeddings (Joulin et al., 2017). Then, the output of BiGRU is fed as input to the capsule network (Sabour et al., 2017). The textual preprocessing has been conducted with standard procedures, e.g. punctuation removal, tokenization, contraction normalization, use of tags for hyperlinks, numbers and mentions. The fourth place has been achieved by the team of *alonzorz* (0.535), which used a novel type of CNN called Multiple Choice CNN on the top of contextual embeddings. These embeddings have been created with a model similar to Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) trained using 50 million unique tweets from the Twitter Firehose dataset. The *SINAI-DL* team ranked fifth with a F_1-score of 0.519. They employ a LSTM model based on the pretrained GloVe Word Embeddings from Stanford-NLP group (Pennington et al., 2014). Since Deep Learning models require a large amount of data for training, they perform data augmentation through the use of paraphrasing tools. For preprocessing the texts in the specific Twitter domain, they convert all the mentions to a common tag and they tokenized hashtags according to the Camel Case procedure, i.e. the practice of writing phrases such that each word or abbreviation in the middle of the phrase begins with a capital letter, with no intervening spaces or punctuation.

For Subtask A in Spanish, we received 39 submissions of which 51% and 100% outperformed the SVC and MFC baseline respectively, in terms of macro-averaged F_1-score. The *Atalaya* and *MineriaUNAM* teams obtained the best macro-averaged F_1-score of 0.73, both taking advantage of Support Vector Machines. The *Atalaya* team studied several sophisticated systems, however the best performances have been obtained by a linear-kernel SVM trained on a text representation composed of bag-of-words, bag-of-characters and tweet embeddings, computed from fastText sentiment-oriented word vectors. The system proposed by the *MineriaUNAM* team is based on a linear-kernel SVM. The study has focused on a combinatorial framework used to search for the best feature configuration among a combination of linguistic patterns features, a lexicon of aggressive words and different types of n-grams (characters, words, POS tags, aggressive words, word jumps, function words and punctuation symbols). The *MITRE* team has achieved the performance of 0.729, presenting a novel method for adapting pre-trained BERT models to Twitter data using a corpus of tweets collected during the same time period of the HatEval training dataset. The *CIC-2* team achieved 0.727 with a word-based representation by combining Logistic Regression, Multinomial Naïve Bayes, Classifiers Chain and Majority Voting. They used TF and TF/IDF after removing HTML tags, punctuation marks and special characters, converting slang and short forms into correct English words and stemming. The participants did not use external resources and trained their systems only with the provided data. Finally, the *GSI-UPM* team obtained the macro-averaged F_1-score of 0.725 with a system where the linear-kernel SVM has been trained on an automated selection of linguistic and semantic features, sentiment indicators, word embeddings, topic modeling features, and word and character TF-IDF n-grams.

Table 3 shows basic statistics computed both for Subtasks A and B, with respect to the relative performance measures. The statistics comprise mean, standard deviation (StdDev), minimum, maximum, median and the first and third quartiles (Q1 and Q3). Concerning Subtask A, we notice that the maximum value in Spanish (0.7300) is higher than the English one (0.6510), while the difference is even higher (23 points) when considering the mean value, from 0.6821 to 0.4484. On the other hand, the variability is very similar between English (0.0569) and Spanish (0.0521).

	Subtask A		**Subtask B**	
	English	**Spanish**	**English**	**Spanish**
Min.	0.3500	0.4930	0.1590	0.4280
Q1	0.4050	0.6665	0.2790	0.5820
Mean	0.4484	0.6821	0.3223	0.6013
Median	0.4500	0.7010	0.3120	0.6160
StdDev	0.0569	0.0521	0.0890	0.0662
Q3	0.4880	0.7165	0.3570	0.6365
Max.	0.6510	0.7300	0.5700	0.7050
SVC Baseline	0.451	0.701	0.308	0.588
MFC Baseline	0.367	0.370	0.580	0.605

Table 3: Basic statistics of the results for the participating system and baselines in Subtask A and Subtask B expressed in terms of macro-averaged F_1-score and EMR respectively.

4.2 Subtask B - Aggressive behaviour and Target Classification

For Subtask B in English, we received 39 submissions, of which no system has been able to outperform the MFC baseline, which achieved 0.580 of EMR, while 61% outperformed the SVC baseline. Among the five best performing teams, only the team of *scmhl5*, which obtained the third position (0.483), has not provided us with a description of the system. The higher EMR result has been obtained by the *LT3* team with a value of 0.570. They considered a supervised classification-based approach with SVM models which combines a variety of standard lexical and syntactic features with specific features for capturing offensive language exploiting external lexicons. The second position has been obtained by the *CIC-1* team. The team achieved 0.568 in EMR with Logistic Regression and Classifier Chains. They trained their model only with the provided data, with a word-based representation and without external resources. The only preprocessing action was stemming and stop words removal. The fourth position was obtained by the team named The Titans. They achieved 0.471 of EMR with LSTM and TF/IDF-based Multilayer Perceptron. To represent the documents, they used the tweet words after removing links, mentions and spaces. They also tokenized hashtags into word tokens. The MITRE team exploits the same approach used for participating in Subtask A, obtaining 0.399 EMR. It is worth mentioning that, despite the fact that the baseline could not be overcome in terms of EMR, the five first performing systems obtained higher F-values. For example, while the baseline obtained 0.421, the *scmhl5* (0.632) and the *MITRE* team (0.614) systems obtained about 20 points over it.

For Subtask B in Spanish, we received 23 submissions of which 52% and 70% outperformed the SVC and MFC baseline respectively, in terms of EMR. The first position has been achieved by the CIC-2 team with 0.705 in terms of EMR, proposing the same approach for Subtask A in Spanish. The *CIC-1* and *MITRE* teams, described previously, achieved the second and third positions with 0.675 and 0.675 in EMR respectively. The fourth position was obtained by the *Atalaya* team that achieved 0.657 EMR by extending the previously presented approach for Subtask A to a 5-way classification problem for all the possible label combinations. Finally, the team of *Oscar-Garibo* achieved the fifth position (0.6444) with Support Vector Machines and statistical embeddings to represent the texts. The proposed method, a variation of LDSE (Rangel et al., 2016), consists of finding thresholds on the frequencies of use of the different terms in the corpora depending on the class they belong to. In this subtask, the correlation between EMR and macro-averaged F_1-score is more homogeneous than in English. However, it is worth mentioning the case of the *CIC-1* team since its macro-averaged F_1-score decreases with respect to the EMR and is 10 points lower than the rest of the best five performing teams.

The comparative results between all the performing teams in the two languages show interesting insights (see Table 3). Firstly, the best result is much higher in the case of Spanish (0.7050) than in English (0.5700) in more than 13 points. In the case of the fifth best results, the difference is much higher (0.2454), from 0.3990 in English to 0.6440 in Spanish. The average value changes from 0.3223 in English to 0.6013 in Spanish, with a difference of 28 points. The variability is also higher in English (0.0890) with respect to the value in Spanish (0.0662).

We can also derive further conclusions by comparing the statistics of the two Subtasks. Looking at the median, it is possible to notice that in both languages, the performances obtained on Subtask B are lower than the performances of Subtask A, with a difference between Subtask A and B of 14 and 8 points for English and Spanish respectively. This suggests that participant systems found much harder to predict the aggressiveness and targets than just the presence of hate speech. The quartile Q1 has highlighted that for the English language 75% of the systems obtained a score higher than 0.41 and 0.28 for Subtasks A and B, in particular 50 out of 69 for Subtask A and 31 out of 41 for Subtask B. While Q3 shows that 25% of the systems achieved a score value higher than 0.49 and 0.36 for Subtasks A and B, in particular 18 out of 69 for Subtask A and 11 out of 41 for Subtask B. For the Spanish language, the value of Q1 indicates that 75% of the systems have a score higher than 0.67 and 0.58 for Subtasks A and B, in particular 30 out of 39 for Subtask A and 17 out of 23 for Subtask B. Observing the quartile Q3, it is possible to observe that 25% of the systems achieved a value higher than 0.72 and 0.64 for Subtasks A and B, in particular 10 out of 39 for Subtask A and 6 out of 23 for Subtask B. Moreover, it is worth mentioning that the smaller the standard deviation the closer are the data to the mean value, highlighting that the Subtask B has shown high variability in terms of results than Subtask A. This statistics remarks again the difficulties of addressing Subtask B compared to Subtask A.

5 Error Analysis

In order to gain deeper insight into the results of the HatEval evaluation, we conducted a first error analysis experiment. For both languages, we selected the three top-ranked systems and checked the instances in the test set that were wrongly labeled by all three of them.

In the English Subtask A, the three top systems (*Fermi*, *Panaetius*, and *YNU_DYX*) predicted the same wrong labels 569 times out of 2,971 (19.1%). In the Spanish Subtask A, the three top systems (*Atalaya*, *mineriaUNAM*, and *MITRE*) predicted the same wrong labels 234 times out of 1,600 (14.6%). The results showing the percentages by wrongly assigned labels are summarized in Table 4.

Subtask	**Errors**	**Predicted 1**	**Predicted 0**
EN A	569	507 (89.1%)	62 (10.9%)
ES A	234	178 (76.1%)	56 (23.9%)

Table 4: Number of instances mislabeled by all the three top-ranked systems, broken down by wrongly assigned label.

The common errors are highly skewed towards the false positives. However, the unbalance is stronger for English (89.1% false positives) than for Spanish (76% false positives).

Two English examples, respectively a false positive and a false negative, are:

> [id: 30249] My mom FaceTimed me to show off new shoes she got and was like "no cabe duda que soy una Bitch" i love her 😂

> [id: 30542] @[redacted] @[redacted] There are NO INNOCENT people in detention centres #SendThemBack

The false positive contains a swear word ("Bitch") used in a humorous, not offensive context, which is a potential source of confusion for a classifier. The false negative is a hateful message towards migrants, but phrased in a slightly convoluted way, in particular due to the use of negation ("no innocent people").

Similarly, a false positive and a false negative in Spanish:

> [id: 33119] Soy un sudaca haciendo sudokus 🙃 https://t.co/vA7nQsfm85
> *I am a sudaca doing sudokus*

> [id: 34455] Estoy escuchando una puta canción y la pelotuda de Demi Lovato se pone a hablar en el medio. CANTÁ Y CALLATE LA BOCA.
> *I am listening to a fucking song and that asshole Demi Lovato starts talking in the middle of it. SING AND SHUT YOUR MOUTH.*

Like in the English example, in this false positive a negative word ("sudaca") is used humorously, for the purpose of a wordplay. In the false negative, there a misogynistic message is expressed, although covertly, implying that the target should "shut up and sing".

6 Conclusion

The very high number of participating teams at HatEval 2019 confirms the growing interest of the community around abusive language in social media and hate speech detection in particular. The presence of this task at SemEval 2019 was indeed very timely and the multilingual perspective we applied by developing data in two different widespread languages, English and Spanish, contributed to include and raise interest in a wider community of scholars. 38 teams sent their system reports to describe the approaches and the details of their participation to the task, contributing in shedding light on this difficult task. Some of the HatEval participants also participated to the OffensEval[11], another task related to abusive language identification, but with an accent on the different notion of *offensiveness*, an orthogonal notion that can characterize also expressions that cannot be featured as hate speech[12]. Overall, results confirm that hate speech detection against women and immigrants in micro-blogging texts is challenging, with a large room for improvement. We hope that the dataset made available as part of the shared task will foster further research on this topic, including its multilingual perspective.

Abstract

In this article, we describe our participation in HatEval, a shared task aimed at the detection of hate speech against immigrants and women. We focused on Spanish subtasks, building from our previous experiences on sentiment analysis in this language. We trained linear classifiers and Recurrent Neural Networks, using classic features, such as bag-of-words, bag-of-characters, and word embeddings, and also with recent techniques such as contextualized word representations. In particular, we trained robust task-oriented subword-aware embeddings and computed tweet representations using a weighted-averaging strategy. In the final evaluation, our systems showed competitive results for both Spanish subtasks ES-A and ES-B, achieving the first and fourth places respectively.

1 Introduction

Hate speech against women, immigrants, and many other groups is a pervasive phenomenon on the Internet. On the early days of the World Wide Web, many academics adventured that prejudices and hatred would be removed in this space by the dissolution of identities (Lévy, 2001; Rheingold, 1993). Twenty years after this hypothesis, we can say that it has not been the case. The prevalence of racism in the "World White Web" has been studied in a number of works (Adams and Roscigno, 2005; Kettrey and Laster, 2014) and so has been the misogyny in the virtual world (Filipovic, 2007; Mantilla, 2013).

Racist and sexist discourse are a constant in social media, but peaks are documented after "trigger" events, such as murders with religious or political reasons (Burnap and Williams, 2015). Most social media companies are concerned about this issue and take actions against it; nonetheless, most of the efforts still need human intervention, making this task very expensive. Therefore, reducing human intervention is vital in order to have effective tools to avoid the escalation of hate speech.

HatEval (Basile et al., 2019) is a SemEval-2019 shared task aimed at the detection of hate speech towards immigrants and women in tweets. It comprises two subtasks, with datasets in English (EN) and Spanish (ES) for both of them, giving a total of four subtasks. Subtask A is the binary classification of tweets into hateful or not hateful (HS). Subtask B is a triple binary classification task where, in addition to HS, tweets are classified into aggressive or not aggressive (AG), and targets of hate speech are classified into single humans or groups of persons (TR).

In this article, we present our participation in HatEval as team Atalaya. We focused our efforts on subtask A for Spanish (ES-A) but also worked at subtask B in Spanish (ES-B) and subtask A in English (EN-A). Our systems are based on our participation in the polarity classification task of Spanish tweets TASS 2018 (*Sentiment Analysis at SEPLN*) (Martínez-Cámara et al., 2018; Luque and Pérez, 2018).

To represent tweets, we experimented with a mixed approach of bag-of-words, bag-of-characters and tweet embeddings, which were calculated from word vectors using different averaging schemes. We used *fastText* (Bojanowski et al., 2016) to get subword-aware representations specifically trained for sentiment analysis tasks.

These word representations are robust to noise since they can be computed for unseen words by using subword embeddings. Moreover, we trained them using a database of 90M tweets from various Spanish-speaking countries, giving wide domain-specific vocabulary coverage. We achieved additional robustness by doing preprocessing using several text-normalization and noise-reduction techniques.

Also, we experimented with *ELMo* (Peters et al., 2018), a deep contextualized word representation that has drawn a lot of attention in the last months. Unlike *fastText*, *ELMo* returns context-dependent embeddings from a multi-layer bidirectional-LSTM language model. These representations improved the state-of-the-art of several NLP tasks.

For the neural approach, we used bidirectional LSTMs to combine the word embeddings. We also did experiments that mix sequential models with complementary representations such as bag-of-words.

The rest of the paper is as follows. Next Section presents the primary tools we used to build our systems. Section 3 presents the configuration and development of both linear and neural models. Section 4 briefly shows our results in the competition, and Section 5 concludes the work with some observations about our experience.

1.1 Previous Work

The detection of hate speech is a sentence classification task quite related to sentiment analysis and has been studied for several social media networks (Thelwall, 2008; Pak and Paroubek, 2010; Saleem et al., 2017). Regarding the detection of hateful content, Greevy and Smeaton (2004) used bag-of-words and SVMs to detect racist content in web pages. Following a similar approach, Warner and Hirschberg (2012) used unigrams and Brown clusters with SVMs to detect anti-semitic messages on Twitter.

Waseem and Hovy (2016) annotated a corpus and used character n-grams to detect hateful comments, and Badjatiya et al. (2017) used the same dataset to train deep learning models and fine-tuned embeddings along with Gradient Boosted Trees. Zhang et al. (2018) trained a deep neural network combining CNNs with Gated-recurrent units (Cho et al., 2014), outperforming previous systems in several datasets.

Anzovino et al. (2018) collected a corpus of misogynous tweets and proposed a taxonomy to distinguish them into different categories. The authors proposed a number of different techniques to classify them, showing that simple approaches (as using linear models along with token n-grams) achieve competitive performance on small-sized datasets.

Regarding shared tasks, Fersini et al. (2018a) presented a challenge on misogyny detection on Twitter –both in Spanish and English– whereas Fersini et al. (2018b) posed a similar challenge but in Italian and English. Bosco et al. (2018) proposed an automatic detection contest over Twitter posts and Facebook comments, comprising general hate speech.

2 Techniques and Resources

2.1 Preprocessing

Preprocessing is crucial in NLP applications, especially when working with noisy user-generated data. Here, we followed Luque and Pérez (2018), defining two levels of preprocessing: basic and sentiment-oriented preprocessing. We used one or the other, depending on the configuration.

Basic tweet preprocessing includes tokenization, replacement of handles, URLs, and e-mails, and shortening of repeated letters.

Sentiment-oriented preprocessing includes lowercasing, removal of punctuation, stopword, and numbers, lemmatization –using TreeTagger (Schmid, 1995)– and negation handling. For negation handling, we followed a simple approach: We find negation words and add the prefix `'NOT_'` to the following tokens. Up to three tokens are negated, or less if a non-word token is found.

2.2 Bags of Words and Characters

The simplest approach considered to build tweet representations was bag-of-words encoding. A bag-of-words (BoW) builds feature vectors for each token seen in training data. For a particular tweet, its BoW vector contains the number of occurrences of each token on it, resulting in high-dimensional and sparse vectors. Variations of BoW include counting not only single tokens but also n-grams of tokens, binarizing counts, and limiting the number of features.

Character usage in tweets may also hold useful information for sentiment analysis. Character n-grams –such as the presence and repetition of uppercase letters, emoticons, and exclamation marks– may indicate a strong presence of sentiment of some kind, where others may indicate a more formal writing style, and therefore an absence of sentiment.

To capture this information, we considered a bag-of-characters (BoC) representation that encodes counts of character n-grams for some values of n. These vectors are computed from original texts of tweets, with no preprocessing at all. BoCs have the same variants and parameters as BoWs.

2.3 Word Embeddings

We used *fastText*, a subword-aware embeddings library (Bojanowski et al., 2016) to get context-independent word representations. Instead of using publicly available pre-trained vectors, we trained our own embeddings on a dataset of $\sim$ 90 million tweets from various Spanish-speaking countries. We prepared two versions of the data: one using only basic preprocessing, and the other using sentiment-oriented preprocessing (with the exception of excepting lemmatization). For these two datasets, skip-gram embeddings were trained using different parameter configurations, including a number of dimensions, size of word and subword n-grams, and size of context window.

2.4 Tweet Embeddings

Linear combinations were used to compute a representation for a single tweet. We followed two simple approaches: plain average and weighted average. In the second case, we used a scheme that resembles Smooth Inverse Frequency (SIF) (Arora et al., 2017), inspired by TF-IDF reweighting. Each word w is weighted with $\frac{a}{a+p(w)}$, where $p(w)$ is the word unigram probability, and a is a smoothing hyper-parameter. Big values of a mean more smoothing towards plain averaging.

2.5 Context-Dependent Embeddings

After the great leap forward that represented context-independent word embeddings, a new wave came in the last years. Instead of having vectors trained for each word, context-dependent representations are generated for each token given a sentence. For instance, McCann et al. (2017) used a deep LSTM encoder for Machine Translation to generate context-aware vectors.

ELMo (Peters et al., 2018) is one of these context-dependent approaches and is based on a deep bidirectional language model (biLM). The architecture of the language model consists of L layers of bidirectional LSTMs, plus a context-independent token representation. Hence, for each token in a sequence, we get $2L + 1$ vector representations. To obtain a final vector for each token, the authors suggest collapsing the layers into vectors by means of a linear combination.

In this work, we used the implementation and pre-trained models from Che et al. (2018). The Spanish model was trained with $L = 2$ layers and 1024 dimensions, and the linear combination was done using a simple average.

3 Models

In this section, we describe the models we used in the competition.

3.1 Linear Classifiers

The first set of models we trained were simple classifying models implemented with scikit-learn (Pedregosa et al., 2011).

We started from the optimal configuration from Luque and Pérez (2018), that combines bag-of-words (BoW), bag-of-characters (BoC) and tweet embeddings as follows:

- BoW: All unigrams and bigrams of words, with binarized counts and TF-IDF reweighting. For the Spanish training dataset, this encoding gives 53504 sparse features.
- BoC: All n-grams of characters for $n \leq 5$, with binarized counts and TF-IDF reweighting. For the Spanish training dataset, it gives 226156 sparse features.
- Tweet embeddings: Computed from *fastText* sentiment-oriented word vectors of 50 dimensions. Weighted averaging was done as described in Section 2.4, with a smoothing value of $a = 0.1$.

Here, the only parameters specifically optimized using the HatEval development set were the n-gram ranges considered for BoW and BoC.

Using this vectorial representation we trained logistic regressions and linear-kernel SVMs with different hyperparameter values. The best results are shown in the first block of Tab. 1, as LR_0 and SVM_0.

Next, to confirm the relevance of each of the three components, we performed ablation tests for each of them. Results are displayed as SVM_{BoW}, SVM_{BoC} and SVM_{emb} in Tab. 1. Drops in the performance show the relevance of all components, especially for BoW and BoC.

Next, we tried adding tweet representations computed from ELMo vectors. Full tweet vectors were obtained by doing simple un-weighted averaging. PCA was optionally used to reduce the dimension of final vectors. The best results were

Model	Acc	F1 (avg)
LR_0	0.84	0.84
SVM_0	**0.85**	**0.85**
SVM_{BoW}	0.81	0.81
SVM_{BoC}	0.81	0.81
SVM_{emb}	0.84	0.84
SVM_{ELMo}	0.84	0.84

Table 1: Experiments with logistic regressions (LRs) and SVMs on the Spanish development set. Models are described in Section 3.1. The best result is in bold.

obtained using PCA to reduce from the original 1024 to 100 dimensions.

Results are shown as SVM_{ELMo} in Tab. 1. It can be seen that, under this configuration, we are not able to improve our results using ELMo.

To participate in the Spanish subtask B (ES-B) we used a very naive approach. We didn't develop or tune a specific system for this subtask but instead used the same system and configuration that was found optimal for subtask A. To do this, we first mapped the triple classification problem to a 5-way classification problem for all the possible label combinations:

HS	AG	TR
0	0	0
1	0	0
1	0	1
1	1	0
1	1	1

Then, we simply trained the classifier using the Spanish subtask B training dataset.

3.2 Neural Models

The second set of models we trained are neural models. We trained Recurrent Neural Networks (RNNs) using pre-trained context-dependent representations for Spanish.

The first model considered was a bidirectional LSTM with a dense layer on top, consuming ELMo vectors; we call this model *LSTM-ELMo*. Also, we tried another model by adding a second input consisting of a bag-of-words, as illustrated in Figure 1. We call this model *LSTM-ELMo+BoW*. Using *fastText* embeddings (of dimension 300 and context window 5) instead of BoW was considered as suggested by Peters et al. (2018) but discarded as it had no positive impact in performance (in the development dataset).

The *biLSTM* layer consists of 256 units. The bag-of-words has the 3500 most-frequent n-grams (having document-frequency less than 0.65), followed by a 512-unit dense layer. The two last dense layers have 64 neurons.

We used Keras (Chollet et al., 2015) to implement and train our models. *Adam* (Kingma and Ba, 2014) was the chosen optimizer, with $lr = 35 * 10^{-5}$ and $decay = 0.01$. To regularize our models, we applied dropout with keep-prob of 0.2 on the first layer, and 0.45 on the second, and we also early-stopped the training monitoring the performance on the development dataset. The hyperparameters were chosen from a small random search, as training ELMo is computationally expensive.

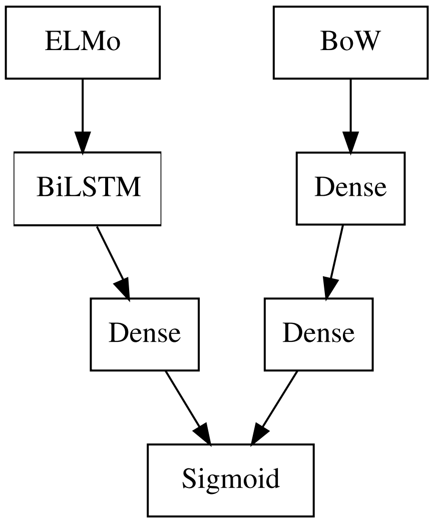

Figure 1: The *LSTM-ELMo+BoW* architecture. ELMo and BoW boxes represent inputs.

4 Results

Table 2 displays the evaluation results for the three classifiers trained for subtask A: SVM_0, and both neural models *LSTM-ELMo* and *LSTM-ELMo+BoW*. For Spanish, the best performing system was SVM_0. Despite its simplicity, it ranked first in terms of average F1 in the official results.

Among the neural models, *LSTM-ELMo+BoW* performed best, and ranked in position 17 for Spanish in terms of average F1.[1] We can observe that *LSTM-ELMo+BoW* performs better on the development set, although its performance decreases sharply in the test set. In spite of the applied regularization, we might have incurred in overfitting during model selection (Cawley and Talbot, 2010) as the chosen model has higher variance

[1]Results shown in Tab. 2 differ from the ones in the leaderboard as we couldn't exactly reproduce the experiments.

	Spanish				English			
	Dev		Test		Dev		Test	
Classifier	Acc	F1 (avg)	Acc	F1 (avg)	Acc	F1 (avg)	Acc	F1 (avg)
SVM_0	**0.850**	**0.850**	0.731	**0.730**	—	—	—	—
LSTM-ELMo	0.820	0.816	**0.732**	0.721	0.705	0.695	**0.508**	**0.471**
LSTM-ELMo+BoW	0.824	0.821	0.719	0.712	**0.743**	**0.738**	0.502	0.461

Table 2: Our evaluation results for subtask A on the development and test sets for Spanish and English. F1 (avg) is the average on positive and negative classes.

than *LSTM-ELMo*. This last model achieved similar results to SVM_0. This difference between the models was not seen in English.

For the Spanish subtask B (ES-B), the same SVM_0 system was used, achieving an average F1 of 0.758 and an EMR score of 0.657 over the test set (fourth place in terms of EMR).

5 Conclusion and future work

As in our previous experience with sentiment analysis, we found that linear models can be a match for neural models. Moreover, this time our SVM ranked in the first place in one of the subtasks.

We believe that –for this kind of challenges with small-sized datasets– preprocessing techniques, data normalization and robustness play a stronger role than model design and hyperparameter tuning. On the other hand, deep neural models are highly expressive and prone to overfitting, requiring being extremely careful with regularization.

Abstract

This paper describes our system (Fermi) for Task 5 of SemEval-2019: HatEval: Multilingual Detection of Hate Speech Against Immigrants and Women on Twitter. We participated in the subtask A for English and ranked first in the evaluation on the test set. We evaluate the quality of multiple sentence embeddings and explore multiple training models to evaluate the performance of simple yet effective embedding-ML combination algorithms. Our team - **Fermi**'s model achieved an accuracy of 65.00% for English language in task A. Our models, which use pretrained Universal Encoder sentence embeddings for transforming the input and SVM (with RBF kernel) for classification, scored first position (among 68) in the leaderboard on the test set for Subtask A in English language. In this paper we provide a detailed description of the approach, as well as the results obtained in the task.

1 Introduction

Microblogging platforms like Twitter provide channels to exchange ideas using short messages called tweets. While such a platform can be used for constructive ideas, a small group of people can propagate their notions including hatred against an individual, or a group or a race to the entire world in a few seconds. This necessitates the need to come up with computational methods to identify hate speech in user generated content.

Using computational methods to identify offense, aggression and hate speech in user generated content has been gaining attention in the recent years as evidenced in (Waseem et al., 2017; Davidson et al., 2017; Malmasi and Zampieri, 2017; Kumar et al., 2018) and workshops such as Abusive Language Workshop (ALW) [1] and Workshop on Trolling, Aggression and Cyberbullying (TRAC) [2].

2 Related Work

In this section we briefly describe other work in this area.

A few of the early works related to hate speech detection employed the use of features like bag of words, word and character n-grams with relatively off-the-shelf machine learning classifiers for detection (Dinakar et al., 2011; Waseem and Hovy, 2016; Nobata et al., 2016). Deep learning methods for hate speech detection were used by Badjatiya et al. (2017) wherein the authors experimented with a combination of multiple deep learning architectures along with randomly initialized word embeddings learned by Long Short Term Memory (LSTM) models.

Papers published in the last two years include the surveys by (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018), the paper by (Davidson et al., 2017) which presented the Hate Speech Detection dataset used in (Malmasi and Zampieri, 2017) and a few other recent papers such as (ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018).

A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017). For studies on languages other than English see (Su et al., 2017) on Chinese and (Fišer et al., 2017) on Slovene. Finally, for recent discussion on identifying profanity versus hate speech see (Malmasi and Zampieri, 2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language.

Some of the similar and related previous workshops are Text Analytics for Cybersecurity and

[1]https://sites.google.com/view/alw2018

[2]https://sites.google.com/view/trac1

Online Safety (TA-COS) [3], Abusive Language Workshop [4], and TRAC [5]. Related shared tasks include GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018).

3 Methodology

In this paper, we make use of several word embedding and sentence embedding methods.

3.1 Word Embeddings

Word embeddings have been widely used in modern Natural Language Processing applications as they provide vector representation of words. They capture the semantic properties of words and the linguistic relationship between them. These word embeddings have improved the performance of many downstream tasks across many domains like text classification, machine comprehension etc. (Camacho-Collados and Pilehvar, 2018). Multiple ways of generating word embeddings exist, such as Neural Probabilistic Language Model (Bengio et al., 2003), Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and more recently ELMo (Peters et al., 2018).

These word embeddings rely on the distributional linguistic hypothesis. They differ in the way they capture the meaning of the words or the way they are trained. Each word embedding captures a different set of semantic attributes which may or may not be captured by other word embeddings. In general, it is difficult to predict the relative performance of these word embeddings on downstream tasks. The choice of which word embeddings should be used for a given downstream task depends on experimentation and evaluation.

3.2 Sentence Embeddings

While word embeddings can produce representations for words which can capture the linguistic properties and the semantics of the words, the idea of representing sentences as vectors is an important and open research problem (Conneau et al., 2017).

Finding a universal representation of a sentence which works with a variety of downstream tasks is the major goal of many sentence embedding techniques. A common approach of obtaining a sentence representation using word embeddings is by the simple and naïve way of using the simple arithmetic mean of all the embeddings of the words present in the sentence. Smooth inverse frequency, which uses weighted averages and modifies it using Singular Value Decomposition (SVD), has been a strong contender as a baseline over traditional averaging technique (Arora et al., 2016). Other sentence embedding techniques include p-means (Rücklé et al., 2018), InferSent (Conneau et al., 2017), SkipThought (Kiros et al., 2015), Universal Encoder (Cer et al., 2018).
Task A (Hate speech detection) is a two-class classification where systems have to predict whether a tweet in English or in Spanish with a given target (women or immigrants) is hateful or not hateful. TASK B (Aggressive behavior and Target Classification) is a two-class classification where systems have to classify hateful tweets (e.g., tweets where Hate Speech against women or immigrants has been identified) as aggressive or not aggressive, and second to identify the target harassed as individual or generic (i.e. single human or group).

We formulate sub-task A of HatEval as a text classification tasks. In this paper, we evaluate various pre-trained sentence embeddings for identifying the offense, hate and aggression. We train multiple models using different machine learning algorithms to evaluate the efficacy of each of the pre-trained sentence embeddings for the downstream task. We observe that there is a class label imbalance in the dataset. To prevent any bias induced due to imbalanced classes, we process the transformed training dataset using SMOTE (Chawla et al., 2002) which synthetically oversamples data and ensures that all the classes have same number of instances.

In the following, we discuss various popular sentence embedding methods in brief.

- InferSent (Conneau et al., 2017) is a set of embeddings proposed by Facebook. InferSent embeddings have been trained using the popular language inference corpus. Given two sentences the model is trained to infer whether they are a contradiction, a neutral pairing, or an entailment. The output is an embedding of 4096 dimensions.

- Concatenated Power Mean Word Embedding (Rücklé et al., 2018) generalizes the concept of average word embeddings to power mean word embeddings. The concatenation of different types of power mean word embeddings

NNLM	66.57	66.46	64.36	62.83	65.56	63.88	66.37	65.74

Table 1: *Dev* Set Accuracy and Macro-F1 scores(in percentage) for **Sub-Task A- English.**

considerably closes the gap to state-of-the-art methods mono-lingually and substantially outperforms many complex techniques cross-lingually.

- Lexical Vectors (Salle and Villavicencio, 2018) is another word embedding similar to fastText with slightly modified objective. FastText (Bojanowski et al., 2016) is another word embedding model which incorporates character n-grams into the skipgram model of Word2Vec and considers the sub-word information.

- The Universal Sentence Encoder (Cer et al., 2018) encodes text into high dimensional vectors. The model is trained and optimized for greater-than-word length text, such as sentences, phrases or short paragraphs. It is trained on a variety of data sources and a variety of tasks with the aim of dynamically accommodating a wide variety of natural language understanding tasks. The input is variable length English text and the output is a 512 dimensional vector.

- Deep Contextualized Word Representations (ELMo) (Peters et al., 2018) use language models to get the embeddings for individual words. The entire sentence or paragraph is taken into consideration while calculating these embedding representations. ELMo uses a pre-trained bi-directional LSTM language model. For the input supplied, the ELMo architecture extracts the hidden state of each layer. A weighted sum is computed of the hidden states to obtain an embedding for each sentence.

Using each of the sentence embeddings we have mentioned above, we seek to evaluate how each of them performs when the vector representations are supplied for classification with various off-the-shelf machine learning algorithms. For each of the evaluation tasks, we perform experiments using each of the sentence embeddings mentioned above and show our classification performance on the *dev* set given by the task organizers.

Using each of the sentence embeddings we have mentioned above, we seek to evaluate how each of them performs when the vector representations are supplied for classification with various off-the-shelf machine learning algorithms. For each of the evaluation tasks, we perform experiments using each of the sentence embeddings mentioned above and show our classification performance on the *dev* set given by the task organizers.

4 Dataset

The data collection methods used to compile the dataset used in HatEval is described in (Basile et al., 2019). We did not use any external datasets to augment the data for training our models.

5 Results and Analysis

The official *test* set results scored on CodaLab have been presented below in Table 2.

System	F1 (macro)	Accuracy
Universal Encoder	0.65	0.65

Table 2: Results for Sub-task A using Universal Encoder Sentence embeddings with SVM classifier using RBF kernel.

Our results on the different algorithms from the ones stated above have been mentioned henceforth and described in Table 1.

As described in Table 1 the dev set macro-averaged F-1 and accuracy is given for the task A-English.

We notice the best performance for task A in English on the official test set was bagged by the model which used pretrained Universal sentence embeddings using SVM with RBF kernel. However, pretrained Infersent embeddings along with XGBoost algorithm outperformed every other combination on the dev test. This can be probably due to the difference between the distributions in the dev and the official test sets.

Overall, this work shows how different set of pretrained embeddings trained from different state-of-the-art architectures and methods when used with simple machine learning classifiers perform very well in the classification task of categorizing text as offensive or not.

6 Conclusions and Future Work

It is also important to note that the experiments are performed using the default parameters, so there is much scope for improvement with a lot of fine-tuning, which we plan on considering for future research purposes. Further, we can explore augmenting data from other similar shared tasks to achieve better performance.

Abstract

We present the results and the main findings of SemEval-2019 Task 6 on Identifying and Categorizing Offensive Language in Social Media (OffensEval). The task was based on a new dataset, the Offensive Language Identification Dataset (OLID), which contains over 14,000 English tweets. It featured three sub-tasks. In sub-task A, the goal was to discriminate between offensive and non-offensive posts. In sub-task B, the focus was on the type of offensive content in the post. Finally, in sub-task C, systems had to detect the target of the offensive posts. OffensEval attracted a large number of participants and it was one of the most popular tasks in SemEval-2019. In total, about 800 teams signed up to participate in the task, and 115 of them submitted results, which we present and analyze in this report.

1 Introduction

Recent years have seen the proliferation of offensive language in social media platforms such as Facebook and Twitter. As manual filtering is very time consuming, and as it can cause post-traumatic stress disorder-like symptoms to human annotators, there have been many research efforts aiming at automating the process. The task is usually modeled as a supervised classification problem, where systems are trained on posts annotated with respect to the presence of some form of abusive or offensive content. Examples of offensive content studied in previous work include hate speech (Davidson et al., 2017; Malmasi and Zampieri, 2017, 2018), cyberbulling (Dinakar et al., 2011), and aggression (Kumar et al., 2018). Moreover, given the multitude of terms and definitions used in the literature, some recent studies have investigated the common aspects of different abusive language detection sub-tasks (Waseem et al., 2017; Wiegand et al., 2018).

Interestingly, none of this previous work has studied both the type *and* the target of the offensive language, which is our approach here. Our task, OffensEval[1], uses the Offensive Language Identification Dataset (OLID)[2] (Zampieri et al., 2019), which we created specifically for this task. OLID is annotated following a hierarchical three-level annotation schema that takes both the target and the type of offensive content into account. Thus, it can relate to phenomena captured by previous datasets such as the one by Davidson et al. (2017). Hate speech, for example, is commonly understood as an insult targeted at a *group*, whereas cyberbulling is typically targeted at an *individual*.

We defined three sub-tasks, corresponding to the three levels in our annotation schema:[3]

Sub-task A: Offensive language identification (104 participating teams)

Sub-task B: Automatic categorization of offense types (71 participating teams)

Sub-task C: Offense target identification (66 participating teams)

The remainder of this paper is organized as follows: Section 2 discusses prior work, including shared tasks related to OffensEval. Section 3 presents the shared task description and the subtasks included in OffensEval. Section 4 includes a brief description of OLID based on (Zampieri et al., 2019). Section 5 discusses the participating systems and their results in the shared task. Finally, Section 6 concludes and suggests directions for future work.

[1]http://competitions.codalab.org/competitions/20011
[2]http://scholar.harvard.edu/malmasi/olid
[3]A total of 800 teams signed up to participate in the task, but only 115 teams ended up submitting results eventually.

2 Related Work

Different abusive and offense language identification problems have been explored in the literature ranging from aggression to cyber bullying, hate speech, toxic comments, and offensive language. Below we discuss each of them briefly.

Aggression identification: The TRAC shared task on Aggression Identification (Kumar et al., 2018) provided participants with a dataset containing 15,000 annotated Facebook posts and comments in English and Hindi for training and validation. For testing, two different sets, one from Facebook and one from Twitter, were used. The goal was to discriminate between three classes: non-aggressive, covertly aggressive, and overtly aggressive. The best-performing systems in this competition used deep learning approaches based on convolutional neural networks (CNN), recurrent neural networks, and LSTM (Aroyehun and Gelbukh, 2018; Majumder et al., 2018).

Bullying detection: There have been several studies on cyber bullying detection. For example, Xu et al. (2012) used sentiment analysis and topic models to identify relevant topics, and Dadvar et al. (2013) used user-related features such as the frequency of profanity in previous messages.

Hate speech identification: This is the most studied abusive language detection task (Kwok and Wang, 2013; Burnap and Williams, 2015; Djuric et al., 2015). More recently, Davidson et al. (2017) presented the hate speech detection dataset with over 24,000 English tweets labeled as non offensive, hate speech, and profanity.

Offensive language: The GermEval[4] (Wiegand et al., 2018) shared task focused on offensive language identification in German tweets. A dataset of over 8,500 annotated tweets was provided for a course-grained binary classification task in which systems were trained to discriminate between offensive and non-offensive tweets. There was also a second task where the offensive class was subdivided into profanity, insult, and abuse. This is similar to our work, but there are three key differences: (*i*) we have a third level in our hierarchy, (*ii*) we use different labels in the second level, and (*iii*) we focus on English.

Toxic comments: The Toxic Comment Classification Challenge[5] was an open competition at Kaggle, which provided participants with comments from Wikipedia organized in six classes: toxic, severe toxic, obscene, threat, insult, identity hate. The dataset was also used outside of the competition (Georgakopoulos et al., 2018), including as additional training material for the aforementioned TRAC shared (Fortuna et al., 2018).

While each of the above tasks tackles a particular type of abuse or offense, there are many commonalities. For example, an insult targeted at an individual is commonly known as cyberbulling and insults targeted at a group are known as hate speech. The hierarchical annotation model proposed in OLID (Zampieri et al., 2019) and used in OffensEval aims to capture this. We hope that the OLID's dataset would become a useful resource for various offensive language identification tasks.

3 Task Description and Evaluation

The training and testing material for OffensEval is the aforementioned Offensive Language Identification Dataset (OLID) dataset, which was built specifically for this task. OLID was annotated using a hierarchical three-level annotation model introduced in Zampieri et al. (2019). Four examples of annotated instances from the dataset are presented in Table 1. We use the annotation of each of the three layers in OLID for a sub-task in OffensEval as described below.

3.1 Sub-task A: Offensive language identification

In this sub-task, the goal is to discriminate between offensive and non-offensive posts. Offensive posts include insults, threats, and posts containing any form of untargeted profanity. Each instance is assigned one of the following two labels.

- Not Offensive (NOT): Posts that do not contain offense or profanity;
- Offensive (OFF): We label a post as offensive if it contains any form of non-acceptable language (profanity) or a targeted offense, which can be veiled or direct. This category includes insults, threats, and posts containing profane language or swear words.

[4] `http://projects.fzai.h-da.de/iggsa/`

@USER Fuk this fat cock sucker	OFF	TIN	IND
@USER Figures! What is wrong with these idiots? Thank God for @USER	OFF	TIN	GRP

Table 1: Four tweets from the OLID dataset, with their labels for each level of the annotation model.

3.2 Sub-task B: Automatic categorization of offense types

In sub-task B, the goal is to predict the type of offense. Only posts labeled as Offensive (OFF) in sub-task A are included in sub-task B. The two categories in sub-task B are the following:

- Targeted Insult (TIN): Posts containing an insult/threat to an individual, group, or others (see sub-task C below);
- Untargeted (UNT): Posts containing non-targeted profanity and swearing. Posts with general profanity are not targeted, but they contain non-acceptable language.

3.3 Sub-task C: Offense target identification

Sub-task C focuses on the target of offenses. Only posts that are either insults or threats (TIN) arwe considered in this third layer of annotation. The three labels in sub-task C are the following:

- Individual (IND): Posts targeting an individual. It can be a a famous person, a named individual or an unnamed participant in the conversation. Insults/threats targeted at individuals are often defined as cyberbullying.
- Group (GRP): The target of these offensive posts is a group of people considered as a unity due to the same ethnicity, gender or sexual orientation, political affiliation, religious belief, or other common characteristic. Many of the insults and threats targeted at a group correspond to what is commonly understood as hate speech.
- Other (OTH): The target of these offensive posts does not belong to any of the previous two categories, e.g., an organization, a situation, an event, or an issue.

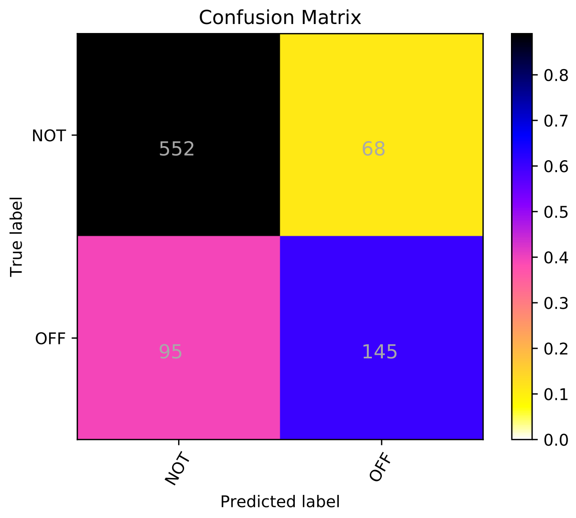

Figure 1: Example of a confusion matrix provided in the results package for team NULI, which is the best-performing team for sub-task A.

3.4 Task Evaluation

Given the strong imbalance between the number of instances in the different classes across the three tasks, we used the macro-averaged F1-score as the official evaluation measure for all three sub-tasks.

At the end of the competition, we provided the participants with packages containing the results for each of their submissions, including tables and confusion matrices, and tables with the ranks listing all teams who competed in each sub-task. For example, the confusion matrix for the best team in sub-task A is shown in Figure 1.

3.5 Participation

The task attracted nearly 800 teams and 115 of them submitted their results. The teams that submitted papers for the SemEval-2019 proceedings are listed in Table 2.[6]

4 Data

Below, we briefly describe OLID, the dataset used for our SemEval-2019 task 6. A detailed description of the data collection process and annotation is presented in Zampieri et al. (2019).

OLID is a large collection of English tweets annotated using a hierarchical three-layer annotation model. It contains 14,100 annotated tweets divided into a training partition of 13,240 tweets and a testing partition of 860 tweets. Additionally, a small trial dataset of 320 tweets was made available before the start of the competition.

A	B	C	Train	Test	Total
OFF	TIN	IND	2,407	100	2,507
OFF	TIN	OTH	395	35	430
OFF	TIN	GRP	1,074	78	1,152
OFF	UNT	—	524	27	551
NOT	—	—	8,840	620	9,460
All			13,240	860	14,100

Table 3: Distribution of label combinations in OLID.

The distribution of the labels in OLID is shown in Table 3. We annotated the dataset using the crowdsourcing platform Figure Eight.[7] We ensured the quality of the annotation by only hiring experienced annotators on the platform and by using test questions to discard annotators who did not achieve a certain threshold. All the tweets were annotated by two people. In case of disagreement, a third annotation was requested, and ultimately we used a majority vote. Examples of tweets from the dataset with their annotation labels are shown in Table 1.

5 Results

The models used in the task submissions ranged from traditional machine learning, e.g., SVM and logistic regression, to deep learning, e.g., CNN, RNN, BiLSTM, including attention mechanism, to state-of-the-art deep learning models such as ELMo (Peters et al., 2018) and BERT (Devlin et al.). Figure 2 shows a pie chart indicating the breakdown by model type for all participating systems in sub-task A. Deep learning was clearly the most popular approach, as were also ensemble models. Similar trends were observed for sub-tasks B and C.

[7]https://www.figure-eight.com/

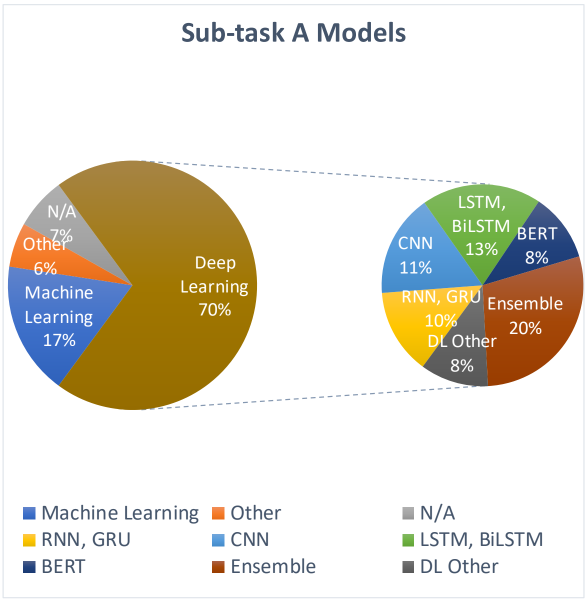

Figure 2: Pie chart showing the models used in sub-task A. 'N/A' indicates that the system did not have a description.

Some teams used additional training data, exploring external datasets such as Hate Speech Tweets (Davidson et al., 2017), toxicity labels (Thain et al., 2017), and TRAC (Kumar et al., 2018). Moreover, seven teams indicated that they used sentiment lexicons or a sentiment analysis model for prediction, and two teams reported the use of offensive word lists. Furthermore, several teams used pre-trained word embeddings from FastText (Bojanowski et al., 2016), from GloVe, including Twitter embeddings from GloVe (Pennington et al., 2014) and from word2vec (Mikolov et al., 2013; Godin et al., 2015).

In addition, several teams used techniques for pre-processing the tweets such as normalizing the tokens, hashtags, URLs, retweets (RT), dates, elongated words (e.g., "Hiiiii" to "Hi", partially hidden words ("c00l" to "cool"). Other techniques include converting emojis to text, removing uncommon words, and using Twitter-specific tokenizers, such as the Ark Tokenizer[8] (Gimpel et al., 2011) and the NLTK TweetTokenizer,[9] as well as standard tokenizers (Stanford Core NLP (Manning et al., 2014), and the one from Keras.[10] Approximately a third of the teams indicated that they used one or more of these techniques.

The results for each of the sub-tasks are shown in Table 4. Due to the large number of submissions, we only show the F1-score for the top-10 teams, followed by result ranges for the rest of the teams. We further include the models and the baselines from (Zampieri et al., 2019): CNN, BiLSTM, and SVM. The baselines are choosing all predictions to be of the same class, e.g., all offensive, and all not offensive for sub-task A. Table 5 shows all the teams that participated in the tasks along with their ranks in each task. These two tables can be used together to find the score/range for a particular team.

Below, we describe the overall results for each sub-task, and we describe the top-3 systems.

5.1 Sub-task A

Sub-task A was the most popular sub-task with 104 participating teams. Among the top-10 teams, seven used BERT (Devlin et al.) with variations in the parameters and in the pre-processing steps. The top-performing team, *NULI*, used BERT-base-uncased with default-parameters, but with a max sentence length of 64 and trained for 2 epochs. The 82.9% F1 score of NULI is 1.4 points better than the next system, but the difference between the next 5 systems, ranked 2-6, is less than one point: 81.5%-80.6%. The top non-BERT model, *MIDAS*, is ranked sixth. They used an ensemble of CNN and BLSTM+BGRU, together with Twitter word2vec embeddings (Godin et al., 2015) and token/hashtag normalization.

5.2 Sub-task B

A total of 76 teams participated in sub-task B, and 71 of them had also participated in sub-task A. In contrast to sub-task A, where BERT clearly dominated, here five of the top-10 teams used an ensemble model. Interestingly, the best team, *jhan014*, which was ranked 76th in sub-task A, used a rule-based approach with a keyword filter based on a Twitter language behavior list, which included strings such as hashtags, signs, etc., achieving an F1-score of 75.5%. The second and the third teams, *Amobee* and *HHU*, used ensembles of deep learning (including BERT) and non-neural machine learning models. The best team from sub-task A also performed well here, ranked 4th (71.6%), thus indicating that overall BERT works well for sub-task B as well.

Sub-task A		Sub-task B		Sub-task C

104	0.171				

Table 4: F1-Macro for the top-10 teams followed by the rest of the teams grouped in ranges for all three sub-tasks. Refer to Table 5 to see the team names associated with each rank. We also include the models (**CNN, BiLSTM, and SVM**) and the baselines (**All NOT and All OFF**) from (Zampieri et al., 2019), shown in bold.

5.3 Sub-task C

A total of 66 teams participated in sub-task C, and most of them also participated in sub-tasks A and B. As in sub-task B, ensembles were quite successful and were used by five of the top-10 teams. However, as in sub-task A, the best team, *vradivchev_anikolov*, used BERT after trying many other deep learning methods. They also used pre-processing and pre-trained word embeddings based on GloVe. The second best team, *NLPR@SRPOL*, used an ensemble of deep learning models such as OpenAI Finetune, LSTM, Transformer, and non-neural machine learning models such as SVM and Random Forest.

5.4 Description of the Top Teams

The top-3 teams by average rank for all three sub-tasks were *NLPR@SRPOL*, *NULI*, and *vradivchev_anikolov*. Below, we provide a brief description of their approaches:

NLPR@SRPOL was ranked 8th, 9th, and 2nd on sub-tasks A, B, and C, respectively. They used ensembles of OpenAI GPT, Random Forest, the Transformer, Universal encoder, ELMo, and combined embeddings from fastText and custom ones. They trained their models on multiple publicly available offensive datasets, as well as on their own custom dataset annotated by linguists.

Table 5: All the teams that participated in SemEval-2019 Task 6 with their ranks for each sub-task. The symbol '-' indicates that the team did not participate in some of the subtasks. Please, refer to Table 4 to see the scores based on a team's rank. The top team for each task is in **bold**, and the second-place team is <u>underlined</u>. Note: *ASE - CSE* stands for *Amrita School of Engineering - CSE*, and *BNU-HBKU* stands for *BNU-HKBU UIC NLP Team 2*.

NULI was ranked 1st, 4th, and 18th on sub-tasks A, B, and C, respectively. They experimented with different models including linear models, LSTM, and pre-trained BERT with fine-tuning on the OLID dataset. Their final submissions for all three subtasks only used BERT, which performed best during development. They also used a number of pre-processing techniques such as hashtag segmentation and emoji substitution.

vradivchev_anikolov was ranked 2nd, 16th, and 1st on sub-tasks A, B, and C, respectively. They trained a variety of models and combined them in ensembles, but their best submissions for sub-tasks A and C used BERT only, as the other models overfitted. For sub-task B, BERT did not perform as well, and they used soft voting classifiers. In all cases, they used pre-trained GloVe vectors and they also applied techniques to address the class imbalance in the training data.

6 Conclusion

We have described SemEval-2019 Task 6 on Identifying and Categorizing Offensive Language in Social Media (OffensEval). The task used OLID (Zampieri et al., 2019), a dataset of English tweets annotated for offensive language use, following a three-level hierarchical schema that considers (*i*) whether a message is offensive or not (for sub-task A), (*ii*) what is the type of the offensive message (for sub-task B), and (*iii*) who is the target of the offensive message (for sub-task C).

Overall, about 800 teams signed up for OffensEval, and 115 of them actually participated in at least one sub-task. The evaluation results have shown that the best systems used ensembles and state-of-the-art deep learning models such as BERT. Overall, both deep learning and traditional machine learning classifiers were widely used. More details about the indvididual systems can be found in their respective system description papers, which are published in the SemEval-2019 proceedings. A list with references to these publications can be found in Table 2; note, however, that only 50 of the 115 participating teams submitted a system description paper.

As is traditional for SemEval, we have made OLID publicly available to the research community beyond the SemEval competition, hoping to facilitate future research on this important topic. In fact, the OLID dataset and the SemEval-2019 Task 6 competition setup have already been used in teaching curricula in universities in UK and USA. For example, student competitions based on OffensEval using OLID have been organized as part of Natural Language Processing and Text Analytics courses in two universities in UK: Imperial College London and the University of Leeds. System papers describing some of the students' work are publicly accessible[11] and have also been made available on arXiv.org (Cambray and Podsadowski, 2019; Frisiani et al., 2019; Ong, 2019; Sapora et al., 2019; Puiu and Brabete, 2019; Uglow et al., 2019). Similarly, a number of students in Linguistics and Computer Science at the University of Arizona in USA have been using OLID in their coursework.

In future work, we plan to increase the size of the OLID dataset, while addressing issues such as class imbalance and the small size for the test partition, particularly for sub-tasks B and C. We would also like to expand the dataset and the task to other languages.

Acknowledgments

We would like to thank the SemEval-2019 organizers for hosting the OffensEval task and for replying promptly to all our inquires. We further thank the SemEval-2019 anonymous reviewers for the helpful suggestions and for the constructive feedback, which have helped us improve the text of this report.

We especially thank the SemEval-2019 Task 6 participants for their interest in the shared task, for their participation, and for their timely feedback, which have helped us make the shared task a success.

Finally, we would like to thank Lucia Specia from Imperial College London and Eric Atwell from the University of Leeds for hosting the OffensEval competition in their courses. We further thank the students who participated in these student competitions and especially those who wrote papers describing their systems.

The research presented in this paper was partially supported by an ERAS fellowship, which was awarded to Marcos Zampieri by the University of Wolverhampton, UK.

Abstract

Transfer learning and domain adaptive learning have been applied to various fields including computer vision (e.g., image recognition) and natural language processing (e.g., text classification). One of the benefits of transfer learning is to learn effectively and efficiently from limited labeled data with a pre-trained model. In the shared task of identifying and categorizing offensive language in social media, we preprocess the dataset according to the language behaviors on social media, and then adapt and fine-tune the Bidirectional Encoder Representation from Transformer (BERT) pre-trained by Google AI Language team[1]. Our team NULI wins **the first place (1st)** in Sub-task A - Offensive Language Identification and is ranked 4th and 18th in Sub-task B - Automatic Categorization of Offense Types and Sub-task C - Offense Target Identification respectively.

1 Introduction

Anti-social online behaviors, including cyberbullying, trolling and offensive language (Xu et al., 2012; Kwok and Wang, 2013; Cheng et al., 2017), are attracting more attention on different social networks. The intervention of such behaviors should be taken at the earliest opportunity. Automatic offensive language detection using machine learning algorithms becomes one solution to identifying such hostility and has shown promising performance.

In SemEval-2019 Task 6: Identifying and Categorizing Offensive Language in Social Media (Zampieri et al., 2019b), the organizers collected tweets through Twitter API and annotated them hierarchically regarding offensive language, offense type, and offense target. The task is divided into three sub-tasks: a) detecting if a post is offensive (OFF) or not (NOT); b) identifying the offense type of an offensive post as targeted insult (TIN), targeted threat (TTH), or untargeted (UNT); c) for a post labeled as TIN/TTH in sub-task B, identifying the target of offense as individual (IND), group of people (GRP), organization or entity (ORG), or other (OTH). The three sub-tasks are independently evaluated by macro-F1 metric.

[1]https://github.com/google-research/bert

The challenges of this shared task include: a) comparatively small dataset makes it hard to train complex models; b) the characteristics of language on social media pose difficulties such as out-of-vocabulary words and ungrammatical sentences; c) the distribution of target classes is imbalanced and inconsistent between training and test data. To address the problem of out-of-vocabulary words especially emoji and hashtags, we preprocess each tweet by interpreting emoji as meaningful English phrases and segmenting hashtags into space separated words. The classifiers we experiment with include: linear model with features of word unigrams, word2vec, and Hatebase; word-based Long Short-Term Memory (LSTM); fine-tuned Bidirectional Encoder Representation from Transformer (BERT) (Devlin et al., 2018). We choose BERT for our official submission, since it performs the best in our experiments.

In the rest of this paper, we organize the content as follows: related work of hostility on social media is stated in section 2; section 3 introduces data description, details of preprocessing, and the methodology of our models; experimental results are discussed in section 4. We also present the conclusion of our work at the end of paper.

2 Related Work

Schmidt and Wiegand (2017) surveyed features widely used for hate speech detection, including simple surface feature, word generalization, knowledge-based features, etc. Davidson et al. (2017) reported hate speech detection results using word n-grams and sentiment lexicon and provided insights on misclassified examples. A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017). (Liu et al., 2018) also discuss that the forecasting of the future hostility on Instagram can be divided into two levels: presence and intensity. In addition to English, researchers also investigated offensive language detection for Chinese (Su et al., 2017) and Slovene (Fišer et al., 2017). In the shared task on aggression identification organised as part of the first workshop on trolling, aggression and cyberbullying (TRAC - 1) at COLING 2018, word/character n-grams and word embeddings were the most commonly used features among the participants, and the most popular classifiers were SVM, LSTM, and RNN. The best performing system employed bidirectional LSTM on Glove embeddings.

3 Data and Methodology

3.1 Data Description

Offensive Language Identification Dataset (OLID) (Zampieri et al., 2019a) is collected from Twitter API by searching certain keywords set. The keywords include some unbiased targeted phrase such as 'she is', 'he is' and 'you are' which have high proportional offensive tweets. The distribution of offensive tweets is controlled around 30% by using different sampling methods. Another observation reported in the paper is political tweets tend to be more likely offensive using keywords as 'MEGA', 'liberal' and 'conservative'.

The main task of this competition is decomposed into three different levels according to the hierarchical annotation: a) Offensive Language Detection b) Categorization of Offensive Language c) Offensive Language Target Identification. All the three different tasks share the same dataset, and the latter one is the subset of the previous one.

The tasks release the dataset into three different parts, which are the startingKit, training dataset and testing dataset. The summary of dataset distribution is concluded in the Table1. From the table, it is easy to observe that the distribution of three splittings is a little twisted which should be expected in real life, and also make the tasks much harder.

Class	StartKit	Training	Testing
NOT	243	8840	620
OFF	77	4400	280
TIN	38	3876	213
UNT	39	524	27
IND	30	2407	100
GRP	7	1074	78
OTH	2	395	35

Table 1: Data Distribution: The first two rows are the class distribution of sub-task A. The mid part two rows are the class distribution of sub-task B. The last three rows are the class distribution of sub-task C.

3.2 Preprocessing

Emoji substitution We use one online emoji project on github [2] which could map the emoji unicode to substituted phrase. We treat such phrases into regular English phrase thus it could maintain their semantic meanings, especially when the dataset size is limited.

HashTag segmentation The HashTag becomes a popular culture cross multi social networks, including Twitter, Instagram, Facebook etc. In order to detect whether the HashTag contains profanity words, we apply word segmentation using one open source on the github [3]. One typical example would be '#LunaticLeft' is segmented as 'Lunatic Left' which is obviously offensive in this case.

Misc. We also convert all the text into lower case. 'URL' is substituted by 'http', since 'URL' does not have embedding representation in some pre-trained embedding and models. Consecutive '@USER's are limited to three times to reduce the redundancy.

3.3 Methodology

Linear model We firstly select Logistic Regression as our baseline model to determine the lower bound performance that we should compare. First we cross-validate hyper-parameters of different vectorizers to build bag of words representation. Secondly, we adopt the pre-trained word2vec model from google [4], then aggregate the maximum and average value in each dimension.

Table 2: Results on Dev Data.

Thirdly, we use the dictionary Hatebase API[5] to aggregate the hate words in each category. We validate all the features combinations, then report the accuracy and F1 with the highest to determine the model parameters.

LSTM Long Short-Term Memory is introduced in 1991 (Hochreiter and Schmidhuber, 1997) which is an more powerful extension of recurrent neural network. The gates inside of LSTM could prevent gradient vanishing problem, to memorize the long time dependency. LSTM has been used in tons of natural language processing task, such as sentiment classification, neural translation, language generation etc. We would also like to use LSTM as our second powerful baseline model to compare and report the result. The specific setting is the following: the input is mapped from one-hot encoder into a shared embedding layers with dimension 140; the hidden units of LSTM is 64 and follower by a dropout layer with rate 0.5. The maximum sequence length is 140, thus the sentences would be either cut off or padded.

BERT Google research team releases Bidirectional Encoder Representation from Transformer (BERT) (Devlin et al., 2018) and achieve state of the art results on many NLP tasks. BERT uses identical multi-head transformer structure that is introduced in (Vaswani et al., 2017). The model is pre-trained on huge corpus from different sources. Since the dataset size in this SemEval-2019 Task 6 is not that big, we pass the dataset into the pre-trained BERT model, and report the loss and accuracy at each epoch. The observation from experiments shows that after 1st or 2nd epochs, the model converges fast and always get very lower loss on the validation set. In such case, in the sub-task B and sub-task C, we report the macro-F1 score after the model trains after 1st, 2nd and 3rd epoch.

[5]http://www.hatebase.org

4 Experiment Results

The evaluation metric of this task is Macro-F1, which is the unweighted-average F1 of all the classes. The imbalance distribution makes the macro-F1 hard to achieve, and usually the score is penalized by the minority class. Weighted-loss is one solution during the training time to balance the model not to lead to the majority class prediction.

In the table 2 and 3, we report the results of our dev-dataset and final test dataset. From the table 2, we list the performance of our three selected models for each sub-task. The data is stratified split into 9:1 as train and test. There is also one independent validation set to determine the model selection that is split from train set. One observation from the table shows the problem of imbalanced data, so that higher accuracy does not guarantee higher macro-F1 score. Thus the stop criterion is based on average loss of validation set we mentioned before. Based on the results of validation, we choose to use BERT as our selected model for the final submission.

In the table 3, it shows the results on official test dataset. It should be noticed that in the sub-task A, we also submit one result of a Bagging classifier with number 50, and Logistic Regression is the weak classifier. The features are the same with linear model we mentioned before. The result from BERT model sub-task A achieves the 1st place among all the participants. BERT-3 denotes we train BERT with only 3 epochs. Same notation with the latter two sub-tables. In the sub-task B and sub-task C, the results are not as good as sub-task A due to two reasons: 1) the class distribution is more skewed than that of sub-task A. 2) the number of training instance is much smaller than sub-task A. The worst performance is sub-task C,

(a) Sub-task A

BERT-2	**0.5598**	0.6948

Table 3: Results on Test Data.

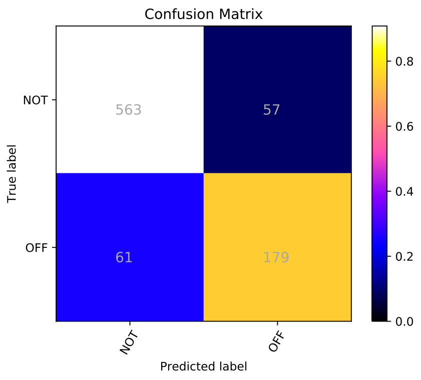

Figure 1: Sub-task A, BERT model after fine-tuning

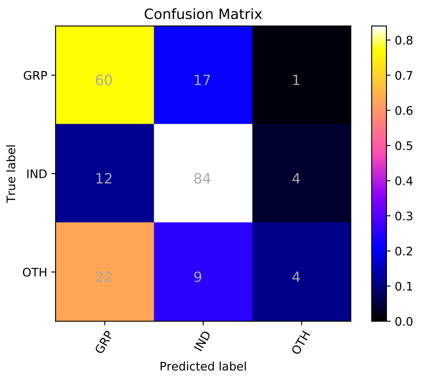

Figure 3: Sub-task C, BERT model after fine-tuning

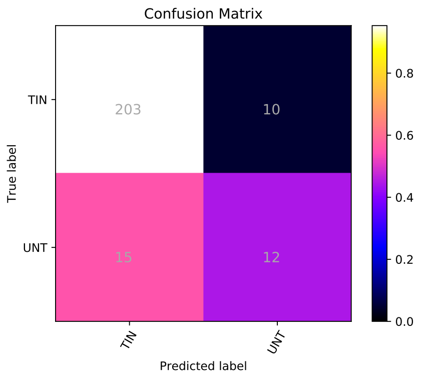

Figure 2: Sub-task B, BERT model after fine-tuning

since it is three-class classification, and the 'OTH' class has very few examples.

The confusion matrix of three sub-tasks are shown in fig 1, 2, and 3. This is another way to explain the results as we discussed before. The figures are provided by the organizers, and we use the figures to summarize test distribution in the table 1. In the previous section, we mentioned the discrepancy of class distribution between training and test datasets. For example, in sub-task C, the class 'OTH' constitutes 0.101 of the training data, while it makes up 0.164 of the test data. This adds difficulty to the task, however, we are often confronted with the same situation in real-world problems.

5 Conclusion

Offensive language and online hostility is crucial on the social network. The minority proportion of the nature and morphological language are the difficulties to achieve high performance. The Diversity and evolution of the language at different ages is another challenge for social media detection task. As a conclusion, our work shows the competitive results in this shared task using customized processing to dataset, as well as the power of pre-trained model. In real life, labeled data is always limited and requires expensive human labors. In such case, transfer learning is always a good option to get started. Domain adaption also has prior knowledge of specific domain before doing any modeling work on hand. How to tune the parameters is nontrivial, and there are a lot of more efficient ways to be explored, which could yield better performance.

Abstract

This paper describes the systems of the CUNY-PKU team in "SemEval 2019 Task 1: Cross-lingual Semantic Parsing with UCCA"[1]. We introduce a novel model by applying a cascaded MLP and BiLSTM model. Then, we ensemble multiple system-outputs by reparsing. In particular, we introduce a new decoding algorithm for building the UCCA representation. Our system won the first place in one track (French-20K-Open), second places in four tracks (English-Wiki-Open, English-20K-Open, German-20K-Open, and German-20K-Closed), and third place in one track (English-20K-Closed), among all seven tracks.

1 Introduction

We participate in all seven tracks in Cross-lingual Semantic Parsing at SemEval 2019. Our submission systems[2] are based on BiLSTM using TUPA (Hershcovich et al., 2017a, 2018).

Then, we built a second single parser using BiLSTM (Bi-directional LSTM) and Multi-Layer Perceptron (MLP) with TUPA (Hershcovich et al., 2017a, 2018). Most importantly, we introduce a new model Cascaded BiLSTM by first pre-training the BiLSTM and MLP model and then to continue training another MLP model. The cascaded BiLSTM parser significantly enhances the parsing accuracy on all tasks. We also complete a Self-Attentive Constituency Parser (Kitaev and Klein, 2018a,b) as comparison. Finally, we ensemble different parsers with a reparsing strategy (Sagae and Lavie, 2006). In particular, we introduce a novel algorithm based on dynamic programming to perform inference for the UCCA representation. This *decoder* can also be utilized as a core engine for a single parser.

In the post-evaluation stage, our improved systems are ranked first in three tracks (French-20K-Open, English-20K-Open and English-Wiki-Open) and second in the other four tracks. A shared task summary paper (Hershcovich et al., 2019) by competition organizers summaries the results.

We will describe our systems in detail, including three single parsers in Section 2 and a voter in Section 3. We focus on two novel technical contributions: the Cascaded BiLSTM model and the Reparsing strategy. In Section 4 we will present experimental setup and results.

2 Single Parsers

2.1 TUPA Parsers

The TUPA parser (Hershcovich et al., 2017a) builds on discontinuous constituency and dependency graph parsing and makes some improvements especially for the UCCA representation. The English parsing is based on Hershcovich et al. (2017a), while French and German parsing is based on Hershcovich et al. (2018).

It has been shown that the choice of model plays an important role in transition-based parsing (Hershcovich et al., 2017b). For TUPA, we built parsers with different models: MLP, BiLSTM, and also invent a new architecture, viz. Cascaded BiLSTM. The three single parsers are described as the following:

The MLP parser (Hershcovich et al., 2017b) applies a feedforward neural network with dense embedding features to predict optimal transitions given particular parser states. This parser adopts a similar architecture to Chen and Manning (2014).

The BiLSTM parser (Hershcovich et al., 2018) applies a bidirectional LSTM to learn con-

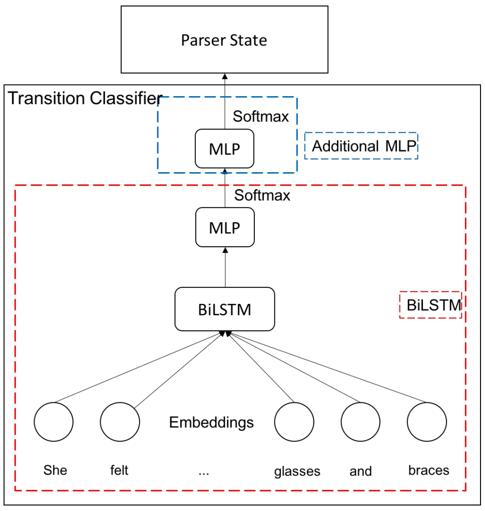

Figure 1: Illustration of the multi-stage Cascaded BiLSTM model. Top: parser state. Bottom: BiLTSM with two MLP architectures. The red box represents BiLSTM (Hershcovich et al., 2018), and the blue box represents a MLP that we add after implementing the BiLSTM architecture. Vector representation for the input tokens is computed by two layers of bidirectional LSTMs then fed into the double MLP with Softmax to select the next transition.

textualized vector-based representations for words that are then utilized for encoding a parser state, similarly to Kiperwasser and Goldberg (2016). The red box in Figure 1 shows the architecture of BiLSTM model, indicating that the representations after BiLSTM are fed into a Multiple-layer perceptron.

The Cascaded BiLSTM parser combines the above two parsing models, which contains a multi-stage training process. First, we use BiLSTM TUPA model to train 100 epochs, then retrain the model using MLP TUPA model for another 50 epochs. It's really interesting that the performances remains as good as BiLSTM TUPA model, even slightly better. Figure 1 shows the architecture of Cascaded BiLSTM model.

2.2 Phrase Constituency Parser

We also built a Constituency Parser as comparison, which uses a self-attentive architecture that makes explicit the manner considering information propagating between different locations in the sentences (Kitaev and Klein, 2018a,b). The constituency parser uses parsing tree structures as input and output. Therefore, we convert the phrase structure tree format into UCCA XML formation and vice versa.

3 The Reparsing System

The reparsing system (voter) takes multiple single parser (as in Section 2) results as input and produces a single, hopefully, improved UCCA graph as output. Briefly, each input UCCA graph is encoded to a chart of scores for standard CKY decoding. In this step, we utilize a number of auxiliary labels to encode remote edges and discontinuous constructions. These scores are summed up to get a new chart, which is used for CKY decoding for an immediate tree representation as the *voting* result. An immediate tree is then enhanced with reference relationships. Finally, a UCCA graph is built via interpreting auxiliary labels.

Span representation Graph nodes in a UCCA graph naturally create a hierarchical structure through the use of *primary edges*. Following this tree structure, we give the definition of span of nodes.

Definition 1. The span of node x is:

1. empty if x is an implicit node;
2. $[p, p+1)$ if x is a leaf node but not an implicit node, where p is the position of the lexical unit corresponding to x;
3. the union of spans of x's children, otherwise.

Assuming that each span of nodes is consecutive (we will deal with nonconsecutive spans in Section 3). We encode the label of edge from x's parent to x as the label of span of x. If there are some implicit nodes in x's children, the labels of edges from x to them are also encoded by the label of the span of x. If the span of x is the same as x's parent, the label of this span will be encoded ordered. This process is well-defined due to the acyclic graph structure. Each parser is assigned a weight to indicate its *contribution* to reparsing. The spans with labels encoded from a UCCA graph are assigned the same score according to which parser they come from. Thus, there is a set of scored spans for each UCCA graph. Following the parsing literature, we call this set a chart. We merge multiple charts produced by different parsers to a single chart simply by adding the corresponding scores.

Handling Remote Edges A remote edge with label L from node x to node y is equal to a primary edge with label L from x to an implicit node, which is referred to node y. Hence, if we can find the relationships of references, the remote edges are able to be recovered.

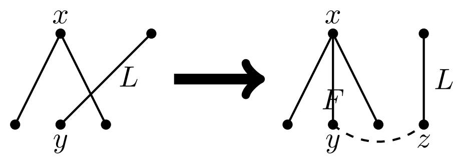

Figure 2: Remove nonconsecutive spans

Since all primary edges from nodes to their parent are encoded in labels of spans, each node could be represented as part of the label of a span. We encode each reference of a remote edge as a pair of two nodes with a score. After building all primary edges through dynamic programming, we search for available references with the maximum score in each implicit node greedily and leverage these references to recover remote edges.

Handling Discontinuous Spans Discontinuous spans are removed by repeating the following steps:

Step 1. Find a node x with a nonconsecutive span with the minimum starting point and minimum height, supposed its consecutive sub-span with minimum starting point is $[a, b)$.

Step 2. Find a node y with a consecutive span with starting point b and maximum height, supposed the primary edge from y's parent to y is e.

Step 3. Create a node z with a special type MIRROR and create a primary edge with the label of e from y's parent to z. Remove the primary edge e and create a primary edge with a special label FAKE from x to y.

After each iteration, the span of y is added to x, and the sum of the length of nonconsecutive spans decreases. Each primary edge in an original UCCA graph can only be removed once. To that end, the running time of this algorithm is linear in the number of lexical units. If all references of MIRROR nodes are correctly predicted, the expected UCCA graph will be obtained. In this way, remote edges can be handled.

4 Experiments

4.1 Data Statistics

The semantic parsing task is carried out in three languages: English, German and French, including three training data sets and parallel four test data sets. For English data, we use the Wikipedia UCCA corpus (henceforth Wiki) as training and development data, testing on English UCCA Wikipedia corpus as the in-domain test. Meanwhile, English UCCA Twenty Thousand Leagues Under the Sea English-French-German parallel corpus (henceforth 20K Leagues) serves as an out-of-domain test set. For German data, we use 20K Leagues corpus for train, development, and test sets. For French data, they provide only limited training data, along with development and test data sets.

Tracks	Training		Dev	Test
	Closed	Open		
En-Wiki	4113	5132	514	515
En-20K	0	5132	0	492
Ge-20K	5211	6360	651	632
Fr-20K	15	547	238	239

Table 1: Sentence number in training, dev, and test sets for English, German and French UCCA data sets.

Table 1 shows the sentences number of data sets for all three languages. We use the closed track data and UCCA's annotation resources for open tracks. We merge those resources and build our open track data[3].

4.2 TUPA Parsers

We build MLP and BiLSTM systems using TUPA (Hershcovich et al., 2017b). For Cascaded BiLSTM model, we add another MLP after the BiLSTM model, which forms a cascaded BiSLTM. For closed tracks, we train models based on the gold-standard UCCA annotation from official resources. For open tracks, We use additional UCCA data from other open sources as training data set. We also generate synthetic data by automatically translating text (Khan et al., 2018) and its parsing labels across languages in our on-going work.

Table 2 shows the results for four models in different tracks. The italicized values are our official submission. However, we have made some improvement after the Evaluation Phrase, and the bold results are our best results. The first three models are single systems and the fourth model (Ensembled) ensembles different frameworks by reparsing systems. The "baseline" represents the baseline that competition provides for reference.

By using feedforward Neural Network and embedding features, MLP models get the lowest scores. BiLSTM models achieve better results than MLP models in F1 scores, both in the in-domain and out-of-domain data sets. However, the

Tracks		MLP	BiLSTM(Submit)	Cascaded BiLSTM	Ensembled	baseline
closed	En-Wiki	0.650	*0.718*	0.721	**0.728**	0.728
	En-20K	0.617	*0.669*	0.673	**0.681**	0.672
	Ge-20K	0.699	*0.797*	**0.797**	0.797	0.731
open	En-Wiki	0.784	*0.800*	0.843	**0.846**	0.735
	En-20K	0.715	*0.739*	0.764	**0.770**	0.684
	Ge-20K	0.598	*0.841*	**0.841**	0.840	0.791
	Fr-20K	0.535	*0.796*	0.795	**0.796**	0.487

Table 2: F1 scores for both closed and open tracks in SemEval Task 1 2019 competition. The italic text represents our official submission in competition and the bold text represents our best F1 scores.

Open Tracks	F1 Scores
English-Wiki	0.75
English-20K	0.785

Table 3: F1 scores on unlabeled data.

Models	test sets	dev sets
CharsLSTM	91.96	92.21
ELMO	94.31	94.75

Table 4: F1 scores for two constituency parsers on both Penn Treebank dev and test data sets.

combination of BiSLTM and MLP models (Cascaded BiLSTM model) performs best among the three models in all results of single systems.

Our in-house reparsing system ensembles the above parsers as described in Section 3. We can see that ensemble results are better at closed track, but not as good as the best results by Cascaded BiLSTM at Open track.

4.3 Phrase Constituency Parser

For Phrase Constituency Parer, we only test the performance on unlabeled data instead of labeled data, while for TUPA we test on labeled data.

First, we use Benepar[4], a parsing tool using out-of domain pre-trained models to predict the labels, the outputs are parsing tree structures.

Second, we convert the constituency parsing tree structure to Conllu Format. We develop a one-shot tool to improve the efficiency of conversion based on TreebankPreprocessing[5], which can automatically convert a batch of files in one directory.

Finally, we convert Conllu format to UCCA XML using format[6].

We only experiment on English-Wiki and English-20K open track, and the results are pretty bad, as shown in Table 3. We hypothesize there are two reasons: 1. The conversion process could unavoidably cause accuracy loss. 2. The third-party pre-trained models are not as efficient as the models trained directly on the specific UCCA data.

To test the accuracy on unlabeled data and to evaluate how many losses are there during the conversion process, we evaluate the accuracy in the parsing tree structure phrase before the conversion. We experimentally validate our system on the English Wiki data set. We use official training data set as training data, splitting official dev set into two parts and separately serving as our dev set and test set. We also use two models of constituency parser: ELMO and CharsLSTM, tested on Penn Treebank (Cross and Huang, 2019) data.

Table 4 indicates that, for Penn Treebank data sets, CharsLSTM model's F1 score achieves 92.21 on dev data set, with F1 score 91.96 on the test dataset. Using ELMo, The dev dataset's F1 score achieves 94.75, with F1 score achieves 94.31 on test data set.

5 Summary

Our submission systems mainly contain a BiLSTM, an MLP, and a cascaded BiLSTM parser, as well as a voted system of above. Our final system ranks first in three tracks, French-20K-Open, English-20K-Open and English-Wiki-Open, and the second place in the other four tracks in the post-evaluation.

Abstract

This paper describes the graph transformation system (GT System) for SemEval 2019 Task 1: Cross-lingual Semantic Parsing with Universal Conceptual Cognitive Annotation (UCCA)[1]. The input of GT System is a pair of text and its unannotated xml, which is a layer 0 part of UCCA form. The output of GT System is the corresponding full UCCA xml. Based on the idea of graph illustration and transformation, we perform four main tasks when building GT System. At the first task, we illustrate the graph form of stanford dependencies[2] of input text. We then transform into an intermediate graph in the second task. At the third task, we continue to transform into ouput graph form. Finally, we create the output UCCA xml.

The evaluation results show that our method generates good-quality UCCA xml and has a meaningful contribution to the semantic representation sub-field in Natural Language Processing.

1 Introduction

In the past few years, semantic representation is receiving growing attention in NLP. Researchers have recently proposed different semantic schemes. Examples include Abstract Meaning Representation (Banarescu et al. 2013), Broad-coverage Semantic Dependencies (Oepen et al. 2014), Universal Decompositional Semantics (White et al. 2016), Parallel Meaning Bank (Abzianidze et al. 2016), Universal Conceptual Cognitive Annotation (Abend and Rappoport 2013). These advances in semantic representation, along with corresponding advances in semantic parsing, text understanding, summarization, paraphrase detection, and semantic evaluation.

In SemEval 2019 Task 1: Cross-lingual Semantic Parsing with Universal Conceptual Cognitive Annotation (UCCA)[1], the Committee focuses on parsing text according to the UCCA semantic annotation. UCCA (Abend and Rappoport 2013) is a cross-linguistically applicable semantic representation scheme, based on Basic Linguistic Theory (Dixon 2010). In general, UCCA represents the semantics of linguistic utterances as directed acyclic graphs (DAGs). In one DAG, nodes and edges belong to one of several layers. There are two types of node: (i) terminal nodes express the text tokens; (ii) non-terminal nodes express semantic units. Edges are labelled, indicating the role of a child in the relation the parent represents. As an example, consider sentence in Example 1: "*The album was recorded in Switzerland .*". Two layers of UCCA xml of this sentence:

- Layer0:

```
<root annotationID="0" passageID="503012">
    <attributes />
    <layer layerID="0">
      <attributes />
      <extra ... />
      <node ID="0.1" type="Word">
        <attributes ... text="The" />
        <extra dep="det" ... tag="DT" />
      </node>
      ...
    </layer>
</root>
```

The relations of NodeID and corresponding lexicon:

```
{[ID="0.1" ➔ dep="det" ➔ "The"]
[ID="0.2" ➔ dep="nsubj:pass" ➔ "album"]
[ID="0.3" ➔ dep="aux:pass" ➔ "was"]
[ID="0.4" ➔ dep="root" ➔ "recorded"]
[ID="0.5" ➔ dep="case" ➔ "in"]
[ID="0.6" ➔ dep="obl" ➔ "Switzerland"]
[ID="0.7" ➔ dep="punct" ➔ "."]}
```

- Layer1:

```
<layer layerID="1">
      <attributes />
      <node ID="1.1" type="FN">
        <attributes />
```

[1] https://competitions.codalab.org/competitions/19160

```
      <edge toID="1.2" type="H">
        <attributes />
      </edge>
    </node>
    <node ID="1.2" type="FN">
      <attributes />
      <edge toID="1.4" type="A">
        <attributes />
      </edge>
      ...
    </node>
    <node ID="1.4" type="FN">
      <attributes />
      <edge toID="1.10" type="E">
        <attributes />
      </edge>
      ...
    </node>
    <node ID="1.10" type="FN">
      <attributes />
      <edge toID="0.1" type="Terminal">
        <attributes />
      </edge>
    </node>
    ...
  </layer>
```

We have the graphical representation of the above UCCA:

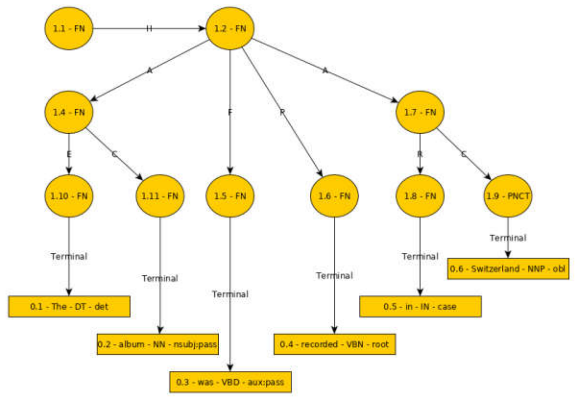

Figure 1: Graph form of UCCA xml of sentence in Example 1.

The primary purpose of this article is to present our system called graph transformation system (GT System) for Task[1]. We perform four tasks when building GT System. At the first task, we illustrate the graph form of Stanford dependencies[2] (Manning et al. 2014; Marie-Catherine et al. 2014) of input text. We then transform into an intermediate graph in the second task. At the third task, we continue to transform into ouput graph form. Finally, we create the output UCCA xml.

The rest of article is separated as follows. We briefly describe Stanford dependencies in Section 2. In Section 3, we introduce our GT system for Task[1]. Section 4 details the experiments and analyzes the results. We offer conclusions in Section 5.

2 Stanford Dependencies

Stanford dependencies[2] (Manning et al. 2014; Marie-Catherine et al. 2014; Marie-Catherine and Manning 2008) provides a representation of grammatical relations between words in a sentence. Stanford dependencies (SD) have three parts: name of the relation, governor and dependent. Consider English sentence in Example 1, below is the xml representation of SD basic dependencies. This representation is the result of running Stanford CoreNLP pipeline (Manning et al. 2014).

```
<dependencies type="basic-dependencies">
     <dep type="root">
       <governor idx="0">ROOT</governor>
       <dependent idx="4">recorded</dependent>
     </dep>
     <dep type="det">
       <governor idx="2">album</governor>
       <dependent idx="1">The</dependent>
     </dep>
     <dep type="nsubjpass">
       <governor idx="4">recorded</governor>
       <dependent idx="2">album</dependent>
     </dep>
     <dep type="auxpass">
       <governor idx="4">recorded</governor>
       <dependent idx="3">was</dependent>
     </dep>
     <dep type="case">
       <governor
idx="6">Switzerland</governor>
       <dependent idx="5">in</dependent>
     </dep>
     <dep type="nmod">
       <governor idx="4">recorded</governor>
       <dependent
idx="6">Switzerland</dependent>
     </dep>
</dependencies>
```

We have the graphical representation of the above SD basic dependencies:

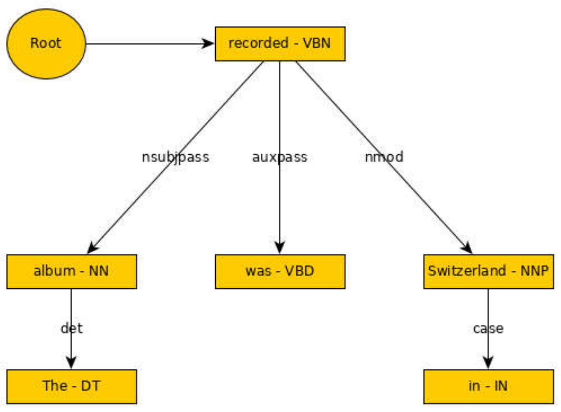

Figure 2: Graph form of SD basic dependencies of sentence in Example 1.

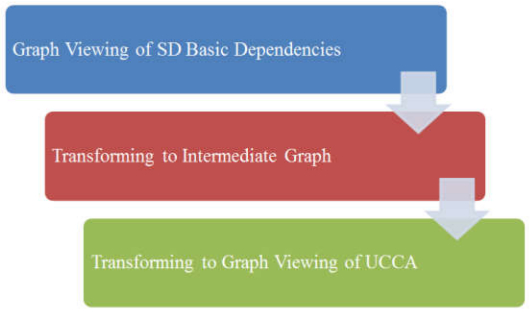
[2] https://stanfordnlp.github.io/CoreNLP/

3 The Graph Transformation System

In this section, we express our GT system for creating UCCA xml of the input text. The general architecture is represented in Figure 2:



Graph Viewing of SD Basic Dependencies
Transforming to Intermediate Graph
Transforming to Graph Viewing of UCCA

Figure 3: Architecture of Graph Transformation System.

When building GT System, we perform two processes: training and testing process. At training process, we build the intermediate graph from UCCA and SD basic dependencies of training data[1]. At the testing process, which can be called the inverse process of training, we build the ouput UCCA from intermediate graph of testing data.

3.1 Intermediate Graph

In general, the intermediate graph is an irreducible representation of UCCA graph form. This intermediate graph is quite similar to graph form of SD basic dependencies. The main difference of the intermediate graph and graph form of SD basic dependencies is: each edge label in the intermediate graph is the combination of UCCA categories (Abend and Rappoport. 2013) and Stanford dependency relations (Marie-Catherine and Manning 2008a, 2008b).

Below is the intermediate graph of sentence in Example 1. This graph is the reduction of graph in Figure 1, and quite similar to graph in Figure 2.

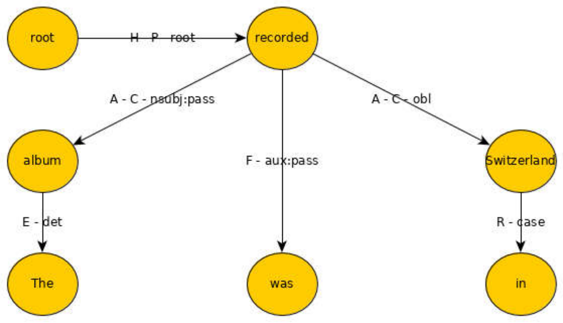


Figure 4: Intermediate graph of sentence in Example 1.

3.2 Training Process

Firstly, at training process, we consider train data[1] and performed main tasks. The first and second task is in turn viewing the graph from of SD basic dependencies and UCCA of input text. At the third task, we propose Left-First-Search liked algorithm with Bottom-Up idea to reduce the graph form of UCCA to intermediate graph. At the final task, we propose rules and heuristics for matching graph form of SD basic dependencies and intermediate graph.

The main steps of Left-First-Search (LFS) algorithm is as follow. ***Step 1***. Browse to terminal on the left. ***Step 2***. Back to parent node of this terminal. Check if parent having any other child or not. Step 2.1. If yes. Repeat Step 1 with root is this child node. ***Step 3***. Swap the position of root of sub-tree with position of child having important annotation. ***Step 4***. Back to parent node of this root. Repeat Step 2 with this parent.

To perform LFS algorithm, we determine the priority of SD and UCCA annotations according to two factors. **First**. The meaning of each annotation, representing the dependency relations and grammatical roles of lexicons. **Second**. The position of each node in graph.

Apply LFS algorithm for graph in Figure 3, we in turn have three level reductions in Figure 5, 6, 4 (respectively):

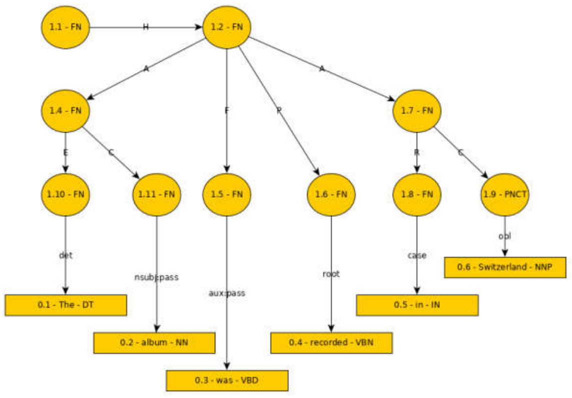

Figure 5: First reduction of Graph form in Figure 1.

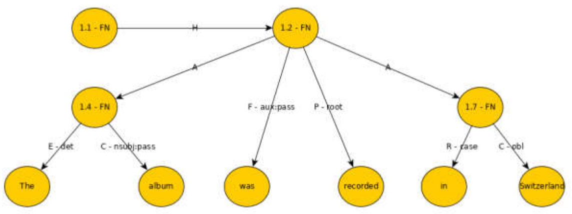

Figure 6: Second reduction of Graph form in Figure 1.

After having the final reduction, which is intermediate graph, of graph form of UCCA, we compare with graph form of SD basic dependencies. We consider the similarities between two graphs and propose rules and heuristics to (i) determine the level of one node, and (ii) determine the group of UCCA annotation for each level. The general idea of mechanism is:

- Collect all SD-type of relations in UCCA and SD basic dependencies of training data. Below is the collection:

SD basic dependencies	acl:relcl / expl / csubjpass / cop / aux / conj / acl / xcomp / dep / appos / advmod / neg / det / cc:preconj / nmod:tmod / ccomp / root / advcl / nsubj / case / iobj / cc / det:predet / nmod:poss / compound:prt / csubj / nsubjpass / nummod / nmod:npmod / nmod / auxpass / parataxis / amod / compound / discourse / mwe / dobj / mark
UCCA	acl:relcl / expl / obl:npmod / cop / aux / conj / acl / appos / xcomp / goeswith / advmod / det / ccomp / nsubj:pass / cc:preconj / nmod:tmod / flat / root / obl:tmod / advcl / punct / nsubj / case / iobj / cc / vocative / det:predet / nmod:poss / compound:prt / csubj / nummod / nmod:npmod / nmod / parataxis / amod / list / compound / discourse / aux:pass / obj / obl / fixed / mark

- Determine the priority order of SD-type relations.

Example 2: dobj -> amod -> dep -> nmod -> case.

- Determine the compound (UCCA and SD) relation in each node level.

Example 3: type conj at level 7: "H - A - E - C - C - C - conj"

3.3 Testing Process

At the testing process, which can be called the inverse process of training, we considered development and test data[1] and performed main tasks. The first task is viewing the graph from of SD basic dependencies of input text. At the second task, we applied proposed rules and heuristics to transform this graph to intermediate graph. We then, at the final task, we proposed Breadth-First-Search liked algorithm with Top-Down idea to re-create the graph form of UCCA from intermediate graph. This BFS algorithm is, in fact, the inverse mechanism of LFS algorithm in Section 3.2.

The main steps of Breadth-First-Search (BFS) algorithm is as follow. ***Step 1***. Reduce the first level of node. ***Step 2***. Determine the intergrated-Child which adheres to this node. ***Step 3***. If there is no intergratedChild. Step 3.1. Repeat Step 1 until node come down to terminal position. Step 3.2. Repeat from Step 1 to Step 4 with each child of this node. ***Step 4***. If there is intergratedChild. Step 4.1. Repeat from Step 1 to Step 4 with each child of this node which are different from intergrated-Child. Step 4.2. Repeat from Step 1 to Step 4 with this node. Step 4.3. Repeat from Step 1 to Step 4 with intergratedChild.

4 Experiment and Evaluation

At the evaluation phase, we focus on English in-domain setting, using the Wiki corpus. In testing data, this domain consists of 515 small texts with corresponding unannotated UCCA xmls.

We test our method for both open and closed track in the English setting: (i) closed track submission is only allowed to use the gold-standard UCCA annotation distributed for the task in the target language, and limited in its use of additional resources; (ii) open track submission is allowed to use any additional resource.

Table 1 and 2 view the results of testing data for open and closed tracks with labeled (first row) and unlabeled scores (second row).

Averaged F1		**P**	**R**	**F1**
0.708	Primary	0.738	0.694	0.715
	Remote	1.000	0.000	0.000
0.822	Primary	0.857	0.806	0.831
	Remote	1.000	0.000	0.000

Table 1: Results of testing data in open track.

Averaged F1		**P**	**R**	**F1**
0.706	Primary	0.737	0.692	0.714
	Remote	1.000	0.000	0.000
0.825	Primary	0.860	0.808	0.833
	Remote	1.000	0.000	0.000

Table 2: Results of testing data in closed track.

The testing results show that our GT system creates good quality UCCA semantic representations in English Wiki testing data.

5 Conclusion

We have presented the graph transformation method for creating UCCA semantic representation from English in-domain setting, using the Wiki corpus[1]. Our method performs four main tasks: (i) illustrate the graph form of Stanford dependencies[2] of input text; (ii) transform into an intermediate graph; (iii) continue to transform into ouput graph form; (iv) create the output UCCA xml. The experiment results show that our method meets the requirements from SemEval Task[1].

In future works, we intend to improve the transformational algorithms and propose more accurate rules for selecting best nodes and dependency tags. Besides, we expand our method and test with other datasets for a broader comparison.

Abstract

This paper describes the system submitted to the SemEval 2019 shared task 1 'Cross-lingual Semantic Parsing with UCCA'. We rely on the semantic dependency parse trees provided in the shared task which are converted from the original UCCA files and model the task as tagging. The aim is to predict the graph structure of the output along with the types of relations among the nodes. Our proposed neural architecture is composed of Graph Convolution and BiLSTM components. The layers of the system share their weights while predicting dependency links and semantic labels. The system is applied to the CONLLU format of the input data and is best suited for semantic dependency parsing.

1 Introduction

Universal Conceptual Cognitive Annotation (UCCA) (Abend and Rappoport, 2013) is a semantically motivated approach to grammatical representation inspired by typological theories of grammar (Dixon, 2012) and Cognitive Linguistics literature (Croft and Cruse, 2004). In parsing, bi-lexical dependencies that are based on binary head-argument relations between lexical units are commonly employed in the representation of syntax (Nivre et al., 2007; Chen and Manning, 2014) and semantics (Hajič et al., 2012; Oepen et al., 2014; Dozat and Manning, 2018).

UCCA differs significantly from traditional dependency approaches in that it attempts to abstract away traditional syntactic structures and relations in favour of employing purely semantic distinctions to analyse sentence structure. The shared task, 'cross-lingual semantic parsing with UCCA' (Hershcovich et al., 2019) consists in parsing English, German, and French datasets using the UCCA semantic tagset. In order to enable multi-task learning, the UCCA-annotated data is automatically converted to other parsing formats, e.g. Abstract Meaning Representation (AMR) and Semantic Dependency Parsing (SDP), inter alia (Hershcovich et al., 2018).

Although the schemes are formally different, they have shared semantic content. In order to perform our experiments, we target the converted CONLLU format, which corresponds to traditional bi-lexical dependencies and rely on the conversion methodology which is provided in the shared task (Hershcovich et al., 2019) to attain UCCA graphs.

UCCA graphs contain both explicit and implicit units [1] However, in bi-lexical dependencies, nodes are text tokens and semantic relations are direct bi-lexical relations between the tokens. The conversion between the two format results in partial loss of information. Nonetheless, we believe that it is worth trying to model the task using one of the available formats (i.e. semantic dependency parsing) which is very popular among NLP researchers.

Typically, transition-based methods are used in syntactic (Chen and Manning, 2014) and semantic (Hershcovich et al., 2017) dependency parsing. By contrast, our proposed system shares several similarities with sequence-to-sequence neural architectures, as it does not specifically deal with parsing transitions. Our model uses word, POS and syntactic dependency tree representations as input and directly produces an edge-labeled graph representation for each sentence (i.e. edges and their labels as two separate outputs). This multi-label neural architecture, which consists of a BiLSTM and a Graph Convolutional Network (GCN), is described in Section 3.

[1] Explicit units (terminal nodes) correspond to tokens in the text, but implicit (semantic) units have no corresponding component in the text.

2 Related Work

A recent trend in parsing research is sequence-to-sequence learning (Vinyals et al., 2015b; Kitaev and Klein, 2018), which is inspired from Neural Machine Translation. These methods ignore explicit structural information in favour of relying on long-term memory, attention mechanism (content-based or position-based) (Kitaev and Klein, 2018) or pointer networks (Vinyals et al., 2015a). By doing so, high-order features are implicitly captured, which results in competitive parsing performance (Jia and Liang, 2016).

Sequence-to-sequence learning has been particularly effective in Semantic Role Labeling (SRL) (Zhou and Xu, 2015). By augmenting these models with syntactic information, researchers have been able to develop state-of-the-art systems for SRL (Marcheggiani and Titov, 2017; Strubell et al., 2018).

As information derived from dependency parse trees can significantly contribute towards understanding the semantics of a sentence, Graph Convolutional Network (GCN) (Kipf and Welling, 2017) is used to help our system perform semantic parsing while attending to structural syntactic information. The architecture is similar to the GCN component employed in Rohanian et al. (2019) for detecting gappy multiword expressions.

3 Methodology

For this task, we employ a neural architecture utilising structural features to predict semantic parsing tags for each sentence. The system maps a sentence from the source language to a probability distribution over the tags for all the words in the sentence. Our architecture consists of a GCN layer (Kipf and Welling, 2017), a bidirectional LSTM, and a final dense layer on top.

The inputs to our system are sequences of words, alongside their corresponding POS and named-entity tags.[2] Word tokens are represented by contextualised ELMo embeddings (Peters et al., 2018), and POS and named-entity tags are one-hot encoded. We also use sentence-level syntactic dependency parse information as input to the system. In the GCN layer, the convolution filters operate based on the structure of the dependency tree (rather than the sequential order of words).

Graph Convolution. Convolutional Neural Networks (CNNs), as originally conceived, are sequential in nature, acting as detectors of N-grams (Kim, 2014), and are often used as feature-generating front-ends in deep neural networks. Graph Convolutional Network (GCN) has been introduced as a way to integrate rich structural relations such as syntactic graphs into the convolution process.

In the context of a syntax tree, a GCN can be understood as a non-linear activation function f and a filter W with a bias term b:

$$c = f\left(\sum_{i \in r(v)} W x_i + b\right) \tag{1}$$

where $r(v)$ denotes all the words in relation with a given word v in a sentence, and c represents the output of the convolution. Using adjacency matrices, we define graph relations as mask filters for the inputs (Kipf and Welling, 2017; Schlichtkrull et al., 2017).

In the present task, information from each graph corresponds to a sentence-level dependency parse tree. Given the filter W_s and bias b_s, we can therefore define the sentence-level GCN as follows:

$$C_s = f(W_s X^T A + b_s) \tag{2}$$

where $X_{n\times v}$, $A_{n\times n}$, and $C_{o\times n}$ are tensor representation of words, the adjacency matrix, and the convolution output respectively.[3] In Kipf and Welling (2017), a separate adjacency matrix is constructed for each relation to avoid overparametrising the model; by contrast, our model is limited to the following three types of relations: 1) the head to the dependents, 2) the dependents to the head, and 3) each word to itself (self-loops) similar to Marcheggiani and Titov (2017). The final output is the maximum of the weights from the three individual adjacency matrices.
The model architecture is depicted in Figure 1.

4 Experiments

Our system participated in the closed track for English and German and the open track for French. We exclusively used the data provided in the shared task. The system is trained on the training data only, and the parameters are optimised using the development set. The results are reported

[2] spaCy (Honnibal and Johnson, 2015) is used to generate POS, named-entity and syntactic dependency tags.

[3] o: output dimension; v: word vectors dimension; n: sentence length

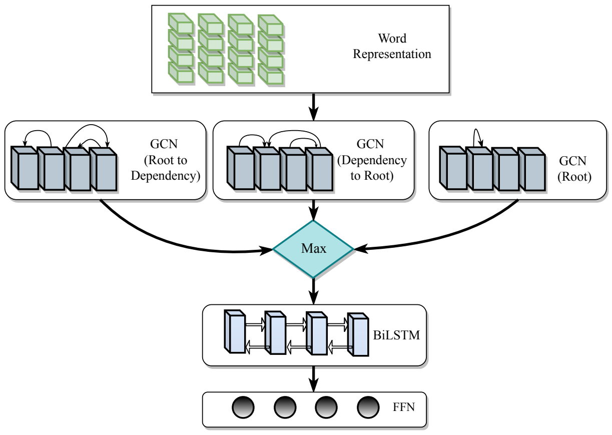

Figure 1: A GCN-based recurrent architecture.

on blind-test data in both in-domain and out-of-domain settings. We focus on predicting the primary edges of UCCA semantic relations and their labels.

4.1 Data

The datasets of the shared task are devised for four settings: 1) English in-domain, using the Wiki corpus; 2) English out-of-domain, using the Wiki corpus as training and development data, and 20K Leagues as test data; 3) German in-domain, using the 20K Leagues corpus; 4) French setting with no training data (except trial data), using the 20K Leagues corpus as development and test data.

Whilst the annotated files used by the shared task organisers are in the XML format, several other formats are also available. We decided to use CONLLU, as it is more interpretable. However, according to the shared task description,[4] the conversion between XML and CONLLU, which is a necessary step before evaluation, is lossy. Hershcovich et al. (2017) used the same procedure of performing dependency parsing methods on CONLLU files and converting the predictions back to UCCA.

4.2 Settings

We trained ELMo on each of the shared task datasets using the system implemented by Che et al. (2018). The embedding dimension is set to 1024. The number of nodes is 256 for GCN and 300 for BiLSTM, and we applied a dropout of 0.5 after each layer. We used the Adam optimiser for compiling the model.

We tested our model in four different settings, as explained in Section 4.1. The parameters are optimised on the English Wiki development data (batch-size = 16 and number of epochs = 100) and used for all four settings. As no training data was available for French, the trained system on English Wiki was used to parse French sentences of 20K Leagues. For this reason the French model is evaluated within the open track.

4.3 Official Evaluation

Our model predicts two outputs for each dataset: primary edges and their labels (UCCA semantic categories). [5]

Table 1 shows the performance (in terms of precision, recall, and F1-score) for predicting primary edges in both labeled (i.e. with semantic tags) and unlabeled settings (i.e. ignoring semantic tags). Table 2 shows F1-scores for each semantic category separately. Although the overall performance of the system, as shown in the official evaluation in Table 1, is not particularly impressive, there are a few results worth reporting. These are listed in Table 2.

Our system is ranked second in predicting four relations, i.e. L (linker), N (Connector), R (Relator), and G (Ground), in all settings displayed in bold. A plausible explanation would be that these relations are somewhat less affected by the loss of information incurred as a result of the conversions between formats.

5 Discussion

Our neural model is applied to UCCA corpora, which are converted to bi-lexical semantic dependency graphs and represented in the CONLLU format. The conversion from UCCA annotations to CONLLU tags appears to have a distinctly negative impact on the system's overall performance. As reported in the shared task description, converting the English Wiki corpus to the CONLLU format and back to the standard format results in an F1-score of only 89.7 for primary labeled edges. This means that our system cannot go beyond this upper limit.

Since our system is trained on CONLLU files and the evaluation involves converting the CONLLU format back to the standard UCCA format,

Table 2: Official results of the shared task evaluation for predicting Primary edges and their labels. (* The results for French are for Post-Evaluation.)

the reported results for our system can be misleading. In order to further investigate this issue, we performed an evaluation using the English Wiki development data, comparing the predicted labels with the gold standard in development set in the CONLLU format. The average F1-score for labelled edges was 0.71 compared to the 0.685 score our system achieved on the development set using the official evaluation script.

This clearly demonstrates that our system fares significantly better if it receives its input in the form of bi-lexical dependency graphs. Therefore, the system is best suited for semantic dependency parsing, although we believe that promising results could also be achieved in UCCA annotation if the conversion between the CONLLU and UCCA formats is improved to map and preserve information more accurately.

6 Conclusion and Future Work

In this paper, we described the system we submitted to the SemEval-2019 Task 1: 'Semantic Parsing using Graph Convolutional and Recurrent Neural Networks'. The model performs semantic parsing using information derived from syntactic dependencies between words in each sentence. We developed the model using a combination of GCN and BiLSTM components. Due to the penalisation resulting from the use of lossy CONLLU files, we argue that the results cannot be directly compared with those of the other task participants. [6]

In the future, we would like to build on the work presented in this paper by applying the architecture to the standard UCCA dataset, or possibly training the system to perform bi-lexical semantic dependency annotation.

Abstract

This paper describes our recursive system for SemEval-2019 *Task 1: Cross-lingual Semantic Parsing with UCCA*. Each recursive step consists of two parts. We first perform semantic parsing using a sequence tagger to estimate the probabilities of the UCCA categories in the sentence. Then, we apply a decoding policy which interprets these probabilities and builds the graph nodes. Parsing is done recursively, we perform a first inference on the sentence to extract the main scenes and links and then we recursively apply our model on the sentence using a masking feature that reflects the decisions made in previous steps. Process continues until the terminal nodes are reached. We choose a standard neural tagger and we focused on our recursive parsing strategy and on the cross lingual transfer problem to develop a robust model for the French language, using only few training samples.

1 Introduction

Semantic representation is an essential part of NLP. For this reason, several semantic representation paradigms have been proposed. Among them we find PropBank (Palmer et al., 2005) and FrameNet Semantics (Baker et al., 1998), Abstract Meaning Representation (AMR) (Banarescu et al., 2013), Universal Decompositional Semantics (White et al., 2016) and Universal Conceptual Cognitive Annotation (UCCA) (Abend and Rappoport, 2013). These constantly improving representations, along with the advances in semantic parsing, have proven to be beneficial in many NLU tasks such as Question Answering (Shen and Lapata, 2007), text summarization (Genest and Lapalme, 2011), dialog systems (Tur et al., 2005), information extraction (Bastianelli et al., 2013) and machine translation (Liu and Gildea, 2010).

UCCA is a cross-lingual semantic representation scheme, has demonstrated applicability in English, French and German (with pilot annotation projects on Czech, Russian and Hebrew). Despite the newness of UCCA, it has proven useful for defining semantic evaluation measures in text-to-text generation and machine translation (Birch et al., 2016). UCCA represents the semantics of a sentence using directed acyclic graphs (DAGs), where terminal nodes correspond to text tokens, and non-terminal nodes to higher level semantic units. Edges are labelled, indicating the role of a child in the relation to its parent. UCCA parsing is a recent task and since UCCA has several unique properties, adapting syntactic parsers or parsers from other semantic representations is not straight-forward. Current state of the art parser TUPA (Hershcovich et al., 2017) uses a transition based parsing to build UCCA representations.

Building over previous work on FrameNet Semantic Parsing (Marzinotto et al., 2018a,b) we chose to perform UCCA parsing using sequence tagging methods along with a graph decoding policy. To do this we propose a recursive strategy in which we perform a first inference on the sentence to extract the main scenes and links and then we recursively apply our model on the sentence with a masking mechanism at the input in order to feed information about the previous parsing decisions.

2 Model

Our system consists of a sequence tagger that is first applied on the sentence to extract the main scenes and links and then it is recursively applied on the extracted element to build the semantic graph. At each step of the recursion we use a masking mechanism to feed information about the previous stages into the model. In order to convert the sequence labels into nodes of the UCCA graph we also apply a decoding policy at each stage.

Our tagger is implemented using deep bidirectional GRU (*biGRU*). This simple architecture is frequently used in semantic parsers across different representation paradigms. Besides its flexibility, it is a powerful model, with close to state of the art performance on both PropBank (He et al., 2017) and FrameNet semantic parsing (Yang and Mitchell, 2017; Marzinotto et al., 2018b).

More precisely, the model consists of a 4 layer bi-directional Gated Recurrent Unit (GRU) with highway connections (Srivastava et al., 2015). Our model uses has a rich set of features including syntactic, morphological, lexical and surface features, which have shown to be useful in language abstracted representations. The list is given below:

- Word embeddings of 300 dimensions [1].
- Syntactic dependencies of each token[2].
- Part-of-speech and morphological features such as gender, number, voice and degree[2].
- Capitalization and word length encoding.
- Prefixes and Suffixes of 2 and 3 characters.
- A language indicator feature.
- Boolean indicator of idioms and multi word expression. Detailed in section 3.2.
- Masking mechanism, which indicates, for a given node in the graph, the tokens within the span as well as the arc label between the node and its parent. See details in section 2.1.

Except for words where we use pre-trained embeddings, we use randomly initialized embedding layers for categorical features.

2.1 Masking Mechanism

We introduce an original masking mechanism in order to feed information about the previous parsing stages into the model. During parsing, we first do an initial inference step to extract the main scenes and links. Then, for each resulting node, we build a new input which is essentially the same, but with a categorical sequence masking feature. For the input tokens in the node span, this feature is equal to the label of the arc between the node and its parent. Outside of the node span, this mask is equal to `O`. A diagram of this masking process is shown in figure 1. The process continues and the model recursively extracts the inner semantic structures (the node's children) in the graph, until the terminal nodes are reached.

[1]Obtained from https://github.com/facebookresearch/MUSE

[2] Using Universal Dependencies categories.

To train such a model, we build a new training corpus in which the sentences are repeated several times. More precisely, a sentence appears N times (N being the number of non terminal nodes in the UCCA graph) each one a with different mask.

2.2 Multi-Task UCCA Objective

Along with the UCCA-XML graph representations, a simplified tree representation in CoNLL format was also provided. Our model combines both representations using a multitask objective with two tasks. `TASK1` consists in, for a given node and its corresponding mask, predicting the children and their arc labels. `TASK1` encodes the children spans using a BIO scheme. The `TASK2` consists in predicting the CoNLL simplified UCCA structure of the sentence. More precisely, `TASK2` is a sequence tagger that predicts the UCCA-CoNLL function of each token. `TASK2` is not used for inference purposes. It is only a support that help the model to extract relevant features, allowing it to model the whole sentence even when parsing small pre-terminal nodes.

2.3 Label Encoding

We have previously stated that `TASK1` uses BIO encoded labels to model the structure of the children of each node in the semantic graph. In some rare cases, the BIO encoding scheme is not sufficient to model the interaction between parallel scenes. For example, when we have two parallel scenes and one of them appears as a clause inside the other. In such cases, BIO encoding does not allow to determine whether the last part of the sentence belongs to the first scene or to the clause. Despite this issue, prior experiments testing more complete label encoding schemes (BIEO, BIEOW) showed that BIO outperforms the other schemes on the validation sets.

2.4 Graph Decoding

During the decoding phase, we convert the BIO labels into graph nodes. To do so, we add a few constraints to ensure the outputs are feasible UCCA graphs that respect the sentence's structure:

- We merge parallel scenes (H) that do not have either a verb or an action noun to the nearest previous scene having one.
- Within each parallel scene, we force the existence of one and only one `State` (S) or `Process` (P) by selecting the token with the highest probability of `State` or `Process`.

The mice ate cheese and fell asleep
A A O O O O O

Figure 1: Masking mechanism through recursive calls. `Step 1` parses the sentence to extract parallel scenes (H) and links (L). Then `Steps 2.A 2.B` use a different mask to parse these scenes and extract arguments (A) and processes (P) which will be recursively parsed until terminal nodes are reached.

- For scenes (H) and arguments (A) we do not allow to split multi word expressions (MWE) and chunks into different graph nodes. If the boundary between two segments lies inside a chunk or MWE segments are merged.

2.5 Remote Edges

Our approach easily handles remote edges. We consider remote arguments as those detected outside the parent's node span (see `REM` in Fig.1). Our earlier models showed low recall on remotes. To fix this, we introduced a detection threshold on the output probabilities. This increased the recall at the cost of some precision. The optimal detection threshold was optimized on the validation set.

3 Data

3.1 UCCA Task Data

In table 1 we show the number of annotations for each language and domain. Our objective is to build a model that generalizes to the French language despite of having only 15 training samples.

When we analyse data in details we observe that there are several tokenization errors. Specially in the French corpus. These errors propagate to the POS tagging and dependency parsing as well. For this reason, we retokenized and parsed all the corpus using a enriched version of UDpipe that we trained ourselves (Straka and Straková, 2017) using the Treebanks from Universal Dependencies[3]. For French we enriched the Treebank with XPOS from our lexicon. Finally, since tokenization is pre-established in the UCCA corpus we projected the improved POS and dependency parsing into the original tokenization of the task.

German 20K	5211	651	652
French 20K	15	238	239

Table 1: number of UCCA annotated sentences in the partitions for each language and domain

3.2 Supplementary lexicon

We observed that a major difficulty in UCCA parsing is analyzing idioms and phrases. The unawareness about these expressions, which are mostly used as links between scenes, mislead the model during the early stages of the inference and errors get propagated through the graph. To boost the performance of our model when detecting links and parallel scenes we developed an internal list with about 500 expression for each language. These lists include prepositional, adverbial and conjunctive expressions and are used to compute Boolean features indicating the words in the sentence which are part of an expression.

3.3 Multilingual Training

This model uses multilingual word embeddings trained using fastText (Bojanowski et al., 2017) and aligned using MUSE (Conneau et al., 2017). This is done in order to ease cross-lingual training. In prior experiments we introduced an adversarial objective similar to (Kim et al., 2017; Marzinotto et al., 2019) to build a language independent representation. However, the language imbalance on the training data did not allow us to take advantage from this technique. Hence, we simply merged training data from different languages.

4 Experiments

We focus on obtaining the model that best generalizes on the French language. We trained our model for 50 epochs and we selected the best one on the validation set. In our experiments we did not use any product of experts or bagging technique and we did not run any hyper parameter optimization.

We trained several models building different training corpora composed of different language combinations. We obtained our best model using the training data for all the languages. This model `FR+DE+EN` achieved 63.6% avg. F1 on the French validation set. Compared to 63.1% for `FR+DE`, 62.9% for `FR+EN` and 50.8% for only `FR`.

4.1 Main Results

In Table 2 we provide the performance of our model for all the open tracks and we provide the results for TUPA baseline in order to establish a comparison. Our model finishes 4th in the French Open Track with an average F1 score of 65.4%, very close to the 3rd place which had a 65.6% F1. For languages with larger training corpus, our model did not outperform the monolingual TUPA.

4.2 Error Analysis

In Table 3 we give the performance by arc type. We observe that the main performance bottleneck is in the parallel scene segmentation (H). Due to our recursive parsing approach, this kind of error is particularly harmful to the model performance, because scene segmentation errors at the early steps of the parsing may induce errors in the rest of the graph. To assert this, we used the validation set to compare the performance of the mono scene sentences (with no potential scene segmentation problems) with the multi scene sentences. For the French track we obtained 67.2% avg. F1 on the 114 mono scene sentences compared to 61.9% avg. F1 on the 124 multi scene sentences.

5 Conclusions

We described an original approach to recursively build the UCCA semantic graph using a sequence tagger along with a masking mechanism and a decoding policy. Even though this approach did not yield the best results in the UCCA task, we believe that our original recursive, mask-based parsing can be helpful in low resource languages. Moreover, we believe that this model could be further improved by introducing a global criterion and by performing further hyper parameter tuning.

Abstract

Our submission for Task 1 'Cross-lingual Semantic Parsing with UCCA' at SemEval-2018 is a feed-forward neural network that builds upon an existing state-of-the-art transition-based directed acyclic graph parser. We replace most of its features by deep contextualized word embeddings and introduce an approximation to represent non-terminal nodes in the graph as an aggregation of their terminal children. We further demonstrate how augmenting data using the baseline systems provides a consistent advantage in all open submission tracks. We submitted results to all open tracks (English, in- and out-of-domain, German in-domain and French in-domain, low-resource). Our system achieves competitive performance in all settings besides the French, where we did not augment the data. Post-evaluation experiments showed that data augmentation is especially crucial in this setting.

1 Introduction

Semantic Parsing is the task of assigning an utterance a structured representation of its meaning. The goal is to assign similar structures to utterances with similar meanings, regardless of their syntactic realizations. In Syntactic Parsing, for instance, the sentence 'John saw Paul.' will have a different structure than 'Paul was seen by John'. Semantic Parsing, in contrast, aims to solely encode the fact that John saw Paul. Deriving a semantic representation of an utterance has various applications. It can serve as a starting point for the evaluation of machine translation systems, as the structure of the semantic representation should be similar across languages. Birch et al. (2016) use human annotated scores of individual UCCA semantic units in their HUME metric to provide a fine-grained analysis of translation quality and improve scalability to longer sentences by approximating human judgement semi-automatically from the annotated scores of each unit. Explicit semantic representations could also provide the structured information necessary to alleviate recent issues in Natural Language Inference (NLI) where McCoy and Linzen (2019) showed that state-of-the-art NLI systems fail to recognize that e.g. 'Alice believes Mary is lying.' does not entail 'Alice believes Mary.'. Using precise semantic representations of the sentences a theorem could be built on which various logical inferences can be performed with a theorem prover such as in Martínez-Gómez et al. (2016).

Universal Conceptual Cognitive Annotation (UCCA) (Abend and Rappoport, 2013) is a semantic grammar formalism where natural language expressions are analyzed as deep directed acyclic graph (DAG) structures, deep meaning the graphs feature non-terminal nodes. Due to it's coarse-grained representation using cognitively motivated categories it is both domain and language independent and quickly learned even by annotators without a linguistic background (Abend and Rappoport, 2013).

The goal of the SemEval-2018 Task 1 'Cross-lingual Semantic Parsing with UCCA' was to develop a parser producing UCCA-DAG structures trained on articles from Wikipedia in English and passages from the book "Twenty Thousand Leagues Under the Sea" in French and German. The parsers were evaluated on the DAG-F1 metric on in-domain passages in English, French and German as well as out-of-domain passages in English in both an open and a closed track (Hershcovich et al., 2018b). Since we made extensive use of external resources we participated only in the open track of all settings.

For our participation, we build upon the transition-based DAG parser Tupa (Hershcovich et al., 2017). Our adaptation reuses the transition system and oracle. We extend Tupa with respect to its representations of non-terminal nodes in a way that they are an aggregation of all their terminal nodes. While Tupa uses a Recurrent Neural Network, our system is a simple feed-forward network that uses a small set of features and ELMo contextualized embeddings (Peters et al., 2018) made available by Che et al. (2018)[1] and Fares et al. (2017).

2 Background

Until recently, semantic parsers were exclusively symbolic rule-based systems (Bos, 2005). These systems rely on complex hand-written and necessarily language-specific sets of rules, requiring a re-implementation for every new language. More recently, neural methods have also arrived in the domain of Semantic Parsing. They achieve state-of-the-art results while being largely language-agnostic. Since these systems usually require large amounts of annotated data, this line of work is largely concerned with the augmentation of training data. Hershcovich et al. (2018a) recognize the similarity between several annotation schemes and jointly learn to parse other semantic formalisms in a multi-task setting, while van Noord et al. (2018) add large amounts of automatically annotated data to their training data. Both approaches led to significant improvements over not using the additional data.

3 Silver Data

We created additional training data for both English and German using the open track baseline systems. The English silver data was taken from the 1B word benchmark (Chelba et al., 2014), the German from the archive of the newspaper taz. For both languages, we took the first 15,000 sentences of the corpora and added UCCA annotation using the baseline systems. Our training datasets then consisted of the concatenation of gold and silver data, and another gold only set. Due to a lack of time we did not create silver data for our French submission. Post-evaluation results for French, trained on v2.0 of the GSD treebank[2] provided by Universal Dependencies (Nivre et al., 2016), are presented in Section 6.1.

[2]https://universaldependencies.org/treebanks/fr_gsd/

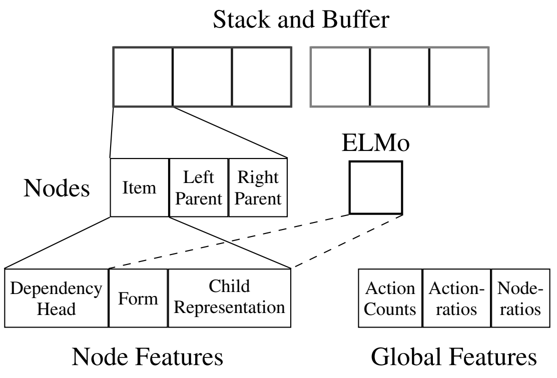

Figure 1: Illustration of the features used by Tüpa. The final feature vector results from the concatenation of all stack and buffer features with the global features. Features dropped after preliminary experiments are omitted for brevity.

4 System

Our system is an ensemble of small feed-forward neural networks. We use three global features: typed absolute counts for previous parser actions and action- and node-ratios (Hershcovich et al., 2017). We further follow the standard in transition-based parsing and extract a set of features based on the top three items on stack and buffer. To capture some of the structure of the partially built graph, we extract the rightmost and leftmost parents and children of the respective items, following Hershcovich et al. (2017). Each of these items is represented by the ELMo embedding of its form, the embedding of its dependency head and the embeddings of all terminal children. We use the average over all ELMo layers to retrieve the embedding of a word. Non-terminal nodes do not have a form or dependency head, hence these are represented by a learned non-terminal embedding. Both the non-terminals and terminals have a third feature, a representation of their children. In the case of terminals, this feature is equal to its form feature. For the non-terminals, it is an aggregation of all its children, produced by the child representation module. Figure 1 illustrates the set of features used by our system. We experimented with richer feature sets, including the last parser actions, named-entity, part-of-speech and dependency types, but dropped them after performing preliminary experiments. The input to the feed-forward module is the concatenation of all features with the output of the child representation module. The classification portion of the system was implemented using Tensorflow (Abadi et al., 2015).

4.1 Representing Non-Terminals

The child representation module aims to enrich the representation of non-terminal nodes. Our initial representation for non-terminal nodes was a set of discrete features describing the number of typed in- and outgoing edges and the nodes' height in the tree. While this might be informative on an abstract level, it does not provide any information about the content covered by this node. We solve this poverty of information by concatenating each of the embeddings of the terminal children of a node with an embedding for the first edge type leading to them. The resulting combination is fed through a dense layer with d neurons, resulting in n vectors with d dimensions where n is the number of terminals under the node. We then reduce the n vectors into a single d dimensional vector by taking the maximum value of each dimension. Figure 2 depicts how the representation of a non-terminal node is obtained. While it would be desirable to process the children using context-aware methods, such as RNNs or self attention, it is not feasible since some of the nodes can have more than 100 children. Future work should explore recursive formulations for representing a node by its direct children instead of relying on all terminal children, performing largely redundant operations for higher nodes.

4.2 Hyperparameters

We apply dropout (Srivastava et al., 2014) with a keep probability of 0.8 to the inputs of all layers. The child processing module is a single layer feed-forward network with 256 hidden units. The feed-forward module is single layer feed-forward network with 512 hidden units. Both modules use the ReLU activation function. Training is performed with the Adam optimizer (Kingma and Ba, 2014) using an initial learning rate of $8\mathrm{e}{-5}$ that is halved every two epochs without an improvement on development accuracy. We halt the training after five epochs without an improvement on development transition accuracy. The models were first trained on the concatenation of the silver and gold data and following the early stopping another time only on the gold data using the same parameters. We use mini-batches of size 192 and evaluate on the development set every 1000 mini-batches. As training time imposes a serious limitation, we did not perform an extensive hyperparameter search and settled on these after initial experiments.

	DAG-F1	Primary F1	Remote F1	Tupa-DAG

Table 1: DAG-F1, primary F1 and remote F1 scores with the DAG-F1 score of the baseline on the test sets in the open tracks.

5 Results and Discussion

Table 1 shows the submission scores of our parser trained using the hyperparameters described in Section 4.2 on the test datasets in the open tracks. Since only 15 French passages were available for training, our French results were obtained by first training a model on the concatenation of the French passages and the German 20k training dataset using French ELMo embeddings. After convergence, it was fine-tuned on only the French passages for two epochs. However, this did not provide a significant increase in F1 score over a model trained exclusively on the French passages. All results were produced using a five model ensemble, consisting of the model with the best transition accuracy and the four following it before early stopping. The results show that our parser achieves competitive performance to the baseline while relying on fewer features. In particular, for the English in-domain data, we achieve the same performance as the baseline, for the out-of-domain data we surpass it by 0.025 DAG-F1. In German and French where only in-domain data exists our approach is outperformed by the baseline which we partially attribute to issues in the creation of the silver data. Post-submission results obtained after performing a more exhaustive hyperparameter search on the development set and with correct silver-data surpass the baseline performance on the test sets in all open settings.

6 Further Experiments

In this section, we will describe the findings of our post-evaluation experiments. We evaluated the effect of silver data and provide results for French with silver data. We further performed experiments on non-terminal representations and investigated the effect of model size. Since this only covers a fraction of our experiments and describing them all would be out of scope, we

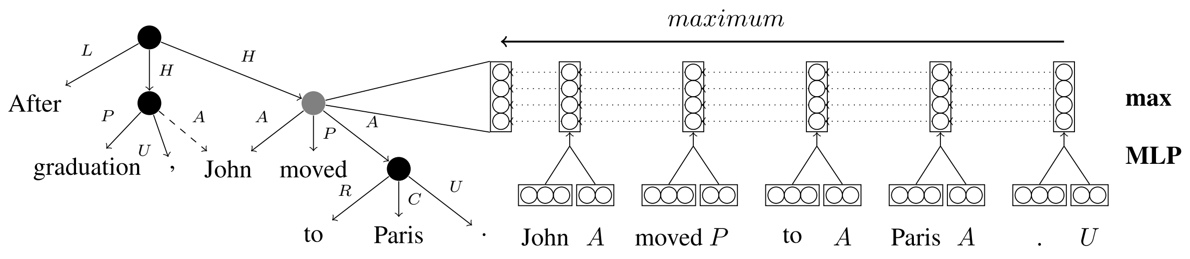

Figure 2: Depiction of a non-terminal representation. The terminal children dominated by the grey node are concatenated with the first edge leading to them and fed through a fully-connected layer. The multiple resulting vectors are reduced into a single one by taking the maximum value of each dimension.

provide the full results alongside their hyperparameters at https://twuebi.github.io/publications/ucca_post_eval.pdf.

6.1 Silver Data

We measured the effect of silver data on English and French by evaluating several model configurations in two settings. The first setting matches the training data used for the submission and is the concatenation of the gold and silver data. In the second setting, the only available data is the gold data.

English: We trained three models for English. The first model configuration uses all features and corresponds to the model described in the end of Section 4, the second is our submission, described in Section 4. The last model uses only embeddings of the forms and dependency heads. As shown in Table 2, additional training data provides a consistent boost in F1 score across all tested feature combinations. Moreover, it seems that there is a larger effect of the silver data on models with more features, indicating a better estimation of the feature representations based on the additional data.

Low resource setting: Table 3 demonstrates the effect of silver data on French for the submission model configuration. The effect of additional data is the largest in the low-resource setting, providing a boost of 0.1 in average F1 score. Adding the silver data also leads to some of the remote edges being correct, whereas there are no correct remote edges for the gold-only model.

6.2 Non-Terminal Representation

To measure the effectiveness of our non-terminal representation, we ran two experiments using silver and gold data. In both cases, we trained one model with aggregated non-terminal representations and one with the discrete representations of typed in- and outgoing edges and the nodes' heights in the tree. The first experiment used all available features. The second was trained with the features of our submission. Table 4 presents the results of the experiments. The explicit child representations provide a clear improvement over the discrete representation. In the second experiment, where no in- and outgoing edges were used and the only non-terminal representations are the left- and rightmost children, the gap increased even further, in fact it is the worst F1 score of all models trained on silver data.

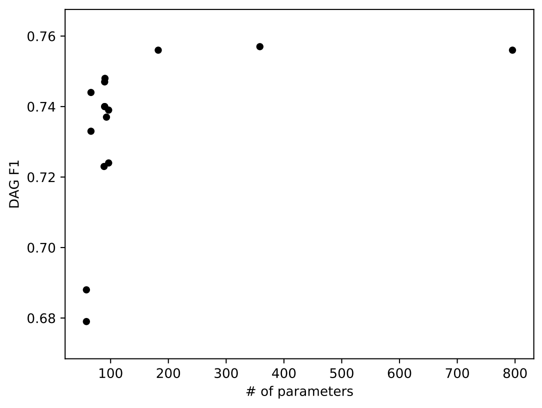

Figure 3: DAG F1 scores on English development data on the y-axis. Million parameters in the models on the x-axis. Larger models seem provide some improvements that begin to level off for big models.

6.3 Bigger means better?

Figure 3 contrasts the number of trainable parameters of the models in our experiments with the F1 score on the English development set. While there are some improvements for larger models, it can be seen that the effect begins to level off at 200M parameters and eventually leads to a small regression with the largest model. Possible causes are overfitting and a lack of training data. Future work should explore whether additional training data allows for larger models. Additional regularization such as L2 regularization might also prove useful. For our experiments, this was out of scope since training so many models was not feasible.

7 Conclusion

In this work, we presented a parser for the semantic grammar formalism UCCA. Our parser relies on a small set of features and achieves competitive performance on the English and German data, but lags behind on French where almost no training data is available. We demonstrated, using ablation experiments, that the explicit representation of non-terminals and additional silver data are crucial for our result. We have further shown that silver data is especially helpful in the low-resource setting where it boosts the average F1 score from 0.456 to 0.557. Future work should investigate how much more improvement additional data can provide. This should be explored both in form of other formalisms (Hershcovich et al., 2018a) and silver data (van Noord et al., 2018). Besides the data aspect, we also believe that improving the non-terminal representation will lead to significant gains. The goal should be to find a representation that leverages the recursive structure of the partially built graph.

Abstract

We present a simple and accurate model for semantic parsing with UCCA as our submission for SemEval 2019 Task 1. We propose an encoder-decoder model that maps strings to directed acyclic graphs. Unlike many transition-based approaches, our approach does not use a state representation, and unlike graph-based parsers, it does not score graphs directly. Instead, we encode input sentences with a bidirectional-LSTM, and decode with self-attention to build a graph structure. Results show that our parser is simple and effective for semantic parsing with reentrancy and discontinuous structures.

1 Introduction

Semantic parsing aims to capture structural relationships between input strings and graph representations of sentence meaning, going beyond concerns of surface word order, phrases and relationships. The focus on meaning rather than surface relations often requires the use of reentrant nodes and discontinuous structures. Universal Conceptual Cognitive Annotation (UCCA) (Abend and Rappoport, 2013) is designed to support semantic parsing with mappings between sentences and their corresponding meanings in a framework intended to be applicable across languages.

SemEval 2019 Task 1 (Hershcovich et al., 2018b, 2019) focuses on semantic parsing of texts into graphs consisting of terminal nodes that represent words, non-terminal nodes that represent internal structure, and labeled edges representing relationships between nodes (e.g. *participant*, *center*, *linker*, *adverbial*, *elaborator*), according to the UCCA scheme. Annotated datasets are provided, and participants are evaluated in four settings: English with domain-specific data, English with out-of-domain data, German with domain-specific data, and French with only development and test data, but no training data. Additionally, there are open and closed tracks, where the use of additional resources is and is not allowed, respectively. Our entry in the task is limited to the closed track and the first setting, domain-specific English using the Wiki corpus, where the relatively small dataset (4113 sentences for training, 514 for development, and 515 for testing) consists of annotated sentences from English Wikipedia.

Our model follows the encoder-decoder architecture commonly used in state-of-the-art neural parsing models (Kitaev and Klein, 2018; Kiperwasser and Goldberg, 2016b; Cross and Huang, 2016; Chen and Manning, 2014). However, we propose a very simple decoder architecture that relies only on a recursive attention mechanism of the encoded latent representation. In other words, the decoder does not require state encoding and model-optimal inference whatsoever. Our novel model achieved a macro-averaged F1-score of 0.753 in labeled primary edges and 0.864 in unlabeled primary edge prediction on the test set. The results confirm the suitability of our proposed model to the semantic parsing task.

2 Related work

Leveraging parallels between UCCA and known approaches for syntactic parsing, Hershcovich et al. (2017) proposed TUPA, a customized transition-based parser with dense feature representation. Based on this model, Hershcovich et al. (2018a) used multitask learning effectively by training a UCCA model along with similar parsing tasks where more training data is available, such as Abstract Meaning Representation (AMR) (Banarescu et al., 2013) and Universal Dependencies (UD) (Nivre et al., 2016). Due to

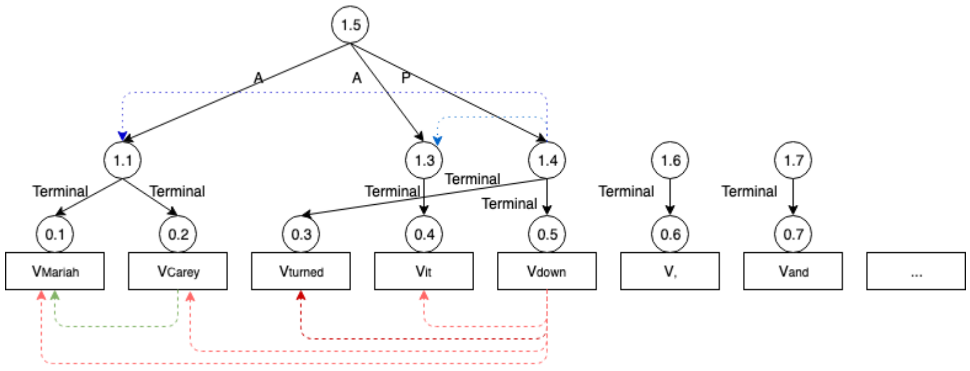

Figure 1: Illustration of the decoder for the beginning of a sentence, "Mariah Carey turned it down, and ...". Each v_i represents the context embedding for each word i from the BiLSTM encoder. Words on edges represent category labels between nodes, where A is participant and P is process. Circles represent nodes in the graph, each with a pair in indices. Circles with 0 as the first index are terminal nodes, and circles with 1 as the first index are non-terminal nodes. (1). Dashed green lines represent the attention mechanism for the word $Carey$, which forms a continuous proper noun "Mariah Carey". (2). Dashed red lines represent the attention mechanism for the word $down$, which forms a discontinuous unit "turned ... down". (3). Dotted blue lines represent the attention mechanism for $node_{1.4}$. The darker the color, the higher the attention score.

the requirements of reentrancy, discontinuity, and non-terminals, other powerful parsers were shown to be less suitable for parsing with UCCA (Hershcovich et al., 2017).

3 Parsing Model

BiLSTM models are capable of providing feature representations with sequential data, and attention mechanisms (Vaswani et al., 2017) have been applied successfully to parsing tasks (Kitaev and Klein, 2018). Inspired by their success, our model uses a BiLSTM encoder and a self-attention decoder. The encoder represents each node (terminal and non-terminal) in the DAG without the need to encode features and the current parser state. The proposed decoder takes the encoded representation as the configuration and uses attention mechanism. Without any additional feature extraction, it serves a similar role as an oracle and a transition-system in transition-based parsers. We jointly train a label prediction model and a discontinuity prediction model. We predict remote edges with a different encoder. An example of the parsing model can be seen in Figure 1.

3.1 Terminal Nodes

To mitigate sparsity due to the small amount of training data available, we concatenate part-of-speech tags embeddings to word embeddings in terminal nodes. In addition, because the connections between terminal nodes and non-terminal nodes often require identification of named entities, we also added entity type and case information as additional knowledge. Given a sentence $\mathbf{x} = x_1, ..., x_n$, the vector for each input token is thus represented as $u_i = emb(x_i) \circ emb(pos_i) \circ emb(entity\_type_i) \circ emb(case_i)$, where $case_i$ is 1 if the first character of the word is capitalized and 0 otherwise. We use pretrained word embeddings from fastText[1] for $emb(x_i)$. POS tags and entity types are predicted using external models[2] and are provided in the training corpus. Each word representation from the encoder is $v_i = BiLSTM(u_i)$. We assign these contextual word embeddings as vectors to terminal nodes.

3.2 Non-terminal Nodes

For non-terminal nodes with only one terminal node as the child, the representation is the same as its corresponding terminal node, i.e. a contextual word embedding from the BiLSTM encoder. For other non-terminal nodes that have more than one terminal children or non-terminal children (i.e. represent more than one word in the text), we use a span representation. Following Cross and Huang (2016), we represent the span between the words x_i, x_j as $v_{i,j} = (f_j - f_i) \circ (b_i - b_j)$ where $f_0, ..., f_n$ and $b_0, ..., b_n$ are the output of the forward and backward directions in the BiLSTM, respectively. However, the linear subtractions from a nonlinear recurrent neural network (RNN) as a span approximation is not intuitive. Instead, we experimented

[1] https://fasttext.cc/
[2] https://spacy.io/

with an additional BiLSTM on the target span $x_i, x_{i+1}, ..., x_j$, similar to the recursive tree representations in (Socher et al., 2013; Kiperwasser and Goldberg, 2016a) but replaced the feed-forward network with an LSTM. In our experiments with the small dataset in the closed track of the English domain-specific track, this method did not result in improved performance.

3.3 Attention Mechanism For Decoding

Our basic decoding model is inspired by the global attention mechanism used in machine translation. The attention averages the encoded state in each time step in the sequence with trainable weights (Luong et al., 2015). We set a maximum sequence length and calculate the attention weights (in probability) for the left boundary index of the span given the node representation $v_{i,j}$ $(i \leq j)$:

$$h_{span} = MLP(v_{i,j}) \tag{1}$$

$$p_{left\_boundary} = softmax(h_{span}) \tag{2}$$

where MLP is a multilayer perceptron and h_{span} is of size (1, max_sequence_length). We choose $\arg\max_i p_{left\_boundary}$ as the index of the left boundary of the predicted span. Let j_l denote the index of the left most child of the node j (for example, in Figure 1, j_l for $node_{1.5}$ is 1 and j_l for $node_{1.6}$ is 6)[3]. If $i \geq j_l$, then the node attends to itself to indicate that a span cannot be created yet (as is the case for $node_{1.6}$ in Figure 1). Otherwise, there is a span that forms a semantic unit and we need to create a parent node. For example, $i = 1$ for the $node_{1.4}$, so we create a new $node_{1.5}$ which connects the nodes within the span [1: 5], i.e. $node_{1.1}$, $node_{1.3}$, and $node_{1.4}$.

We do this recursively to attend to a previous index until the node attends to itself. Then we repeat the procedure on the next word in the sequence. The illustration is shown in Figure 1 with dotted blue lines. The algorithm is presented in Algorithm 1 below. $primary\_parent$ indicates the parent node to which the current node is not a remote child (in the DAG setting, a child node may have multiple parents). We set the maximum number of recurrence to be 7 to prevent excessive node creation during inference.

Despite its simplicity, there are two limitations to this method. One is the restriction of the maximum sequence length. The other is the distinction

[3]For simplicity, word indices start at 1 in the Figure.

Algorithm 1 Index-attention decoder

```
1: for recur_num = 1 to max_recur do
2:     if $i \geq j_l$ then
3:         break
4:     end if
5:     $h_{span} = MLP(v_{i,j})$
6:     $i_{attn} = \underset{i}{\text{argmax}}\ softmax(h_{span})$
7:     $i = primary\_parent(v_{i_{attn}})_l$
8: end for
```

between the indices and the actual words in each sentence. The model may cheat during training to attend to specific indices regardless of the actual words in these indices.

Motivated by the success of biaffine attention(Dozat and Manning, 2016) and self-attention models (Vaswani et al., 2017), we replace the index attention decoder with a multiplication model where we can leverage fast optimized matrix multiplication. Similar to the left most child, let j_r denote the index of the right most child of $node_j$. $v_o = v[1 : j_r]$ where v is the output from the encoder of size (sequence_length, batch_size, hidden_size). The scoring function is defined as:

$$h_i = ReLU(W \times v_i + b) \tag{3}$$

$$h_o = ReLU(W \times v_o + b) \tag{4}$$

$$mm = matrix\_multiplication(h_i, h_o^T) \tag{5}$$

$$p_{left\_boundary} = softmax(mm) \tag{6}$$

Compared to the index attention decoder above, this decoder considers both the index and the span representation and thus is more flexible and robust to new texts. The recurrence call remains the same by replacing line 5 and 6 in Algorithm 1 with equations 3 − 6.

3.4 Label Prediction

Contextual information is important to label prediction. For instance, in the sentence "It announced Carey returned to the studio to start ... ", the phrase "Carey returned to the studio" should be labeled as a participant (A) instead of a scene (H) according to the context. Ideally the encoder will capture the information from the whole sentence so that we only need the current span to predict its label (since the span has the context information from both sides). However, as shown in previous research with RNN models, the contextual information is lost for a relatively long sentence. Therefore, similar to the label prediction problem with dependency parsers, we use a MLP to predict the label of a span $v_{i,j}$ given its context $p = primary\_parent(v_{i,j})$.

$$h = ReLU(W_l^1 \times (p \circ v_{i,j}) + b_l^1) \quad (7)$$

$$l = \underset{l}{argmax}\ softmax(W_l^2 * h + b_l^2) \quad (8)$$

We also experimented with only using span representation as seen in constituency parsing (Gaddy et al., 2018) by replacing $(p \circ v_{i,j})$ with $v_{i,j}$ in equation 7. Surprisingly, this increased the F1 score on the development set by 1.4 points. We conjecture that this is due to the limited amount of training data, which makes it more difficult to learn noisier representations.

3.5 Discontinuous Unit

After finding the left boundary of the current span unit as shown in section 3.3, we use two MLPs for binary classification to check (1) if the span forms a proper noun with which we need to combine multiple terminal nodes to one non-terminal node (as "Mariah Carey" in Figure 1) and (2) if the span forms a discontinuous unit (such as "turn ... down" in Figure 1).

$$prob_{propn} = W_p^2 \times ReLU(W_p^1 \times v_{i,j} + b_p^1) + b_p^2 \quad (9)$$

$$prob_{discont} = W_d^2 \times ReLU(W_d^1 \times v_{i,j} + b_d^1) + b_d^2 \quad (10)$$

If the node span attends to a node in the left and the model predicts a proper noun, we will create a non-terminal node and links all the terminal nodes $i, i+1, ..., j$ as its terminal children (shown as dashed green lines in Figure 1).

If the model predicts that the span is a discontinuous unit, instead of connecting all the terminal nodes as its children, the new created node only connects $node_i$ and $node_j$, and do the recurrence checks afterwards as shown in Algorithm 1 (illustrated as dashed red lines in Figure 1).

3.6 Remote Edges

We predict remote edges the same way as the matrix multiplication decoder for primary edges. We use a different BiLSTM encoder to learn representations and avoid confusion between attention to primary edges and remote edges.

	unlabeled(F1)	labeled(F1)
official	0.746	0.866
+ max_recur = 7	0.747	0.867
+ child_pred	0.760	0.87
+ $\beta_2 = 0.9$	0.762	0.87
+ bug_fix	**0.769**	**0.873**

Table 1: F1 score on primary edges evaluated on the development set

4 Training and Inference

During training, $node_i$ attends to the left most child of its primary parent ($node_p$) recursively until $node_p$ is not the left most child of $node_p$'s parent. Because a span representation contains information from both left to right and right to left, $node_i$ with the highest attention score not only contains the embedding of its terminal node, but also the span between index i and j in the text. We use cross entropy loss to jointly train for embeddings, the BiLSTM encoder, and the decoder.

For inference, we take the output of each token in the text from the BiLSTM encoder as input and create a non-terminal node for each terminal node. We create a new node when the token embedding attends to a different token outside of the current span boundary. The recurrence algorithm for each newly created non-terminal node shown in Algorithm 1 is applied.

5 Experiments

For the encoder, we use a 2-layer, 500 dimensional BiLSTM with 0.2 dropout. The word embedding size is 300 with feature embedding size of 20 each (pos tagging, entity type, and case information). We use Adam optimizer (Kingma and Ba, 2014) with β_2 set to 0.9 as suggested by Dozat and Manning (2016). Development set is used for early stopping. Because of the small dataset (4113 training sentences), the model overfits after 4 epochs.

6 Results

Table 1 provides the results on the development set and Table 2 shows the results on the test set. *official* shows results of the model we submitted to the competition with a maximum recursion number of 5 and a $\beta_2 = 0.99$. We obtained higher scores by increasing the recursion limit as in section 3.3 (+ max_revur = 7), using current span only

	primary		remote	
	unlabeled	labeled	unlabeled	labeled
baseline	0.733	0.858	**0.472**	**0.484**
official	0.73	**0.864**	-	-
final	**0.753**	**0.864**	0.447	0.447

Table 2: F1 score on primary and remote edges reported on the test set

as explained in section 3.4 (+ child_pred), changing β_2 as shown in section 5 (+ $\beta_2 = 0.9$) and fixing minor bugs (+ bug_fix) incrementally. *baseline* shows the results of the baseline model (TUPA) from Hershcovich et al. (2017). *final* shows the results of the model fine-tuned on the development set mentioned in Table 1.

Since there are normally 0 or 1 remote edges in each sentence in the training corpus, the remote edge prediction model is not as effective. Still, the model captures some remote relations. For example, in the sentence "Additionally, Carey's newly slimmed Figure began to change, as she stopped her exercise routines and gained weight", the node "gained weight" is predicted to point to "Carey" where the target annotated remote child is "she". Discontinuous unit prediction also suffers from the problem of insufficient training samples.

7 Conclusion

This paper describes the system that the UC Davis team submitted to SemEval 2019 Task 1. We propose a recursive self-attention decoder with a simple architecture. Our model is effective in UCCA semantic parsing, ranking third in the close track in-domain task with modest fine-tuning, highlighting the suitability of our approach.

Abstract

We present our system for semantic frame induction that showed the best performance in Subtask B.1 and finished as the runner-up in Subtask A of the SemEval 2019 Task 2 on unsupervised semantic frame induction (QasemiZadeh et al., 2019). Our approach separates this task into two independent steps: verb clustering using word and their context embeddings and role labeling by combining these embeddings with syntactical features. A simple combination of these steps shows very competitive results and can be extended to process other datasets and languages.

1 Introduction

Recent years have seen a lot of interest in computational models of frame semantics, with the availability of annotated sources like PropBank (Palmer et al., 2005) and FrameNet (Baker et al., 1998). Unfortunately, such annotated resources are very scarce due to their language and domain specificity. Consequently, there has been work that investigated methods for unsupervised frame acquisition and parsing (Lang and Lapata, 2010; Modi et al., 2012; Kallmeyer et al., 2018; Ustalov et al., 2018). Researchers have used different approaches to induce frames, including clustering verb-specific arguments as per their roles (Lang and Lapata, 2010), subject-verb-object triples (Ustalov et al., 2018), syntactic dependency representation using dependency formats like CoNLL (Modi et al., 2012; Titov and Klementiev, 2012), and latent-variable PCFG models (Kallmeyer et al., 2018).

The SemEval 2019 task of semantic frame and role induction consists of three subtasks: (A) learning the frame type of the highlighted verb from the context in which it has been used; (B.1) clustering the highlighted arguments of the verb into specific roles as per the frame type of that verb, e.g., *Buyer*, *Goods*, etc.; (B.2) clustering the arguments into generic roles as per VerbNet classes (Schuler, 2005), without considering the frame type of the verb, i.e., *Agent*, *Theme*, etc.

Our approach to frame induction is similar to the word sense induction approach by Arefyev et al. (2018), which uses tf–idf-weighted context word embeddings for a shared task on word sense induction by Panchenko et al. (2018). In this unsupervised task, our approach for clustering mainly consists of exploring the effectiveness of already available pre-trained models.[1] Main contributions of this paper are:

1. a method that uses contextualized distributional word representations (embeddings) for grouping verbs to frame type clusters (Subtask A);

2. a method that combines word and context embeddings for clustering arguments of verbs to frame slots (Subtasks B.1 and B.2).

The key difference of our approach with respect to prior work by Arefyev et al. (2018) and Kallmeyer et al. (2018) is that we have only used pre-trained embeddings to disambiguate the verb senses and then combined these embeddings with additional features for semantic labeling of the verb roles.[2]

[1]HHMM is an abbreviation for Hansestadt Hamburg, Mannheim, and Moscow. It is chosen to avoid confusion with hidden Markov models.

[2]Our code is available at `https://github.com/uhh-lt/semeval2019-hhmm`.

The remainder of the paper is organized as follows. The methodology and the results for each subtask are discussed in Sections 2, 3 and 4 respectively, followed by the conclusion in Section 5.

2 Subtask A: Grouping Verbs to Frame Type Clusters

In this subtask, each sentence has a highlighted verb, which is usually the predicate. The goal is to label each highlighted verb according to the frame evoked by the sentence. The gold standard for this subtask is based on the FrameNet (Baker et al., 1998) definitions for frames.

2.1 Method

Since sentences evoking the same frame should receive the same labels, we used a verb clustering approach and experimented with a number of pre-trained word and sentence embeddings models, namely Word2Vec (Mikolov et al., 2013), ELMo (Peters et al., 2018), Universal Sentence Embeddings (Conneau et al., 2017), and fastText (Bojanowski et al., 2017). This setup is similar to treating the frame induction task as a word sense disambiguation task (Brown et al., 2011).

We experimented with embedding different lexical units, such as verb (V), its sentence (context, C), subject-verb-object (SVO) triples, and verb arguments. Combination of context and word representations (C+W) from Word2Vec and ELMo turned out to be the best combination in our case.

We used the standard Google News Word2Vec embedding model by Mikolov et al. (2013). Since this model is trained on individual words only and the SemEval dataset contained phrasal verbs, such as *fall back* and *buy out*, we have considered only the first word in the phrase. If this word is not present in the model vocabulary, we fall back to a zero-filled vector. When aggregating a context into a vector, we used the tf–idf-weighted average of the word embeddings for this context as proposed by Arefyev et al. (2018). We tuned these weights on the development dataset.

We used the ELMo contextualized embedding model by Peters et al. (2018) that generates vectors of a whole context. Similarly to fastText (Bojanowski et al., 2017), ELMo can produce character-level word representations to handle out-of-vocabulary words. In all our experiments we used the same pre-trained ELMo model available on TensorFlow Hub.[3] Among all the layers of this model, we used the mean-pooling layer for word and context embeddings.

2.2 Results and Discussion

We experimented with different clustering algorithms provided by scikit-learn (Pedregosa et al., 2011), namely agglomerative clustering, DBSCAN, and affinity propagation. After the model selection on the development dataset, we have chosen agglomerative clustering for further evaluation. Although both ELMo and Word2Vec showed the best results on the development dataset with single linkage, we opted average linkage after analyzing t-SNE plots (van der Maaten and Hinton, 2008).

Table 1 shows our results obtained on Subtask A. Our final submission (🔥) used agglomerative clustering of normalized vectors obtained by concatenating the context and verb vectors from the Word2Vec model. In particular, we found that the best performance is attained for Manhattan affinity and 150 clusters. During our post-competition experiments (⌛), we found that ELMo performed better than Word2Vec when a higher number of clusters, 235, was specified.

3 Subtask B.1: Clustering Arguments of Verbs to Frame-Specific Slots

In this subtask, each sentence has a set of highlighted nouns or noun phrases corresponding to the slots of the evoked frame. Additionally, each sentence is provided with the same highlighted verb as in Subtask A (Section 2). The goal is to label each highlighted verb according to the evoked frame and to assign each highlighted to-

ken a frame-specific semantic role identifier. The gold standard for this subtask is annotated with FrameNet frames and roles (Baker et al., 1998).

3.1 Method

Since Subtask B.1 asks to assign role labels to highlighted tokens as per the frame type of the verb, we attempted this by merging the output of verb frame types from Subtask A (Section 2) and the output of generic role labels from Subtask B.2 (Section 4). We used `UKN` (unknown) slot identifier for the tokens present in Subtask B.1, but missing in Subtask B.2.

3.2 Results and Discussion

Table 2 shows the results from merging our solutions for Subtasks A and B.2, as described in Sections 2 and 4, correspondingly. For our final submission (🔥), we merged the frame types obtained by clustering the Word2Vec embeddings of the sentence (context, C) and verb (word, W), and the role labels obtained by clustering the vector of inbound dependencies (ID). However, we observed that the logistic regression model demonstrated better performance in Subtask B.2 than any clustering technique we tried, including our final submission (🔥) and the baselines. But this performance was further improved by combining the results from post-competition experiments of Subtask A and Subtask B.2 (⌛).

4 Subtask B.2: Clustering Arguments of Verbs to Generic Roles

In Subtask B.2, similarly to Subtask B.1 (Section 3), each sentence has a set of highlighted nouns or noun phrases that correspond to the slots of the evoked frame. The goal is to label each highlighted token with a high-level generic class, such as *Agent* or *Patient*. However, unlike Subtask B.1, the verb frame labeling part is omitted. The gold standard for this subtask is annotated as according to the VerbNet classes (Schuler, 2005).

4.1 Method

When addressing this subtask, we experimented with combining the embeddings of the word (W) filling the role, its sentence (context, C), and the highlighted verb (V). To handle the out-of-vocabulary roles in the case of Word2Vec embeddings, each role was tokenized and embeddings for each token were averaged. If a token is still not present in the vocabulary, then a zero-filled vector was used as its embedding. During prototyping we developed several features that improved the performance score, namely *inbound dependencies* (ID), which represent the dependency label from the head to the role (dependent) and two trivial baselines: *Boolean* (B) and *123*.

We built a negative one-hot encoding feature vector to represent the *inbound* dependencies of the word corresponding to the role. Thus, for each dependency of the given role (in case of a multiword expression), we fill `-1` if the dependency relationship holds, otherwise `0` is filled. During our experiments for the development test, we also used the outbound dependencies, which represent the dependency label from the role (head) to the dependent words. So we used `-1` for inbound and `1` for outbound. But since they did not perform well in comparison to inbound dependencies, they were not considered for submitted runs.

For the *Boolean* baseline, given the position of the verb in the sentence p_v and the position of the target token p_t, we assign the role `0` to t if $p_v < p_t$, otherwise `1`. For the *123* baseline, we assign its index to each highlighted slot filler. For example, if five slots need to be labelled, the first one will be labelled as `1` and the last one will be labelled as `5`.

4.2 Results and Discussion

Table 3 shows our results on Subtask B.2. We found that the trivial Boolean approach outper-

🏆	Winner	64.16	45.65

Table 3: Our results on Subtask B.2: Clustering Arguments of Verbs to Generic Roles. Purity F_1-score is denoted as *Pu F_1*, B-Cubed F_1-score is denoted as *B^3 F_1*. 🔥 denotes *our* final submission (# 535480), ⚡ denotes a supervised *Logistic Regression* submission that does not comply to the task rules, ⌛ denotes *our* post-competition result, ⏲ denotes a baseline, and 🏆 denotes the submission of the winning team.

formed LPCFG (Kallmeyer et al., 2018) and all the standard baselines, including cluster per dependency role (`OneClustPerGrType`), on the development dataset.[4]

Similarly to our solution for Subtask A (Section 2), we tried different clustering algorithms to cluster arguments of verbs to generic roles and found that the best clustering performance is shown by agglomerative clustering with Euclidean affinity, Ward's method linkage, and two clusters. Our final submission (🔥) used the combination of inbound dependencies and Word2Vec embedding for sentence (context, C), which performed marginally better than the cluster per dependency role (`OneClustPerGrType`) baseline, but still not better than such trivial baselines as *Boolean* or 123. Replacing Word2Vec with ELMo in our post-competition experiments have lowered the performance further.

In order to estimate our upper bound of the performance, we compared our best-performing clustering algorithm, i.e., agglomerative clustering, to a logistic regression model. We found that the combination of sentence (context, C), target word (W), and verb (V) vectors, enhanced with our other features, shows substantially better results than a simple clustering model (⚡). However, we did not observe a noticeable difference between the performance of the underlying embedding models.

[4]On the development dataset for Subtask B.2, the *Boolean* baseline demonstrated B-Cubed $F_1 = 57.98$, while LPCFG and cluster per dependency role yielded $F_1 = 40.05$ and $F_1 = 50.79$, correspondingly.

As the model was trained on the development dataset that contained 20 roles in contrast to the test set which contained 32 roles, this approach has its limitations due to this difference of the number and meaning of roles. We believe that the performance could be improved using semi-supervised clustering methods, yet during prototyping with the pairwise-constrained k-Means algorithm (Basu et al., 2004) we did not observe any performance improvements.

5 Conclusion

We presented an approach for unsupervised semantic frame and role induction that uses word and context embeddings. It separates the task into two independent steps: verb clustering and role labelling, using combination of these embeddings enhanced with syntactical features. Our approach showed the best performance in Subtask B.1 and also finished as the runner-up in Subtask A of this shared task, and it can be easily extended to process other datasets and languages.

Acknowledgments

We acknowledge the support of the Deutsche Forschungsgemeinschaft (DFG) under the "JOIN-T" and "ACQuA" projects and the German Academic Exchange Service (DAAD). We thank the SemEval organizers for an inspiring shared task and their quick responses to all our questions. We are grateful to four anonymous reviewers who offered useful comments. Finally, we thank the Linguistic Data Consortium (LDC) for the provided Penn Treebank dataset (Marcus et al., 1993).

Abstract

Building large datasets annotated with semantic information, such as FrameNet, is an expensive process. Consequently, such resources are unavailable for many languages and specific domains. This problem can be alleviated by using unsupervised approaches to induce the frames evoked by a collection of documents. That is the objective of the second task of SemEval 2019, which comprises three subtasks: clustering of verbs that evoke the same frame and clustering of arguments into both frame-specific slots and semantic roles.

We approach all the subtasks by applying a graph clustering algorithm on contextualized embedding representations of the verbs and arguments. Using such representations is appropriate in the context of this task, since they provide cues for word-sense disambiguation. Thus, they can be used to identify different frames evoked by the same words. Using this approach we were able to outperform all of the baselines reported for the task on the test set in terms of Purity F_1, as well as in terms of BCubed F_1 in most cases.

1 Introduction

The Frame Semantics theory of language (Fillmore, 1976) states that one cannot understand the meaning of a word without knowing the context surrounding it. That is, a word may evoke different semantic frames depending on its context. Considering this relation, sets of frame definitions and annotated datasets that map text into the semantic frames it evokes are important resources for multiple Natural Language Processing (NLP) tasks (Shen and Lapata, 2007; Aharon et al., 2010; Das et al., 2014). The most prominent of such resources is the FrameNet (Baker et al., 1998), which provides a set of more than 1,200 generic semantic frames, as well as over 200,000 annotated sentences in English. However, this kind of resource is expensive and time-consuming to build, since both the definition of the frames and the annotation of sentences require expertise in the underlying knowledge. Furthermore, it is difficult to decide both the granularity and the domains to consider while defining the frames. Consequently, such resources only exist for a reduced amount of languages (Boas, 2009) and even English lacks domain-specific resources in multiple domains.

The problem of building semantic frame resources can be alleviated by using unsupervised approaches to induce the frames evoked by a collection of documents. The second task of SemEval 2019 aims at comparing unsupervised frame induction systems for building semantic frame resources for verbs and their arguments (Qasemi Zadeh et al., 2019). It is split into three subtasks. The first, Task A, focuses on clustering instances of verbs according to the semantic frame they evoke while the others focus on clustering the arguments of those verbs, both according to the frame-specific slots they fill, on Task B.1, and their semantic role, on Task B.2.

In this paper, we address the three subtasks by following an approach that takes advantage of the recent developments on the generation of contextualized word representations (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018). Such representations are able to disambiguate different word senses by varying the position of a word in the embedding space according to its context. This ability is important in the context of semantic frame induction, since different word-senses typically evoke different frames. To identify words that evoke the same frame or have the same role, our approach consists of clustering their representations by applying the Chinese Whispers algorithm (Biemann, 2006) to a similarity-based graph. This way, we do not need to define the number of clusters and there is no bias towards the generation of clusters of similar size.

In the remainder of the paper, we start by providing an overview of previous studies related to the task, in Section 2. Then, in Section 3, we describe our approach and explain how it differs from previous approaches. Section 4 describes our experimental setup. The results of our experiments are presented and discussed in Section 5. Finally, Section 6 summarizes the conclusions of our work and provides pointers for future work.

2 Related Work

Following the motivation described in the previous section, previous studies have employed unsupervised approaches for the induction of semantic frames and roles. However, most studies have focused on semantic role induction. For instance, Titov and Klementiev (2012) proposed two models based on the Chinese Restaurant Process (Ferguson, 1973). The factored model induces semantic roles for each predicate independently using an iterative clustering approach, starting with one cluster per argument. On the other hand, the coupled model takes into consideration a distance-dependent prior shared among different predicates. Arguments from different predicates are then used as vertices of a similarity graph and each argument selects another argument as a member of the same cluster based on that similarity. Overall, the coupled model performs slightly better than the factored one. In both cases, each argument is represented by a set of syntactic features – sentence voice, argument position, syntactic relation, and existing prepositions.

Lang and Lapata (2014) proposed a graph partitioning approach over a multilayer graph. Each layer corresponds to a feature, i.e., each pair of vertices (arguments) is connected through multiple edges, each corresponding to their similarity according to that feature. Then, two clustering approaches were considered, achieving similar results. The first is an adaptation of agglomerative clustering to the multilayer setting. Instead of combining the similarity values into a single score, it clusters the arguments in each layer and then combines the obtained scores into a multilayer score. Clusters with greater multilayer similarity are then merged together, with larger clusters being prioritized. The second clustering approach consists of propagating cluster membership along the graph edges. In both cases, the combination of the scores of each layer is based on a set of conditions, in order to avoid having to learn or guess weights for each feature.

In contrast to the previous approaches, Titov and Khoddam (2015) proposed a reconstruction-error maximization framework which comprises two main components: an auto-encoder, responsible for labeling arguments with induced roles, and a reconstruction model, which takes the induced roles and predicts the argument that fills each role, i.e., it tries to reconstruct the input. The learning error is obtained by comparing the reconstructed argument to the original one. This enables the use of a larger feature set and more complex features, similarly to supervised approaches.

Concerning frame induction, Ustalov et al. (2018a) proposed a graph-based approach for the triclustering of Subject-Verb-Object (SVO) triples extracted using a dependency parser. Each vertex in the graph is the SVO triple, represented by the concatenation of word embeddings for the three elements. Vertices are connected to their k-nearest neighbours (k=10) according to their cosine similarity. The clusters are then generated using the Watset fuzzy graph clustering algorithm (Ustalov et al., 2017), which induces word-sense information in the graph before clustering. For each cluster, the corresponding triframe is generated by aggregating the subjects, verbs, and objects into separate sets and generating a triple using those sets. This approach outperformed hard clustering approaches, as well as topic-based approaches, such as LDA-Frames (Materna, 2012).

3 Induction Approach

Considering the subtasks we are approaching, we must use an approach that is able to induce not only semantic roles, but also semantic frames and its slots. In this sense, of the approaches described in the previous section, the triclustering approach proposed by Ustalov et al. (2018a) is the only one able to induce frames. However, in the context of our task, it has two major flaws. First, it focuses on the clustering of SVO triples, i.e., a frame is defined by a head and two slots. In our case, each instance has a variable number of arguments. Thus, the triclustering approach is not appropriate. Furthermore, since the arguments are clustered in combination with the verb, this approach is particularly inappropriate for semantic role induction. The second flaw is related to the approach used for inducing word-sense information, which requires a thesaurus to provide synonymity information. Such resources must be manually built and, thus, may not be available for every language or lack domain-specific information.

We approach the first flaw by clustering the verb and its arguments independently. This way, we are able to cluster the instances of verbs to identify the frame heads, as required for Task A, and the instances of arguments to identify semantic roles, as required for Task B.2. To identify the slots of each frame, as required for Task B.1, we combine the clusters of the verbs with those of the arguments.

To deal with the second flaw, we replace the per-word embeddings used by Ustalov et al. (2018a) with contextualized word representations. These include information concerning the context in which a word appears and, thus, the position of a word in the embedding space varies according to that context. By using such representations, we are able to discard the fuzzy clustering approach used by Ustalov et al. (2018a) to induce word-sense, since it is revealed by the contextual variations of the representation of a word. Therefore, a hard clustering algorithm can be applied directly.

Algorithm 1 Induction Approach

```
Input: $T$ // The set of head tokens to cluster
Input: EMBED // The contextualized embedding approach
Input: THRESH // The function for computing the neighboring threshold
Output: $C$ // The set of clusters
1: $V \leftarrow \{\text{EMBED}(t) : t \in T\}$ // The whole sentence is required for embedding generation
2: $D \leftarrow \{1 - \cos(\theta_{v,v'}) : (v, v') \in V^2, v \neq v'\}$ // $\theta_{v,v'}$ is the angle between the two vectors
3: $t \leftarrow \text{THRESH}(D)$
4: $E \leftarrow \{(v, v', D_{v,v'}) : (v, v') \in V^2, v \neq v', D_{v,v'} < t\}$ // The edge is weighted with the cosine distance between the vertices
5: $C \leftarrow \text{CHINESEWHISPERS}(V, E)$
6: return $C$
```

Our approach is summarized in Algorithm 1. It starts by generating the contextualized representation of each instance to be clustered. In cases where the verb or argument to cluster consists of multiple words, we use a dependency parser to identify the head word and use its contextualized representation, since it contains information from the other words. Then, in order to build a graph, we compute the pairwise distances between the instances. These distances are used to decide which instances are considered neighbors. Since each instance is represented as a vector in the embedding space, we use the cosine distance. Moreover, since using a fixed number of neighbors is not realistic, we decided to use a threshold based on this distance. This threshold defines the granularity of the clusters and varies according to the set of instances. Instead of using a fixed threshold, we define it based on the parameters of the pairwise distances distribution. The actual combination of the parameters varies according to the subtask and is further discussed in the subsections below. Finally, to obtain the clusters, we apply the Chinese Whispers algorithm (Biemann, 2006) on a graph where the vertices are the instances and the edges connect neighbor instances. The weight of each edge is given by the distance between neighbors. We use the Chinese Whispers algorithm since it chooses the number of clusters on its own and is able to handle clusters of different sizes, thus being appropriate for the task. Furthermore, it has been proved successful in NLP clustering tasks.

3.1 Verb Clustering

The first subtask focuses on clustering verbs that evoke the same frame. The number of frames evoked in a set of documents is typically larger than the number of semantic roles and even larger in comparison to the number of slots per frame. Thus, a lower neighboring threshold is required to achieve such granularity. In our experiments, we achieved the best results when defining the neighboring threshold for clustering verbs, t_f, as

$$t_f = \frac{\mu + \sigma}{2}, \tag{1}$$

where μ and σ are the mean and standard deviation of the pairwise distance distribution, respectively. Using this threshold may lead to the induction of frames with different granularity, depending on the sense similarity between the verbs present in the dataset. However, if the induced frames are considered too abstract, the approach can be applied hierarchically on the instances of each cluster to obtain finer-grained frames.

3.2 Argument Clustering

Both the second and third subtasks focus on clustering arguments. However, while the second focuses on doing so in a per-frame manner to induce its slots (frame elements), the third focuses on clustering them independently of the frame, i.e., to induce generic semantic roles. In the first case it would make sense to cluster the arguments of verbs that evoke each frame independently of the others. However, that may not be feasible on small datasets. Thus, we opted for clustering all the arguments together in both cases. The slot clusters for the second subtask are then given by the combination of the verb and argument clusters. Thus, this approach considers that slots are per-frame specializations of the semantic roles, which is accurate in most situations.

As previously stated, the number of semantic roles is typically smaller than the number of frames. Thus, a higher neighboring threshold can be used. In our experiments, we achieved the best results when defining the neighboring threshold while clustering arguments, t_a, as

$$t_a = \mu - 1.5\sigma. \qquad (2)$$

Finally, since the arguments are highly dependent on the verb, we also performed experiments in which we combined the contextualized representation of the argument with that of the verb before applying the clustering approach.

4 Experimental Setup

In this section we describe our experimental setup in terms of data, implementation details, and evaluation metrics and baselines.

4.1 Dataset

In our experiments, we used the dataset provided by the task organization, built with sentences from the Penn Treebank 3.0 (Marcus et al., 1993), and annotated with FrameNet frames (Task A), frame elements or slots (Task B.1) and generic semantic roles (Task B.2). The development set consists of 600 verb-argument instances, 588 sentences and 1,211 arguments. The (blind) test set comprises 4,620 verb-argument instances, 3,346 sentences, 9,466 arguments labeled for semantic role and 9,510 arguments labeled for frame slot. Additionally, morphosyntactic information is provided in the CoNLL-U format (Buchholz and Marsi, 2006).

4.2 Implementation Details[1]

In our experiments we compared the performance of two approaches to generate the contextualized word representations. The first, ELMo (Peters et al., 2018), is based on bi-directional LSTMs (Hochreiter and Schmidhuber, 1997) and was the first approach to generate contextualized representations. Its output provides a context-free representation of the word and context information at two levels. In our experiments we use the sum of all information, since it leads to variations of the context-free representation according to the context. The second representation, BERT (Devlin et al., 2018), is based on the Transformer architecture (Vaswani et al., 2017) and currently leads to state-of-the-art results on multiple benchmark NLP tasks. Its output can be extracted from a single layer or the multiple layers included in the model. Contrarily to the ELMo layers, these do not have an associated semantics. Thus, we use the output of the last layer, since it contains information from all that precede it. In both cases we used pre-trained models. To obtain embedding vectors with the same dimensionality, 1,024, we used the ELMo model provided by the AllenNLP package (Gardner et al., 2017) and the large uncased BERT model provided by its authors.

To apply the Chinese Whispers algorithm, we relied on the implementation by Ustalov et al. (2018b), which requires the graph to be built using the NetworkX package (Hagberg et al., 2004). We did not use weight regularization and performed a maximum of 20 iterations. Furthermore, in order to avoid result changes based on non-deterministic factors, we fixed the random seed as 1337.

Finally, to obtain the syntactic dependencies used to determine the head token of multi-word verbs or arguments, we used the annotations provided with the task dataset.

4.3 Baselines

For comparison purposes, in addition to our results, we report the baselines provided by the task scorer. For the frame induction subtask (Task A), the baseline consists of assigning each verb lemma to a frame (*Lemma*). For the semantic role induction subtask (Task B.2), arguments are assigned to clusters according to their syntactic relation to the head verb (*Dep*). For the frame slot induction subtask (Task B.1), the previous baselines are combined by assigning each pair of verb lemma and argument's syntactic dependency to a cluster (*Lemma + Dep*). On the test set, we also consider a random assignment to the gold number of clus-

ters as a baseline. Due to space constraints, we do not report the results of the remaining baselines proposed by Kallmeyer et al. (2018).

We report the results of an additional baseline for Task B.2 which considers both the argument's syntactic relation to the head verb and its Part-of-Speech (POS) tag (*Dep + POS*).

4.4 Evaluation metrics

We report our results using the metrics defined for the task: number of clusters (*#C*), purity, inverse-purity, and their harmonic mean (Purity F_1), as proposed by Steinbach et al. (2000), and BCubed (B^3) precision, recall, and F_1, as proposed by Bagga and Baldwin (1998).

5 Results

The results obtained on the development set are reported in Table 1. We can see that using ELMo to obtain the contextualized word representations leads to better results than BERT on every subtask. This is somewhat surprising since BERT is the state-of-the-art approach to generate contextualized representations. A possible explanation may lie in the fact that the two levels of ELMo which provide context information can be related to syntax and semantics (Peters et al., 2018), making them highly related to the task. On the other hand, the information provided by BERT representations is not as easy to categorize. Moreover, in every case, the number of clusters is underestimated when using ELMo and overestimated when using BERT.

On the frame induction subtask (Task A), our approach surpasses every baseline, but only when using ELMo embeddings. The lemma baseline is surpassed by over 5 percentage points on Purity F_1 and 7.5 on BCubed F_1. The same is not true on the other tasks, with the clustering based on the dependency relation between the argument and verb achieving the best results. It outperforms our approach in terms of both F_1 metrics by around 6.5 percentage points on the slot induction subtask (Task B.1) and around 4 points on the semantic role induction subtask (Task B.2). We believe that this happens because the development set is small and the kind of arguments does not vary much.

Combining the verb representation with that of the argument leads to worse results on Task B.2, since it is clustering the semantic roles per verb. On Task B.1, the result is the same as without using the verb representation, which suggests that the information provided by the verb is not able to improve the induced slots, but only to attribute them to the corresponding frame.

The approach which combines the dependency relation with the POS tag obtains worse results on Task B.2, as it leads to additional partitioning of the clusters. Thus, a large number of clusters is generated, which is not consistent with the nature of semantic roles.

The results obtained on the test set are reported in Table 2. We only submitted the clusters obtained using ELMo, since it outperformed BERT on the development set. Similarly, we did not consider the combination of verb and argument representation for the argument clustering tasks. However, we assessed the performance of the baseline based on the dependency relation and the POS tag.

On Task A, our approach surpasses all the baselines in terms of Purity F_1, but by less than 2 percentage points. In fact, it has a similar perfor-

	Approach	#C	Purity	inv-Purity	Purity F_1	B^3 Precision	B^3 Recall	B^3 F_1
Task A	**ELMo**	222	72.84	77.84	**75.25**	61.25	69.96	65.32
	BL: Lemma	273	82.16	66.95	73.78	75.98	57.33	**65.35**
	BL: Random	**149**	15.30	5.74	8.34	6.82	3.85	4.92
Task B.1	**ELMo**	526	58.26	64.30	**61.13**	44.79	53.21	**48.64**
	BL: Lemma + Dep	1203	78.46	45.99	57.99	71.11	33.77	45.79
	BL: Random	**436**	11.25	6.09	7.90	6.07	4.82	5.37
Task B.2	**ELMo**	6	58.29	71.19	**64.10**	36.80	60.15	**45.66**
	Dep + PoS	159	57.39	26.25	36.03	41.41	15.07	22.1
	BL: Dep	37	61.44	51.53	56.05	40.89	37.33	39.03
	BL: Random	**32**	34.77	4.85	8.51	21.92	3.46	5.98

Table 2: Results obtained on the test set. The baselines are identified with *BL*.

mance to the lemma baseline in terms of BCubed F_1. This happens because it overestimates the number of clusters, which suggests that the problem may be related to the threshold. However, using a threshold that leads to the induction of a number of frames similar to the gold standard ends up generating clusters of lower quality. This suggests that additional features must be introduced.

On the remaining tasks, our approach performs better than every baseline, which supports the claim that the better performance of the clustering approach based on the dependency relation on the development set is due to the limited variation in the kinds of argument present in that set. We observed an improvement of around 4 percentage points on Task B.1 on both F_1 metrics, and above 8 percentage points on Purity F_1 and nearly 7 on BCubed F_1 on Task B.2.

Once again, the approach which combines the dependency relation with the POS tag leads to worse results on Task B.2, due to additional partitioning of the clusters. In this case, the number of semantic roles is even more overestimated.

6 Conclusions

In this paper we presented our approach on unsupervised semantic frame, slot, and role induction in the context of the second task of SemEval 2019. The approach is based on the clustering of contextualized word representations of verbs and arguments. Using such representations is appropriate for the task since they provide word-sense information which is important for distinguishing the evoked frames.

We were able to achieve results that surpassed or performed on par with every baseline proposed for the three subtasks on the test set. However, the results are far from perfect and below those achieved by more complex approaches on the task, which suggests that the contextualized representations on their own are not able to provide all the information required to perform an accurate frame induction. Thus, as future work, we intend to assess the cases that our approach fails to cluster, and introduce additional features that provide relevant information for those cases, either by using a weighted combination of per-feature distance functions or a multilayer graph similar to that proposed by Lang and Lapata (2014).

Furthermore, since the number of instances in the test set is larger than in the development set, it may be feasible to apply a per-frame clustering approach for the slot induction task. This way, the induced slots are no longer mere specifications of the generic semantic roles.

Finally, although the number of semantic roles is not consensual in the literature, there is a set of core semantic roles which is common to every theory. Thus, it would be interesting to take advantage of that information to apply clustering approaches with a pre-defined number of clusters for semantic role induction. In fact, it would be interesting to explore other clustering approaches on every task and compare their performance with that of the Chinese Whispers algorithm.

BrainEE at SemEval-2019 Task 3: Ensembling Linear Classifiers for Emotion Prediction

Vachagan Gratian
Universität Stuttgart
vgratian@utopianlab.am

Abstract

We present a homogeneous ensemble of linear perceptrons trained for emotion classification as part of the SemEval-2019 shared-task 3. The model uses a matrix of probabilities to weight the activations of the base-classifiers and makes a final prediction using the *sum rule*. The base-classifiers are multi-class perceptrons utilizing character and word n-grams, part-of-speech tags and sentiment polarity scores. The results of our experiments indicate that the ensemble outperforms the base-classifiers, but only marginally. In the best scenario our model attains an F-Micro score[1] of 0.672, whereas the base-classifiers attained scores ranging from 0.636 to 0.666.

1 Introduction

Our task is to detect emotions in multi-turn chat messages (see examples in table 1). The four emotion categories the model has choose from are `happy, sad, angry` and `others`. A major caveat of the task is the imbalance of class distribution in the dataset, as described in 4.1. The dataset, as well as the task itself are described in detail in (Chatterjee et al., 2019).

We choose to deploy ensemble of linear classifiers for this task, rather than a single model for a number of reasons. Firstly, given the inherent ambiguity of emotions (Brainerd, 2018) we expect that ensembles are better suited for any emotion prediction task. Secondly, it has been shown that ensembles are more immune to overfitting in similar tasks (Dong and Han, 2004). And finally, a single model trained on a large number of feature sets, tend to perform significantly worse than an ensemble where each model is trained on a different subset (or combinations) of feature types.

[1]This is a custom F-Micro score. See more details under 4.3 Evaluation

Conversation	Emotion
A: Yes B: How so? A: Don't message me ever	angry
A: I am fine B: I am good how is ur week A: I am single	others

Table 1: Two samples from the dataset with *angry* and *others* respectively as gold labels.

For this purpose, we deploy *BrainT*, a multi-class perceptron model utilizing word n-grams and POS-tags, built and trained for implicit emotion detection in Tweets (Gratian and Haid, 2018). In the current scenario, we extend the feature sets of *BrainT* with character n-grams and Sentiment polarity scores. We combine $n = 11$ and $n = 5$ classifiers into an ensemble model where a final prediction is made based on the activations. Our model also calculates a matrix of probabilities used to weigh the input activations. Each element in the matrix is the probability of a given node making correct prediction for a given emotion class. In the initial experiments the nodes are trained on the full train data. In the second group of experiments, nodes are assigned a random subsets of the train data separately. We hope that this will promote diversity in the base-classifiers and boost the performance of the ensemble.

The results of our experiments indicate that in both cases the ensemble outperforms the base-classifiers, however only slightly. In the following sections we describe the architecture of the model, the actual results on the SemEval shared-task. Finally we suggest ways to maximize the effectiveness of ensemble models as ideas for future work.

2 Related Work

Ensemble learning aims at exploiting the ”shared knowledge” of multiple classifiers based on Statistical Learning theory. A theoretical analysis of ensemble learning using linear perceptrons, can be found in (Hara and Okada, 2005) and (Miyoshi et al., 2005). The authors demonstrate that the generalization error of ensemble learning depends on (hence, can be calculated from) two cosine measures: the similarity between the base-classifiers and the training data and the mutual similarity of the base-classifiers. In plain English, to maximize the performance of the ensemble model, we want to increase the accuracy of the base-classifiers but in such a way that we promote diversity in the base-classifiers.

A simple way of combining the base-classifiers is to take the average of their weights after training. A more common approach is to exploit the output activations using different techniques. In (Xia et al., 2011a) three such techniques are analyzed for sentiment classification: fixed combination, weighted combination and meta-classifier combination. The authors found fixed combination to be the weakest of all three, while weighted combination and meta-classifier added on average 3-4% improvement over the performance of the best base-classifier.

In our work, we deploy the weighted combination technique with the addition of a learned probability matrix, as described below.

3 The Model

3.1 Base-Classifiers

We use as base-classifier the linear perceptron model described in (Gratian and Haid, 2018) which reduces the task of multi-class prediction into $|Y|$ binary classification problems (where $|Y|$ is the number of emotion classes) following the ”one-against-all” approach described by Xia et al. (2011b).

The output of each base-classifier is a vector α of size $|Y|$ corresponding to the number of emotions. Before passing this vector to the ensemble model, each activation α_y is calibrated as follows:

$$\hat{\alpha}_y = \frac{\alpha_y}{\sum\limits_{\hat{y} \in Y} \alpha_{\hat{y}}}$$

By doing so, each $\hat{\alpha}_y$ can be treated as a confidence level of the node that the instance x_i expresses the emotion class y. The advantage of this approach is that even when the true emotion class is not the one predicted by the node (i.e., it is not the highest activation), it can still contribute to the true class being predicted by the ensemble if it has a positive value.

3.2 Ensemble

The ensemble model M represents a matrix of probabilities of size $n \times m$:

$$M = \begin{pmatrix} \varphi_{1,1} & \varphi_{1,2} & \cdots & \varphi_{1,m} \\ \varphi_{2,1} & \varphi_{2,2} & \cdots & \varphi_{2,m} \\ \vdots & \vdots & \ddots & \vdots \\ \varphi_{n,1} & \varphi_{n,2} & \cdots & \varphi_{n,m} \end{pmatrix}$$

The ij-th element of this matrix is the probability that i-th node’s prediction for j-th class is correct. This parameter is initialized to 1 and is learned during training as:

$$\varphi_{i,j} = \frac{|R_{ij}|}{|R_{ij}| + |R'_{ij}|}$$

where $|R_{ij}|$ and $|R'_{ij}|$ are respectively the correct and incorrect predictions of node i for class j during training. This probability value, thus, corresponds to the Precision metric.

The input of the model is a matrix of equal size: those are the activations of n nodes, each a vector of size m (or $|Y|$). We weigh these activations by the probabilities learned by the model by taking the Hadamard product of the two matrices. The final prediction is made by the ensemble following the *sum rule* as described by (Xia et al., 2011b). The predicted class $\hat{y}$ is the one that has the highest sum of weighted activations:

$$\hat{y} = \text{argmax}_{i=1}^{m} \sum_{j=1}^{n} \varphi_{i,j}\, \hat{a}_{i,j}$$

4 Experiments

4.1 Dataset

The dataset we use is provided by the SemEval2019 shared-task 3 and is described in detail by (Chatterjee et al., 2019). It contains a train set with 30,160 and a test set with 5,509 conversations. In both sets the emotion class *others* is disproportionately overrepresented. Moreover, there

Angry	Sad	Happy	Others	Total
5,506	5,463	4,243	14,948	30,160
18.3%	18.1%	14.1%	49.6%	100%

Table 2: Class distribution in the train dataset.

Angry	Sad	Happy	Others	Total
298	250	284	4,677	5,509
5.4%	4.5%	5.2%	84.9%	100%

Table 3: Class distribution in the test dataset.

is a significant difference between the class distributions in the train and test datasets as can be seen in tables 2 and 3 imposing an additional challenge for the classification task.

The evaluation metric of the shared task is a custom F-micro measure which takes only into account the three emotion classes (`happy`, `angry`, `sad`) and disregards the overrepresented class `others`.

4.2 Preprocessing

As in the previous experimental setup, we apply minimal preprocessing. We don't normalize tokens and don't filter stopwords as this proved to decrease system performance in our previous experiments. We treat the 3 turns in each conversation as one stream of tokens by concatenating them using the special token $\langle STOP \rangle$.

4.3 Features

Our feature types are word and character n-grams, as well as POS tags extracted with the NLTK part-of-speech tagger and polarity scores from the `Sentiment Classification using WSD` library [2].

The word n-grams include unigrams, bigrams, trigrams and tetragrams where one token is replaced with the placeholder $\langle SKIP \rangle$ tag as this feature type proved to be highly efficient in our previous experiments.

The list of feature types used in our experiments is in table 4.

4.4 Experimental Setup

We assign each node 2 to 4 feature types. In the preparatory stage of the experiments we train nodes with different combinations of the feature types and select the 11 highest ranking nodes. Table 6 lists these nodes.

[2]The library is free-software and is available online: `https://github.com/kevincobain2000/sentiment_classifier`

Feature Set	Description
1GR 2GR 3GR 4GR-S1	word n-grams
1CH 2CH 3CH	character n-grams
POS SENTA	Lexicon-based

Table 4: The feature types utilized by the base-classifiers.

	False Positives	False Negatives
Happy, Sad, Angry	0.8	1.5
Others	0.1	0.5

Table 5: Learning rates

To overcome overrepresantation of the class `others` we apply a lower learning rate for this class. We furthermore apply a higher learning rate for false negatives than false positives, since in the preparatory experiments all nodes showed a significantly lower Recall than Precision. Table 5 lists those learning rates.

Finally, we test the ensemble model in two experimental setups: *uniform learning* and *distributed learning*. In the first scenario, the entire train data is used to train the 11 nodes. Either all 11 node activations are passed to the ensemble or only those of the 5 highest performing nodes. In the second scenario, each node is assigned and trained on a random 50% subset of the train data.

For all our experiments we choose the number of epochs to be 60.

5 Results

5.1 Uniform Learning

In all of our experiments the ensemble performs only slightly better than the best performing node(s). The results of the experiment with uniform training are in Table 6. We observe that reducing the number of nodes from 11 to 5, decreases Precision of the ensemble, but increases Recall, however in both cases the difference is insignificant.

Node	Precision	Recall	F-micro
1GR_3GR_3CH_POS	0.604	0.672	0.636
2GR_4GR-S1_3CH_POS	0.627	0.675	0.65
2GR_4GR-S1_3CH	0.622	0.69	0.654
1GR_2GR	0.613	0.706	0.656
2GR_SENTA	0.661	0.661	0.661
2GR_3CH_SENTA	0.649	0.677	0.662
1GR_2GR_POS	0.632	0.695	0.662
1GR_2GR_SENTA	0.636	0.692	0.663

Table 7: Results for Exp 2 with 11 nodes and distributed training.

We also observe that while the ensemble outperforms the nodes in the F-micro measure, it has a lower Precision and Recall than at least one of the nodes.

5.2 Distributed Learning

In the second experiment each node is trained on a 50% random subset of the train data. We observe a drop in the performance of both the ensemble and the nodes, although the ensemble outperforms the nodes with a slightly larger margin.

Compared to the results of uniform learning, we see that the ensemble has roughly the same Precision, but a lower Recall. However when we compare the performance of the ensemble with the base-classifiers, we see that the ensemble now has now a higher Precision score than any of the nodes. This indicates that the ensemble benefits more from the "shared knowledge" of the base-classifiers.

6 Discussion

The goal of our experiments was to build an ensemble that makes better predictions than any of the base-classifiers individually. While the results of our experiments prove this to be a success, they also indicate that the ensemble exploits the strengths of the nodes weakly. For most of the emotion classes, the ensemble underperforms at least one of the nodes.

This disparity is especially vivid in the Recall measure. We presume that this due to the fact that the probabilities matrix learned by the model reflects only Precision, not Recall. As a future improvement to the model, we could adapt the probabilities to reflect Recall as well.

7 Future Work

In our future work we want to adopt a different approach to ensemble learning. Firstly, we think an important starting point should be a concrete estimation of the ensemble's upper bound performance given n base-classifiers. This can then serve as banchmark to evaluate the actual performance of an ensemble model. In most, if not all, real-world situations, the probability that a node n_i makes a correct prediction for an instance x_j will always be conditional to the probability of another node n_j. This means that the upper boundary of the ensemble model depends on the conditional probabilities of its nodes.

This implies that in our future work we will describe ensemble learning as the task to minimize joint entropy of the base-classifiers in addition to maximizing accuracy.

8 Conclusion

In this paper we describe an ensemble model trained for emotion classification. We evaluate our model on uniform and distributed learning of the train data. The results of the experiments indicate that while the model outperforms the strongest model, it benefits weakly from the strengths and variance of the base-classifiers.

Abstract

Detecting emotion from dialogue is a challenge that has not yet been extensively surveyed. One could consider the emotion of each dialogue turn to be independent, but in this paper, we introduce a hierarchical approach to classify emotion, hypothesizing that the current emotional state depends on previous latent emotions. We benchmark several feature-based classifiers using pre-trained word and emotion embeddings, state-of-the-art end-to-end neural network models, and Gaussian processes for automatic hyper-parameter search. In our experiments, hierarchical architectures consistently give significant improvements, and our best model achieves a 76.77% F1-score on the test set.

1 Introduction

Customer service can be challenging for both the givers and receivers of services, leading to emotions on both sides. Even human service-people who are trained to deal with such situations struggle to do so, partly because of their own emotions. Neither do automated systems succeed in such scenarios. *What if we could teach machines how to react under these emotionally stressful situations of dealing with angry customers?*

This paper represents work on the SemEval 2019 shared task (Chatterjee et al., 2019b), which aims to bring more research on teaching machines to be empathetic, specifically by contextual emotion detection in text. Given a textual dialogue with two turns of context, the system has to classify the emotion of the next utterance into one of the following emotion classes: Happy, Sad, Angry, or Others. The training dataset contains 15K records for emotion classes, and contains 15K records not belonging to any of the aforementioned emotion classes.

The most naive first step would be to recognize emotion from a given flattened sequence, which has been researched extensively despite the very abstract nature of emotion (Socher et al., 2013; Felbo et al., 2017a; McCann et al., 2017; Xu et al., 2018; Chatterjee et al., 2019a). However, these *flat* models do not work very well on dialogue data as we have to merely concatenate the turns and flatten the hierarchical information. Not only does the sequence get too long, but the hierarchy between sentences will also be destroyed (Hsu and Ku, 2018; Kim et al., 2018). We believe that the natural flow of emotion exists in dialogue, and using such hierarchical information will allow us to predict the last utterance's emotion better.

Naturally, the next step is to be able to detect emotion with a hierarchical structure. To the best of our knowledge, this task of extracting emotional knowledge in a hierarchical setting has not yet been extensively explored in the literature. Therefore, in this paper, we investigate this problem in depth with several strong hierarchical baselines and by using a large variety of pre-trained word embeddings.

2 Methodology

In this task, we focus on two main approaches: 1) feature-based and 2) end-to-end. The former compares several well-known pre-trained embeddings, including *GloVe* (Pennington et al., 2014), *ELMo* (Peters et al., 2018), and *BERT* (Devlin et al., 2018), as well as emotional embeddings. We combine these pre-trained features with a simple Logistic Regression (LR) and XGBoost (Chen and Guestrin, 2016) model as the classifier to compare their effectiveness. The latter approach is to train

*Equal contribution.

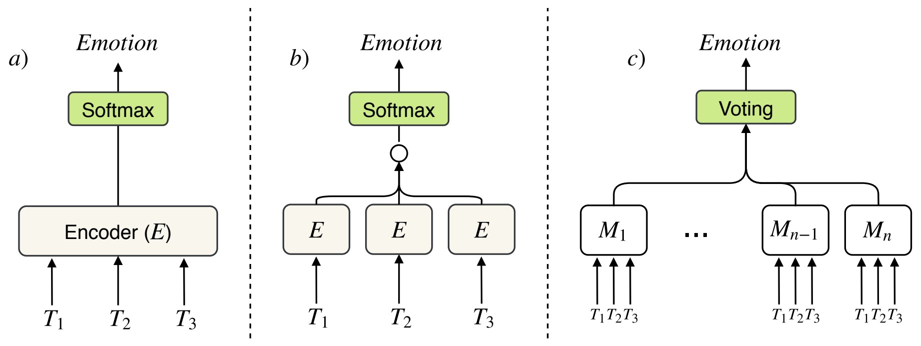

Figure 1: a) Flat model; b) Hierarchical model; c) Voting scheme

a model fully end-to-end with back-propagation. We mainly compare the performances of *flat* models and *hierarchical* models, which also take into account the sequential turn information of dialogues.

2.1 Feature-based Approach

The pre-trained feature-based approach can be subdivided into two categories: 1) word embeddings pre-trained only on semantic information, and 2) emotional embeddings that augment word embeddings with emotional or emoji information. We also examine the use of both categories.

Word Embeddings These include the standard pre-trained non-contextualized GloVe (Pennington et al., 2014), the contextualized embeddings from the bidirectional long short term memory (biLSTM) language model ELMo (Peters et al., 2018), and the more recent *transformer* based embeddings from the bidirectional language model BERT (Devlin et al., 2018).

Emotional Embeddings These refer to two types of features equipped with emotional knowledge. The first is a word-level emotional representation called Emo2Vec (Xu et al., 2018). It is trained with six different emotion-related tasks and has shown extraordinary performance over 18 different datasets. The second is a sentence-level emotional representation called DeepMoji (Felbo et al., 2017b), trained with a biLSTM with an attention model to predict emojis from text on a 1,246 million tweet corpus. Finally, we use Emoji2Vec (Eisner et al., 2016) which directly maps emojis to continuous representations.

2.2 End-to-End Approach

We consider four main models for the end-to-end approach: fine-tuning ELMo (Peters et al., 2018), fine-tuning BERT (Devlin et al., 2018), Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), and Universal Transformer (UTRS) (Dehghani et al., 2018).[1] In the latter model, we also run a Gaussian process for automatic hyper-parameter selection.

ELMo This model from Peters et al. (2018) is a deep contextualized embedding extracted from a pre-trained bidirectional language model that has shown state-of-the-art performance in several natural language processing (NLP) tasks.

BERT This is the state-of-the-art bidirectional pre-trained language model that has recently shown excellent performance in a wide range of NLP tasks. Here, we use $BERT_{BASE}$[2] as our sentence encoder. However, the original model failed to capture the emoji features due to the fact that all the emoji tokens are missing in the vocab. Therefore, we concatenate each sentence representation from BERT with bag of words *Emoji2Vec* (Eisner et al., 2016). Then, a UTRS is used as a context encoder to encode the whole sequence.

LSTM and Universal Transformer LSTM is the widely known model used almost ubiquitously in the literature, while UTRS is a recently published recurrent extension of the multi-head self-attention based model, Transformer from (Vaswani et al., 2017). Finally, for all models, we consider a hierarchical extension which considers the turn information as well. We add another instance of the same model to also encode sentence-level information on top of the word-level representations. We also apply word-level attention to

[1]We also tested Transformer, but had an overfitting issue
[2]We used a PyTorch implementation from https://github.com/huggingface/pytorch-pretrained-BERT

Table 1: The table shows the F1 score on LR and XGBoost.

Feature(s)	Classifier	F1
DeepMoji	LR	64.87
ELMo	LR	63.86
GLoVe	LR	55.11
Emo2Vec	LR	50.91
BERT	LR	44.51
Emoji2Vec	LR	30.45
ELMo + DeepMoji	**LR**	**65.63**
ELMo + Emo2Vec	LR	65.42
Emoji2Vec + GLoVe	LR	58.00
ELMo + DeepMoji	**XGBoost**	**69.86**

Table 2: The table shows F1 score on flat and hierarchical end-to-end models. GP denotes as Gaussian process.

Model	Flat	Hierarchical
LSTM	72.53	73.45
LSTM+GLoVe	**73.95**	**75.64**
LSTM+GLoVe+Emo2Vec	73.85	74.59
UTRS	72.41	74.06
ELMo	68.14	70.55
BERT	66.12	73.29

Table 3: The table shows F1 score on different ensemble models. XGB denotes XGBoost with ELMo and DeepMoji features. ALL denotes all ensemble models.

Model	F1
Ensemble$_1$ (3 HLSTMs)	76.08
Ensemble$_2$ (HBERT + HLSTM + HUTRS)	75.76
Ensemble$_3$ (HBERT + 3 HLSTMs + HUTRS)	76.26
Ensemble$_4$ (HBERT + 5 HLSTMs + HUTRS)	76.24
Ensemble$_5$ (HBERT + 5 HLSTMs + HUTRS)	76.20
Ensemble$_{final}$ (ALL + HLSTM + XGB)	**76.77**
- Angry	75.88
- Happy	73.65
- Sad	81.30

select the important information words on each dialogue turn.

3 Evaluation

In this section, we present the evaluation metrics used in the experiment, followed by results on feature-based, end-to-end, and ensemble approaches and Gaussian process search.

3.1 Training Details

Feature-Based For the feature-based approach, we run LR and XGBoost on features using the Scikit-Learn toolkit (Pedregosa et al., 2011) without any additional tuning.

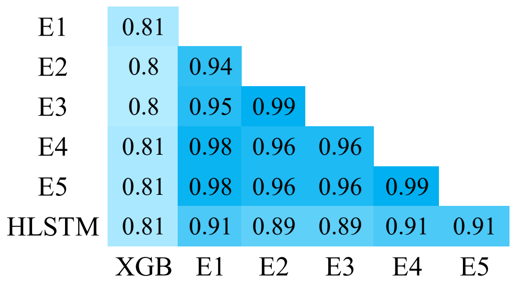

Figure 2: Pearson correlation matrix of a model to other models. E1–E5 denote ensemble models.

ELMo For the flat model, we pre-train ELMo by only fine-tuning the scalar-mix weights, as suggested in Peters et al. (2018). We extract a 1024-dimension bag-of-words representation for each turn and concatenate the three turns into a 3072-dimension vector which is passed to a multilayer perceptron (MLP). For the hierarchical model, we employ two methods: 1) run an LSTM model over each turn's representation 2) pre-extract all three layer weights (LSTM and CNN) and concatenate them into a 3072-dimension vector representation for each turn, which is then passed to an LSTM model. We report the results of the latter pre-extracted method as it performs better.

BERT For the implementation details of $BERT_{BASE}$, we refer interested readers to Devlin et al. (2018). Note that for hierarchical BERT, we use a six-layer UTRS as the context encoder. Each layer of UTRS consists of a multi-head attention block with four heads, where the dimension of each head is set to be ten, and a convolution feed forward block with 50 filters. We use modified Adam optimizer from Devlin et al. (2018) to train our model. The initial learning rate and dropout are 5e-5 and 0.3 respectively.

LSTM and Universal Transformer We train hierarchical LSTMs with hidden sizes of {1000, 1500} using different dropouts {0.2,0.3,0.4,0.5}. The best LSTMs (without additional features, with GLoVE, with GLoVE+Emo2Vec) reported in Figure 2 have a hidden size of 1000 and dropout of 0.5, a hidden size of 1500 and dropout of 0.2, and a hidden size of 1000 and dropout of 0.4 respectively. Then, we train the UTRS using the best hyper-parameters found by the GP. It has a hidden size of 488 with a single hop and ten attention multi-heads. Noam (Vaswani et al., 2017) is used as the learning rate decay.

Gaussian Processes GP hyper-parameter search returns a set of hyper-parameters, both continuous and discrete, and it returns the validation set F1 score. We implement the GP model using an existing library called GPyOpt.[3] We run a GP for 100 iterations using the Expected Improvement (Jones et al., 1998) acquisition function with 0.05 jitter as a starting point. We use a hierarchical universal transformer (HUTRS) as the base model since is the model with the most hyper-parameters to tune with a single split.

3.2 Evaluation Metrics

The task is evaluated with a micro F1 score for the three emotion classes, i.e., Happy, Sad and Angry, and by taking the harmonic mean of the precision and the recall. This scoring function has been provided by the challenge organizers (Chatterjee et al., 2019b).

3.3 Voting Scheme

For each model, we randomly shuffle and split the training set ten times and we apply a voting scheme to create a more robust prediction. We use a majority vote scheme to select the most often seen predictions, and in case of ties, we give the priority to *Others*. This scheme is applied to all end-to-end models since it improved the validation set performance.

3.4 Ensemble Models

To further refine our predictions, we build ensembles of different models. We create five ensemble models by combining the hierarchical version of BERT, LSTM, and UTRS. Finally, we gather two lesser-performing models, a hierarchical LSTM and the best feature-based model (XGBoost with ELMo and DeepMoji features), and we combine them with five ensemble predictions using majority voting to get our final prediction. Finally, we show the Pearson correlation between models in Figure 2.

3.5 Experimental Results

From Table 1, we can see that the DeepMoji features outperforms all the other features by a large margin. Indeed, DeepMoji has been trained using a large emotion corpus, which is compatible with the current task. Emoji2Vec get a very low F1-score since it includes only emojis, and indeed, by adding GLoVe, a more general embedding, we achieve better performance. For the end-to-end approach, hierarchical biLSTM with GLoVe word embedding achieves the highest score with a 75.64% F1-score. Our ensemble achieves a higher score compared to individual models. The best ensemble model achieves a 76.77% F1-score. As shown in Table 3, the ensemble method is effective to maximize the performance from a bag of models.

4 Related work

Emotional knowledge can be represented in different ways. Word-level emotional representations, inspired from word embeddings, learn a vector for each word, and have shown effectiveness in different emotion related tasks, such as sentiment classification (Tang et al., 2016), emotion classification (Xu et al., 2018), and emotion intensity prediction (Park et al., 2018). Sentence-level emotional representations, such as DeepMoji (Felbo et al., 2017a), train a biLSTM model to encode the whole sentence to predict the corresponding emoji of the sentence. The learned model achieves state-of-the-art results on eight datasets. Sentiment lexicons from Taboada et al. (2011) show that word lexicons annotated with sentiment/emotion labels are effective in sentiment classification. This method is further developed using both supervised and unsupervised approaches in Wang and Xia (2017). Also, other models, such as a deep averaging network (Iyyer et al., 2015), attention-based network (Winata et al., 2018), and memory network (Dou, 2017), have been investigated to improve the classification performance. Practically, the application of emotion classification has been investigated on interactive dialogue systems (Bertero et al., 2016; Winata et al., 2017; Siddique et al., 2017; Fung et al., 2018).

5 Conclusion

In this paper, we compare different pre-trained word embedding features by using Logistic Regression and XGBoost along with flat and hierarchical architectures trained in end-to-end models. We further explore a GP for faster hyper-parameter search. Our experiments show that hierarchical architectures give significant improvements and we further gain accuracy by combining the pre-trained features with end-to-end models.

CECL at SemEval-2019 Task 3: Using Surface Learning for Detecting Emotion in Textual Conversations

Yves Bestgen
Centre for English Corpus Linguistics
Université catholique de Louvain
Place Cardinal Mercier, 10 1348 Louvain-la-Neuve Belgium
yves.bestgen@uclouvain.be

Abstract

This paper describes the system developed by the Centre for English Corpus Linguistics for the SemEval-2019 Task 3: EmoContext. It aimed at classifying the emotion of a user utterance in a textual conversation as happy, sad, angry or other. It is based on a large number of feature types, mainly unigrams and bigrams, which were extracted by a SAS program. The usefulness of the different feature types was evaluated by means of Monte-Carlo resampling tests. As this system does not rest on any deep learning component, which is currently considered as the state-of-the-art approach, it can be seen as a possible point of comparison for such kind of systems.

1 Introduction

This paper presents the participation of the Centre for English Corpus Linguistics (CECL) in the SemEval-2019 Task 3 "EmoContext: Contextual Emotion Detection in Text". The objective of the task is to classify the emotion of a user utterance in a textual conversation with a bot as happy, sad, angry or other. Contextual information is provided by means of the two previous utterances, the one just before, which was produced by the bot, and the first one of the triplet produced by the same person as the third. This task can be seen as a difficult problem in absence of any non-written information (Gupta et al., 2017).

Because of its recent and important development for the analysis of big data and especially for natural language processing, deep learning has become the preferred procedure to take up this kind of challenge (Chatterjee et al., 2019a). However, detecting emotion in texts is a well-established field of research for which unsupervised approaches have been proposed in content analysis (e.g. Anderson and McMaster, 1982; Bestgen, 1994) as well as less recent supervised approaches such as SVM (Chatterjee et al., 2019a; Pang and Lee, 2008). SVM has long been considered as the state-of-the-art in text categorization (Joachims, 2002). Therefore, it seemed interesting to get an idea of its effectiveness for the present task in comparison to deep learning approaches that should be used by many participants in this challenge. Trying to determine what level of performance can be achieved with a surface learning system was thus the main focus of this study. It should be noted that the developed system does not rely on complementary training data, nor on lexical emotional norms produced manually or automatically (Bestgen and Vincze, 2012), nor on semantic knowledge extracted from large databases or large corpora (Miller et al., 1990). However, several attempts have been made to increase its effectiveness by adding more complex features to the usual token n-grams.

The remainder of this report describes the datasets made available for this challenge, the systems developed, and the results obtained as well as the analyses performed to get a better idea of the factors that affect the system performance as well as the usefulness of the various types of features used.

2 Data

The challenge organizers divided the materials into three datasets (see Chatterjee et al. (2019b) for details):

- The learning set (Learn) that contained 30160 instances of which approximately 16.7% of the three emotion categories and the remaining 50% of Other,
- The development set (Dev) that contained 2755 instances of which approximately 5% of the emotion categories and the remaining 85% of Other

- The test set (Test) that contained twice as many instances as the Dev set and the same proportion of the four categories as in that set.

The true labels for the Learn set were available from the beginning of the training phase, those for the Dev set on December 10 and those for the Test set after the end of the challenge. Between the beginning of the development phase (August 21, 2018) and the beginning of the test phase (January 18, 2019), it was possible to use Codalab to evaluate the systems on the Dev set.

3 Systems

This section describes the systems developed to maximize the approach effectiveness. The feature extraction was performed by means of a custom SAS program running in SAS University (freely available for research at http://www.sas.com/en_us/software/university-edition.html). The predictive models used during the development phase were built on the Learn set and evaluated on the Dev set (see section 4 for a justification) by means of the L1-regularized L2-loss Support Vector Machine for classification (L1-L2-SVM) available in the LIBLINEAR package (-s 5, Fan et al., 2008).

3.1 Base System

The main part of the system consists of tokens and tokens n-grams present in the three utterances of an instance to be categorized. First, the utterances are processed by a Perl script that group the most frequent contracted forms with their corresponding full forms (e.g. I'm > I am). Then, an ad-hoc tokenizer splits each sequence of characters separated by a space in tokens composed of (lowercased) letters, numbers, punctuation marks or emojis, trying not to cut the potential emoticons such as :-) and :D. In the case of tokens composed exclusively of alphabetic characters, the encoder detects the presence of the same character at least three times at the end of the token (e.g. ahhh) and keeps only one occurrence.

The features for the SVM were generated from these tokens. These are mainly unigrams and bigrams of tokens, present in each utterance, to which a tag is added to keep trace of the utterance it comes from. The tokens, bigrams, and trigrams from the first and the last utterances, those produced by the human participant, are also outputted without being distinguished by a tag so that their frequencies add up. The emojis of the first and third utterances are also processed specifically. Each token composed of several emojis is not only produced as it is, but the different emojis that compose it are also outputted separately.

Finally, a feature frequency dictionary based on all the available materials, thus also on the Test set, is produced in order to be able to use a minimum frequency threshold (set in all the analyses reported here at 2). This dictionary is also used to number the features in order to put them in LIBLINEAR format. The weight of each feature is equal to the logarithm in base 10 of its frequency in the instance to which one is added.

3.2 Extended System

The basic system was extended during the development period with a series of meta-features that seemed to improve its predictive power. They consist in a dozen simple global statistics computed on each of the utterances: number of tokens, number of characters without the spaces, number of capital letters and a potential index of emotional intensity based on the number of characters repeated at least three times, the number of emoticons and of emojis (whatever their meaning). These statistics were divided by the maximum values observed in the dataset.

Another addition was made specifically for the instances whose third utterance contained only the "yes" token: the content of the first utterance was copied to this third one.

3.3 Parameters

The regularization meta-parameter C of the SVM was optimized using a grid search. Although LIBLINEAR has a built-in program for optimizing C, we used our optimization program to have more flexibility in choosing the values to test. To take into account the differences between the frequencies of the four categories in the Learn and the other two datasets, the LIBLINEAR -wi parameter, which allows modulating the C parameter according to the category, was used. The values were set using a heuristic approach.

4 Analyses and Results

All the results reported below are expressed in terms of the challenge metric, which is the microaveraged F1 score (F1μ) for the three emotion classes (see Chatterjee et al. (2019b) for details). A first analysis was aimed to determine whether it was possible to extract several development datasets from the Learn set that produced similar performances to those obtained by using the Dev set provided by the organizers so as to limit the risk of overfitting when only one evaluation dataset is used. To this end, ten development samples were independently extracted from the Learn set in such way that they contained exactly the same number of instances in each of the four categories as in the official Dev set[1]. The results showed that the performances on these ten samples were systematically much higher than those obtained on the Dev set (0.78 vs. 0.69 for the version of the system available at that time). It would thus seem that the Dev set has specificities that distinguish it quite clearly from the Learn set and therefore all the developments have been made on the Dev set, accepting the risk of overfitting.

4.1 Official Performance on the Test Set

During the test phase, teams were allowed to submit 30 trials during 9 days. The base system (System 1) was first submitted to Codalab and obtained a F1μ of 0.721[2]. The remaining 29 trials were used to try improving performance. Three tracks were followed:

- First, I tried to optimize the number of instances assigned to each category in order to obtain better recall and precision values. To this end, I used the L1-regularized logistic regression (L1-LR) available in LIBLINEAR (-s 6) which is for the present datasets a little less effective than the L1-L2-SVM used previously but is able to estimate the probabilities of each instance belonging to each class. The most effective approach found was to classify into a category the same number of instances as the one actually presents in the Test set (the needed counts were obtained during the test phase by means of the procedure described in Note 1). This system 2 obtained a F1μ of 0.726.
- Then, the predictions of these two first systems were combined to try maximizing the F1s in each category because it was observed that System 1 was less accurate than System 2 for the Angry and Sad categories, but more accurate for the Happy category. Since the prediction differences between the two systems were systematically changes from one emotion category to the Other category or vice versa, but never from one emotion category to another one, it was easy to combine the two systems by taking the Happy predictions of System 1 and the Sad and Angry predictions of System 2 and placing the remaining instances in the Other category. This System 3 reached a F1μ of 0.73.
- Finally, System 3 was combined with a model based only on the third utterance. This model was used to move to the Other category instances assigned to one of the three emotional categories for which the probability of membership (provided by the logistic regression) was the lowest. A series of tests carried out on Codalab to optimize the decision rules made it possible to reach the final system performance of 0.736 (F1_Angry=0.7331, F1_Happy=0.7035, F1_Sad=0.7746).

4.2 Factors that Affect the System Performance

The remainder of this report analyzes the impact of several factors, including the different types of features, to the system performance. All these analyses were conducted using various versions of System 1. They aimed at categorizing the Dev set using the Learn set to build the model and the Test set using the Learn and Dev sets to build the model. In these analyses, the L1-L2 SVM was used with the parameters considered as optimal for each evaluation dataset. In order to determine if the observed differences were statistically significant, two Monte-Carlo resampling tests (Howell, 2008, Chap. 18) were used, a test for related samples to compare two different models on the same evaluation set and a test for independent samples to compare the performance on the Dev and Test sets.

A first analysis showed that using only the Learn set for predicting the Test set instead of the concatenation of the Learn and Dev sets hurt the performance (0.716 vs. 0.721), but the dif-

[1]As these analyses were performed before the labels for the Dev set had been released, I used the number of instances assigned to each category in a submission and the precision and recall for each category outputted by CodaLab for that submission to calculate the actual category frequencies.

[2]SVM parameters for this system were as following: $C = 0.67$, $w\_angry = 0.275$, $w\_happy = 0.31$ and $w\_sad = 0.275$.

System description	Dev Set F1μ	Dev Set Diff.	Dev Set p	Test Set F1μ	Test Set Diff.	Test Set p
Full (System 1)	0.762			0.721		
Without Meta-Features	0.752	-0.010	0.018	0.719	-0.002	0.715
Without 3grams	0.752	-0.010	0.007	0.719	-0.002	0.621
Without 2grams and 3grams	0.735	-0.027	0.002	0.710	-0.011	0.107
Without Utterance 2	0.751	0.012	-0.041	0.726	+0.005	0.193
Without Emojis Processing	0.746	-0.016	0.010	0.709	-0.012	0.006
Without Repeated Letters Processing	0.760	-0.002	0.508	0.722	+0.001	0.411

Table 1: F1μ, difference from the full system, and p-value for the ablation approach.

ference was far from being statistically significant ($p > 0.30$).

A second analysis showed that the system was more efficient on the Dev set (0.762) than on the Test set (0.721), a statistically significant difference ($p = 0.043$). Providing that the Dev and Test sets were randomly extracted from the same sample, this result suggests that the system suffers from overfitting since it was developed on the basis of the Dev set.

The ablation approach was then used to assess the independent contribution of each type of features to the overall performance. It consists in removing some sets of features of the model and reevaluating it. As Table 1 shows, the impact of removing feature types was often quite different on the two evaluation sets. Suppressing most of the feature types for the Dev set produced a sizable decrease in performance while a very small decrease or even an increase in performance was observed for the Test set. Significance tests, which compare the ablated systems to the full one, confirm this analysis. Table 1 also shows that the specific treatment of emojis seemed particularly useful for both datasets.

A final analysis consisted in constructing a system from which all feature types in Table 1 were simultaneously removed except the specific treatment of emojis. This system obtained a F1μ of 0.743 on the Dev set, a decrease of 0.019, and a F1μ of 0.731 on the Test set, an increase of 0.01.

5 Conclusion

The main goal of this study was to try to determine what level of performance could be reached in the EmoContext task by employing a non-deep learning approach. The achieved F1μ was between 0.721 and 0.736, ranking the system approximately in the first quarter of the 165 teams who submitted a prediction for the Test set, yet far enough from the top teams who achieved a F1μ of 0.79. Looking at the other system description papers should allow to find out whether other teams used a surface learning approach while achieving better performance.

To conclude, it seems useful to underline an observation reported above that could have greatly affected the performance of the system, but also of other systems. The analyses carried out showed that the Dev set provided by the organizers gave rise to significantly lower performances than those obtained by using evaluation datasets from the Learn set as similar as possible to the actual Dev set. This led me to develop the system on the basis of the Dev set provided by the organizers and the consequence was a statistically significant overfit on the Dev set when compared to the Test set. In the absence of information about how the three datasets were created, it is not possible to comment on the origin of these differences.

Acknowledgments

The author wishes to thank the organizers of the EmoContext task for putting together this valuable event. The author is a Research Associate of the Fonds de la Recherche Scientifique - FNRS.

Abstract

This paper describes the *CLaC Lab* system at SemEval 2019, Task 3 (*EmoContext*), which focused on the contextual detection of emotions in a dataset of 3-round dialogues. For our final system, we used a neural network with pretrained *ELMo* word embeddings and POS tags as input, GRUs as hidden units, an attention mechanism to capture representations of the dialogues, and an SVM classifier which used the learned network representations to perform the task of multi-class classification. This system yielded a micro-averaged F1 score of 0.7072 for the three emotion classes, improving the baseline by approximately 12%.

1 Introduction

Automatic emotion detection has been the focus of much research in a variety of fields, including emotion detection based on images (Rao et al., 2019), speech signals (Davletcharova et al., 2015), electroencephalography (EEG) signals (Ackermann et al., 2016), and texts (Tafreshi and Diab, 2018).

With the advent of social media, emotion detection from text has been used to track bloggers' mental health and has been explored using different techniques, such as lexicon-based approaches and machine learning (Canales and Martínez-Barco, 2014). Lexicon-based approaches include keyword-based and ontological approaches. In a keyword-based approach (e.g. Ma et al., 2005), a specific set of opinion terms and their WordNet synonyms and antonyms are used to determine the emotion class of the text. On the other hand, ontology-based approaches (e.g. Sykora et al., 2013) try to detect emotions by taking into account the knowledge of concepts, the interconnection between them, and their final emotional impact. To achieve better generalization, the resources used in lexicon-based approaches can be employed as input features to supervised or unsupervised machine learning models.

The drawback with supervised machine learning approaches lies in the need for a large corpus of labelled data. Abdul-Mageed and Ungar (2017) collected a labelled twitter dataset of 1/4 billion tweets, spanning over 8 primary emotions, using distant supervision, i.e. collecting tweets with emotion hashtags that can be used as labels. Then using a gated recurrent neural network for classification, they achieved an accuracy of 95.68%, superior to the best previously published results by Volkova and Bachrach (2016).

Although much research has focused on the detection of emotions in tweets and blog posts (e.g. Mohammad, 2012; Desmet and Hoste, 2013; Liew and Turtle, 2016), emotion detection in dialogues, as well as in single utterances has received very little attention. This topic can have significant impact for the development of social chatbots, with the aim of creating an emotional connection between a user and a chatbot (Banchs, 2017). Task 3 of SemEval 2019 (*EmoContext*) has focussed on contextual emotion detection over 4 classes: *happy*, *sad*, *angry*, and *others* (Chatterjee et al., 2019b). We participated in this shared task under the name *CLaC Lab* and used a combination of artificial neural networks (with recurrent units and attention mechanism) and Support Vector Machines (SVM) to address this multi-class classification task.

The rest of the paper is organized as follows: Section 2 describes the overall methodology. Section 3 presents a detailed explanation of the different components of the system. Section 4 presents the results of the system. Section 5 discusses some interesting findings from our participation to this task. Finally, Section 6 is dedicated to the conclusion of this work.

2 Methodology

This section presents the overall methodology used to perform the task of contextual emotion detection. An overview of the system architecture is presented; while more detailed explanation can be found in Section 3.

2.1 Neural Architecture

The core of our system is a neural network that is trained to learn the feature representations necessary to train our final classifier. Figure 1 shows the overall architecture of the neural network that we used.

The Input As shown in Figure 1, each input sample consists of three consecutive utterances of a dialogue between two interlocutors. We consider each utterance as a sequence of tokens (words). As a result, each utterance is represented as a vector, such as $[x_{i,1}, x_{i,2}, \dots, x_{i,t}, \dots, x_{i,n}]$, where $x_{i,t}$ is the vector representation of the t-th word in the i-th utterance, and n is the length of the i-th uttermace.

The Recurrent Component The input layer is followed by a bidirectional hidden recurrent component. Each utterance is fed to a separate hidden component, who is responsible to process that specific utterance in a forward and backward pass.

For the forward pass, the content value of the hidden component at a specific time-step, h_t, relies on both the value of the current input, x_t, and the content value of the hidden component itself at the previous time-step, h_{t-1} (Equation 1). The content value produced at this stage is then passed through another mapping function, f_y, which generates the output value of the hidden component at the current time-step, y_t (Equation 2).

$$h_t = f_h(x_t, h_{t-1}) \tag{1}$$

$$y_t = f_y(h_t) \tag{2}$$

The backward pass differs from the forward pass, in that in Equation 1, h_{t-1} is replaced by h_{t+1}, meaning that the content value of the hidden component relies on the content value at its next time-step instead of the previous one. The output calculation is identical to the forward pass (see Equation 2).

Attention Mechanism Vaswani et al. (2017) describes an attention mechanism as the weighted sum of several values (i.e. vectors), where the weight assigned to each value can be computed using a compatibility function. Using this description, the overall function of the attention mechanism for our task can be defined using Equation 3, where $\omega(y_{t'})$ refers to the weight assigned to the output of the hidden layer at time-step t', and N is the number of time-steps (i.e. the length of the utterance).

$$attn = \sum_{t'=1}^{N} y_{t'}\omega(y_{t'}) \tag{3}$$

Although originally developed for the task of machine translation (Bahdanau et al., 2014), attention mechanisms have been shown to significantly improve text classification tasks (e.g. Yang et al., 2016; Zhou et al., 2016; Wang et al., 2016; Cianflone et al., 2018). Following these works, we used attention in our system (see Figure 1).

Classification Once the neural network has created a representation of the input, a final feed-forward classification network, which takes as input the concatenated vectors from the attention units of the three utterances, performs the classification task.

2.2 Support Vector Classifier

The neural network was not used to do the final classification, but was used only as a feature extractor. This is illustrated in Figure 1 by the dotted connections between the attention units and the classifier. The extracted features were fed to an SVM (Cortes and Vapnik, 1995), which acted as the classifier.

Our main drive for using an SVM was due to explicit handling of margin size versus misclassification rate (i.e. variance versus bias). This, alongside the deterministic nature of an SVM and its faster training process (in comparison to a neural network), enabled us to play with its several configurations in order to find the optimal one for our task.

3 System Overview

In this section, we provide detailed information on the final system's architecture.

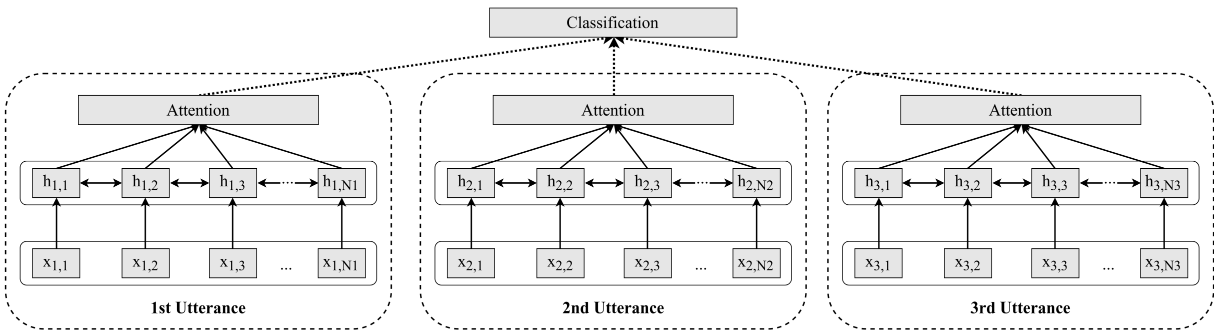

Figure 1: The overall framework of the neural network model.

3.1 The Neural Network

We developed the neural network using *PyTorch* (Paszke et al., 2017). Detailed explanations of the neural network's architecture are provided below.

Input Features Each word in each utterance is sent to the neural network by using their word embeddings, concatenated to their one-hot part-of-speech (POS) tag.

For word embeddings, we used a pretrained *ELMo* word embedder (Peters et al., 2018), which extracts the embeddings of each token in a textual context from their constituent characters. The suitability of *ELMo* for the current task lies in its ability to take into consideration the context of the tokens when generating the word embeddings, and also the handling of out-of-vocabulary words. We used pretrained *ELMo* embeddings of size 1024.

We followed the Penn Treebank tagset standard (Marcus et al., 1993) for assigning POS tags to each token. For this, we used *spaCy*[1] for tokenization and POS tagging of the data.

Recurrent Unit The system uses the bidirectional Gated Recurrent Unit (GRU) architecture, proposed by Cho et al. (2014), and stacks two layers of 25 bidirectional GRUs for the recurrent component of each utterance.

Attention Layer Equations 4, 5 and 6 show the mechanisms used in the attention layer. Using Equation 4, the weight matrix w is applied to the output of the GRU component at each time-step, y_t, which maps each output vector of the recurrent unit (with the size of 2×25 in our case) to a single value, ν_t. Then, using Equation 5, the weights, ω, are calculated. These will be used to calculate the output of the attention layer in Equation 6 (N represents the number of time-steps for each utterance, i.e. the length of the utterance).

$$\nu_t = y_t \times w \tag{4}$$

$$\omega = Softmax([\nu_1, \nu_2, \nu_3, \ldots, \nu_N]) \tag{5}$$

$$attn = \sum_{t'=1}^{N} \omega_{t'} y_{t'} \tag{6}$$

The Classifier The outputs of the attention layers from the three utterances are concatenated, and fed to a fully-connected feed-forward layer, which uses a softmax activation function at the end. The output of the classifier includes a vector of 4 reals, which represent the estimated probability for each of the 4 classes (*happy*, *sad*, *angry*, and *others*).

Optimization Technique Cross-entropy is used as the loss function and weights are applied to each class proportional to the inverse of number of their samples, in order to handle the unbalanced distribution of the four different classes over the data. The Adam optimizer (Kingma and Ba, 2014) was used and the learning rate was set to 10^{-4}. For computational reasons, minibatches of size 32 were used for training the neural network model, and different sequence sizes was handled by zero-padding.

Experiments showed that, when trained on the training dataset only, the neural network reaches its maximum performance on the development dataset (in our case, the micro-averaged F1 score for the three emotion classes) in approximately 7 epochs.

[1] https://spacy.io/

3.2 The SVM

The *scikit-learn* library (Pedregosa et al., 2011) was used for the SVM, which utilized a polynomial kernel with degree of 4. The γ parameter was set to the inverse of the number of features, which was 1/150 in our case (since the model uses 50 features from each utterance's attention layer, and there were 3 utterances for each sample), and set the penalty parameter C equal to 2.5. To train the SVM, we used the samples from both the training and the development datasets.

4 Results

We tested the system using two different configurations: 1) Using the neural network for feature extraction and classification (*NN*); and 2) Using the neural network for feature extraction and the SVM for classification (*NN+SVM*). We compared the two systems with the baseline system provided by the *EmoContext* organizers (Chatterjee et al., 2019a), which uses a neural network with LSTM units (Hochreiter and Schmidhuber, 1997) in the hidden layer and *GloVe* embeddings (Pennington et al., 2014). Table 1 shows the results from our two models in comparison to the baseline configuration.

System	*angry*	*happy*	*sad*	Micro
NN+SVM	**0.7130**	**0.6667**	**0.7443**	**0.7072**
NN	0.6206	0.6374	0.6800	0.6430
Baseline	N/A	N/A	N/A	0.5868

Table 1: F1 scores on the shared task test dataset for each emotion class and the micro-average. The final system (*NN+SVM*) is highlighted in bold.

The results in Table 1 show that, both our system configurations outperformed the baseline system, while the *NN+SVM* is significantly better than the others. We hypothesize that, given the same set of features, an SVM constitutes a stronger classifier due to its deterministic and more robust nature, and also due to its explicit design to optimize the margin size between different classes.

5 Discussion

Several interesting findings are worthy of discussion:

- The use of LSTMs in the neural network design instead of GRU yielded lower results with the development dataset. We believe that this is because the LSTM model was more prone to overfitting due to a higher number of parameters. Also, since most of the utterances were quite short (5.19 tokens on average), a GRU was enough to capture the necessary information.
- The use of POS tags alongside word embeddings did not help in improving the system performance, but it was helpful in stabilizing the output of the system (i.e. less performance fluctuations during training).
- For the SVM, an increase in the parameter C from its default value of 1 to 2.5 achieved slightly better results. We believe that this is due to the neural based features being quite representative of the final classes, and as a result, more penalty had to be assigned to errors during training as opposed to trying to achieve larger decision margins.

6 Conclusion

This paper presented the system that we developed for our participation to SemEval 2019, Task 3 (*EmoContext*). The task focused on detecting four classes of emotions, *happy*, *sad*, *angry*, and *others* in a dataset consisting of small dialogues between two people.

For this task, we developed a system that used pretrained *ELMo* word embeddings alongside POS tags as input features to a bidirectional GRU, followed by an attention layer and outputting a representation of a sample dialogue. This representation was, in turn, used as input to a final SVM classifier. Using this method, we could significantly outperform the baseline system, and achieved a micro-averaged F1 of 0.7072 for the three emotion classes on the test dataset.

Acknowledgments

We would like to express our gratitude to Parsa Bagherzadeh for insightful discussions throughout the course of our participation to *EmoContext*.

jcummings@u.northwestern.edu

Jason R. Wilson
Northwestern University
jrw@northwestern.edu

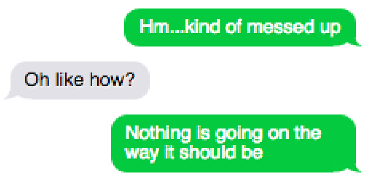
Abstract

With text lacking valuable information available in other modalities, *context* may provide useful information to better detect emotions. In this paper, we do a systematic exploration of the role of context in recognizing emotion in a conversation. We use a Naïve Bayes model to show that inferring the *mood* of the conversation before classifying individual utterances leads to better performance. Additionally, we find that using context while training the model significantly decreases performance. Our approach has the additional benefit that its performance rivals a baseline LSTM model while requiring fewer resources.

1 Introduction

Recognizing affect (emotional content) in text has been an ongoing research challenge for roughly 20 years. While earlier work focused on larger bodies of text, like movie reviews for sentiment analysis (Pang et al., 2002) or classifying mood in blog posts (Mishne et al., 2005), more recent work has looked at small bodies of text, particularly text from social media. With smaller bodies of text inherently having less information, current efforts are investigating how context may supplement the information. However, it is not yet clear how best to incorporate context. To this end, we explore how mood and emotion from previous messages may be used to better recognize emotions.

Mood and emotion are generally regarded as two types of affect. Emotions are reactions and have a limited duration (Ortony et al., 1990; Schwarz and Clore, 2006). While emotions are dynamic and constantly changing, mood reflects a more persistent affect that can influence cognitive processes (Busemeyer et al., 2007), including how people recognize emotions (Schmid and Mast, 2010). For this work, we view mood as the affect present in the whole conversation and emotion as what is expressed in a given turn.



Hm...kind of messed up

Oh like how?

Nothing is going on the way it should be

Figure 1: Example of a three turn conversation

Our goal is to take a short, online conversation (see Figure 1) and categorize the last utterance as happy, sad, angry, or others. In this paper, we present our model Conversational Lexical Affect Recognition Kit (CLARK), which is the result of a systematic exploration into how context may be used during the training and classification phases of a model to improve emotion recognition. To assess context we infer the mood of the conversation and the emotions of previous utterances. Although context would seem to be useful, providing additional information, we find that is only beneficial during classification. Conversely, including context while training the model leads to significantly degraded performance.

2 Related Work

There are several approaches to recognizing affect in a body of text. Many have used classification methods on a large body of text, such as movie reviews (Pang et al., 2002), blogs (Mishne et al., 2005; Mihalcea and Liu, 2006), and fairy tales (Alm et al., 2005; Mohammad, 2011), using techniques like SVMs (Pang et al., 2002; Mishne et al., 2005), Naïve Bayes (Mihalcea and Liu, 2006), HMMs (Ho and Cao, 2012), and Deep Learning (Zhang et al., 2018).

More recently, the rise of instant messaging and social media has led to greater interest in recognizing emotion in a smaller body of text. While lexicon based approaches were initially used for detecting emotions in smaller bodies of text (Thelwall et al., 2010; Staiano and Guerini, 2014), Deep Learning models dominate the recent work (Abdul-Mageed and Ungar, 2017; Chatterjee et al., 2019a).

Our approach is a blend of using a larger and smaller body of text. For the larger body, we detect the mood in a whole conversation. Additionally, we consider a smaller body of text, a single message in a conversation, and detect the emotion in that message. In contrast to many recent approaches using Deep Learning techniques, we use a Naïve Bayes model that requires less data and is trained faster while exhibiting no noticeable degradation in performance in comparison to a baseline SS-LSTM model.

3 Model

We model the task of detecting emotions as a multi-class classification problem. Given a user utterance, the model outputs probabilities of it belonging to the four output classes: happy, sad, angry, or others. Our approach uses CLARK, which at its base level, utilizes a Naïve Bayes model (McCallum and Nigam, 1998) with prior probabilities, which we take to be the frequency of tokens per class. To explore the role of context, we examine several variants of training and classification, detailed later. Keeping the feature set small, we use only unigram and bigrams. We also remove stop words and the following set of punctuation: period, dash, underscore, ampersand, tilde, comma, and backslash. To tokenize the tweets, we utilize Natural Language Toolkit's (NLTK) casual tokenize functionality, which places an emphasis on informal language and is able to pick up emoticons and collections of characters that are semantically equivalent to emoticons, e.g. ':)' is a smiley face.

3.1 Training

The model is trained on three turn conversations from Twitter with the last utterance classified according to the context of the first two utterances via semi-automated techniques (Chatterjee et al., 2019b). 30,160 conversations were provided for training and validation, consisting of 4,243 happy, 5,463 sad, 5,506 angry, and 14,947 others.

We test two variants for training the model, Conv, which we use to infer mood, and only Turn 3 (T3), to calculate feature probabilities given our set of four emotions. Conv consists of all words from the entire conversation, whereas T3 is the third and final utterance.

3.2 Classification

Our classification is a two step chaining process as shown in Algorithm 1. In the first step we find the initial probabilities for each class, denoted by the variable *post*. If we are using mood, denoted by the variable $Mood$, then this distribution is calculated using our model on $Conv$ (see line 7). Otherwise, it is set to the prior probabilities generated from the training (line 9). The resulting probabilities for each class are then used as the priors in step two.

In the second step, we classify the following combinations of individual turns in the conversation: {T3}, {T1, T3}, {T1, T2, T3}. Processing a combination consists of finding the posterior of the first turn and using it as the prior for the next turn and continuing until getting a final posterior, from which we take the highest probability class and return it as the final classification.

Algorithm 1 Classification sequence

```
 1: procedure ClassifyInContext
 2:     $Mood \leftarrow True \vee False$
 3:     $Conv \leftarrow$ words from current conversation
 4:     $default \leftarrow$ prior probabilities of all classes
 5:     $Turns \in \{\{T3\}, \{T1, T3\}, \{T1, T2, T3\}\}$
 6:     if $Mood$ then                                      ▷ Step 1
 7:         $post = $ runModel($Conv, default$)
 8:     else
 9:         $post = default$
10:     end if
11:     for each turn $t$ do                                ▷ Step 2
12:         if $t \in Turns$ then
13:             $post = $ runModel($t, post$)
14:         end if
15:     end for
16:     return argmax($post$)
17: end procedure
```

4 Results

Our results show that inferring mood via Conv in the conversation before recognizing emotion in individual utterances yields improved performance. Furthermore, the best performances focus on the first user, utilizing only the first and third utterances in the second step of classification. We also see that in training the model, the best performance comes from limiting our set to just T3.

Results are organized by analysis on the internal model, followed by a comparison against a baseline Deep Learning model - the one provided by the EmoContext organizers. CLARK is tested with two parameters - classification method and training method. Our best results on the test set yielded a micro F_1 score of 0.5637, roughly equiv-

Classification Method	Acc.	Precision	Recall	F_1
Conv (C)	0.4256	0.2788	0.4170	0.3342
Turn 3 (T3)	0.2651	0.2211	0.4105	0.2874
C, T3	0.5575	0.4073	0.5571	0.4705
T1, T2, T3	0.5308	0.3730	0.5120	0.4316
C, T1, T2, T3	0.5358	0.3823	0.5276	0.4433
T1, T3	0.5369	0.3874	0.5235	0.4431
C, T1, T3	0.5732	0.41915	0.5684	0.4825

Table 1: Results from varying parameter classification method and training on the whole conversation.

Classification Method	Acc.	Precision	Recall	F_1
Conv (C)	0.7125	0.7283	0.5366	0.6178
Turn 3 (T3)	0.7155	0.6366	0.7456	0.6867
C, T3	0.8131	0.7875	0.7766	0.782
T1, T2, T3	0.7997	0.7745	0.7516	0.7629
C, T1, T2, T3	0.7979	0.769	0.7573	0.7631
T1, T3	0.8168	0.7921	0.7778	0.7848
C, T1, T3	**0.8169**	**0.7848**	**0.7892**	**0.7870**

Table 2: Results from varying parameter classification method and training on only T3.

alent to the model from the EmoContext organizers. This score is considerably lower than we got from our evaluations on the training data, possibly attributed to the quality of the labels for the training set versus the test set. We chose not to focus our analysis on the test set because we are not able to do a deep analysis as a result of the data not being readily available at the time. The remaining results we discuss are obtained using a 10-fold cross validation on the training set. Tables 1 and 2 show results from using the 30,160 conversations.

From the difference in results between these tables, it is clear that the biggest improvements in the model comes from training on only T3 as opposed to Conv. The difference in the average micro F_1 score (Rijsbergen, 1979) of training on T3 and the average F_1 score of training on Conv is determined to be statistically significant ($p < 0.005$) using a t-test (Kim, 2015).

Within the classification method, we see that using T1 in coordination with T3 provides F_1 scores at least 14% higher than just classifying with T3. In addition, using Conv consistently provides better performances, albeit close. Thus, the best model is one which utilizes a classification combination of Conv, T1, and T3, with a micro F_1 score of 0.7870.

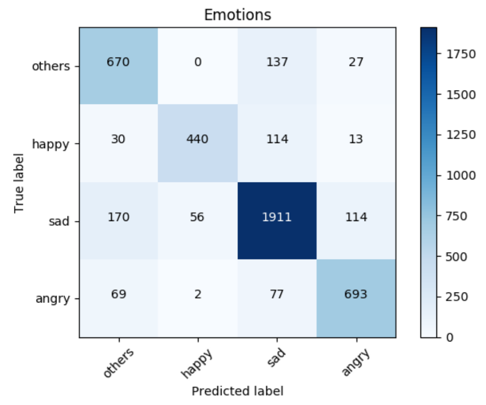


Figure 2: CLARK Confusion Matrix on a 9:1 ratio training to testing split.

As shown in Figure 2, CLARK is incredibly precise in the classification of the sad class and does moderately well in others and angry. However, others and sad are commonly predicted even when not the correct class predicted leading to lower recall scores.

A few concrete examples of these strengths and weaknesses are shown in Table 3. Because CLARK does not place weight on the specific T2 utterance, we see that in no. 2, we miss the positive emotion and misclassify the conversation as others. However, this is largely an anomaly - in fact, we see that T2 usually involves an interrogative or can be associated with a tangential class.

To demonstrate the efficiency of CLARK, we compare it to the baseline SS-LSTM model provided by the SemEval-2019 Task 3 organizers (Chatterjee et al., 2019a) as shown in Table 4. We compare both on time to train and quantity of data needed to produce certain performance. Time to train is normalized to CLARK. The SS-LSTM model performs at 0.6796 when trained with 1 Epoch (used as the very minimum required for a neural model) and takes 26 times longer than CLARK. For 3 Epochs, it performs at 0.7832 and takes 70 times longer than CLARK.

We also examine the effect the size of the training dataset has on the performance of each model, as shown in Figure 3. CLARK vastly outperforms the SS-LSTM models with minimal data. The SS-LSTM (3) model takes the full 30,160 data point

#	T1 (User 1)	T2 (User 2)	T3 (User 1)	True Label	Predicted Label
1	Same to you	:)...hws life going?	Bad	Sad	Sad
2	You are funny	Why, thank you!	So start a fun conversation	Happy	Others
4	Yes	annoys me so much	I really love it	Happy	Happy

Table 3: Results from adjusting classification method and training on only T3.

dataset to achieve an equivalent F_1 score.

Model	Time	Micro F_1
CLARK	1	0.7870
SS-LSTM(1)	26	0.6796
SS-LSTM(3)	70	0.7834

Table 4: Comparison between CLARK and baseline Deep Learning models in terms of normalized time to train and classification performance.

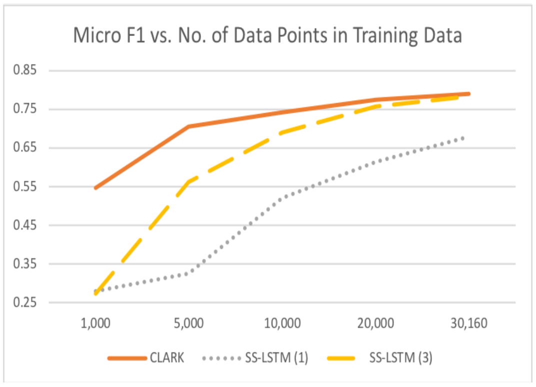

Figure 3: Comparisons of CLARK, SS-LSTM(1), and SS-LSTM(3) at varying amount of training data.

5 Discussion

We investigated a way to model emotion from text in the context of a conversation, instead of a single utterance. In doing so, we analyzed the performance of two different types of models, one based on a Naïve Bayes approach, which we call CLARK, and one on a Deep Learning approach. CLARK trained on T3 and classified using {Conv, T1, T3} leads to the best performance.

One way to utilize context is during training, but our results in experiments with CLARK show that the including more context (i.e., the whole conversation) significantly degrades performance. Training just on T3 produces much better results than training on Conv. This makes sense as T3 is the utterance directly associated with the assigned label and as such, represents the words that we can associate to the label with the highest confidence.

Some notion of "context" is important in determining the overall emotion of a conversation. When classification uses Conv and the final utterance (T3), the model produces the best results, as demonstrated by consistently producing a better F_1 score. This reflects the idea that as humans, mood affects how we judge the emotion a person is currently expressing (Schmid and Mast, 2010).

Our approach to incorporating context is fundamentally different from the approach taken in the baseline model. The SS-LSTM is more similar to a training method using all three utterances and classification method using {T1, T2, T3}. It also takes exponentially longer to train than CLARK and produces roughly equivalent performance, when examining the full dataset. Any attempt to speed up the model by using less training data would be in vain as shown in Figure 3. In cases where efficiency is paramount, the Deep Learning approach is lacking because of these requirements. Being able to produce good results with less training data can be a valuable asset.

Many of this work's limitations come from the data and the way the data was processed. The set of 30,160 three turn conversations is not balanced - there is far more in the others class than the rest. Because Naïve Bayes is a probabilistic model, it will prefer the others class. A solution could be to utilize a Complement Naïve Bayes, which estimates parameters from data using complement classes (Rennie et al., 2003). In addition, the data was labelled using a semi-automatic technique. Human subjects labeled a small subset of tweets, and key word embeddings were then extrapolated to label the rest of the conversations. This method leaves a lot of room for error and even suggests the function our model is trying to learn is this labelling mechanism. In future work, we will use only data labelled by human subjects.

6 Conclusion

Context plays an important role in recognizing emotions, but blindly including context can actually make recognizing emotions more difficult. As a response to the SemEval-2019 Task 3 challenge, we performed a systematic exploration of how to use context in classifying emotions in a short conversation. The resulting model, CLARK, performs best when trained on just the third turn of conversations (no context) and then classification uses Conv to infer mood and emotions from previous turns (with context). The relatively simple Naïve Bayes model, which performs on par with a baseline LSTM model while requiring less data and time to train, demonstrates one successful approach to using context that is usable in resource-constrained scenarios. Furthermore, we believe that while our results are demonstrated using a Naive Bayes model, our approach to using context only when classifying has the potential of being applicable to other classification approaches.

Abstract

In this paper, we describe the participation of team ”CLP” in SemEval-2019 Task 3 “Contextual Emotion Detection in Text” that aims to classify emotion of user utterance in textual conversation. The submitted system is a deep learning architecture based on Hierarchical Attention Networks (HAN) and Embedding from Language Model (ELMo). The core of the architecture contains two representation layers. The first one combines the outputs of ELMo, hand-craft features and Bidirectional Long Short-Term Memory with Attention (Bi-LSTM-Attention) to represent user utterance. The second layer use a Bi-LSTM-Attention encoder to represent the conversation. Our system achieved F1 score of 0.7524 which outperformed the baseline model of the organizers by 0.1656.

1 Introduction

Emotion detection has been widely researched in psychology, sociology and computer science. Being able to recognize the emotion of text is of vital importance in the human-computer interaction (Cowie et al., 2001). However, detecting emotion in text is generally considered very challenging in absence of facial expression or voice modulation. In domain of natural language processing, emotion detection is a task of associating words, phrases or documents with emotions using psychological models (Duppada et al., 2018). Traditional rule-based approaches (Balahur et al., 2011; Chaumartin, 2007) and machine learning approaches (Alm et al., 2005; Balabantaray et al., 2012) rely on extracting word-level features to classify emotion. These methods suffer from low recall as many texts do not contain emotion words. To tackle the problem, recent deep learning approaches (Mundra et al., 2017) take the advantage of Word2Vec representation (Mikolov et al., 2013a) to extract semantic features and achieve remarkable performance. However, limited researches have been done in classifying textual conversation emotions, which is further compounded by difficulty in the context understanding.

Task 3 “Contextual Emotion Detection in Text” in SemEval-2019 aims to find better solutions for those difficulties in contextual emotion detection (Chatterjee et al., 2019). The task considers textual emotion classification on four-point scale(Happy, Sad, Angry along with an Others category). It classifies emotion of user utterance along with 2 turns of context in conversation.

This paper describes the components and results of our emotion recognition system. The proposed system is a deep learning model based on HAN, which combines multiple encoding methods including ELMo, hand-craft features and Bi-LSTM-Attention encoder. Our system yields a micro-averaged F1 score of 0.7524 on test-set of Task 3 of SemEval 2019.

2 System Description

Figure 1 provides a overall architecture of our approach, which consists of three components: (1) preprocessing, where we use a specially designed text processing method to prepare inputs for our neural network, (2) utterance encoder, where we use ELMo, hand-craft features and Bi-LSTM-Attention encoder to represent user utterance, (3) conversation encoder, where we use a Bi-LSTM-Attention layer to represent the conversation.

2.1 Preprocessing

Twitter limits that a tweet should not exceed 140 characters, which makes users use informal ways to express themselves. Emotion detection for these kinds of tweets is very challenging. To ensure effective feature extraction, we use Ekphrasis (Baziotis et al., 2017) to normalize the utterance.

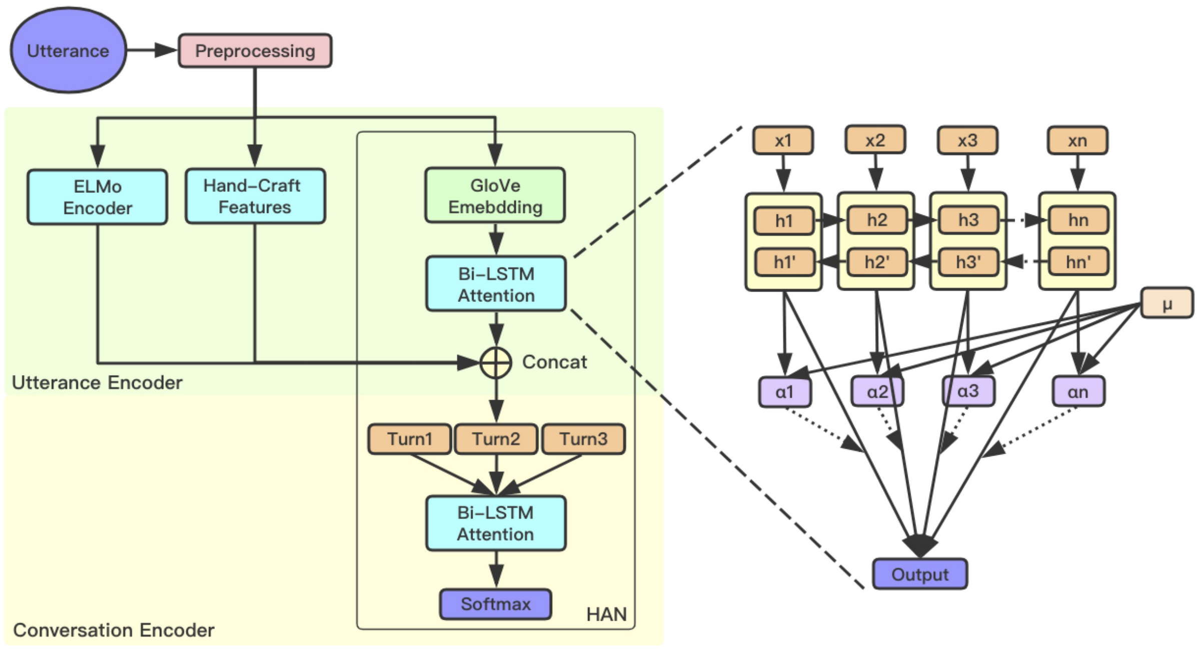

Figure 1: Overall architecture of our approach.

Ekphrasis contains a text processing pipeline that is specially designed for social network texts. The following steps are applied to utterances and lexicons in corpus:

1. **Tokenization.** We use the tokenizer in Ekphrasis to split utterance into word tokens and extract text emoticons from raw texts. The tokenizer is effective in splitting compounded words that are commonly used in Twitter. For example, the output of "#ifeelsad" will be "# i feel sad".

2. **Normalization.** We use regex regressions to detect and normalize categories, such as url/email/money/time/date. These categories are not sensitive features in the task.

3. **Annotation.** We annotate all uppercase words, repeated words and elongated words with corresponding tags, e.g. "hellooooooo" to "hello <elong>"; "yesyesyes" to "yes <repeated>"; "HELLO" to "hello <allcaps>". These informal words are vital features for prediction because they are rich in emotion.

4. **Spelling Correction.** We manually build a dictionary for out-of-vocabulary words (not in pre-trained word vectors) based on the provided datasets. 921 words are collected and corrected. The spelling correction reduces percentage of unknown words from 18% to 12%.

5. **Emoji and Emoticon Normalization.** We normalize emojis/emoticons because some of them have the same meaning. For example, "<3" and "<<33" both indicate heart, while ":(((" and ":(" both represent unhappy.

6. **Lowercase.** All characters in user utterance are converted to lowercase.

2.2 ELMo

ELMo (Peters et al., 2018) is an off-the-shelf pretrained language model that produces deep contextualized word representation, which captures both syntax and semantic information. ELMo can be easily integrated into existing model and usually leads to performance improvement. For most state-of-the-art Natural Language Processing (NLP) tasks, pre-trained word representation is a key component (Mikolov et al., 2013b; Pennington et al., 2014). We assume that different word representations allow the model to benefit from diversified information, so we make ELMo a part of our utterance encoder. Specifically, to generate ELMo representation, we use pre-trained model provided by TensorFlow Hub [1], which outputs a mean-pooling vector of all contextualized

[1]https://tfhub.dev/google/elmo/2.

Dataset	Others	Happy	Sad	Angry	Total
original training	14948	4243	5463	5506	30160
cleaned training	14865	4231	5447	5476	30019
cleaned + augmented training	20351	14566	11240	8319	54476

Table 1: Emotion Distribution of Datasets.

word representations with 1024 dimensions in our model.

2.3 Hand-craft Features

Hand-craft features represent prior knowledge. We extract hand-craft features related to emoji and emoticon because they are frequently used as emotion indicators in Twitter and vital to textual emotion detection. We create a list that contains 300 emojis and emoticons based on this corpus. With the list, we build a Term Frequency–Inverse Document Frequency (TF-IDF) vectorizer. Finally, we convert the utterance to a 300 dimensions vector.

2.4 HAN

HAN (Yang et al., 2016) is designed to capture hierarchical structure in document. Conversation has the same hierarchical structure (words form sentence, sentences form conversation) as document, so we use HAN as the main structure of our system. Our HAN structure has two layers: utterance encoder and context encoder.

Utterance Encoder. We use pre-trained word vectors of GloVe (Pennington et al., 2014) for Twitter as our word embedding. The word embedding is put into a 1-layer Bi-LSTM followed by an attention layer (Vaswani et al., 2017). Figure 1 gives the architecture of Bi-LSTM-Attention. The Bi-LSTM summarizes utterance from both directions and incorporates the contextual information, while the attention mechanism extracts word importance. After the Bi-LSTM-Attention, we combine the output of Bi-LSTM-Attention, ELMo and hand-craft feature vector to represent user utterance.

Conversation Encoder. Given the utterance representation of each turn, we get the conversation representation in a similar way. We use another Bi-LSTM layer to summarize the contextual information in conversation, and we apply attention mechanism to capture the importance of each turn. The output vector of the conversation encoder is a high level representation of the conversation and can be used as features for classification, which is a final softmax layer that predict the emotion.

3 Experiments and Evaluation

3.1 Data Preparation

The organizers provide 30160 conversations for training, 2755 for development and 5509 for test. Before training, we remove conversations that might not be correctly labeled. Then we create more datasets by data augmentation.

Data Cleaning. We firstly train our models with five-fold cross validation. 500 false positive data points with high confidence are picked out. Among them, we manually filter and delete 141 wrong labeled conversations.

Data Augmentation. Data augmentation (DA) is frequently used in Computer Vision (Fawzi et al., 2016). However, this method is less powerful in NLP because NLP data is discrete. Even small perturbations may change the meaning of a whole sentence. In this task, we assume that the positions of emojis and emoticons do not influence the emotion of sentences, so DA can be considered reliable. Our DA includes two steps, 1) all emojis and emoticons in an utterance are extracted by using Ekphrasis, 2) we relocate the emojis and emoticons to the start and the end of the utterance, thus we create 2 additional utterances (not applied for utterances that contain emojis/emoticons only, or utterances begin or end with emojis/emoticons). In total, we get at most 3 utterances for each turn, which means 27 conversations for three turns.

Table 1 describes the emotion distribution of original, data cleaned, data cleaned and augmented training datasets. The proportion of each class in original training dataset is around 4:1:1:1 (Others:Happy:Sad:Angry) and it remains the same after data cleaning. However, DA changes the proportion to around 5:4:3:2 because Twitter users are more likely to use emojis/emoticons when they post happy, sad and angry tweets. In total, 24457 additional data points are created and the distribution of Angry, Sad and Happy classes is improved.

Model	$\mathbf{F1}_{Angry}$	$\mathbf{F1}_{Happy}$	$\mathbf{F1}_{Sad}$	$\mathbf{F1}_{Micro}$
Baseline of Organizers	0.5945	0.5461	0.6149	0.5868
HAN	0.6585	0.6716	0.7667	0.6935
HAN+ELMo	0.6922	0.6973	0.7462	0.7102
HAN+ELMo+HCF	0.7062	0.6997	0.7575	0.7199
HAN+ELMo+HCF+Preprocessing	0.7552	0.6935	0.7959	0.7459
HAN+ELMo+HCF+Preprocessing+DA	**0.7607**	**0.7013**	**0.7961**	**0.7524**

Table 2: Class-wise and micro-averaged F1 scores for models. Our best result comes from HAN + ELMo + Hand-craft Feature (HCF) + Preprocessing + DA.

3.2 Hyper-parameters

We minimize the cross-entropy loss function by using back-propagation with Adam (Kingma and Ba, 2015) and mini-batches of size 64. In order to optimize our results, we introduce class weights in loss function to reduce the impact of the unbalanced training set. The value of class weights is set based on the distribution of classes. The configuration of hyper-parameters includes as follows: the word embedding size is 200; the dimension of hidden layer size in LSTM is 200; the max length of the utterance in each turn is set 25, as nearly 99% of the utterances have less than 25 word tokens; the dropout rate is 0.2 to prevent over-fitting; the learning rate is 10e-3 and the learning rate decay is 10e-5 for each update.

3.3 Results and Discussion

Table 2 presents the results of different approaches. The organizers provide a baseline model with 0.5878 F1 score. Our best model achieves F1 score of 0.7524 which outperforms the baseline by 0.1656. We present 5 models to show how different components (Preprocessing, ELMo, Hand-craft features and DA) affect the performance. The results indicate that HAN is well performed in this task, which alone increases F1 score from 0.5878 to 0.6935. With ELMo encoder and hand-craft features, the performance improves by 0.0264 and continues to rise to 0.7449 if we apply preprocessing to the utterances. DA improves the F1 score of Angry, Sad and Happy, suggesting that more data points of these three classes are beneficial for the task.

Attention weight in HAN reflects how utterances contribute to emotion classification. Therefore, we calculate the average attention weight of three turns in conversation of test-set. Figure 2 shows that the third turn contributes the most to emotion detection, complying with the objective of the task which is to predict third turn emotion. We also find that the weight of first turn is higher than the second, which can be explained by the fact that the first turn and the third turn come from the same user.

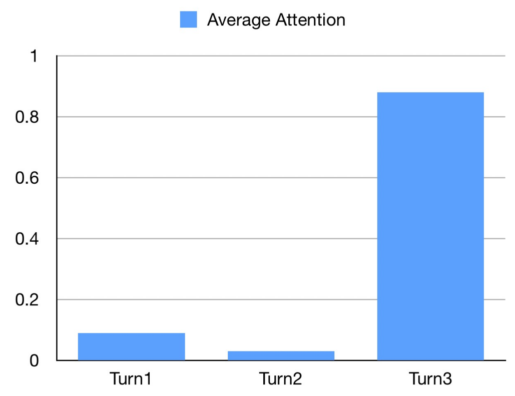

Figure 2: Attention weight of three turns.

4 Conclusion

In this paper we describe our solution to SemEval 2019 Task 3. To classify contextual emotion in a conversation, we propose a HAN based deep learning model that combines multiple encoding methods including ELMo, hand-craft features and Bi-LSTM-Attention encoder. We also build a preprocessing method to improve inputs quality and we apply data augmentation to create more data points. With all these components, our system achieves micro-averaged F1 score of 0.7524 and ranks 17th out of 165 teams on Task 3 leaderboard.

Abstract

This work describes the system presented by the CoAStaL Natural Language Processing group at University of Copenhagen. The main system we present uses the same attention mechanism presented in (Yang et al., 2016). Our overall model architecture is also inspired by their hierarchical classification model and adapted to deal with classification in dialogue by encoding information at the turn level. We use different encodings for each turn to create a more expressive representation of dialogue context which is then fed into our classifier. We also define a custom preprocessing step in order to deal with language commonly used in interactions across many social media outlets. Our proposed system achieves a micro F1 score of 0.7340 on the test set and shows significant gains in performance compared to a system using dialogue level encoding.

1 Introduction

Recognizing emotion is crucial to human-human communication and has for a long time been a goal in human-machine interaction. Although there has been growing interest in emotion detection across many fields (Liscombe et al., 2005; Agrafioti et al., 2012; Craggs and Wood, 2004), much of the work has focused on developing empathetic systems using multimodal approaches i.e. speech and gestures as well as text (Hazarika et al., 2018). Approaching emotion detection as a multimodal problem certainly makes sense, as face-face human communication involves many modalities, however, this fails to consider all the communication that is increasingly happening solely via chat, or written means. Detecting emotion in textual dialogue without the other modalities, such as work done by Gupta et al., can allow us to improve a number of applications dealing with social media interactions, opinion mining, and customer interactions, unfortunately, this is a great challenge that has remained largely unexplored. SemEval 2019 Task 3 attempts to encourage research in this direction. Given a user utterance and the previous two turns of context, the task consists in classifying the user utterance according to one of four emotion classes: happy, sad, angry or other. For a full description of the task see (Chatterjee et al., 2019). In this paper, we describe our turn-level attention model used to tackle this task, specifically using the attention mechanism presented in (Yang et al., 2016). Our model encodes turns in a conversation separately using an Attentive Bidirectional LSTM encoder. In the model presented in the shared task, the turn encoders do not share parameters, achieving a micro F1 score of 0.7340. The code for all experiments presented here is available. [1]

2 Related Work

Due to its many potential applications across many fields, detection of speaker emotional state in spoken dialogue systems has been studied extensively. Early studies showed that the use of prosody as well as speaking style features leads to increases in accuracy for emotion prediction (Ang et al., 2002; Devillers et al., 2002). Researchers have also shown that using domain specific features as well as speech signals can improve performance (Ai et al., 2006). Furthermore, there is plenty of work that tries to improve detection of affect in text using multiple modalities such as video or an embodied conversational agent (Alonso-Martin et al., 2013; Dmello and Graesser, 2010), however, detection of emotion solely based on text conversation data has not seen the same breakthroughs.

[*] Authors contributed equally

[1] https://github.com/coastalcph/emocontext

Very recently, work has started to emerge dealing with emotion detection in textual dialogue only. Majumder et al. introduced an attentive RNN model that treats each party of a conversation independently in order to provide specific representations for speaker and listener at a given point in a conversation. This model assumes that in a dialogue, the emotion of speaker A will be influenced by the utterances expressed by speaker B. Using this approach, the model achieves state of the art performance in two affect datasets (Schuller et al., 2011; Busso et al., 2008)). The model presented by us falls in this line of research, as we also attempt to exploit turn level information independently, however, our work differs in the fact that we create representations for each turn as opposed to creating representations for each speaker.

3 Data Preprocessing

Due to the casual text language used in many of the dialogues in the dataset, properly preprocessing these is an essential part of the classification process. The preprocessing pipeline consists of multiple steps that we describe in more depth below.

Text Normalization We use a custom normalization function which takes commonly used contractions in social media and maps them to a normalized version by unpacking them i.e. *idk* $\rightarrow$ *i don't know* and *plz* $\rightarrow$ *please*.

Spell Correction We normalize elongated words and use a spell correction tool which replaces misspelled words with the most probable candidate based on 2 corpora (Wikipedia and Twitter) (Baziotis et al., 2017a).

Tokenization We employ a tokenizer which emphasizes expressions and words typically used in social media. These include: 1) censored words, 2) words with emphasis, 3) elongated words, 4) splitting emoticons etc. All words are also lowercased when tokenized.

Emoji Descriptions As the dialogues contain a wide variety of emojis, which can contain a great deal of information about a users emotions (Felbo et al., 2017), we replace the emojis found in the utterances with their textual description. We used the emoji descriptions utilized for training Emoji2Vec (Eisner et al., 2016) which can be found in the Unicode emoji standard [2].

For most of the preprocessing steps described above, we relied on the Ekphrasis[3] text processing tool (Baziotis et al., 2017b).

4 Model Description

This section describes our conversational sentiment classification model as was used in the EmoContext shared task. Our architecture is illustrated in figure 1.

Embedding Layer We initiate the embedding layer with an embedding matrix computed using pretrained GloVe embeddings trained on 2 Billion tweets[4]. We do not finetune the weights during training.

Turn Encoder We use bidirectional LSTMs to encode a single turn in the conversation. Given a turn T_k made up of N_k words i.e. $T_k = (w_{1_k}, w_{2_k}, ..., w_{N_k})$, the representation of a given word w_{N_k} consists of the concatenation of the forward hidden state $\overrightarrow{h}_{N_k}$ and backward hidden state $\overleftarrow{h}_{N_k}$, i.e. $h_{N_k} = [\overleftarrow{h}_{N_k}, \overrightarrow{h}_{N_k}]$. This bidirectional representation is then fed through a batch normalization layer and then into the attention layer. The different turn encoders do not share their weights.

Turn Attention We use the attention mechanism introduced by (Yang et al., 2016) in order to extract important words in a single turn. The representation h_{N_k} is fed into a one-layer MLP to obtain the representation u_{N_k}. The similarity between u_{N_k} and a randomly initialized word context vector u_c is computed using the dot product and then the normalized weights α_{N_k} are obtained through a softmax function:

$$\alpha_{N_k} = \frac{exp(u_{N_k} \cdot u_c)}{\sum_k exp(u_{N_k} \cdot u_c)}$$

The final turn representation T_k is the weighted sum of the word vectors based on α_{N_k}.

$$T_k = \sum_k \alpha_{N_k} h_{N_k}$$

[2]http://www.unicode.org/emoji/charts/full-emoji-list.html

[3]https://github.com/cbaziotis/ekphrasis

[4]https://nlp.stanford.edu/projects/glove/

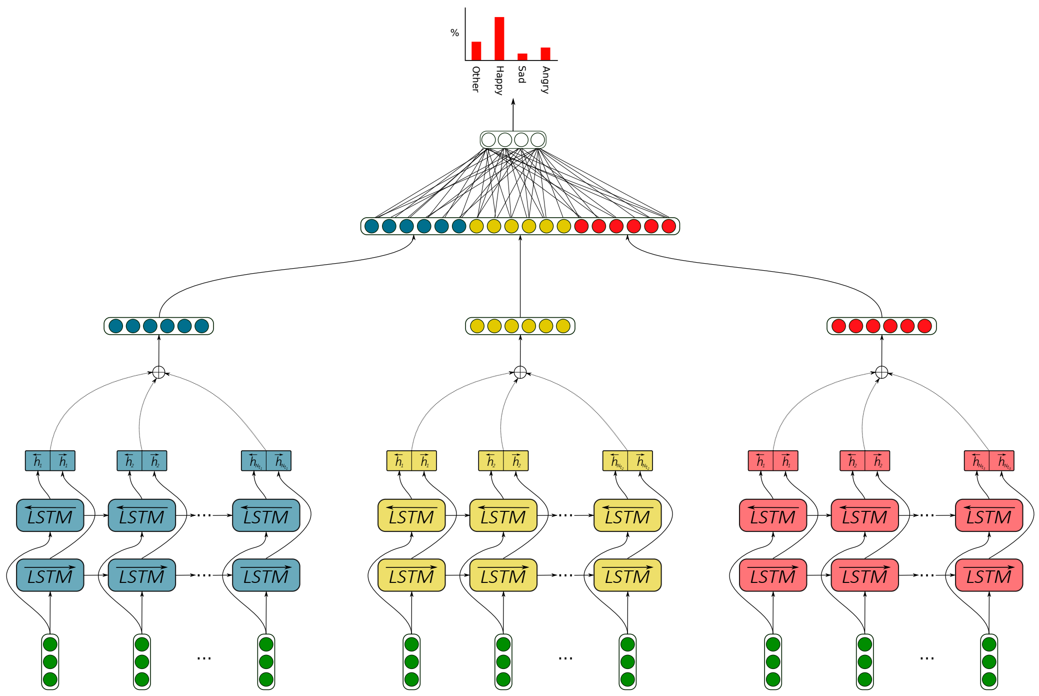

Figure 1: Our proposed model architecture. The turns are preprocessed and embedded using pretrain GloVe embeddings (trained on Twitter data) and fed into their respective BiLSTMs, which are attended over, and combined into a dialogue representation that is classified into one of the 4 classes.

Dialogue Representation For each turn of the conversation we use separate turn encoders and turn attention mechanisms and concatenate the final representations. So for a dialogue of k turns, we end up with a dialogue vector $D = [T_1, T_2, T_3, ..., T_k]$. This representation was chosen as the dialogue length was fixed to 3, but in a variable turn number setting, an LSTM could be utilized to create the final dialogue representation.

Emotion Classification The representation of dialogue D is fed into a softmax layer in order to estimate the probability distribution over the four possible emotion classes.

5 Baselines

Dialogue-level LSTM The main baseline model we compare performance to is the one provided by the task organizers. The system consists of one LSTM encoder, which encodes all turns in the conversation in the same sequence, separated by an end-of-turn token. We show the performance of the baseline given the provided preprocessing script by the organizers. In addition, we include the results of the baseline model using our custom preprocessor.

Dialogue-level TF-IDF with no added features For comparison with the dialogue-level LSTM, we include the performance of a SVM model with stochastic gradient descent. As input we use TF-IDF features computed over all turns. We encode the entire dialogue into a vector of the top 5k features.

Dialogue-level TF-IDF with added features In order to investigate the effect of additional information beyond TF-IDF features, we compute the ratio of words that are 1) elongated and 2) capitalized at the dialogue-level. In addition, we compute the average embeddings of the emojis (Eisner et al., 2016) occurring in the dialogue and concatenate all features with the dialogue level TF-IDF features.

Turn-level TF-IDF with no added features As our main system is a turn encoder, for comparison we also include the performance of an SVM classifier using stochastic gradient descent. using turn level TF-IDF vectors, concatenated into a final dialogue representation.

Turn-level TF-IDF with added features In order to quickly investigate the effect of additional information at the turn level, we compute the same features as mentioned earlier: 1) the ratio of words that are capitalized in a given turn, 2) the ratio of words that are elongated, and 3) the average embeddings of the emojis (Eisner et al., 2016) occurring in a given turn. All features are concatenated.

6 Setup and Results

In addition to our proposed system that is described in Section 4 (BiLSTM-Att) and the baselines in Section 5, we also report results for two other variants of BiLSTM-Att. The first model (BiLSTM-Att-Shared) shares weights between the RNNs, ie. we encode all turns individually with the same BiLSTM, and a model that simply encodes the entire dialogue as a single turn (BiLSTM-Att-Dia). We train the models with BiLSTM hidden state size of 256, a dropout rate between the LSTM layer and attention layer of 0.5 , a batch size of 200, and we use a word embedding dimension of 200. We optimize using the ADADELTA algorithm (Zeiler, 2012) with a learning rate of 1.0, $\rho = 0.95$ and $\varepsilon = 10^{-6}$.

System	Micro F1	Precision	Recall
LSTM	0.5613	0.4743	0.6862
Dialogue-tfidf	0.5528	0.6202	0.4986
Dialogue-tfidf-added	0.6064	0.7127	0.5276
Turn-tfidf	0.5918	0.6394	0.5507
Turn-tfidf-added	0.6955	**0.7632**	0.6388
BiLSTM-Att	**0.7340**	0.7132	0.7560
BiLSTM-Att-Shared	0.7243	0.6715	**0.7861**
BiLSTM-Att-Dia	0.6789	0.6039	0.7752

Table 1: The table shows the results of our models on the EmoContext shared task test set.

Our results are shown in Table 1. From the results we can observe that our proposed attentive turn-level BiLSTM outperforms all baselines, including the task organizers LSTM model, with a Micro F1 score of 0.7340. What is interesting to note is that almost all of our proposed simple SVM baselines also outperforms the baseline LSTM, with even Turn-tfidf-added by a significant margin. In general we see that encoding the dialogue on the turn level achieves better performance than its dialogue level counterparts.

7 Discussion

We saw that in all cases, encoding information at the turn level led to improvements in classifier performance over the dialogue level encoding. This observation is in line with work that exists trying to encode conversational context beyond the single turn or the dialogue level (Majumder et al., 2019; Webb et al., 2005). In addition, in the results shown in Table 1, we can observe that the dialogue level attention LSTM achieves a high recall but low precision. In contrast, the differences in all metrics for our proposed model are much smaller and more balanced. This suggests that without the turn level encoding, the classifier becomes more biased towards a specific class. In Table 2, we show the scores of the individual emotion classes for our turn and dialogue-level models. We can see that across all classes the models have a harder time when it comes to classifying dialogues labeled as Happy, suggesting that the happy conversations might have a tendency to be more neutral in language, resulting in a higher mislabelling rate with the Other class. This becomes more apparent when inspecting the data itself. What is also noteworthy is that the BiLSTM-Att-Shared, which shared a turn encoder between turns, achieves a lower F1 score than BiLSTM-Att, which used separate turn encoders. This could indicate that the different turns carry different weights in the context when it comes to determining the sentiment of the most recent speaker.

Emotion class	Micro F1	Precision	Recall
BiLSTM-Att			
Angry	0.751	0.686	0.829
Happy	0.692	0.721	0.666
Sad	0.757	0.742	0.772
BiLSTM-Att-Dia			
Angry	0.699	0.590	0.859
Happy	0.648	0.601	0.704
Sad	0.687	0.687	0.760

Table 2: F1, precision and recall scores for each of the emotion classes for two of our proposed models, BiLSTM-Att and BiLSTM-Att-Dia

8 Conclusion

Overall, our very straight forward model shows the important effect that encoding turn level information separately has when it comes to classifying dialogues. Using the entire dialogue with an end-of-turn token, we see that the model is not able to capture important features of individual turns that might affect the overall sentiment of the conversation. Our results also shows that, although less sophisticated, simpler and more interpretable models does also give decent results, compared to the LSTM baseline model.

ConSSED at SemEval-2019 Task 3: Configurable Semantic and Sentiment Emotion Detector

Rafał Poświata
National Information Processing Institute
al. Niepodległości 188b, 00-608 Warsaw, Poland
rafal.poswiata@opi.org.pl

Abstract

This paper describes our system participating in the SemEval-2019 Task 3: EmoContext: Contextual Emotion Detection in Text. The goal was to for a given textual dialogue, i.e. a user utterance along with two turns of context, identify the emotion of user utterance as one of the emotion classes: Happy, Sad, Angry or Others. Our system: ConSSED is a configurable combination of semantic and sentiment neural models. The official task submission achieved a micro-average F1 score of 75.31 which placed us 16th out of 165 participating systems.

1 Introduction

Emotion detection is crucial in developing a "smart" social (chit-chat) dialogue system (Chen et al., 2018). Like many sentence classification tasks, classifying emotions requires not only understanding of single sentence, but also capturing contextual information from entire conversations. For the competition we were invited to create a system for emotion detection of user utterance from short textual dialogue i.e. a user utterance along with two turns of context (Chatterjee et al., 2019b). The number of emotion classes has been limited to four (Happy, Sad, Angry and Others).

The rest of the paper is organized as follows. Section 2 briefly shows the related work. Section 3 elaborates on our approach. It shows preprocessing step and architecture of our system. Section 4 describes the data set, used word embeddings and hyper-parameters, adopted research methodology and experiments with results. Finally, Section 5 concludes our work.

2 Related Work

Detection of emotions in dialogues can be divided into two types: based only on the text of the dialogue (Chen et al., 2018) and based on many channels (video, speech, motion capture of a face, text transcriptions) (Busso et al., 2008). Regardless of the type, the most common solution is the use of neural networks, in particular variations of Recurrent Neural Networks, such as LSTMs (Hochreiter and Schmidhuber, 1997), BiLSTMs (Schuster and Paliwal, 1997) and GRUs (Cho et al., 2014) or Convolutional Neural Networks (Krizhevsky et al., 2012). Our solution uses LSTMs and BiLSTMs and is based on the ideas from SS-BED system (Chatterjee et al., 2019a).

3 Our Approach

Figure 1 provides an overview of our approach. We wanted to create a system that would benefit from the advantages of semantic and sentiment embeddings (like SS-BED). At the same time, it would be easily configurable both in terms of the selection of parameters/network architecture as well as the change of applied embeddings, both static and dynamic. In the next subsections, we describe in details our approach.

3.1 Preprocessing

For the preprocessing, we adjusted the ekphrasis tool (Baziotis et al., 2017). We use this tool for tokenization and to do the following:

- Normalize URLs, emails, percent/money/time/date expressions and phone numbers.
- Annotate emphasis and censored words and phrases with all capitalized letters.
- Annotate and reduce elongated (e.g. Whaaaat becomes <elongated> What) and repeated words (e.g. !!!!!!!!! becomes <repeated> !).

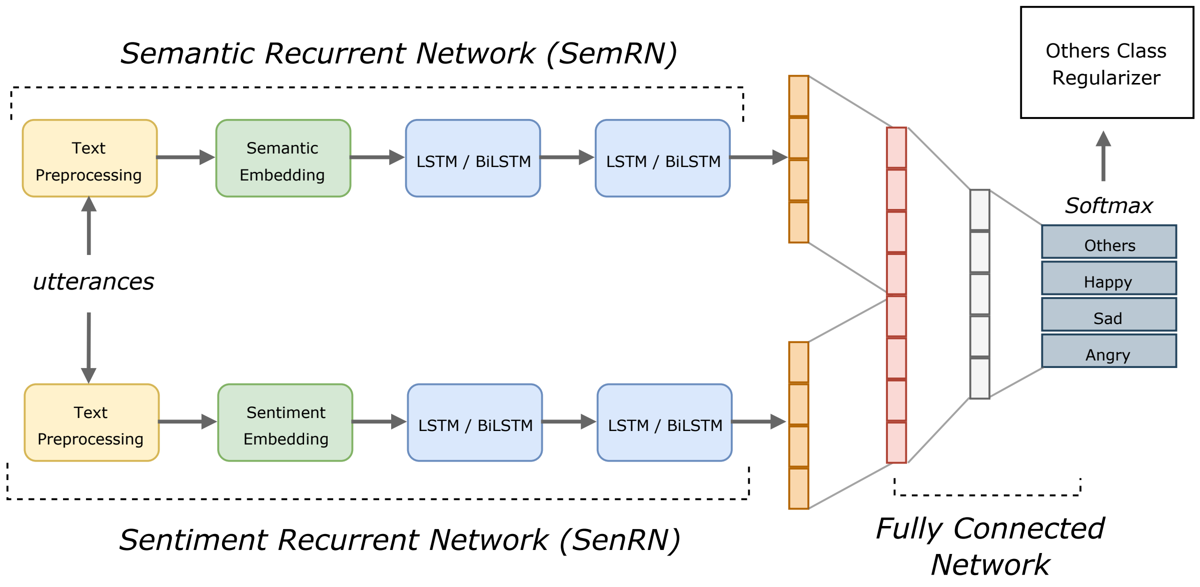

Figure 1: High level architecture of Configurable Semantic and Sentiment Emotion Detector (ConSSED).

- Unpack hashtags (e.g. #GameTime becomes <hashtag> game time </hashtag>) and contractions (e.g. "didn't" becomes "did not").
- Simplify emoticons e.g. :-] is changed to :).

We also prepare and apply dictionaries with common abbreviations and mistakes to reduce vocabulary size and deal with Out of Vocabulary (OOV) issue.

3.2 Model

Our model contains four parts: Semantic Recurrent Network (SemRN), Sentiment Recurrent Network (SenRN), Fully Connected Network and Others Class Regularizer. SemRN and SenRN are independent of each other and have similar architecture: Text Preprocessing, suitable Word Embedding and 2-layer LSTM or bidirectional LSTM (BiLSTM) - which is configurable. Outputs of those two modules are concatenated and become input for Fully Connected Network. This network has one hidden layer and Softmax layer which represents probabilities of classes. The last element of our model is Others Class Regularizer (used only during the prediction on validation/test set).

3.3 Others Class Regularizer

This component was created due to the fact that a real-life distribution is about 4% for each of Happy, Sad and Angry class and the rest is Others class. This component works by grouping records into three sets, depending on whether they are predicted as Happy, Sad or Angry. Next, for all of these sets, it checks if there are more representatives than the assumed percentage of all records. If yes, it increases the probability for Others class by 0.01 (independently in each set) until it reaches the number of representatives lower than the assumed percentage. The assumed percentage value was defined as 5.5% taking into account the validation set.

4 Experiments and Results

4.1 Data

In our work on the system, we used only official data sets made available by the organizers. However, we noticed that there are cases when conversations occur twice, but with different labels. We have removed these records and received sets which are shown in Table 1.

	Number of records
train	29977
validation	2755
test	5509

Table 1: Data sets statistics.

4.2 Word Embeddings

For our experiments, we chose five word embeddings: three semantic and two sentiment. Semantic embeddings are GloVe (Pennington et al., 2014) trained on Twitter data[1], Word2Vec (Mi-

kolov et al., 2013) with ten affective dimensions trained by NTUA-SLP team as part of their solution for SemEval2018 (Baziotis et al., 2018)[2] (we call it NTUA_310) and ELMo (Peters et al., 2018) trained on 1 Billion Word Benchmark[3]. As sentiment embeddings we chose Sentiment-Specific Word Embedding (SSWE) (Tang et al., 2014)[4] and Emo2Vec (Xu et al., 2018)[5].

4.3 Hyper-parameters Search

In order to tune the hyper-parameters of our model, we adopt a Bayesian optimization by using Hyperopt library[6]. The names of hyper-parameters with possible values (list or range) are shown in Table 2. Parameters with SEM prefix apply to the Semantic Recurrent Network, and with SEN prefix to the Sentiment Recurrent Network. LSTM_DIM parameter is for BiLSTM baseline systems. In order to cope with the differences in the distribution of classes in the training set and the validation and test sets, as well as the previously mentioned actual distribution of emotion classes in relation to the Others class, apart from the use of Others Class Regularizer we also used class weight for Others class (OTHERS_CLASS_WEIGHT parameter).

4.4 Methodology

We train all models using the training set and tune the hyper-parameters using the validation set. Due to the time frame of the competition, we limited the search of hyper-parameters to 10 iterations for each model. Then, for the best parameters (found in a limited number of iterations), we once again learned this model with a training and validation set. The final model validation took place on the test set. During all experiments, we used the preprocessing described in section 3.1.

4.5 Experiments

The results of our experiments are shown in Table 3. We have divided them into two stages: validation of the baseline systems and our solution.

For the first stage, we used the 2-layer bidirectional LSTM model (BiLSTM) with all the word embedding presented in section 4.2 and compared this approach to the baseline model prepared by the organizers (Baseline). The model using NTUA_310 embedding (73.34) performed best, compared to the Baseline, we have an improvement of about fifteen percent. The second best model was a solution using ELMo embedding (72.42). From sentiment embeddings the best was Emo2Vec (71.18).

The second stage was focused on the validation of the ConSSED model. In this experiment, we trained six models to verify all possible pairs of semantic embedding-sentiment embedding. The results show that the use of the ConSSED model allows better results than corresponding baseline systems. As we could have guessed from the first stage, the best was a combination of NTUA_310 and Emo2Vec (75.31), which was our official solution during the competition. In parentheses, we presented the results without the use of Others Class Regularizer. As we can see, the use of this component improves the results but only slightly. In addition, after the competition, we have rerun the search for hyper-parameters (this time increasing the number of iterations) for the ConSSED-

Table 4: Comparison between two ConSSED-NTUA_310-Emo2Vec models: official **Competition Model** and **Best Model** trained after the end of the competition.

NTUA_310-Emo2Vec model, which give us a better result than our official competition result (76.64). Hyper-parameters found for ConSSED-NTUA_310-Emo2Vec models and differences between them are shown in Table 4.

4.6 Competition Results

The best result we have obtained on official leaderboard is equal to 75.31 according to micro-averaged F1 score. Our solution is ranked 16th out of 165 participating systems.

5 Conclusion

In this paper, we present Configurable Semantic and Sentiment Emotion Detector (ConSSED) - our system participating in the SemEval-2019 Task 3. ConSSED has achieved good results, and subsequent studies show that it can achieve even better which results from a further search for hyper-parameters. We think that the use of fine-tuned ELMo model (e.g. by Twitter data) would improve the result even more. In addition, we would like to integrate our system with the BERT embedding (Devlin et al., 2018).

For developing our system we used Keras[7] with TensorFlow[8] as backend. We make our source code available at `https://github.com/rafalposwiata/conssed`.

CX-ST-RNM at SemEval-2019 Task 3: Fusion of Recurrent Neural Networks Based on Contextualized and Static Word Representations for Contextual Emotion Detection

Michał Perełkiewicz
National Information Processing Institute
al. Niepodległości 188b, Warsaw, Poland
michal.perelkiewicz@opi.org.pl

Abstract

In this paper, I describe a fusion model combining contextualized and static word representations for approaching the EmoContext task in the SemEval 2019 competition. The model is based on two Recurrent Neural Networks, the first one is fed with a state-of-the-art ELMo deep contextualized word representation and the second one is fed with a static Word2Vec embedding augmented with 10-dimensional affective word feature vector. The proposed model is compared with two baseline models based on a static word representation and a contextualized word representation, separately. My approach achieved officially 0.7278 microaveraged F1 score on the test dataset, ranking 47th out of 165 participants.

1 Introduction

The EmoContext task in the Semantic Evaluation 2019 (SemEval 2019) competition focuses on the classification of textual dialogues i.e. a user short conversation with a bot, into ’happy’, ’sad’, ’angry’ and ’others’ sentiment classes. Understanding emotions in textual conversations is a challenging task mainly because of an absence of others expression channels such as voice modulations and facial expressions usually accompanying a people conversation. In textual conversation determining the emotion of a given statement is very dependent on the context of previous statements.

A sentiment detection field has been thoroughly analysed. The first attempts to manage this problem included mainly extracting hand-crafted features and knowledge-based systems (Balahur et al., 2011; Chaumartin, 2007; Joulin et al., 2016).

Neural machine learning approaches, especially Recurrent Neural Networks (RNN) like LSTM and GRU and Convolutional Neural Networks (CNN), are effective tools for detecting sentiment from text and were widely used in this area (Tang et al., 2015; Liu et al., 2016; dos Santos and Gatti, 2014). Except that, one of the approaches employs Hierarchical Attention Networks (HAN) to determining emotions from textual dialogues data (Saxena et al., 2018).

In this work, I propose a deep neural fusion model that combines two Bidirectional LSTM Recurrent Neural Networks for detecting sentiments in textual dialogues. I use static Word2Vev word representation and a contextualized ELMo word representation to create a unified model. This architecture of the model is inspired by the work presented in (Gupta et al., 2017).

The rest of the paper is structured as follows. Section 2 describes the proposed approach and word representations. The experiments and results are presented and discussed in Section 3. Finally, in the last section, the conclusions are presented.

2 Approach

The following section provides details on preprocessing I used to normalize textual data provided by the task organizers, the method to manage unbalanced datasets problem and describes the model architecture and used word embeddings.

2.1 Preprocessing

To clean and normalize textual data, I adapt the *ekphrasis* text processing library[1] with some changes. It was designed with a focus on text from social networks, such as Twitter or Facebook. It provides tools to process text, such as tokenization, word normalization, word segmentation and spell correction, using word statistics from 2 big corpora (English-language Wikipedia and Twitter)(Baziotis et al., 2017).

The *ekphrasis* preprocessing techniques I used includes: Twitter-specific tokenization, omitting

[1] https://github.com/cbaziotis/ekphrasis

special words and phrases (like emails, phone numbers, nicknames, dates and time, URLs), spell correction, words annotations (for uppercased, repeated, hashtagged and elongated words), reducing emoticons variations by replacing emoticons expressing similar emotions to the same form (e.g ':)' and ':-)' emoticons are both mapped to the ⟨happy⟩ mark).

To better normalize texts and suit the tool to EmoContext datasets, I did following modifications in the text processing library:

– adding a new dictionary to expand English contractions (e.g. can't → can not, couldn't've → could not have), normalize slang words (e.g. plz → please) and correct typos (whhat → what).

– extending the emoticons dictionary with emoticons found in the training and the testing corpora to reduce them to the basic form.

– adding new map for emoticons expressing strong emotions by adding the *very* word before them (e.g ':)))))))' → very ⟨happy⟩)

– changing emoticons mapping by adding the prefix 'emo_' to emotion marks[2], like ':)': '⟨emo_happy⟩'.

2.2 Altering the Training Balance

According to information pointed out by the task organizers on the EmoContext web page[3], provided datasets are unbalanced. Training data consists of about 5000 (about 17%) samples each from 'angry', 'sad', 'happy' class, and about 15000 (about 50%) samples from 'others' class, whereas, both the development dataset and the test dataset sets have a real-life distribution, which is about 4% each of 'angry', 'sad', 'happy' class and the rest is 'others' class.

To deal with unbalanced datasets and avoid to bias model towards the 'other' class, I created two derivative training datasets: the binary one, by mapping 'happy', 'sad', 'angry' labels to the one 'sentiment' label and left the 'others' label unchanged. This binary set contains about 50% of dialogues covey some sentiment and about 50% dialogues conveys no sentiment (the original 'other' label). The second derivative dataset contains dialogues labelled one of the following labels: 'happy', 'sad', 'angry'. So, this dataset contains examples originally conveys some sentiment. Classes distributions of these two derivative datasets are more balanced. These derivative datasets are used to learn a two-stage model based on two Recurrent Neural Networks as described in Subsection 2.4.

Furthermore, I extend the training dataset by carrying 1753 examples from the development dataset and left 1000 examples to valid my model.

[2]only used by the contextualized embedding

[3]https://competitions.codalab.org/competitions/19790#learn_the_details-data-set-format

2.3 Word Embeddings

Word embeddings are representations of words as n-dimensional vectors, previously learned on large text corpus. The proposed model is fed both a static word embedding and a contextualized (dynamic) word embedding.

Static Word Embedding Static word embeddings map the same word to the same vector, independently of the word context. The advantages of static word embeddings are easy interpretability and capturing semantic properties of words (embedding vectors for words semantically similar are similar as well). However, they suffer from some problems, for example a meaning conflation deficiency – the inability to discriminate among different meanings of a word.

To embed textual data to a static representation I adapt pretrained 300-dimensional Word2Vec word embedding vector augmented with a 10-dimensional vector of word affective features proposed in (Baziotis et al., 2018). It was trained on the collection of 550 million Twitter messages preprocessed by the *ekphrasis* text processing library. Such very similar preprocessing stage can better suit EmoContext textual data to this pretrained embedding.

Therefore, the static word embedding I use maps every sentence in EmoContext datasets to a 310 dimensional n-length list where n is a number of words in a sentence.

Contextualized Word Embedding As opposed to static embeddings, contextualized word embeddings generate words representation vectors dynamically, depending on the context in which a given word appears. They need the whole sentence to generate words embeddings because of a need to know the context of each word in a sentence.

I employee the Embeddings from Language Models (ELMo) word embedding, where word vector representations are learned functions of the internal states of a deep bidirectional language model (biLM) (Peters et al., 2018). I use official available, pretrained ELMo original model[4] which was learned on the dataset of 5.5 billion tokens consisting of Wikipedia (1.9 billion) and all of the monolingual news crawl data from WMT 2008-2012 (3.6 billion). To vectorize words, I get the state of the last biLM layer built on 1024 neurons, therefore the embedding vectors are the length of 1024 elements. To better suit this embedding to the EmoContext datasets, I fine-tuned the ELMo model by learning pretrained biLM. For this purpose, I used all utterances from the datasets provided by the organizers.

To generate more context-aware representations of words, for each dialogue in the datasets I merged the previous one or two utterances with the second or the third utterance in a dialogue, respectively. Such a context extending allows generating vector representations for two last utterances taking into account the context of the previous utterances in whole dialogue. For a first utterance, I use only the first utterance without any extension.

2.4 Model Architecture

Next, I present in detail the submitted model. My final model is based on the fusion of two deep, two-layer Bidirectional LSTM Neural Networks with Attention Mechanism. First one consumes 310-dimensional vectors and produces a 250-dimensional encoding as a averaged Bidirectional LSTM network states over time. The second one consumes 1024-dimensional vectors and produces a 300-dimensional encoding vector, as in the previous case, as a averaged Bidirectional LSTM network states over time. Then these two encodings are merged and are consumed by a Fully Connected layer with 120 neurons. The activation function of this layer is a softmax function to get probabilities of output classes. The architecture is depicted in Figure 1.

To avoid overfitting during learning the model, I use the following regularization techniques:

– Dropout inputs to BiLSMT networks, for each layer.

– Dropout input to Fully Connected Layer.

[4] https://allennlp.org/elmo

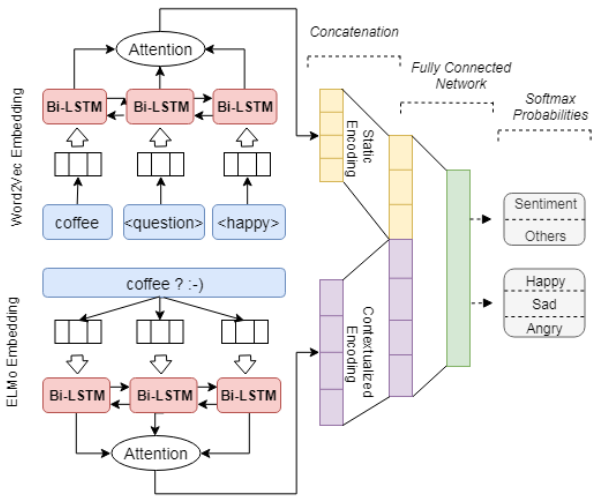

Figure 1: The proposed model architecture.

– Recurrent Dropout to dropout connections between the recurrent units in Recurrent Networks for each layer.

I learnt two models based on described architecture separately using datasets describing in Section 2.2. These two networks are stacked and the prediction process runs as follows:

– the general model (called sent-others network) predicts if a dialogue conveys some sentiment or not. This model predicts one of two labels: ’sentiment’ or ’others’ to input data.

– if the general model has predicted the ’sentiment’ label, the input data is carried forward to the second model (called happy-sad-angry network). The responsibility of this model is to determine the sentiment of an input data and put one of three labels: ’angry’, ’sad’, ’happy’.

After this two-stage classification, the model labels input data as ’happy’, ’sad’, ’angry’, ’others’ example.

Furthermore, because of different class distributions in the datasets, I added an parameter T to the sent-others network to fit the model to development/test datasets classes distribution. This parameter specifies the minimum value that the softmax probability for ’sentiment’ class has to achieve to label input data as ’sentiment’. For predicting on the test dataset, I set the parameter T to 0.75, which was the value that achieved the best result on the validation dataset.

Parameter	Value		Tested Values
	sent-others	happy-sad-angry	
LAYERS_NUMBER	2	2	2
NEURONS_NUMBER	300, 300	250, 250	200, 200; 250, 250; 300, 300
BI-LSTM_INPUT_DROPOUT	0.3, 0.5	0.3, 0.5	0.2, 0.5; 0.3, 0.5
RECURRENT_DROPOUT	0.3, 0.5	0.3, 0.5	0.2, 0.5; 0.3, 0.5
FULL_CONNECTED_LAYER_DROPOUT	0.3	0.3	0.3, 0.4, 0.5
FULL_CONNECTED_LAYER_SIZE	120	120	100, 120
BATCH_SIZE	32	32	32
THRESHOLD_T	0.75	-	0.25, 0.55, 0.75

Table 1: The parameters of the proposed model.

Model	Validation(1000)			Test		
	sent-others	happy-sad-angry	2-stage	sent-others	happy-sad-angry	2-stage
ELMo	0.9456	**0.9700**	0.7511	0.9517	**0.9447**	0.7192
Word2Vec-310	0.9534	0.9641	0.7500	**0.9568**	0.9351	0.7180
Word2Vec-310 + ELMo	**0.9542**	0.9672	**0.7558**	0.9537	0.9422	**0.7278**

Table 2: Microaveraged F1 score of baselines models and the fusion model on the validation and the test datasets.

Table 1 presents tested model parameters and the best parameters set for the validation dataset.

3 Results

Table 2 presents microaveraged F1 score achieved on the test and the validation datasets for the proposed model containing also F1 scores for the first (sent-onthers network) and the second (happy-sad-angry network) classification stages. I compared the proposed fusion model against 2 baselines based on the static and contextualized models used in the proposed method, separately. Therefore the first baseline model uses 2-layer Bi-LSTM Neural Network which is learned on static, *Word2Vec* with affective features word representation, and the second one is a baseline model 2-layer BI-LSTM Neural Network as well but is learned on contextualized ELMo word representation embedding. The results of such baseline models allow better insight into the performance of the proposed fusion model.

The best results for 2-stage classification for the test dataset achieved the fusion model (0.7558 for validation and 0.7278 for the test dataset) despite the worse results in the sent-others and the happy-sad-angry classification stages. For the validation dataset, the proposed fusion model achieved the best score as well. The best result for 2-stage classification was better by about 1 percent from baselines results.

4 Conclusion

In this paper, we have presented the fusion model, a sentiment classifier that combines the features of static and contextualized word embedding. This approach achieved officially 0.7278 F1-score, ranking 47th out of 165 participants.

My results show that combining word embeddings can improve sentiment detection models based only on one, static or contextualized, embedding. The two-stage classification model can better insight to classification process and parameterized each stage separately.

Abstract

This paper describes our proposed system & experiments performed to detect contextual emotion in texts for SemEval 2019 Task 3. We exploit sentiment information, syntactic patterns & semantic relatedness to capture diverse aspects of the text. Word level embeddings such as Glove, FastText, Emoji along with sentence level embeddings like Skip-Thought, DeepMoji & Unsupervised Sentiment Neuron were used as input features to our architecture. We democratize the learning using ensembling of models with different parameters to produce the final output. This paper discusses comparative analysis of the significance of these embeddings and our approach for the task.

1 Introduction

Emotion Classification is more nuanced version of Sentiment Analysis. While Sentiment Analysis gives you a general idea about user experience by categorizing statements into positive or negative, Emotion Classification extracts specific attributes about each of these 2 categories. Contextual Emotion Classification needs to keep the context of an ongoing conversation to predict their emotional state and therefore comes with its own challenges. Detecting emotions has become a crucial part of understanding user generated content and to generate emotion aware responses. This paper describes our approach for SemEval 2019 Task 3: EmoContext. The task is Emotion Classification in the conversational scenario. Complete details about the task, evaluation and dataset can be found in paper released by organizers (Chatterjee et al., 2019). We use various state-of-the-art Machine Learning models and perform domain adaptation (Pan and Yang, 2010) from their source task to the SemEval EmoContext task. Our solution uses multiple types of feature embeddings viz Skip-Thought vectors (Kiros et al., 2015), Unsupervised Sentiment Neuron (Radford et al., 2017), DeepMoji's attention and last layer (Felbo et al., 2017) embedding along with Glove (Pennington et al., 2014), Emoji Embedding (Eisner et al., 2016) and FastText (Joulin et al., 2016). These feature embeddings are passed to a Deep Learning architecture. We train multiple models with different hyper-parameters. Finally, the results from each models are stacked together in an ensemble (Polikar, 2006). Our main approach for the literature survey was to look for similar research work used in previous SemEval tasks and other published state-of-the-art methodologies in the same domain. Infact, SemEval 2018 task of finding Affect in Tweet (Mohammad et al., 2018) demonstrates how detection of emotion plays an important role in understanding content as well as its creators. It was helpful to learn about how various architectures such as Siamese (Ghosh and Veale, 2018), CNNs (Khosla, 2018) and Deeply connected LSTMs (Wu et al., 2018) can be used to effectively learn emotional context of text. Methodologies such as ensembling (Polikar, 2006) and use of diverse features embeddings (Duppada et al., 2018) plays an important role when the data is limited, imbalanced and confusing to classify accurately. In this paper, we discuss our approach and experiments to solve this problem. The remainder of this paper is organized as follows. Section 2 explains the System Description and our analysis. Experiment setup and Results are discussed in section 3, followed by conclusion in the last section.

2 System Description

The following section describes our analysis of the task and data. We then discuss preprocessing steps, features used and system design with architecture flow.

Proceedings of the 13th International Workshop on Semantic Evaluation (SemEval-2019), pages 185–189
Minneapolis, Minnesota, USA, June 6–7, 2019. ©2019 Association for Computational Linguistics

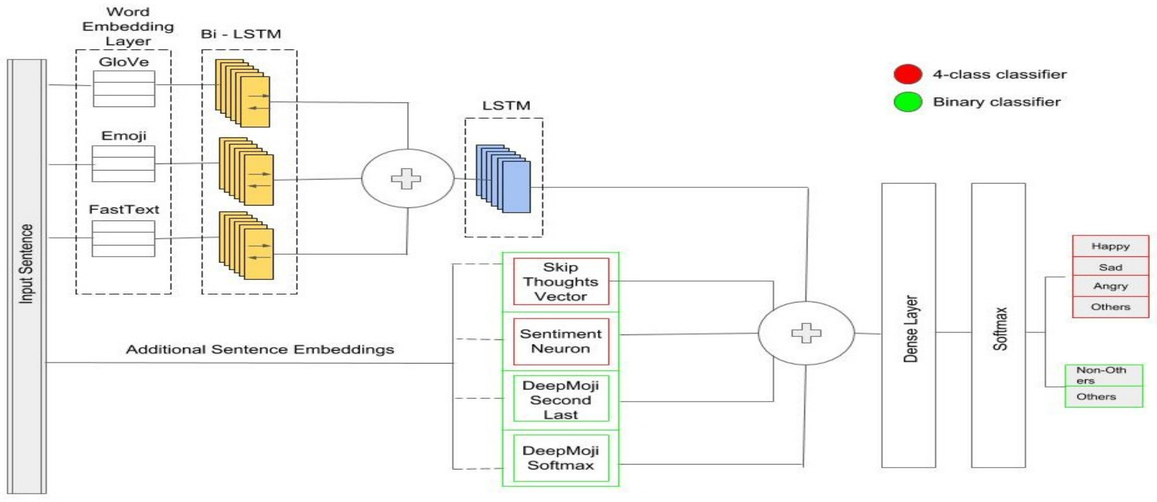

Figure 1: For each input sentence, word-level embeddings are passed to Bi-LSTMs, the output is concatenated and then passed through an LSTM. The sentence-level embeddings are then concatenated with LSTMs output and passed to the dense layer with softmax. First, the input is classified into others or non-others emotion category, the latter classified input is then passed to a second 4 class model for final classification.

2.1 Task and Data Analysis

The Data consists of 3 consecutive utterances in a conversation called turn1, turn2 and turn3. The task is to classify the emotion of the user on turn3. There are 4 labels which includes three emotions viz happy, sad, angry and others is used for emotionless label. After analysing the data we found some inconsistency like use of slangs (lol, xoxo), spelling errors(hellooo, frnd) and incomplete sentences. There is also difficulty in determining emotion because of ambiguity, for ex. I am not talking to u which can be either interpreted as sad or angry statement. Another important discovery shows that every labelled emotion is highly associated with the emojis used. The major issue with the data we faced was of class imbalance, 4% of data belonged to three emotion class and 88% belonged to the others category, which ultimately causes confusion between others and each emotion class. Hence, we decided to first classify the utterances into others or non others, and then further the non others into the 4 classes.

2.2 Pre Processing

We avoided removing stop words and lemmatization since it results in loss of information. We followed standard pre-processing steps: 1) All three utterances are concatenated using a placeholder <eos>. 2) All characters are converted to lowercase. 3) A contiguous sequence of emojis is split into individual emojis. 4) All repeated punctuation (???, ...) and white spaces are removed.

2.3 Features

During literature survey, we discovered different features that helped us capture an informal conversation as a whole. To tackle the ambiguity and other inconsistencies, we have used both word-level and sentence-level embeddings as input features to the model.

2.3.1 Word Level Embeddings

- Glove Embedding - We used 300 dimension Glove embedding to capture the general semantics of each word in the utterance.

- Emoji Embedding - Emoticons played a central role to understand the context of emotion in the text. We used a 300 dimension Emoji Embedding pre trained on large emoji corpus, to capture each emoji in the corpus which were being missed by Glove.

- FastText Embedding - We trained 300 dimension FastText embeddings on the training data to capture data specific semantics of the words.

2.3.2 Sentence Level Embeddings

- Skip-thought Vectors - We extracted 4800 dimension sentence embedding of the data using Skip-Thought vectors encoder, which capture generic sentence representation.

- Unsupervised Sentiment Neuron (USN)- We trained USN to obtain a 4096 dimension sentence embedding to capture the representation of sentiment in the text.

- DeepMoji - DeepMoji is trained on a huge corpus of 1.3 billion tweets for sentiment, emotion and sarcasm. Felbo et al.(Felbo et al., 2017) released the pre-trained model for the sole purpose of transfer learning for similar tasks. We extracted 2 feature sets on our dataset: DeepMoji Attention layer Embedding - 2304 dimension, DeepMoji Softmax Layer Embedding - 64 dimension.

2.4 Architecture

Our system comprises of 2 models. The first model is a binary classifier. It classifies the data into others and non-others. The second model is a 4-class classifier which further classifies non-others classes into all the 4 labels. For both models, vocab size is 20000, maximum sequence length is 100, word-level embedding size is 300, categorical cross entropy loss, and Adam optimiser is used, refer Figure 1. The type of additional sentence features to baseline are the only differentiating features to each model. The 4 class classifier exclusively takes Skip thought and USN sentence embeddings. On contrary, Binary classifier classifier takes Skip thought, USN, DeepMojis attention and softmax layer.

Baseline : For both models the basic architecture is same; All three word level embeddings, each learned by a Bi-LSTM, concatenated together is passed through LSTM to finally classify by a softmax dense layer.

2.5 Ensembling

We train five different classifiers for each of the model to perform stacked ensembling (Polikar, 2012). We use different configurations by changing value of learning rate, epoch size, LSTM dimensions and dropout rate to diversify the learning. The results from the models are given to meta classifier as input. The output of this meta model is treated as the final output of the system. Among different meta classifiers, our system achieved best results with logistic regression.

3 Experiments and Results

In this section, several experiments that were conducted to prove the effectiveness of our method are explained. All experiments and models concluded to benefit from (i) Pre-processing (ii) Emoji Embeddings (iii) Sentence Embeddings as extra features. The evaluation metrics used to compare results in the below section is micro F1 score. The metric used for evaluation on leaderboard score is micro averaged F1 of all three emotion classes.

3.1 Benchmarking on State-of-the-Art Architectures

We fine-tune 2 models on the EmoContext data viz. DeepMoji (Felbo et al., 2017) and Universal Language Model Fine-tuning (ULMFiT) (Howard and Ruder, 2018). Fine tuning DeepMoji on our data achieved an averaged F1 score of 0.65. The ULMFiT pretrains a language model (LM) on a large general-domain corpus and fine-tunes it on the target task. We deployed ULMFiT pretrained on standard Wikitext-103 (Merity et al., 2018) which limits the classifier for chat conversations data. It only achieved F-1 score of 0.56. Refer Table 1 for results.

3.2 Impact of Embeddings

Glove does not have embeddings for emoticons and removing emoji from the text results in emotional context loss. To overcome this challenge we employed a separate Emoji Embedding which played a crucial role to interpret the underlying emotion in a conversation as seen in Table 2. Emoji Embeddings turned out to give better results than replacing emojis with their description. To capture sentence representation for different aspects, sentence embeddings played an important role as explained in feature section. Results show major improvement in score with combination of sentence-embeddings and word embeddings, and in turn yields better performance than word-embeddings alone.

3.3 Impact of Extra Features

We also tried traditional approach to extract features from the data. They have shown to benefit the Machine Learning models in the past. In our case, including several sentence level features (number of words, number of special characters, number of emojis, average word length, readability index, compound valence score, 'negative valence score', neutral valence score, POS valence score, number of nouns, number of verbs) reduced the F-1 score below our baseline for test set. This is shown in Table 1. It is assumed the reason for the same is inconsistent and noisy data.

Model	**F-1 (avg)**	**Happy**	**Sad**	**Angry**	**Others**
ULMFiT	0.5600	0.47	0.63	0.59	0.93
DeepMoji	0.6551	0.62	0.71	0.65	0.93
4-Class classifier (M)	0.6954	0.68	0.71	0.70	0.95
M + Resampled data	0.6869	0.61	0.72	0.72	0.95
M + Extra features	0.7055	0.67	0.72	0.72	0.95
M + Ensemble (ME)	0.7128	**0.69**	0.72	0.73	0.95
Binary classifier (B) + ME	0.7180	0.68	0.72	0.74	0.95
(B + Ensemble) + ME*	**0.7201**	0.68	**0.75**	**0.74**	**0.96**

Table 1: Results with Additional Resources. * Final results for competition.

Embedding Feature Set	**F-1(avg)**	**Happy**	**Sad**	**Angry**	**Others**
Glove	0.5971	0.58	0.58	0.62	0.92
Glove + FastText	0.6657	0.66	0.70	0.64	0.93
Glove + FastText + Emoji Embeddings (WE)	0.6833	**0.70**	**0.71**	0.66	0.94
WE + Sentence Embeddings	**0.6954**	0.68	**0.71**	**0.70**	**0.95**

Table 2: Comparative Results on Embeddings.

Datasets	**F-1 (avg)**	**Happy**	**Sad**	**Angry**	**Others**
Emotion Push Chat Logs	**0.89448**	**0.87**	**0.86**	**0.96**	0.88
SemEval 2019 - Task 3	0.683386	0.70	0.71	0.66	**0.94**

Table 3: Experiments with Baseline.

3.4 Imbalance Data

To solve the problem of data imbalance, generating synthetic data is one of the many techniques. However, adding synthetic data which is made from down-sampling majority class and simultaneously up-sampling the minority classes didn't bring much improvement, and in this case even reduced the accuracy of the test result.

3.5 Final Classification

All the above experiments, after detailed analysis shows that major confusion exists between each emotion and 'others' label. This led us to the conclusion, to improve F1, a binary classification could be done first. Results also helped us to decide the number of classes for the second model to be 4 instead of 3 because 4 class model classifies the incorrect non-others back to the others category.

3.6 Effectiveness of Baseline

EmotionPush chat logs are conversations between friends on Facebook Messenger collected by an app called EmotionPush[1] (Chen et al., 2018). We take sample of this data in the same format as EmoContext. We trained our baseline architecture on both datasets. Comparative results in Table 3 shows how our simple baseline performs extremely well for EmotionPush texts, Moreover contrasting the subjective effect of noisy data on model performance for SemEval data.

4 Conclusion

Contextual Emotion detection, like any multi-class text classification requires powerful ability to comprehend the sentence in variety of aspects. In this contest, our model performed decent, scoring 72.01 on final leader board. For our method, emoji played very important role in understanding emotion in the text, and just by using Emoji Embedding we gained a significant improvement in F1. We proved how feature engineering can be very powerful on skewed and imbalanced data to capture contexts in NLP. We present a simple baseline of our model that gives commendable results for a general Emotion Classification scenario as proven for EmotionPush sample data.

[1]Participants consented to make their private conversations available for research purposes.

E-LSTM at SemEval-2019 Task 3: Semantic and Sentimental Features Retention for Emotion Detection in Text

Harsh Patel
Dhirubhai Ambani Institute of Information and Communication Technology, Gandhinagar
201701021@daiict.ac.in

Abstract

This paper discusses the solution to the problem statement of the SemEval19: EmoContext competition(Chatterjee et al., 2019b) which is "Contextual Emotion Detection in Texts". The paper includes the explanation of an architecture that I created by exploiting the embedding layers of Word2Vec and GloVe using LSTMs as memory unit cells which detects approximate emotion of chats between two people in the English language provided in the textual form. The set of emotions on which the model was trained was Happy, Sad, Angry and Others. The paper also includes an analysis of different conventional machine learning algorithms in comparison to E-LSTM.

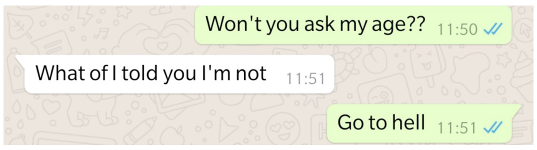
1 Introduction

Emotions are the basic human quality that almost every human possesses. According, to a recent study by Glasgow University[1], human emotions can be divided into six basic classes which are happiness, sadness, anger, fear, surprise and disgust, surprise being the most difficult one as both positive and negative statements can lead to a sense of surprise. For example, the statement *Your application for CSE branch in Stanford University is accepted* is positive and it leads to surprise whereas the statement *Your brother met with an accident* is a negative statement which all leads to a surprise.

Problem Statement: *Given a text for three turn conversation, classify the emotion of the text in the following four categories - Happy, Sad, Angry, Others.*

[1]https://www.gla.ac.uk/news/archiveofnews/2014/february/headline_306019_en.html

[2]WhatsApp is used as a messaging platform to illustrate the three turn conversation approach



Won't you ask my age?? 11:50
What of I told you I'm not 11:51
Go to hell 11:51

Figure 1. Example of three turn conversation[2]

Detecting human emotions only from the text is very difficult as the emotions are a combination of the situation and the facial expressions of a person(Cowie et al., 2001). So, merely classifying it from the conversation is not a very accurate way.

In this paper, I have proposed an extended approach to the original model(Chatterjee et al., 2019a) which combines deep learning along with some techniques used in Natural Language Processing(NLP) using semantic and embedding approach (Franco-Salvador et al., 2018; Shivhare and Khethawat, 2012) called as "Emotion LSTM" or E-LSTM to detect emotions in the provided training set. The E-LSTM is a combination of both count-based and predictive techniques which are widely used in Natural Language Processing.

2 Approach

My approach in solving the given problem statement was to maintain the semantic and sentimental relationship among the words(Gupta et al., 2017). So, as shown in Figure 2, I modeled the architecture such that the lower part contains the embeddings for sentiment analysis whereas the upper part contains the embeddings for maintaining a semantic relationship. The embeddings are then passed onto a network of LSTM layers which memorize the relationship among the words. The output of the final LSTM cell is then flattened and is combined with the output of the LSTM cell in the other half. The combined matrix is then passed as an input to a dense network with two sub-levels

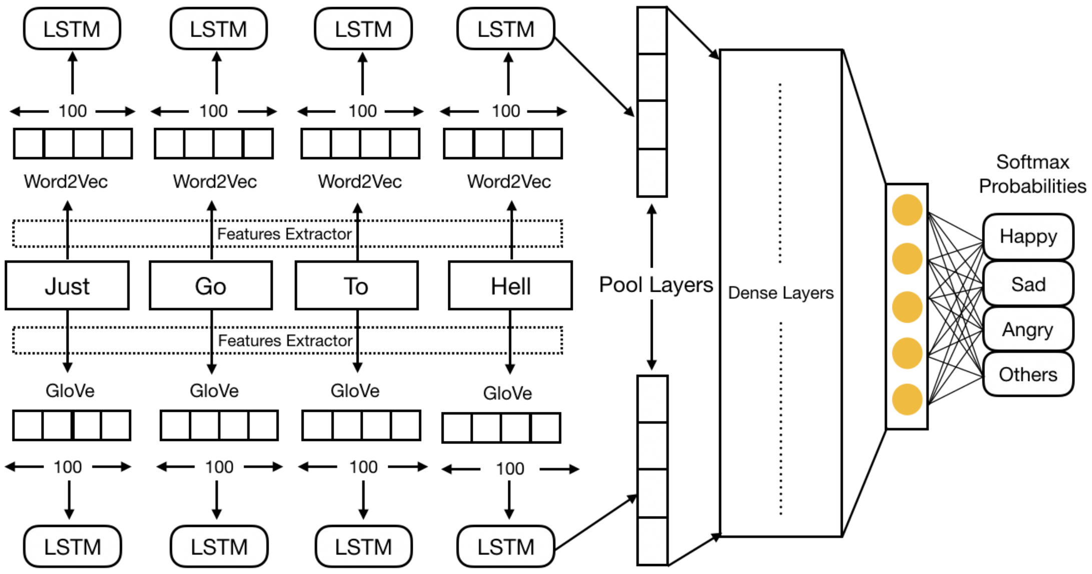


Figure 2. Architecture of E-LSTM model

Data	Labels	Happy	Sad	Angry	Others	Total
First Phase	#	4243	5463	5506	14948	30160
	%	14.07	18.11	18.26	49.56	100
Final Phase	#	142	125	150	2338	2755
	%	5.15	4.53	5.44	84.86	100

Table 1. Statistics of Training Dataset

whose output is then treated as a probability for the given four possible emotions using Softmax function.

2.1 Training Dataset

For the EmoContext SemEval-2019 Task 3, I was provided initially with a training dataset of about 30,000 entries containing 3 turn conversation and labels corresponding to each conversation. After successfully completing the first round, I was then provided with a final training dataset of about 2,700 entries. Statistics of both the datasets are shown in Table 1.

For the first phase, I proceeded with the provided dataset as a whole fro training whereas, in the second phase, I merged the provided new dataset with the dataset of Phase I and then used it for the model training.

2.2 Handling Repetition and Emoticons

After thoroughly analyzing the provided dataset, it was observed that emoticons were frequently used in the statements to describe the feeling or to end the statement. Similarly, special characters like . and * were also frequently used along with repetition. For example, You've got me blushing...☺ and Go to hell☹ statements. So, the first step of my data preprocessing was to remove the multiple instances of special characters and emoticons. So, the statement You've got me blushing...☺ after preprocessing became You've got me blushing. Other than normal preprocessing, the emoticons were also stored according to the sentence index in a dictionary and were used at the last step to verify if the predicted emotion matches partly or fully with the emotion depicted by used emojis using a weighted approach.

Word1,Word2	Word2Vec	GloVe
sad,:(	0.25	0.78
better,great	0.81	0.19

Table 2. Comparison of Word2Vec and GloVe embeddings in classifying relation among two words

2.3 Embedding Layers

The main challenge in the architecture of the model was to identify a proper embedding layer

#	Turn 1	Turn 2	Turn 3	True Label	Comments
1	You broke my heart	It was never mine to break !	See you are arrogant	sad	LSTM-Word2Vec failed because of word ”arrogant”
2	I like to cry	why are you crying	It was a joke	happy	Almost all model failed except E-LSTM model
3	You’re not giving me coupon nor photo	your phone is on mute hahahha	☹☹☹☹	sad	All the models failed but the last emoji comparing technique passed for the E-LSTM model
4	its only being childish	Your username is sad. ’-’ hug =/	how?	others	Counting based models failed becasue of negative words

Table 3. Qualitative Analysis of baseline models along with proposed E-LSTM model

to increase the model accuracy. The initial evaluations were passed only by using the baseline structure of GloVe embedding along with LSTM layers which proved to be costly as the micro F1 score that I got was comparatively less (about 0.57 for phase I and 0.61 for phase II) whereas the training time for significantly high. So, the accuracy of the model was improved through maintaining the semantic and syntactic features of statements intact by using the two novel types of research in the Natural Language Processing field which are Word2Vec(Word to Vector)(Mikolov et al., 2013; Rahmawati and Khodra, 2016) and GloVe(Global Vectors)(Baroni et al., 2014; Pennington et al., 2014) embedding layers. The Word2Vec embedding layers maintained the sentiments of the provided text whereas the GloVe embedding maintained the semantic feature of the text. As shown in Table 2, Word2Vec was better in classifying a relationship between sad and :(as it is a predictive model and was thus trained accordingly, whereas GloVe embedding was better in classifying relation between words better and great as the approach is completely based on counting i.e. counting involved in matrices operation.

2.4 Model Training

For training my E-LSTM model, I have used Keras library. As the data was limited, I have used the K-fold cross-validation method to train the model better. For training, I used K=5 i.e. 5 fold cross-validation. This number was chosen specifically after training on the data multiple times and comparing the obtained accuracy with the training time. The most optimal hyperparameters for my model were using CrossEntropy with Softmax as my loss function along with SGD(Stochastic Gradient Descent) as an optimizer with a learning rate of 0.003. For fully connected dense layers, I used a dropout of 0.3 to prevent over-fitting of the model. The batch size that I used while training the model was 800. Apart from hyperparameters, the main thing to note while concatenation of results obtained from the LSTM layers is the Leaky-ReLU layer that I have used. Reason being some negative input values which were completely discarded by normal ReLU layer.

3 Experimental Setup

In this section, I have described the statistics of my testing data along with a comparison of the obtained results with other models. I have also discussed some of the glitches that are evident in my model in the latter half.

3.1 Test Dataset

Similar to training dataset, test dataset was also provided in both the phases i.e. initial phase and final phase. But before the System-Design submission, one gold test dataset was also provided to test the model if it’s changed before paper submission. All the three test dataset files contained an index number and three turn conversation as their entry.

Model	Happy			Sad			Angry		
	Precision	Micro F1	F1	Precision	Micro F1	F1	Precision	Micro F1	F1
NB	45.4	56.32	50.27	74.22	70.1	72.10	43.21	38.21	40.57
SVM	75.21	32.1	45	94.45	66.66	78.16	92.11	62.21	74.26
CNN	64.3	49.32	55.82	76.21	70.12	73.04	74.12	49.44	59.32
CNN-GloVe	57.9	58.43	58.16	92.11	77.43	84.13	73.11	74.47	73.78
GloVe-LSTM	69.31	49.87	58	82.6	87.42	84.94	79.12	64.21	70.89
W2V-LSTM	75.42	45.55	56.8	84.32	78.12	81.1	80.2	64.34	71.4
E-LSTM	76.68	61.3	**64.47**	92.11	82.12	**86.83**	94.32	69.89	**80.29**

Table 4. Comparison of accuracy of different models ran on validation dataset of Task-2

3.2 Baseline Approaches

For comparison and proving my model better, I compared it with two different categories - 1. Machine Learning based and 2. Deep Learning based

For Machine Learning based baseline models, I have used Naive Bayes(NB) and Support Vector Machine(SVM). As the used models are inefficient with large datasets, so I used a subset of provided dataset to train them.

For Deep Learning based baseline models, I have used normal Convolutional Neural Networks(CNNs), CNN combined with Long Short Term Memory(LSTM) memory unit cells for data remembering, CNN combined with embedding layer of Global Vectors(GloVE) which maintains the sentiments in the text, LSTMs combined with GloVe embedding layer to find the sentiments among words and Word2Vect embedding layer combined with LSTMs which is used to maintain the semantic features in a statement. For all the deep learning baseline architectures, text in batches was given as input.

4 Results

As seen in the table Table 4, E-LSTM model outperformed all other models in both F1 score and average F1 score for all classes of emotion. Hence, it can be concluded that combining semantic and sentiment features of a statement can lead to better accuracy of emotion detection. It is also evident that Deep Learning models like CNNs, LSTMs, and RNNs are better than normal Machine Learning models like SVMs.

4.1 Qualitative Analysis

It is evident from Table 3 that E-LSTM model performed best as it tackled all the cases where counting based models when actual emotion is different from the words used in the conversation. Sentimental features also provided wrong results sometimes due to the predicted and true emotions being very close. The third entry in the table involves conversation which is highly contradicting from the true emotion. Thus, almost all the models failed in this type of case. But the verification of predicted emotion with the emoticons as described earlier saved the E-LSTM model from failing. Thus, the handcrafted features at the end of the model are very useful in this type of scenarios.

5 Conclusion

Evaluation of the given test data set shows that my model outperforms classical machine learning algorithms and also simple CNN and LSTM layers based models. Thus, it can be concluded that maintaining the semantic and syntactic relationship among words can be useful to identify emotions from texts accurately.

Abstract

This paper describes the approach developed by the ELiRF-UPV team at SemEval 2019 Task 3: Contextual Emotion Detection in Text. We have developed a Snapshot Ensemble of 1D Hierarchical Convolutional Neural Networks to extract features from 3-turn conversations in order to perform contextual emotion detection in text. This Snapshot Ensemble is obtained by averaging the models selected by a Genetic Algorithm that optimizes the evaluation measure. The proposed ensemble obtains better results than a single model and it obtains competitive and promising results on Contextual Emotion Detection in Text.

1 Introduction

Emotion Detection problem arises in the context of conversational interactions, among two or more agents, when one agent is interested in knowing the emotional state of other agent involved in the conversation. The detection of emotions is a difficult task when the content is expressed by using only text, due to the lack of facial and hand gesture expressions, voice modulations, etc. Moreover, the task becomes more complex if the detection of emotions is applied only on a short piece of text without including context. This is because the context can act as an emotion modifier of a given turn in the conversation.

Although, researchers mainly focus on emotion detection on text in absence of context (Mohammad et al., 2018) (Klinger et al., 2018), tipically extracted from social media, recently, there are few works that approach the emotion detection in conversations by using context information (Hazarika et al., 2018b) (Majumder et al., 2018) (Hazarika et al., 2018a). These contextual systems work on long conversations where different users are involved and they use multimodal data, specifically, text, audio and video in order to address the emotion detection problem on large multi-party conversations.

In this work, we present an approach to the Semeval 2019 Task 3: Contextual Emotion Detection in Text (Chatterjee et al., 2019). This task is a simplification of the text emotion detection problem on conversations where each conversation have only three utterances. Only two different users are involved in each conversation, where the first and third turn corresponds to the first user and the second turn corresponds to the second user. The goal of this tasks is to predict the emotion of the third turn. We propose a Snapshot Ensemble (SE) of 1D Hierarchical Convolutional Neural Networks (HCNN) trained to extract useful information from 3-turn conversations. Our system was designed following some ideas of (Morris and Keltner, 2000) and (Majumder et al., 2018). Concretely, we consider the inter-turn and self-turn dependencies (Morris and Keltner, 2000) along with the context given by the preceding utterances (Majumder et al., 2018) to determine the emotion of a given turn.

2 System Description

2.1 Preprocessing

For the tokenization process, our system used TweetTokenizer from NLTK (Loper and Bird, 2002). In addition, we performed some other actions. All the text was transformed to lowercase. Multiple spaces were converted to a single space. Urls were replaced by the tag "url". We transformed multiple instances of punctuation marks in a single one (e.g., "???" $\rightarrow$ "?"). In order to extract semantic representations of the unicode emojis, they are replaced by their description using the Common Locale Data Repository (CLDR) Short Name (e.g., 🤩 $\rightarrow$ "grinning face with star eyes"). Moreover, non relevant and common words are removed from these descriptions ("grinning face with star eyes" $\rightarrow$ "grinning star eyes").

2.2 Word Embeddings

It is well known that word embeddings (WE) learned from the same domain of a downstream task usually lead to obtain better results than those obtained using general domain WE. Due to the fact that we did not have sentences of the task to learn word embeddings from them, we used embeddings learned from Twitter posts because we considered that the characteristics of tweets are similar to the task language. Both of them have a noisy nature and they share common features of the internet language (slang, letter homophones, onomatopoeic spelling, emojis, lexical errors, etc.). Therefore, we used 400-dimensional WE obtained from a skip-gram model trained with 400 million tweets gathered from 1/3/2013 to 28/2/2014 (Godin et al., 2015).

2.3 Hierarchical Convolutional Neural Networks

We considered several characteristics of the task in order to design our system. First, the utterances are short and there are many short-term dependencies among these words. Therefore, we propose to use 1D Convolutional Neural Networks (Kim, 2014) (CNN) to extract a rich semantic representation of each utterance. Second, the conversations are composed only by 3 utterances, for that reason, it is not required to uses models with high capacity to learn long contexts. Thus, we propose to use another CNN on top of the first CNN that extracts sentence representations, in order to obtain representation of conversations. We called this approach Hierarchical Convolutional Neural Networks (HCNN) following the work of (Yang et al., 2016).

As input to the model, each utterance j (composed by a maximum of N words) in a conversation i is arranged in a matrix $M_j \in \mathbb{R}^{N\times d}$, where each row corresponds with a word in the utterance j, represented by using d-dimensional WE. As each conversation is a sequence of three utterances, these conversations are arranged in a 3-dimensional matrix where each channel j is the representation of the utterance j in the conversation, i.e. for the conversation i, $M_i \in \mathbb{R}^{3\times N\times d}$. On all the matrices of M_i, 1D Dropout (Srivastava et al., 2014) was used to augment the dataset, by deleting words of each utterance with $p = 0.3$.

Given the representation of the conversation i, M_i, for each utterance independently, a CNN with kernels of different sizes is applied in order to obtain a composition of word embeddings that can extract semantic/emotional properties from each utterance. At this first level, we use $f_1 = 256$ kernels of sizes $\{2, 4, 6\}$ and their weights are shared among the three channels. From that, for each utterance, three new matrices are obtained. These matrices capture relevant features for each kernel size and utterance. These features are pooled into a vector by using 1D Global Max Pooling (GMP).

The resulting three vectors from the previous level were concatenated as rows to obtain a matrix representation of the conversation i composed by the CNN map of its sentences, $Wi \in \mathbb{R}^{3\times f_1}$. We considered that conversation features could be relevant for the task. At this level, in order to extract these relevant features and following the ideas in (Morris and Keltner, 2000) (Majumder et al., 2018), the system is intended to take into account the context and potentially the emotions given by preceding utterances to determine the emotion expressed by the last utterance. To do this, a CNN with $f_2 = 256$ kernels of sizes $\{1, 2, 3\}$ were used. The size of the filters is crucial to understand what features the system is capable to learn.

Concretely, 3-size kernels: semantic/emotional features over all the contexts (full conversation); 2-size kernels: inter-turn features and semantic/emotional features of preceding and later utterances given a context of two utterances; 1-size kernels: self-turn features and semantic/emotional features of each utterance independently.

On the output maps of this second CNN[1], GMP is used in order to extract the most relevant features from each dimension and the resulting vectors are concatenated. Later, a fully connected layer L_1 with 512 neurons is used to fuse the concatenated vectors. Finally, to obtain a probability distribution over $\mathbb{C}$ classes ({happy, sad, angry, others}) we use a softmax fully connected layer L_2. Figure 1 shows the proposed model architecture.

2.4 Snapshot Ensemble

Generally, ensemble models outperform single models in similar tasks (Duppada et al., 2018) (Rozental et al., 2018). Therefore, we decided

Figure 1: Hierarchical Convolutional Neural Networks.

to use ensemble methods instead of trying different architectures. We used the ideas of Snapshot Ensemble (SE) (Huang et al., 2017) to combine HCNN trained until reaching good and diverse local minima by using SGD and a cosine learning rate with $T = 24$ training iterations, $M = 6$ learning cycles, and initial learning rate $alpha = 0.4$.

From this training method, we took 24 snapshots (one for each training iteration). From the set of snapshots $S = \{s_i \ / \ 1 \leq i \leq 24 \wedge s_i : \mathbb{R}^{3 \times N \times d} \rightarrow \mathbb{R}^{\mathbb{C}}\}$, we generate 4 different systems:

1. Best snapshot of all iterations

$$f_1 = \underset{s_i}{\text{argmax}} \ \mu F_1(s_i(x), y) \qquad (1)$$

2. Average of all snapshots

$$f_2 = \frac{1}{|S|} \sum_{s_i \in S} s_i(x) \qquad (2)$$

3. Average of best snapshot at each learning cycle

$$f_3 = \frac{M}{T} \sum_{i=0}^{\frac{T}{M}-1} \underset{s_i \in S[\frac{T}{M} \cdot i, \frac{T}{M} \cdot (i+1)]}{\text{argmax}} \mu F_1(s_i(x), y) \qquad (3)$$

4. Average of genetic selected snapshots

$$f_4 = \frac{1}{|g(S)|} \sum_{s_i \in g(S)} g(S)_i \ s_i(x) \qquad (4)$$

where x and y are the input and the target, respectively, and $g(S)_i$ is the decision of a genetic algorithm to include the snapshot s_i in the ensemble. We used this method in order to discretely select ($g(S)_i \in \{0, 1\}$) what snapshots are well-suited for the final averaging ensemble which tries to optimize μF_1. The genetic algorithm (Mitchell, 1998) starts with a population of 400 individuals, they are crossed by using two point crossover, mutated with flip bit and selected by using tournament selection during 100 generations. Moreover, this algorithm addresses a multi-objective problem, it must to reach combinations of snapshots whose averaged predictions yield to high values of μF_1 while minimizing the number of models in the ensemble (the final genetic ensemble is composed by 6 system, i.e. as many systems as learning cycles) These decisions were taken in order to reduce the overfiting risk during the learning of the ensemble i.e. we prioritize simpler ensembles which are composed by discretely selected snapshots.

3 Analysis of Results

In order to evaluate different configurations of our system we used the development set given by the task organizers. On this development set, ablation analysis on single HCNN was carried out in order to observe if the input Dropout and the incorporation of L_1 layer yield to better results (the capacity of HCNN must be greater when including both techniques). The results of this ablation analysis are shown in Table 1.

System	$\boldsymbol{\mu P}$	$\boldsymbol{\mu R}$	$\boldsymbol{\mu F_1}$
Vanilla	70.65	75.06	72.79
Dropout	71.78	**76.26**	73.95
$\boldsymbol{L_1}$	72.36	75.23	73.84
Dropout + $\boldsymbol{L_1}$	**75.42**	75.78	**75.60**

Table 1: Ablation analysis of input Dropout and L_1 layer on HCNN (development set)

Vanilla system is a single HCNN without input Dropout neither the L_1 layer. It can be observed that, the systems with Dropout and L_1 outperformed the **Vanilla** version of HCNN in terms of μP, μR and μF_1. In terms of μP, the systems which incorporate L_1 achieved better results. However, although **Dropout +** $\boldsymbol{L_1}$ obtained the best improvement in terms of $\boldsymbol{\mu P}$, the highest $\boldsymbol{\mu R}$ was obtained using only **Dropout**. This could indicate that data augmentation could be useful to increase the $\boldsymbol{\mu R}$ but it is required more network capacity to handle this augmentation in order to increase also the $\boldsymbol{\mu P}$.

These results were obtained by using a single HCNN with *adam* as update rule (Kingma and Ba, 2014) with default learning rate. However, the SE training mode with Vanilla SGD and cosine learning rate, along with the proposed ensemble generation, allows the **Dropout + L_1** system to reach better results (Table 2).

Ensemble	μP	μR	μF_1
Best snapshot (single)	74.82	78.41	76.58
Average All	74.38	77.93	76.18
Best per Cycle	75.29	77.45	76.35
Genetic Average	**75.73**	**80.09**	**77.85**

Table 2: Results on development set with several SE of HCNN.

In this case, the best single model (**Best snapshot**) obtained in the SE training mode, provided higher μR than **Dropout + L_1** at the expense of a reduction in μP. This improvement of 3 points of μR yields also an increase of the μF_1 measure.

Among the ensembles, only **Genetic Average** improves the **Best snapshot** and **Dropout + L_1** systems in all the metrics. This is due to a big increase in μR. This suggests that it is possible to improve the μF_1 results by balancing μP and μR.

The other ensembles obtain lower results in terms of μR and μF_1 than **Best snapshot**, which is a single model. Moreover, all SE (including **Best snapshot**) except **Genetic Average** are less accurate (lower μP) than **Dropout + L_1**. However, all of them improved considerably the μR.

Due to the SE HCNN models generally outperformed the best single model **Dropout + L_1** in terms of μF_1 on the development set, we submitted all these systems to be evaluated on the test set. The results are shown in Table 3. It can be seen that the best system is **Genetic Average**, the same behavior observed on the development set. Although **Best snapshot** is more accurate than the ensembles (higher μP), two of the three ensembles yields better results μF_1. Moreover, a big degradation in the results are observed, all systems goes from 77 μF_1 on the development set, to 74 μF_1 on the test set.

System	μP	μR	μF_1
Best snapshot (single)	**75.69**	72.60	74.11
Average All	73.15	75.00	74.07
Best per Cycle	73.27	75.12	74.18
Genetic Average	73.43	**75.72**	**74.56**

Table 3: Results on test set with several SE of HCNN.

Table 4 shows the results of our best system (**Genetic Average**) at class level. The worse classified classes in terms of F_1 were Angry and Happy.

Class	P	R	F_1
Angry	68.73	78.19	73.16
Happy	75.19	69.37	72.16
Sad	77.82	80.00	78.90

Table 4: Results at class level of **Genetic Average** on test set.

4 Conclusion and Future Work

In this paper, we have presented Snapshot Ensembles of Hierarchical Convolutional Neural Networks to address the Semeval 2019 Task 3: Contextual Emotion Detection in Text. Our system is based on the use of a Genetic Algorithm in order to ensemble different snapshots of the same model. This ensemble outperformed single models and also classical snapshot ensembles, obtaining competitive results in the addressed task.

Due to the fact that in the proposed system, the semantic and emotional information is only provided by the representation of the words and the utterances, as future work we plan to study different word and sentence embeddings. It would be also interesting to incorporate other emotional or sentiment features such as: Sentiment Unit (Radford et al., 2017), DeepMoji (Felbo et al., 2017), Sentiment Specific WE (Tang et al., 2014); or polarity lexicons. Moreover, we are also interested in work with more powerful word embeddings such as BERT (Devlin et al., 2018) in order to incorporate a richer semantic word representation.

Abstract

Task 3, EmoContext, in the International Workshop SemEval 2019 provides training and testing datasets for the participant teams to detect emotion classes (Happy, Sad, Angry, or Others). This paper proposes a participating system (EmoDet) to detect emotions using deep learning architecture. The main input to the system is a combination of Word2Vec word embeddings and a set of semantic features (e.g. from AffectiveTweets Weka-package). The proposed system (EmoDet) ensembles a fully connected neural network architecture and LSTM neural network to obtain performance results that show substantial improvements (F1-Score 0.67) over the baseline model provided by Task 3 organizers (F1-score 0.58).

1 Introduction

The past decades have seen an explosive growth of user-generated content through social media platforms. People are expressing online their feelings and opinions on a variety of topics on a daily basis. Tracking and analyzing public opinions from social media can help to predict certain political events or predicting people's attitude towards certain products. Therefore, detecting sentiments and emotions in text have gained a considerable amount of attention(Mohammad et al., 2018). Researchers and scientists in different fields considered this a promising topic (Abdullah et al., 2018; Liu, 2012). Many machine learning approaches have been used to detect and predict emotions and sentiments. Recently, the deep neural network (DNN) is attracting more researchers as they have been benefited from the high-performance graphics processing unit (GPU) power (Abdullah et al., 2018; Dos Santos and Gatti, 2014).

The shared task (Task 3: "EmoContext") in SemEval-2019 workshop has been designed for understanding emotions in textual conversations (Chatterjee et al., 2019). In this task, the participants are given a textual dialogue i.e. a user utterance along with three turns of context. The participant teams have to classify the emotion of user utterance as one of the emotion classes: Happy, Sad, Angry or Others. Further details about Task 3 and the datasets appear in Section 3.

This paper describes our team approach to detect and classify emotions. The input has been represented as word vectors (Mikolov et al., 2013b) and a set of different features which are applied to different neural network architecture to obtain the results. The performance of the system shows substantial improvements F1-Score over the baseline model provided by Task 3 organizers.

The remainder of this research paper is organized as follows: Section 2 gives a brief overview of existing work on social media emotion and sentiment analyses. Section 3 presents the requirements of SemEval Task3 and examines our proposed system to determine the presence of emotion in conversational text. Section 4 summarizes the key findings of the study and the evaluations and concludes with future directions for this research.

2 Related Work

Defining and theorizing emotions had been investigated by several psychology researchers (Plutchik, 1990; Ekman and Keltner, 1997). The basic emotions according to Ekman (Ekman and Keltner, 1997) had been identified as anger, disgust, fear, happiness, sadness, and surprise. A little corpus exists for emotion labeling with text. Recently, several shared tasks and challenges had been introduced for detecting the intensity of emotion felt by the speaker of a tweet (Mohammad et al., 2018; Strapparava and Mihalcea, 2007). A group of researchers (Mohammad and Bravo-Marquez, 2017) introduced the WASSA- 2017 shared task of detecting the intensity of emotion felt by the speaker of a tweet. The previous Semeval Task1 (Mohammad et al., 2018) also introduced a dataset (annotated tweets) for emotion detection. The state-of- the-art systems in the previous competitions used different approaches of ensembling different deep neural network-based models, representing tweets as word2vec/doc2vec embedding vectors and extracting semantic features. Our system is using word2vec embedding vectors (Mikolov et al., 2013a) and extracted features using a Weka package, AffectiveTweet, (Bravo-Marquez et al., 2014), also extracting embedding from the text using deeMoji model (Felbo et al., 2017).

3 Our Approach

Our system has the ability to determine the emotion (Happy, Sad, Angry and Other) in English textual dialogue with F1-Score over 0.67. Figure 1 shows the general structure of the system. More details for the systems components are shown in the following subsections: Section 3.1 describes the systems input and preprocessing step. Section 3.2 lists the extracted feature vectors, and Section 3.3 details the system's architecture of neural networks. Section 3.4 discusses the output details.

3.1 Input and Preprocessing

The shared task (Task 3: EmoContext) provides training and testing datasets to be used by all participants. The number of training and testing datasets for each emotion can be shown in Table 1.

	Train Data	**Test Data**
Anger	5656	298
Happy	4385	284
Sad	5588	250
Other	17286	4677
Total	32915	5509

Table 1: Training and Testing Datasets

The training dataset contains 5 columns:

ID - Contains a unique number to identify each training sample.

Turn 1 - Contains the first turn in the three turn conversation, written by User 1.

Turn 2 - Contains the second turn, which is a reply to the first turn in conversation and is written by User 2.

Turn 3 - Contains the third turn, which is a reply to the second turn in the conversation, which is written by User 1.

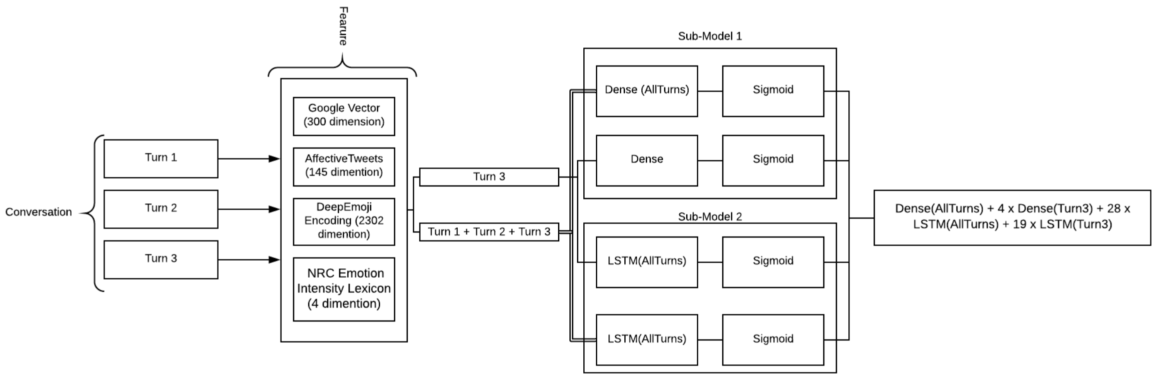
Label - Contains the human-judged label of Emotion of Turn 3 based on the conversation for the given training sample. It is always one of the four values - 'happy', 'sad, 'angry' and 'others'.

For testing dataset, the 5th column - 'Label' is absent. See Table 2 for more clarification.

The prepossessing methods applied for the data include converting the text into lower case, stemming the words and removing of extraneous white spaces. Punctuation has been treated as individual words (".,?!:;()[]#@'). It's worth mentioning that removing stop-words dissolved the meaning of the sentence, therefore we didn't remove them.

3.2 Feature Vector

We have explored different features to represent each turn and the concatenated turns. Our approach extracts feature vectors from texts with a total of 2753 dimensions (Check Table 3). We have applied the same methods for each turn and the concatenated turns.
Each turn is represented as a 300-dimensional vector using the pretrained word2vec embedding model that is trained on Google News (Mikolov et al., 2013a). We have used the summation technique to represent every turn or conversation. In addition to that, each turn/conversation is represented as 145 dimensional vectors by concatenating three vectors obtained from the AffectiveTweets Weka-package bravo2014meta, mohammad2017wassa, 43 features have been extracted using the TweetToLexiconFeatureVectorattribute that calculates attributes for a tweet using a variety of lexical resources; two-dimensional vector using the sentiments strength feature from the same package, and the final 100 dimensional vectors is obtained by vectorizing the tweets to embeddings attribute also from the same package. We have also extracted 2302 dimensions vector using the attention layer of DeepMoji model (Felbo et al., 2017). Finally, we have used the NRC Valence, Arousal, and Dominance Lexicon to extract the last 4-dimensional



Feature

3.3 Network Architecture

Knowing that Deep Neural Networks (DNN) is showing significant improvements over traditional Machine Learning (ML) based approaches on classification tasks(LeCun et al., 2015). This derives more researchers to apply it recently for detecting sentiments and emotions. The standard Recurrent Neural Network (RNN) is distinguished from Feed-forward network with a memory. A special kind of RNNs are Long Short-Term Memory Network (LSTM) (Hochreiter and Schmidhuber, 1997), which is composed of a memory cell, an input gate, an output gate and a forget gate.

The architecture of our system consists of two sub-models that use both: feed-forward (Dense) and LSTM. For our first sub-Model, the Input 2753-dimensional vector feeds a fully connected neural network with three dense hidden layers of 500, 200 and 80 neurons for each layer. The activation function for each layer is ReLU (Goodfellow et al., 2013). Two dropouts have been added to this sub-model, which are 0.3 and 0.2 after the first and the second layers. The output layer consists of 4 sigmoid neurons to predict the class of emotion in each conversation. For optimization, we use Stochastic Gradient Descent (SGD) optimizer (lr=.001, decay=1×10^{-6}, and momentum = 0.9) augmenting for MSE loss function and ACCURACY metrics. We have also saved the output predictions weights to predict the testing data sets. The fit function uses number of epochs = 60, batch size=32, validation split= 33%.

In the second sub-model, the same 2753-dimensional vector feeds an LSTM by using an embedding layer of 500-dimensions. The LSTM layer consists of 300 neurons with using Dropout 0.3 after the LSTM layer to avoid over-fitting. A dense layer with 200 neurons is added and followed by four sigmoid neurons to predict the emotion class in each conversation. For optimization, we use the same method as the first sub-model. We have also used early stopping technique to get the best result. finally, we have saved the output prediction weights to predict the testing data sets. The fit function uses number of epochs = 80, batch size=8, validation split= 33%.

Formula	**micro-F1**
$Dense(Turn1) + 2 \times Dense(Turn3)$	0.605355
$Dense(Turn1) + 2 \times Dense(Turn3) + 2 \times Dense(All)$	0.618162
$2 \times Dense(All) + 3 \times Dense(Turn3) + 3 \times LSTM(All)$	0.626
$Dense(All) + part3 + 3 \times LSTM(All)$	0.636
$Dense(All) + part3 + 10 \times LSTM(All)$	0.656165
$Dense(All) + 4 \times Dense(Turn3) + 28 \times LSTM(All) + 19 \times LSTM(Turn3)$	0.6714

Table 4: Weight Ensembling

Conversation	**Turn 1**	**Turn 2**	**Turn 3**
micro-F1	0.26379	0.08435	0.58920

Table 5: Using Sub-model 1 - Dense Layer

Conversation	**Turn 1**	**Turn 2**	**Turn 3**
micro-F1	0.20734	0.13543	0.44364

Table 6: Using Sub-model 1 - Dense Layer plus removing 70% of others randomly

System	**Epoch**	**micro-F1**
LSTM (All Conversation)	40	0.5376
LSTM (All Conversation)	80	0.6094
LSTM (All Conversation)	114	0.5096
Dense (All Conversation)	60	4677

Table 7: Best Epoch for both LSTM and Dense

3.4 Output and result

In the beginning, we have analyzed all the conversation (turn1 + turn2 + turn3) using both sub-model systems. We have noticed that the third turn of the conversation provides better predictions of emotion's class, see in Table 5. Removing 70% of the others randomly in the training data set led to bad predictions so we didn't apply this method, see Table 6. One of the key findings is noticing that LSTM gives better prediction than the feed-forward system for the whole conversation, see the result in Table 7. For the final stage, we have combined both sub-models results to produce a real value number between 0 and 1. It has shown that the second sub-model gives higher accuracy than the first sub-model. Applying different amount of weights for four prediction led us to find out that the correct formula for our system using turn3 alone as a sub-model and All-Conversation prediction and from the second sub-Model turn3 and All-Conversation and combining them together in a formula, It showed a higher F1-Score equal to 0.67. Also, it's worth mentioning that we used Grid Search to find the best parameters for the formula (Check Table 4).

4 Conclusion

In this paper, we have presented our system EmoDet that uses deep learning architectures for detecting the existence of emotions in a text. The performance of the system surpasses the performance of the baselines model indicating that our approach is promising. In this system, we uses word embedding models with feature vectors extracted using the AffectiveTweets package and Deepmoji model. These vectors feed different deep neural network architectures, feed-forward and LSTM, to obtain the predictions. We use the SemEval-2019 Task 3s datasets as input for our system and show that EmoDet has a high proficiency in detecting emotions in a conversational text and surpasses the F1-score Baseline models performance, which is provided by the SemEval-Task 3 organizers.

vijayasaradhi.indurthi@teradata.com

Abstract

This paper describes our participation in the SemEval 2019 Task 3 - Contextual Emotion Detection in Text. This task aims to identify emotions, viz. happiness, anger, sadness in the context of a text conversation. Our system is a stacked Bidirectional LSTM, equipped with attention on top of word embeddings pre-trained on a large collection of Twitter data. In this paper, apart from describing our official submission, we elucidate how different deep learning models respond to this task.

1 Introduction

Sentiment analysis is an established field in NLP, but just identifying positive and negative sentiments may not be enough. Applications require systems to go further beyond sentiment analysis and perform emotion analysis, which deals with identifying discrete emotions like anger, joy, sadness, etc. The task is challenging because the importance of context in emotion analysis cannot be overstated (Malik et al., 2017; Vanzo et al., 2014). Also, text in a conversation often contains language slangs, emoticons, emojis and other noisy data that make it difficult to identify the type of feeling expressed.

Many approaches have been put forward to identify emotions in a text. Purver and Battersby (2012); Balabantaray et al. (2012) used SVM classifier on twitter data to carry out emotion analysis. Potapova and Gordeev (2016) deployed a model based on Random Forests to identify aggression in texts. These approaches are often assisted by lexicons and require heavy feature engineering.

In recent years, deep learning approaches have outperformed traditional algorithms in NLP tasks (Bahdanau et al., 2014). Felbo et al. (2017); Gupta et al. (2017) utilized LSTMs to achieve emotion identification in text. Abdul-Mageed and Ungar (2017) showed that GRNNs achieved a very good performance on 24 fine-grained types of emotions. Kratzwald et al. (2018) proposed sent2affect, a tailored form of transfer learning for affective computing, where the network is pre-trained for sentiment analysis task, and subsequently the output layer is tuned to the task of emotion recognition. In this paper, we propose a stacked Bidirectional LSTM architecture to recognize emotions in text.

happy	sad	angry	others
14.06%	18.11%	18.25%	49.56%

Table 1: Train dataset composition.

The rest of the paper is organized as follows. In sec. 2 we give a brief explanation of the shared task. In sec. 3 we describe the process of feature engineering from the text. In sec. 4 we discuss system architecture. It is followed by sec. 5 which contains the various settings used in our experiments. In sec. 6, we analyse the results and conclude our paper in sec. 7 with future ideas and vision.

2 Shared Task Description

The SemEval 2019 Task 3 is as follows: Given three turns of a conversation by two users, say turn1 by user1, turn2 by user2 and turn3 by user1, the system must identify the emotion of turn3 based on the conversation. It has to be one of the four values - happy, sad, angry and others. The dataset is provided by the organizers of the task. The composition of the dataset is described in Table 1. More details about the task can be found in the task description paper (Chatterjee et al., 2019).

3 Feature Engineering

3.1 Pre Processing

We perform the following pre-processing operations on the text before feature engineering.

- All text is converted to lower case.
- All contractions are replaced with their full form. For example, *don't* will be replaced by *do not* and *can't* will be replaced by *can not*.
- All punctuation marks are removed.
- **Spell correction and Emoji expansion:** Many conversations include words in an elongated form (*nooooo, youuuuu, heyyyyyy etc.,*) and slangs(*wassup, 4u, lolz etc.,*). We perform spell corrections (Jurafsky and Martin, 2018) on these words to reduce the vocabulary size and to account for better results. Text8[1] is utilized to generate unigram and bigram word statistics with ekphrasis (Baziotis et al., 2017) to perform spell correction.

  Emojis play a crucial part in identifying the emotion of a conversation. A conversation often contains a high number of emojis that intrinsically determines its nature. Identifying this quintessential importance, we use a python package named emoji[2] to expand the emojis into representative keywords. Eg: 'unamused face'
- **Parts Of Speech**: Part-of-speech (POS) tagging is an important and fundamental step in Natural Language Processing. The Part-of-speech gives a large amount of information about a word and its neighbours, syntactic categories of words and similarities and dissimilarities between them. NLTK (Steven Bird and Loper, 2009) is used to extract the Parts Of Speech tags for each word in the conversation, and then concatenated them with GloVe vectors. As a result, Glove vectors will have syntactic information of words (Rezaeinia et al., 2017).

3.2 Feature Extraction

- **Word Embeddings:** Glove840B - common crawl (Pennington et al., 2014) pre-trained word embeddings are used to convert each of the words in the conversation to a 300-dimensional feature vector.
- **One Hot Encoding:** The POS tags generated in the previous step are converted to a constant vector using One-Hot Encoding
- **Lexicon:** We exploit the DepecheMood affective lexicon Deepechemood++ (Araque et al., 2018) that has been built in a completely unsupervised fashion, from affective scores assigned by readers to news articles. DepecheMood++ allows for both high-coverage and high-precision, providing scores for 187k entries on the following affective dimensions: Afraid, Happy, Angry, Sad, Inspired, Don't Care, Inspired, Amused, Annoyed.

4 System Architecture

4.1 Embedding Layer1 (EL1)

This embedding layer takes as input a fixed sequence of 200 words and converts each word into its corresponding 300 dimensional glove word vector (Pennington et al., 2014).

4.2 Embedding Layer2 (EL2)

This embedding layer takes as input a fixed sequence of 200 Parts Of Speech tags and converts each of them into a constant one-hot vector.

4.3 Embedding Layer3 (EL3)

This embedding layer takes as input a fixed sequence of 200 words and converts each of them into a vector based on the values in DepecheMood affective lexicon.

4.4 BiLSTM

Long Short-Term Memory (LSTM) is a recurrent neural network (RNN) architecture that has been designed to address the vanishing and exploding gradient problems of conventional RNNs. Unlike feed-forward neural networks, RNNs have cyclic connections making them powerful for modelling sequences. They have been successfully used for sequence labelling and sequence prediction tasks (Sak et al., 2014). An LSTM has 3 types of gates, the forget gate, the input gate and the output gate. The information flow is governed by the following equations.

[1] http://mattmahoney.net/dc/textdata.html

S.No	Setting	$F1\mu_{avg}$
1	EL1 + LSTM(256) + dropout(0.3)	0.8891
2	EL1 + BiLSTM(256) + dropout(0.2)	0.8903
3	EL1 + LSTM(256) + dropout(0.3) + Attention	0.8950
4	EL1 + BiLSTM(256) + dropout(0.3) + Attention	0.8918
5	EL1 + BiLSTM(128) + dropout(0.2) + BILSTM(128) + dropout(0.3)	0.8951
6	EL1 + BiLSTM(128) + dropout(0.2) + BILSTM(128) + dropout(0.3) + Attention	**0.8956**
7	EL1 + EL2 + BiLSTM(128) + dropout(0.2) + BiLSTM(128) + dropout(0.3)	0.8965
8	EL1 + EL3 + BiLSTM(128) + dropout(0.2) + BiLSTM(128) + dropout(0.3)	0.8969
9	EL1 + EL2 + EL3 + BiLSTM(128) + dropout(0.2) + BiLSTM(128) + dropout(0.3)	0.8931

Table 2: Results of different settings. S.No 1-6 are the variations of the system that are evaluated for the competition. S.No 7-9 provide further analysis of the system after the competition ended. All results shown are obtained with five fold cross validation on the train set.

$$\begin{aligned}
f_t &= \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) && (1)\\
i_t &= \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) && (2)\\
\tilde{C}_t &= \tanh(W_C \cdot [h_{t-1}, x_t] + b_C) && (3)\\
C_t &= f_t \times C_{t-1} + i_t * \tilde{C}_t && (4)\\
o_t &= \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) && (5)\\
h_t &= o_t \times \tanh C_t && (6)
\end{aligned}$$

Where:

- W_i, W_f, W_o, W_c : are the trained weights.
- b_i, b_f, b_o, b_c : are the trained biases
- σ: is the sigmoid function.
- x_t : is the input at time step t
- c_t : is the cell state at time t
- h_t : is the output at time step t

Single directional LSTM can only use the contextual information from the past. Bidirectional LSTM can use the contexts of the past as well as the future, generating two independent sequences of LSTM output vectors (Schuster and Paliwal, 1997). The output at each time step is the concatenation of two output vectors from both the directions, i.e.,

$$h_t = \overrightarrow{h_t} \oplus \overleftarrow{h_t}$$

4.5 Dropout

Dropout is a regularization technique in which units and their connections are randomly dropped from the neural network during training (Srivastava et al., 2014). This prevents units from co-adapting too much. Dropout of *p* sets *p* fraction of units to 0 at each update during training time. We employ dropout in our system to avoid overfitting.

4.6 Attention

Not all words in a sentence contribute to a sentiment. A neural network armed with an attention mechanism can actually understand how to disregard the noise and focus on what's relevant. This is especially effective in sequence tasks as the network can choose to remember only that context that's relevant (Zhang et al., 2018).

5 Experiments

5.1 Evaluation Metrics

Evaluation will be done by calculating micro averaged F1 score($F1\mu$) for the three emotion classes i.e. *Happy*, *Sad* and *Angry*. The *Others* class is ignored in the evaluation.

- $P\mu = (\sum TPi) \div (\sum (TPi + FPi))$ $\forall i \in Happy, Sad, Angry$
- $R\mu = (\sum TPi) \div (\sum (TPi + FNi))$ $\forall i \in Happy, Sad, Angry$
- $F1\mu = (2 \times P\mu \times R\mu) \div (P\mu + R\mu)$

TPi is the number of samples of class i which are correctly predicted, FNi and FPi are the counts of Type-I and Type-II errors respectively for the samples of class i. Please note that both the precision and recall are micro-averaged.

5.2 Methodology

All the experiments are developed using the Scikit-Learn (Pedregosa et al., 2011) machine learning library and keras deep learning library (Chollet et al., 2015) with Tensorflow backend (Abadi et al., 2015). We concatenate turn1, turn2 and turn3 using a separator 'eos', read as 'end of sentence'. Similarly, we concatenate the POS tags of all the turns as well using the same separator. Five-fold cross validation is used to evaluate our models. In all our experiments, the batch size is 200, the learning rate is 0.008 and the number of epochs is 10. The loss is categorical cross-entropy and the optimizer used is rmsprop. In all the settings, the activation for LSTM/BiLSTM is tanh and the last layer is a dense layer of 4 units with sigmoid activation. Attention layer, if employed, is used after the last LSTM/BiLSTM layer. All our code is publicly available in a Github repository.[3]

Table 2 shows the results of different variations of the system.

6 Results and Analysis

The results show that attention based models outperform their corresponding equivalents. It is interesting to see from S.No 1-4 that BiLSTM outperforms LSTM when no attention is used but in the presence of attention, LSTM performs better than BiLSTM. The two layer BiLSTM with attention in S.No 6 surmounted all the other variations during the competition. Hence, we submitted this model and achieved an F1μ score of 0.6939.

S.No 7-9 show our further analysis of the system when different embedding layers are merged. We see that concatenating any one of POS and DepecheMood to the word vectors increased the performance in S.No 7-8, but not by much. However, concatenation of word vectors, POS and DepecheMood decreased performance, as shown in S.No 9.

7 Conclusion and Future Work

In this paper, we described a stacked BiLSTM deep learning model to detect emotion in context. We used glove pre-trained embeddings to convert each word into its corresponding word vector and then passed it on to two layers of BiLSTM, applied attention mechanism and finally, passed the intermediate inputs on to a dense layer of 4 units with sigmoid activations. We also depicted the results of adding different features to the pre-trained word vectors. Inspired by the work of Rezaeinia et al. (2017), in the future, we would like to examine more lexicon combinations to analyze the performance of the system. We would also like to make the system deeper to scrutinize how it responds.

EmoSense at SemEval-2019 Task 3: Bidirectional LSTM Network for Contextual Emotion Detection in Textual Conversations

Sergey Smetanin
National Research University Higher School of Economics
Moscow, Russia
sismetanin@gmail.com

Abstract

In this paper, we describe a deep-learning system for emotion detection in textual conversations that participated in SemEval-2019 Task 3 “EmoContext”. We designed a specific architecture of bidirectional LSTM which allows not only to learn semantic and sentiment feature representation, but also to capture user-specific conversation features. To fine-tune word embeddings using distant supervision we additionally collected a significant amount of emotional texts. The system achieved 72.59% micro-average F_1 score for emotion classes on the test dataset, thereby significantly outperforming the officially-released baseline. Word embeddings and the source code were released for the research community.

1 Introduction

Emotion detection has emerged as a challenging research problem that can make some valuable contribution not only in basic spheres like medicine, sociology and phycology but also in more innovative areas such as human-computer interaction. Nowadays, people increasingly communicate using text messages with dialogue systems, for which it is crucial to provide emotionally aware responses to users. The SemEval-2019 Task 3 “EmoContext” is focused on the contextual emotion detection in textual conversation. In EmoContext, given a textual user utterance along with 2 turns of context in a conversation, we must classify whether the emotion of the next user utterance is “happy”, “sad”, “angry” or “others” (4-point scale). For a detailed description see (Chatterjee et al., 2019).

In this paper, we present bidirectional LSTM for contextual emotion detection in textual conversations that participated in SemEval-2019 Task 3 “EmoContext”. The proposed architecture aims to capture not only semantic and sentiment feature representation from the conversation turns, but also to capture user-specific conversation features. We avoided using traditional NLP features like sentiment lexicons and hand-crafted linguistic features by substituting them with word embeddings which were calculated automatically from the text corpora. Based on this paper, we make the following contributions[1] freely available for the research community:

- The source code of the deep-learning system for emotion detection.
- Word embeddings fine-tuned for emotional detection in short texts.

The rest of the article is organized as follows. Section 2 gives a brief overview of the related work. In section 3 we describe the proposed architecture of LSTM used in our system. Section 4 is focused on the texts pre-processing and training process. Section 5 lays emphasis on the different system architectures and approaches we have tried. In conclusion, the performance of our system and further ways of research are presented.

2 Related Work

In recent years deep learning techniques have captured the attention of researchers due to their ability to significantly outperform traditional methods in sentiment analysis task (Tang et al., 2015). This fact has also been confirmed by previous iterations of SemEval competition, where leading solutions used convolutional neural networks (CNN) and long short-term memory (LSTM) networks (Cliche, 2017; Baziotis et al., 2017, 2018) as well as transfer learning techniques (Duppada et al., 2018). However, limited research was focused

[1] https://github.com/sismetanin/emosense-semeval2019-task3-emocontext

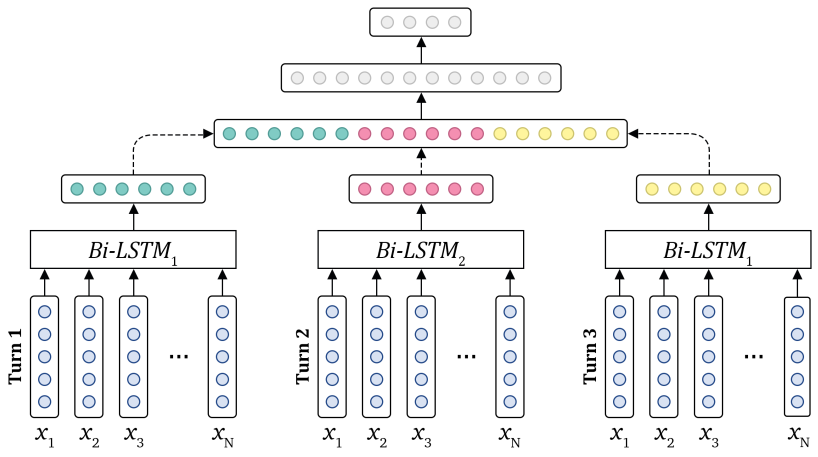

Figure 1: The architecture of a smaller version of the proposed architecture. LSTM unit for the first turn and for the third turn have shared weights.

on emotion identification in textual conversations. Since recurrent neural networks (RNNs) and their variations have been efficient in capturing sequential information, they have been successfully applied in emotion recognition systems (Poria et al., 2017; Gupta et al., 2017). Consequently, we draw our primary attention to the emotion classification in conversations using RRNs.

3 System Description

A recurrent neural network (RNN) is a family of artificial neural networks which is specialized in processing of sequential data. In contrast with traditional neural networks, RRNs are designed to deal with sequential data by sharing their internal weights processing the sequence. For this purpose, the computation graph of RRNs includes cycles, representing the influence of the previous information on the present one. As an extension of RNNs, Long Short-Term Memory networks (LSTMs) have been introduced in 1997 (Hochreiter and Schmidhuber, 1997). In LSTMs recurrent cells are connected in a special way in order to avoid vanishing and exploding gradient issues. Traditional LSTMs only preservs information from the past since they process the sequence only in one direction. Bidirectional LSTMs combine output from two hidden LSTM layers moving in opposite directions, where one moves forward through time, and another moves backwards through time, thereby enabling to capture information from both past and future states simultaneously (Schuster and Paliwal, 1997).

A high-level overview of our approach is provided in Figure 1. The proposed architecture of the neural network consists of the embedding unit and two bidirectional LSTM units $(dim = 64)$. The former LSTM unit is intended to analyze the utterance of the first user (i.e. the first turn and the third turn of the conversation), and the latter is intended to analyze the utterance of the second user (i.e. the second turn). These two units learn not only semantic and sentiment feature representation, but also how capture user-specific conversation features, which allows classifying emotions more accurately. At the first step, each user utterance is fed into corresponding bidirectional LSTM unit using pre-trained word embeddings. Next, these three feature maps are concatenated in a flatten feature vector and then passed to a fully connected hidden layer $(dim = 30)$, which analyzes interactions between obtained vectors. Finally, these features proceed through the output layer with the softmax activation function to predict a final class label. To reduce overfitting, regularization layers with Gaussian noise were added after the embedding layer, dropout layers (Srivastava et al., 2014) were added at each LSTM unit $(p = 0.2)$ and before the hidden fully connected layer $(p = 0.1)$.

4 Training

To train this model we had access to 30160 human-labelled tweets provided by task organizers, where about 5000 samples each from “angry”, “sad”, “happy” class and 15000 for “others” class (Table 1). Dev and test sets, which were also provided by organizers, in contrast with train set, have a real-life distribution, which is about 4% for each

Dataset	Happy	Sad	Angry	Others	Total
Train	14.07%	18.11%	18.26%	49.56%	30160
Dev	5.15%	4.54%	5.45%	84.86%	2755
Test	5.16%	4.54%	5.41%	84.90%	5509
Distant	33.3%	33.3%	33.3%	0%	900k

Table 1: Emotion class label distribution in datasets.

emotional class and the rest for the “others” class. Data provided by Microsoft.

In addition to this data, we collected 900k English tweets in order to create a distant dataset of 300k tweets for each emotion. To form the distant dataset, we based on the strategy of Go et al. (2009), under which we simply associate tweets with the presence of emotion-related words such as ’#angry’, ’#annoyed’, ’#happy’, ’#sad, ’#surprised’, etc. The list of query terms was based on the query terms of SemEval-2018 AIT DISC (Duppada et al., 2018).

The key performance metric of EmoContext is a micro-average F_1 score for three emotion classes, i.e. ‘sad’, ‘happy’, and ‘angry’. It is calculated as the harmonic mean of Precision and Recall.

4.1 Pre-processing

Before any training stage, texts were pre-processed by text pre-processing tool Ekphrasis (Baziotis et al., 2017). This tool helps to perform spell correction, word normalization and segmentation and allows to specify which tokens should be omitted, normalized or annotated with special tags. We used the following techniques for the pre-processing stage:

- URLs, emails, the date and time, usernames, percentage, currencies and numbers were replaced with the corresponding tags.
- Repeated, censored, elongated, and capitalized terms were annotated with the corresponding tags.
- Elongated words were automatically corrected based on built-in word statistics corpus.
- Hashtags and contractions unpacking (i.e. word segmentation) was performed based on built-in word statistics corpus.
- A manually created dictionary for replacing terms extracted from the text was used in order to reduce a variety of emotions.

In addition, Emphasis provides with the tokenizer which is able to identify most emojis, emoticons and complicated expressions such as censored, emphasized and elongated words as well as dates, times, currencies and acronyms.

4.2 Unsupervised Training

Word embeddings have become an essential part of any deep-learning approaches for NLP systems. To determine the most suitable vectors for emotions detection task, we try Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and FastText (Joulin et al., 2017) models as well as DataStories pre-trained word vectors (Baziotis et al., 2017). The key concept of Word2Vec is to locate words, which share common contexts in the training corpus, in close proximity in vector space. Both Word2Vec and Glove models learn geometrical encodings of words from their co-occurrence information, but essentially the former is a predictive model and the latter is a count-based model. In other words, while Word2Vec tries to predict a target word (CBOW architecture) or a context (Skip-gram architecture), i.e. to minimize the loss function, GloVe calculates word vectors doing dimensionality reduction on the co-occurrence counts matrix. FastText is very similar to Word2Vec except for the fact that it uses character n-grams in order to learn word vectors, so it’s able to solve the out-of-vocabulary issue. For all techniques mentioned above, we used the default training prams provided by the authors. We train a simple LSTM model $(dim = 64)$ based on each of these embeddings and compare effectiveness using cross-validation. According to the result, DataStories pre-trained embeddings demonstrated the best average F_1 score.

4.3 Distant Pre-training

To enrich selected word embeddings with the emotional polarity of the words, we consider performing distant pre-training phrase by a fine-tuning of the embeddings on the automatically labelled distant dataset. The importance of using pre-training was demonstrated in (Deriu et al., 2017). We use the distant dataset to train the simple LSTM network to classify angry, sad and happy tweets. The embeddings layer was frozen for the first training epoch in order to avoid significant changes in the embeddings weights, and then it was unfrozen for the next 5 epochs. After the training stage, the fine-tuned embeddings was

System	Happy			Sad			Angry			Happy&Sad&Angry		
	F_1	P	R	F_1	P	R	F_1	P	R	F_1	P	R
$Baseline$	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	58.61	n/a	n/a
$Random$	8.89	5.36	26.06	7.96	4.70	26.00	8.45	5.14	23.67	8.43	5.06	25.18
$LSTM_1$	67.07	59.07	77.68	76.95	71.57	83.36	71.18	61.75	84.67	71.37	63.31	81.89
$LSTM_2$	68.16	61.25	77.25	78.19	74.34	82.72	72.51	63.32	85.13	**72.58**	65.34	81.73
$LSTM_3$	67.33	60.70	75.77	75.23	69.60	82.00	70.06	59.08	86.27	70.58	62.34	81.41
$LSTM_s$	64.83	56.70	77.30	73.53	67.27	81.84	66.93	55.10	86.78	67.89	58.34	82.07
$LSTM_a$	66.50	58.71	77.00	75.64	71.40	80.71	69.88	59.27	85.56	70.30	62.15	81.19
$LSTM_w$	68.67	62.30	76.60	77.51	73.87	81.60	70.35	60.25	84.67	71.77	64.45	81.00

Table 2: Comparison of various models on dev dataset using micro-average Precision, Recall and F_1-score for emotional classes. $Baseline$ is an official baseline approach released by task organizers.

saved for the further training phases.

4.4 Supervised Training

At the final stage, the training dataset provided by SemEval-2019 was split into training and validation subsets. The validation subset was utilized as an unbiased accuracy evaluation of a model to fine-tune hyperparameters during training. The embedding layer was initialized with pre-trained word vectors from the previous distant training step. We use Adam optimizer (Kingma and Ba, 2014) with the initial learning rate of 0.001 and categorical cross-entropy as a loss function.

We train our network with frozen embeddings for the 15 epochs. We tried to unfrozen embeddings on the different epoch with the simultaneous reduction of learning rate but failed to get better results. It is probably connected with the size of the training dataset (Baziotis et al., 2017). The model was implemented using Keras with Tensorflow (Abadi et al., 2016) backend.

5 Experiments and Results

In the process of searching for optimal architecture, we experimented not only with the number of cells in layers, activation functions and regularization parameters but also with the architecture of the neural network. Let us take a closer look at the latter type of experiments. Comparison of various models presented in Table 2.

- $LSTM_1$ is a model with one bidirectional LSTM unit for all three conversation turns.
- $LSTM_2$ is a final model with two bidirectional LSTM units described in Section 2.
- $LSTM_3$ is a model with three bidirectional LSTM unit, where each unit is intended to analyze the corresponding conversation turn.
- $LSTM_w$ is $LSTM_2$ with an additional regularization based on class weights.
- $LSTM_s$ is $LSTM_2$ with an additional LSTM unit above concatenated layer.
- $LSTM_a$ is $LSTM_2$ with additional context-attention layer (Yang et al., 2016).

Since $LSTM_2$ demonstrated the best scores on the dev dataset, it was used in the final evaluation stage of the competition. On the final test dataset, it achieved 72.59% micro-average F_1 score for emotional classes. This is well above the official baseline released by task organizers, which was 58.68%.

6 Conclusion

In this paper, we presented the deep-learning system for emotion detection in textual conversations we used to compete in SemEval-2019 Task 3 ”EmoContext” competition. Utilizing state-of-the-art approaches in the literature, we decided to use RNNs to detect emotions. We designed a specific architecture of LSTM which allows not only to learn semantic and sentiment feature representation, but also to capture user-specific conversation features. In this work, we didn’t use any traditional NLP features such as sentiment lexicons or hand-crafted linguistic by substituting them with word embeddings which were calculated automatically from the text corpora with an advanced preprocessing stage.

Our approach achieved 72.59% micro-average F_1 score for emotion classes at the test dataset, thereby significantly outperform the officially-released baseline, namely larger in 14%. Further research will be focused on the advanced usage of techniques to handle imbalanced data. It also can be useful to consider the application of character-level language models.

Abstract

Messaging platforms like WhatsApp, Facebook Messenger and Twitter have gained recently much popularity owing to their ability in connecting users in real-time. The content of these textual messages can be a useful resource for text mining to discover and unhide various aspects, including emotions. In this paper we present our submission for SemEval 2019 task 'EmoContext'. The task consists of classifying a given textual dialogue into one of four emotion classes : *Angry*, *Happy*, *Sad* and *Others*. Our proposed system is based on the combination of different deep neural networks techniques. In particular, we use Recurrent Neural Networks (LSTM, B-LSTM, GRU, B-GRU), Convolutional Neural Network (CNN) and Transfer Learning (TL) methods. Our final system, achieves an $F1\mu$ score of 74.51% on the subtask evaluation dataset.

1 Introduction

The world of text conversations has undergone drastic changes during the last few years. The generation and sharing of such information have become much easier than before with the advent of popular social media platforms such as Twitter, Facebook, *etc.* According to *Statistica*[1] WhatsApp is the most popular mobile messaging app in the world with one billion monthly active users. Facebook Messenger closely follows with 900 million monthly active users. The content of these messages can be useful resource for text mining to discover and unhide various aspects, including emotions (Chatterjee et al., 2019a).

Capturing and analysing these emotions from peoples conversations has raised growing interest within the scientific community in varied fields like cognitive and social psychology, signal processing and natural language processing (Gupta et al., 2017; Zhang et al., 2018; Majumder et al., 2018).

The goal of detecting emotions in SemEval2019 task3 described in (Chatterjee et al., 2019b) is to classify a given conversation into one of four classes - *happy*, *sad*, *angry* and *others*, that best represents the mental state of the users. This can be seen as a multiclass classification problem.

In this paper, we propose an approach to detect emotions like *happy*, *sad* or *angry* in textual messages using a combination of deep learning models. We apply, also, a transfer learning approach, from a model trained on a similar task consists on the prediction of the sentiment of the conversation, *i.e. positive*, *negative* or *neutral*. Then, the pretrained model is re-used to classify the dialogue into one of four classes : *happy*, *sad*, *angry* and *others*.

The rest of the paper is organized as follows. Section 2 provides a brief literature review on emotion detection in textual datasets. The description of our proposed system is presented in Section 3. The experimental set-up and results are described in Section 4. Finally, a conclusion is given with a discussion of future works in Section 5.

2 Related Work

Emotions are closely related to sentiment with more analysis of the inferred polarity. For example, a negative sentiment can be caused by sadness or anger, while a positive sentiment can be caused by happiness or anticipation. Thus, following the way in sentiment analysis, many deep learning models are applied to detect emotions (Zhang et al., 2018; Poria et al., 2017).

(Zhou et al., 2018) proposed an Emotional Chatting Machine (ECM) that can generate appropriate responses grammatically relevant and emotionally consistent based on GRU. Their system

1. `https://www.statista.com/topics/1145/internet-usage-worldwide/`

is modeling the emotion factor, using emotion category embedding, internal emotion memory, and external memory. A bilingual attention network model was proposed by (Wang et al., 2016) for code-switched emotion prediction. The authors used a LSTM model to construct a document level representation of each post, and an attention mechanism to capture the informative words from bilingual and monolingual contexts. (Abdul-Mageed and Ungar, 2017) built a large, automatically curated dataset for emotion detection using distant supervision and then used GRNNs to model fine-grained emotion. They extended the classification to model (Plutchik, 2001)'s 8 primary emotion dimensions.

(Felbo et al., 2017) show how millions of readily available emoji occurrences on Social Media can be used to pre-train models to learn a richer emotional representation. They transfer this knowledge to emotion, sarcasm and sentiment detection tasks using a new layer-wise fine-tuning method. In (Daval-Frerot et al., 2018) the authors used a transfer learning approach, from a model trained on a similar task. They propose to pre-train a model to predict if a tweet is positive, negative or neutral by applying a B-LSTM on an external dataset. Then, they used the pre-trained model to classify a tweet according to the seven-point (range from 5 to +5 respectively from very negative to very positive) scale of positive and negative sentiment intensity.

3 Proposed System

Figure 1 provides a high-level overview of our system, which consists of three steps :

1. First step applies the basic text processing (Tokenisation, lemmatisation, filtering the noise from the raw text data, *etc*) and represents words in textual dialogue as vectors.
2. In the second step, we learn a model for each one of the emotions : *angry*, *happy* and *sad*.
3. The last step does the prediction based on the probabilities of our three models. The system classifies the dialogue in one of four classes (*angry*, *happy*, *sad* and *others*).

In this work, we consider each conversation as one single input, *i.e.* we didn't take into account the writing turn (utterance). Our decision was based on the fact that the language and the size of these conversations are similar to the standard user generated content type of data sets.

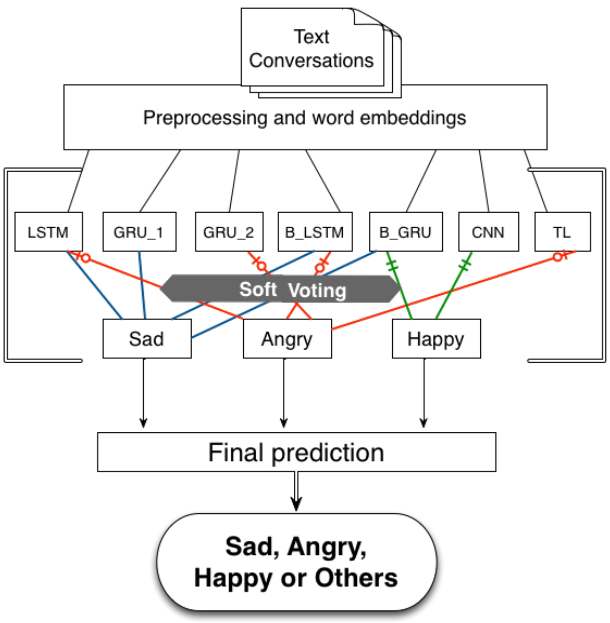

Figure 1 – Our proposed system architecture

3.1 Pre-processing and word representation

The textual dialogues are processed using *ekphrasis*[2] tool which allows performing the following tasks : tokenization, word normalization, word segmentation (for splitting hashtags) and spell correction (*i.e* replace a misspelled word with the most probable candidate word). All words are lowercased. E-mails, URLs and user handles are normalized. A detailed description of this tool is given in (Baziotis et al., 2017).
Each word in the text is represented by a vector of real numbers capturing the semantic meanings of words. We used datastories embeddings (Baziotis et al., 2017) trained on 330M english twitter messages posted from 12/2012 to 07/2016. The embeddings used in this work are 300 dimensional.

3.2 Neural Networks

With the recent advances in deep learning, the ability to analyse sentiments has considerably improved. Indeed, many experiments have used state-of-the-art systems to achieve high performance. For example, (Baziotis et al., 2017) use Bidirectional Long Short-Term Memory (B-LSTM) with attention mechanisms while (Deriu et al., 2016) use Convolutional Neural Networks (CNN). Both systems obtained the best performance at the the 2016 and 2017 SemEval 4-A task respecti-

2. https://github.com/cbaziotis/ekphrasis

vely. In this work, we use Long Short-Term Memory (LSTM), B-LSTM, Gated Recurrent Unit (GRU), Bidirectional-GRU (B-GRU) and CNN models and we, also, apply a Transfer Learning (TL) approach.

3.2.1 LSTM, GRU_1 and GRU_2 models

LSTM (Schuster and Paliwal, 1997) and GRU (Cho et al., 2014) are a special kind of RNN, capable of learning long-term dependencies. This ability comes from LSTM cells, that can decide which information to add and remove to the cell state regulated by gates (input gate, output gate and forget gate). The GRU cell is a simplified version of the LSTM cell.
LSTM and GRU_1 contain 2 layers of 128 neurons each. Similarly to (Baziotis et al., 2017), we added a Gaussian noise at the embedding layer with $\sigma = 0.3$ and dropout of 0.3 at LSTM/GRU layers. GRU_2 is similar to GRU_1, with some little differences where GRU_2 contains 3 layers of 100 neurons and dropout of 0.2 at the embedding layer.

3.2.2 B-LSTM and B-GRU models

The B-LSTM become a standard for deep sentiment analysis (Baziotis et al., 2017; Daval-Frerot et al., 2018; Moore and Rayson, 2017). B-LSTM and B-GRU consists of two LSTMs and two GRUs respectively in different directions running in parallel : the first forward network reads the input sequence from left to right and the second backward network reads the sequence from right to left. Each LSTM / GRU yields a hidden representation : $\vec{h}$ (left to right vector) and $\overleftarrow{h}$ (right-to-left vector) which are then combined to compute the output sequence. For our problem, capturing the context of words from both directions allows to better understand the textual conversations semantic. We use the same parameters of LSTM and GRU_1 models.

3.2.3 CNN model

The application of CNN models started with visual imagery. Many works apply CNN for sentiment analysis and obtained interesting results (Kim, 2014; Ouyang et al., 2015; Deriu et al., 2016). CNN is typically composed of three types of layers : convolution, pooling, and fully connected layers. Each neuron in the convolutional layer is connected only to a local region. In this work, we use multiple convolutional filters of sizes 3, 4 and 5.

3.2.4 TL-BLSTM model

In this work, we apply a TL, which allows to avoid learning from scratch. TL consists of transferring the knowledge learned on one task to a second related task. We start by training a first model to predict the sentiment of the dialogue : *positive*, *negative* or *neutral*. For this, we added a dense layer of 3 neurons to our B-LSTM (see subsection 3.2.2) . The model is learned using an external dataset[3] composed of 50333 tweets (7840 negatives, 19903 positives and 22590 neutrals). Then, the first model is re-used as the starting point to train a new model that classifies the dialogue into one of four classes : *happy*, *sad*, *angry* and *others*. For this, we remove the last layer of the pre-trained model and we add a fully-connected layer of 128 neurons followed by an output layer of 3 neurons (similar to our previous work (Daval-Frerot et al., 2018)).

4 Experimental settings and results

For each emotion, we use only the best models which maximizes the $F1\mu$ score. Table 2 presents the selected models for each emotion. Then, we combine these models using the soft voting approach considering only the probability of the selected emotion : *happy*, *sad* or *angry*.

For example, suppose that the CNN model gives 0.7, 0.1, 0.2 and 0.0 respectively for *happy*, *sad*, *angry* and *others*. And the GRU_1 model gives 0.6, 0.2, 0.0 and 0.2 for the same classes. We know, based on our results in table 2, that the CNN and GRU_1 are the best models for the emotion *happy*. So the soft voting combination is the average probability of 0.7 and 0.6, *i.e* 0.65.

In the last step we are applying a threshold after getting all prediction probabilities for our three classes. We choose threshold scores of 0.75 for angry and sad, and 0.67 for happy based on our experiments on the development set. These scores were high in order to avoid any possible confusion with the class *others*. This confusing can be caused by the fact that our training data is unbalanced.

Table 1 illustrates the performances of our system on *Dev* and *Test* sets. We can see an overall similarity in term of performance the system in both data sets. Indeed, the system achieves 74.4% and 74.5% on *Dev* and *test* sets respectively. The re-

	LSTM	80.1	71.2	75.4
	GRU_1	80.4	70.8	75.3
Angry	B-GRU	72.5	76.1	74.3
	GRU_2	69.5	78.1	73.6
	TL-BLSTM	70.1	76.5	73.1
	LSTM	72.2	71.4	71.8
Happy	CNN	69.4	68.6	69.6
	GRU_1	71.8	67.2	69.4

Table 2 – Models used for each emotion and their scores on test set.

sults shows a good performance for the *happy* and *Angry* and a better detection for the class *Sad* with a score around 78%.

Our final combination system, achieves an $F1\mu$ score of 74.51% on the test set gaining more than 3.5% compared to the best model before the combination which is B-GRU. This improvement comes from the fact that all systems used for the combination are using different methods that allows the diversification of their results and maximise the effect the soft voting.

Finally we can mention that after analysing our results, we have seen that most of errors came from the confusion between the class *Others* and the rest (*Happy*, *Angry* and *Sad*) which will be investigated in our future work.

5 Conclusion

In this paper, we propose to use a combination of different deep neural networks techniques including LSTM, B-LSTM, GRU, B-GRU, CNN and TL methods for the SemEval2019 task 3 of Emotions detection in textual conversations. Our system achieves a final $F1\mu$ of 74.51% on the subtask evaluation dataset.

As future work, we plan to develop an attention model to determine the importance of each part of the conversation (utterance) and its specific contribution to the emotion classification. We plan, also, to extend our work to other modalities such as audio emotions classification.

Figure Eight at SemEval-2019 Task 3: Ensemble of Transfer Learning Methods for Contextual Emotion Detection

Joan Xiao
Figure Eight Inc.
San Francisco, CA 94103
`joan.xiao@gmail.com`

Abstract

This paper describes our transfer learning-based approach to contextual emotion detection as part of SemEval-2019 Task 3. We experiment with transfer learning using pre-trained language models (ULMFiT, OpenAI GPT, and BERT) and fine-tune them on this task. We also train a deep learning model from scratch using pre-trained word embeddings and BiLSTM architecture with attention mechanism. The ensembled model achieves competitive result, ranking ninth out of 165 teams. The result reveals that ULMFiT performs best due to its superior fine-tuning techniques. We propose improvements for future work.

1 Introduction

Traditionally sentiment analysis attempts to classify the polarity of a given text at the document, sentence, or feature/aspect level, i.e., whether the expressed opinion in the text is positive, negative, or neutral. More advanced sentiment classification looks at emotional states such as “Angry”, “Sad”, and “Happy”.

Due to the increasing popularity of social media, over the past years sentiment analysis tasks in SemEval competitions have been mostly focused on twitter (Rosenthal et al., 2014) (Rosenthal et al., 2015; Nakov et al., 2016; Rosenthal et al., 2017). SemEval-2018 Task 1: Affect in Tweets (Mohammad et al., 2018) includes an array of subtasks on inferring the emotions (such as joy, fear, valence, and arousal) of a person from his/her tweet.

As we increasingly communicate using text messaging applications and digital agents, contextual emotion detection in text is gaining importance to provide emotionally aware responses to users. SemEval-2019 Task 3 (Chatterjee et al., 2019) introduces a task to detect contextual emotion in conversational text.

Deep-learning based approaches have recently dominated the state-of-the-art in sentiment analysis. However, a good performing model often requires large amounts of labeled data and takes many days to train. In computer vision, transfer learning has enabled deep learning practitioners to leverage models that have been pre-trained on ImageNet, MS-COCO, and other large datasets (Razavian et al., 2014; Shelhamer et al., 2017; He et al., 2016; Huang et al., 2017). Fine-tuning such pre-trained models in computer vision has been a far more common practice than training from scratch.

In Natural Language Processing (NLP), the most common and simple transfer learning technique is fine-tuning pre-trained word embeddings (Mikolov et al., 2013). These embeddings are used as the first layer of the model on the new dataset, and still require training from scratch with large amounts of labeled data to obtain good performance.

In 2018 several pre-trained language models (ULMFiT, OpenAI GPT and BERT) emerged. These models are trained on very large corpus, and enable robust transfer learning for fine-tuning NLP tasks with little labeled data.

In SemEval-2019 Task 3, we apply transfer learning approach using both pre-trained word embeddings and pre-trained language models. Our model achieves highly competitive result.

In this paper we describe our approach and experiments. The rest of the paper is laid out as follows: Section 2 provides an overview of the task, Section 3 describes the system architecture, and Section 4 reports results and performs an error analysis to obtain a better understanding of strengths and weaknesses of our approach and subsequently proposes improvements. Finally

Table 1: Train/Dev/Test set in SemEval2019 Task 3.

we conclude in Section 5 along with a discussion about future work.

2 Task Overview

2.1 Dataset

The organizers provide a training, development, and test set. Each row in the dataset is a 3-turn conversation between two people. The task is to classify the emotion of a conversation as “Happy”, “Sad”, “Angry”, or “Others”. Table 1 shows the distribution of the datasets across the labels. No other dataset is used in our experiments.

2.2 Evaluation Metric

Evaluation metric is micro-averaged F1 score for the three emotion classes i.e. Happy, Sad and Angry (excluding the class “Others”). This is referred as micro F1 score throughout the paper.

3 System Description

3.1 System Architecture

Figure 1 details the System Architecture. We now describe how all the different modules are tied together. The input raw text is pre-processed as described in Section 3.2. The processed text is passed through all the models described in Sections 3.3 to 3.8. Finally, the system returns the average of the predicted probabilities from all models as the output.

3.2 Pre-processing

The conversation text in the dataset is similar to tweets in that it may contain one or many emojis, and may have misspelled words. We use ekphrasis tool [1] to preprocess the data. The tool performs the following steps: tokenization, spell correction (i.e replace a misspelled word with the most probable candidate word), word normalization, and word segmentation. All words are lower-cased.

[1]https://github.com/cbaziotis/ ekphrasis

After the text in each turn is processed, we concatenate them with a separator ”$\langle$eos$\rangle$”.

3.3 Fine-tuning ULMFiT

Universal Language Model Fine-tuning (ULMFiT) (Howard and Ruder, 2018) trains language models on Wikitext-103 (Merity et al., 2017b), which consists of 28,595 preprocessed Wikipedia articles and 103 million words. It’s based on the language model AWD-LSTM (Merity et al., 2017a), a regular LSTM (with no attention, shortcut connections, or other sophisticated additions) with various tuned dropout hyperparameters. It provides two pre-trained models: a forward model trained from left to right, a backward model trained from right to left.

Furthermore, it introduced several novel techniques for transfer learning: discriminative fine-tuning, slanted triangular learning rates, and gradual unfreezing, to retain previous knowledge and avoid catastrophic forgetting during fine-tuning.

We first fine-tune the forward language model. We combine all data including training, dev and test set, and split into a training and validation set. We use fast.ai’s lr_find [2] method to find the optimum learning rate, and use early stopping on validation loss to tune the dropout values from 0.7 to 2.5.

Then we fine-tune the classifier on the training set using 10-fold cross validation. We use early stopping on the evaluation metric of the task (micro F1 with ”Others” class excluded). We experiment with dropout values from 0.7 to 0.85.

We repeat the same process for the backward language model.

3.4 Fine-tuning BERT

Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) trains language models on BooksCorpus (800M words) (Zhu et al., 2015) and English Wikipedia (2,500M words). It trains a deep bidirectional language models by masking some percentage of the input tokens at random, and then predicting only those masked token. This creates deep bidirectional representations by jointly conditioning on both left and right context in all layers.

In addition, it also trains a binarized next sentence prediction task which helps with understanding relation between two sentences, important for

[2]https://github.com/fastai/fastai

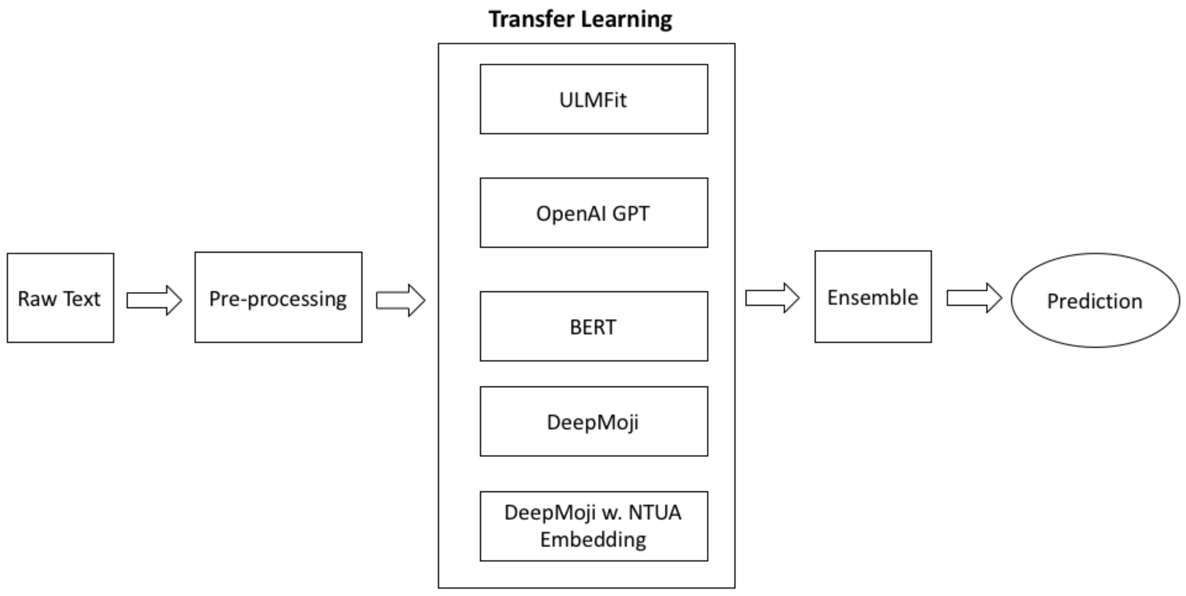

Figure 1: System Architecture.

Question Answering and Natural Language Inference tasks.

BERT provides pre-trained base and large models in multiple languages. In our experiments we use the large uncased English model. And we use the pytorch implementation by huggingface [3].

We experiment with fine-tuning the language model on a training and validation set split from a combined data set including training, dev and test set. We use early stopping on validation loss.

We then add a classifier layer on top of the output from the language model, and train it using the training set from the task with 10-fold cross validation. We use early stopping on the evaluation metric of the task (micro F1 with "Others" class excluded). We experiment with learning rate from 7e-6 to 3e-5.

3.5 Fine-tuning OpenAI GPT

OpenAI's Generative Pre-Training (GPT) (Alec et al., 2018) trains a language model using Transformer architecture on BooksCorpus. It obtains state-of-the-art result on many tasks including Natural Language Inference, Question answering and commonsense reasoning, Semantic Similarity, and Text Classification.

We tune the hyperparameters (clf_pdrop, embd_pdrop, resid_pdrop and attn_pdrop) in different combinations of values 0.1 and 0.2 (default value is 0.1) on the dev set. Due to that the dev score is less promising than the previous approaches, we do not use cross validation as it would take significant more time and compute resources. In fact this model was not included in the final submission.

3.6 Fine-tuning DeepMoji

DeepMoji (Felbo et al., 2017) performs distant supervision on a dataset of 1246 million tweets containing one of 64 common emojis. It obtained state-of-the-art performance on 8 benchmark datasets within sentiment, emotion and sarcasm detection using a single pretrained model.

We perform fine-tuning using the training set for training, and dev set as a validation set. We adopt the gradual unfreezing apporach (introduced by ULMFiT): first unfreeze the last layer and fine-tune all unfrozen layers for one epoch. We then unfreeze the next lower frozen layer and repeat, until we fine-tune all layers until convergence at the last iteration.

We do not use 10-fold cross validation due to that the highest micro F1 score on dev set does not seem promising.

3.7 Training a DeepMoji model with NTUA embedding

We also train a model from scratch using the DeepMoji's architecutre, but replace its embedding with a 310 dimensional embedding trained by NTUA-SLP team (Baziotis et al., 2018), which was trained on a dataset of 550M English twit-

Figure 2: Prediction examples by ULMFiT and BERT. Red indicates incorrect prediction.

ter messages. It was trained based on word2vec and has 310 dimensional embeddings, consisting of 300 dim word2vec embeddings and 10 dim affective dimensions.

We use the keras_lr_finder [4] method to find the optimum starting learning rate (with the fastest decrease in training loss), and train the model on the training set using 10-fold cross validation and early stopping on the evaluation metric of micro F1 score.

3.8 Ensembling

We combine the predictions of all models above by taking the unweighted average of the posterior probabilities for these models, and the final prediction is the class with the largest averaged probability.

4 Results and Analysis

Table 2 shows the results of various models on the dev set and test set. ULMFiT has the best performance on both dev and test sets, outperforming all other pre-trained models. The DeepMoji model trained from scratch with NTUA embedding ranks the second.

Figure 2 shows some examples where the ULMFiT or BERT makes incorrect predictions for the same conversations. We observe that BERT often makes incorrect predictions when emojis are present in the text, while ULMFiT is more robust to emojis. This suggests that the high performance of ULMFiT is due to not only the large corpus on which the language model is pre-trained on, but also the superior fine-tuning methods, such as discriminative fine-tuning, slanted triangular learning rates, and gradual unfreezing.

5 Conclusion

In this paper we describe our methods for contextual emotion detection. We achieved very competitive results in SemEval-2019 Task 3 using an ensemble of Transfer Learning models. We demonstrate that with sophisticated fine-tuning techniques in ULMFiT, transfer learning using pre-trained language models yields the highest performance, outperforming models trained from scratch. For future work we plan to explore these techniques with OpenAI GPT and BERT as well.

GenSMT at SemEval-2019 Task 3: Contextual Emotion Detection in tweets using multi task generic approach

Dumitru C. Bogdan

Human Language Technologies Research Center, University of Bucharest
bogdan27182@gmail.com

Abstract

In this paper, we describe our participation in SemEval-2019 Task 3: EmoContext - A Shared Task on Contextual Emotion Detection in Text. We propose a three layer model with a generic, multi-purpose approach that without any task specific optimizations achieve competitive results (f1 score of 0.7096) in the EmoContext task. We describe our development strategy in detail along with an exposition of our results.

1 Introduction

In recent years, emotion detection in text has become more popular due to its vast potential applications in marketing, artificial intelligence, education, politics, psychology, human-computer interaction, etc. Social platforms like Twitter and Facebook, enabled access to huge amount of textual data facilitating both theoretical and experimental research.

Consequently, sentiment analysis and emotion detection have gained the interest of researchers in natural language processing and other fields. While sentiment analysis refers to classifying a subjective text as positive, neutral, or negative; emotion detection identify specific types of feelings such as anger, joy, fear, or sadness.

SemEval is the International Workshop on Semantic Evaluation that has evolved from SensEval. The purpose of this workshop is to evaluate semantic analysis systems. Task 3 (Chatterjee et al., 2019) in this workshop, presents the task of detecting contextual emotion in a given three turn conversation where every turn is a short phrase (or tweet).

Our proposed model factors a *generic* approach to sentiment and emotion detection in tweets thus being suitable for several tasks in 2019 SemEval competition like task 3, task 5 or task 6. By not exploiting to the fullest specificity of task 3 (being a three turn conversation) and by not including transfer learning from any similar task we assumed a lower accuracy, being confident that in a longer term this approach will be useful for a large class of emotion detection tasks in text.

We leverage the latest developments in natural language processing, like *deep contextualized word representation* and a specially build submodel (encoder) as we will see in section 4.

2 Previous work

Sentiment classification, the task of detecting whether a text is positive or negative, has a long history of research. From the moment when (Pak and Paroubek, 2010) constructed a corpus of tweets for this task research in this area, on this type of corpus, increased considerably. Classifying tweets according to sentiment has many applications in political science, social sciences, market research, and many others (Martínez-Cámara et al., 2012).

It was only natural to extend research in this area to include a more fine grained classification of text, more than positive or negative. As result emotion classification in tweets started to gain interest.

Emotion detection is part of the broader area of Affective Computing that has the goal to help machines detect and simulate emotions (Picard, 1995). Psychology offers us a number of theories about how to represent emotions while two are the most important and the most often used in existing approaches in sentiment analysis: emotional categories and emotional dimensions.

Emotional categories approaches are concentrated on model emotions based on distinct emotion classes. The categorical model assumes that emotion categories clearly separable, are discrete

Proceedings of the 13th International Workshop on Semantic Evaluation (SemEval-2019), pages 225–229
Minneapolis, Minnesota, USA, June 6–7, 2019. ©2019 Association for Computational Linguistics

. Ekman presented a basic emotion model that fits categorical model approach. (Ekman, 2005) concluded that the six basic emotions are anger, disgust, fear, happiness, sadness and surprise.

Anger, sadness and happiness are the subject of the current task with one important addition: the absence of context which can add ambiguity making the task classification task much more complex, without access to facial expression and speech. Important amount of work has been done regarding to speech and facial emotion recognition however text based emotion detection systems still needs attraction of researchers (Sebea et al., 2005). Various methods where developed in the past like: *Keyword Spotting Technique*, *Lexical Affinity Method* or *Learning-based Methods*.

A similar research area is where emotions or more precisely emotion combinations plays a significant role is detection of optimism/pessimism in texts (Caragea et al., 2018).

Hopefully participants to this task will provide models and tools that will add value and will contribute to this field in a similar manner as previous SemEval tasks did (Mohammad et al., 2018).

3 Data preparation

Being a multi-task system, data preparation was also constrained to basic text preparation and tweets specific procedures. In effect we have treated all three sentences as a paragraph. We have concatenated turn1, turn2, turn3 separated by dot thus transforming the dataset in a list of pairs (label, text).

Tweets specific prepossessing involved sanitisation (links were replaced with *_url_* tag and user mentions were replaced with *_entity_* tag) and most important, we have translated emoji to text (e.g an emoji representing a face with tears of joy was expanded to "face with tears of joy" text). Emoji conversion is very important and based on intermediary tests it can greatly influence accuracy of models on datasets containing tweets.

To run our experiments, we used the dataset provided by the task organizers (Chatterjee et al., 2019) as follows. In pre-evaluation period we have trained our models on *training-set* and evaluated our model versions on *dev-set*. Dataset provided by the organizers contained 30160 entries and we have separated them into 24999 entries for *training-set* and remaining 5161 for *dev-set*. Table 1 provides more information about categories split in each set.

Data	Angry	Sad	Happy	Others	Total
All	5506	5463	4243	14948	30160
Train	4560	4504	3544	12391	24999
Dev	946	959	699	2557	5161

Table 1: Data split by sets and categories

4 Approach

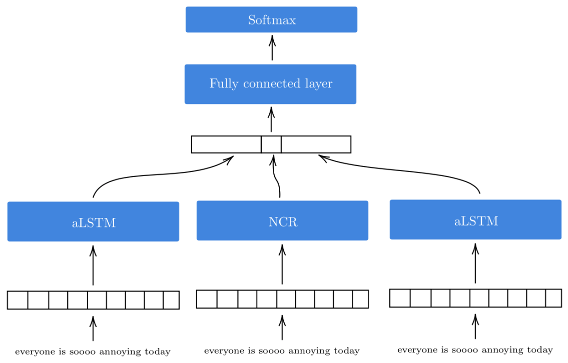
Our selected model has a classical layered approach as outlined in figure 1.

The first layer consists of few embedders, that receives the input data as a text sequence and converts it into a specific representation.

Resulted transformation is next feed to the middle layer where few encoders individually transforms input vectors to a final representation of input texts.

Next, final representations are concatenated into a large vector and transmitted to the final layer which is a dense layer those output is transformed into a probability distribution consisting of k probabilities, where k is the number of classes depending on the selected SemEval task: $k = 4$ for task 3, $k = 2$ for task 5 and task 6.

Along with layered approach, a parallel text transformation was considered, meaning that the input text was transformed into three different internal representations using three different encoders.



Softmax
Fully connected layer
aLSTM
NCR
aLSTM
everyone is soooo annoying today
everyone is soooo annoying today
everyone is soooo annoying today

Figure 1: GenSMT model structure

First encoder is ELMo (Peters et al., 2018), a deep contextualised word representation that models both complex characteristics of words syntax and semantics, and variations across linguistic contexts. Previous research and test showed significant improvements in various canonical NLP problems. A short description of this encoder is: ELMo word representations consists of functions of the entire input sentence computed on top of two-layer biLMs using character convolutions, as a linear function of the internal model states.

We can formalize this encoder as follows:

$$ELMo(x_{1:n}^{E_1}) = \gamma \sum_{j=0}^{l} s_j h_j^{LM}$$

where γ is a scalar parameter, l is the number of representation, s are softmax-normalized weights and h represents LSTM outputs.

Second encoder is NCR and works as follows: based on a list of words proposed by (Mohammad, 2018) it selects all occurrences of those words and their synonyms presented in the input text. Next it simply counts occurrences for each category (sad, anger, happy) and concatenates the results into a fixed size output vector.

We can formalize this encoder as follows:

$$NCR(x_{1:n}^{E_2}) = [\underset{cat \in \{anger, \dots\}}{count}(< cat >, x_{1:n})]$$

where $< cat >$ represents category and $count$ is the counting function.

Other NCR variations where proposed where we do not use a count function but we add, sub or dot product word representation and next we perform an operation of averaging, minimum or maximum.

Third encoder, RHN is an extended LSTM with recurrent dropout and possibility to use highway connections between internal layers.

We can formalize this encoder as follows:

$$RHN(x_{1:n}^{E_3}) = h \cdot t + x \cdot c$$

where h, t and c are internal compositions of nonlinear and linear functions.

Input data of the above encoders is formalized as follows:

$$\begin{aligned} x_{1:n}^{E_1} &= embedder_1(x_{1:n}) \\ x_{1:n}^{E_2} &= embedder_2(x_{1:n}) \\ x_{1:n}^{E_3} &= embedder_3(x_{1:n}) \end{aligned}$$

where $embedder_1$ produce character level representation of input text, $embedder_2$ and $embedder_3$ transform input words into their word embedding representation.

Now, we can formalize the full model as follows:

$$\begin{aligned} GenSMT(x_{1:n}) =& softmax(MLP(\Theta)); \\ \Theta =& [ELMo(x_{1:n}^{E_1}), \\ & NCR(x_{1:n}^{E_2}), \\ & RHN(x_{1:n}^{E_3})] \end{aligned}$$

As word representation we have use used various pretrained models in various configuration of GenSMT: Glove, Glove Twitter (Pennington et al., 2014), FastText (Joulin et al., 2016) and Wikipedia2vec (Yamada et al., 2018).

For development and testing we have used Python with ML related library like pytorch, numpy, pandas and others. Initial prototyping was done using Flair framework (Akbik et al., 2018) and development was done with AllenNLP (Gardner et al., 2017).

Training, validation and testing were performed on a single GPU machine. Training times were below one hour for each model configuration thus making this model suitable for hyper-parameters optimisation using grid search.

5 Experiments and results

As described in section 3 dataset was split in train and dev sets after being lightly pre-processed.

For training we use the model structure described in section 4 and we only changed model parameters and word embeddings of the embedders. We did not use any hyperparameters optimisation methods. Various model configurations were selected based on our previous experience with this kind of models.

Table 2 shows accuracy on dev tests of few selected configurations of GenSMT.

Model configuration	Accuracy
GenSMT$_1$	0.90
GenSMT$_2$	0.87
GenSMT$_3$	0.88
GenSMT$_4$	0.89

Table 2: Accuracy of various model configurations

$GenSMT_1$ configuration has the following general characteristics:

- $embeder_1$ performs character encoding
- $embeder_2$ uses 100d glove embeddings
- $embeder_2$ uses 500d wikipedia2vec embeddings
- ELMo large model
- MLP has three layers with ReLU activation
- batch size of 16
- Adam optimiser with a cosine learning rate scheduler
- 20 epochs with a patience of 5

Table 3 shows $GenSMT_1$ configuration where only default word embeddings of $embedder_3$ was changed. Results indicate that choosing word embeddings may influence accuracy.

Model configuration	Accuracy
GenSMT$_1(500d - wikipedia2vec)$	0.90
GenSMT$_1(300d - glove)$	0.89
GenSMT$_1(300d - fasttext)$	0.89

Table 3: Word-embeddings variations for a given configuration

We were interested to measure how each encoder contributes to model accuracy and for that ablation tests were performed. Table 4 shows $GenSMT_1$ configuration with one encoder removed.

Model configuration	Accuracy
GenSMT$_1(no\, ELMo)$	0.88
GenSMT$_2(no\, NCR)$	0.88
GenSMT$_3(no\, RHN)$	0.89

Table 4: Ablation tests on best performing configuration

While ELMo is powerful encoder, the gap between his absence and NCR absence, a simple encoder, is almost unnoticeable which is a surprise. This mean that a simpler model, with similar results, can be considered in scenarios where training or prediction speeds are of great importance (e.g mobile or IoT devices with low computing resources or low power resources).

For final, competition test we have used few $GenSMT_1$ configurations and the best performing one had an f1 score of 0.7096 placing this model in the upper half of the competition board.

6 Conclusions and future work

In this paper we have presented GenSMT model build as a generic system for SemEval 2019 task3, task 5 and task 6. It is a three layer model with three parallel embedders and encoders those outputs are concatenated and feed to dense layer which is next transformed into a probability distribution that produce text classification.

GenSMT was build with two constraint in mid. First we wanted to eliminate task specific dependencies as result we did not included any task specificity into the model. Second we did not use task specific transfer learning (e.g pretraining our model on a twitter sentiment dataset). This two constrains gave us the advantage to use the same model more than one task however reducing our accuracy capacity.

We have showed that choosing specific pretrained word embeddings can slightly improve the results, however greater gains are obtained by altering model hyperparameters.

By performing ablation tests we have showed that using a powerful encoder like ELMo increase the accuracy but not with an impressive score thus giving the option to use a simple and lower computational model to attain similar results much faster for both training and prediction.

Future work should explore two hypothesis. First as an upgrade of the model, it will be interesting to study how the model will perform if we remove the initial constraints and pretrain our model with a large twitter sentiment dataset followed by task specific data manipulation (e.g remove turn1 from dataset or inverse turns order). Second, as an update of the model, we can replace current encoder and embedders with new, state of the art ones.

Another aspect, specific for micro-blogging text is emoji presence and importance. While also present in larger texts, in short micro-blogging texts, emoji have more meaning, they carry a high quantity and quality of information that can be used for emotion detection thru data preprocessing or maybe using a model/encoder especially for them.

Abstract

In this paper we present an emotion classifier models that submitted to the SemEval-2019 Task 3 : *EmoContext*. The task objective is to classify emotion (*i.e.* happy, sad, angry) in a 3-turn conversational data set. We formulate the task as a classification problem and introduce a Gated Recurrent Neural Network (GRU) model with attention layer, which is bootstrapped with contextual information and trained with a multigenre corpus. We utilize different word embeddings to empirically select the most suited one to represent our features. We train the model with a multigenre emotion corpus to leverage using all available training sets to bootstrap the results. We achieved overall %56.05 f1-score and placed 144.

1 Introduction

In recent studies, deep learning models have achieved top performances in emotion detection and classification. Access to large amount of data has contributed to these high results. Numerous efforts have been dedicated to build emotion classification models, and successful results have been reported. In this work, we combine several popular emotional data sets in different genres, plus the one given for this task to train the emotion model we developed. We introduce a multigenre training mechanism, our intuition to combine different genres are a) to augment more training data, b) to generalize detection of emotion. We utilize Portable textual information such as subjectivity, sentiment, and presence of emotion words, because emotional sentences are subjective and affectual states like sentiment are strong indicator for presence of emotion.

The rest of this paper is structured as followings: section 2 introduce our neural net model, in section 3 we explain the experimental setup and data that is been used for training and development sets, section 4 discuss the results and analyze the errors, section 5 describe related works, section 6 conclude our study and discuss future direction.

2 Model Description

Gates Recurrent Neural Network (GRU) (Cho et al., 2014; Chung et al., 2015) and attention layer are used in sequential NLP problems and successful results are reported in different studies. Figure 1 shows the diagram of our model. [1]

GRU- has been widely used in the literature to model sequential problems. RNN applies the same set of weights recursively as follow:

$$h_t = f(W_{x_t} + U h_{t-1} + b) \tag{1}$$

GRU is very similar to LSTM with the following equations:

$$r_t = \sigma(W^r_{x_t} + U^r h_{t-1} + b^r) \tag{2}$$

$$z_t = \sigma(W^z_{x_t} + U^z h_{t-1} + b^z) \tag{3}$$

$$\hat{h_t} = \tanh(W_{x_t} + r_t \times U^{\hat{h}} h_{t-1} + b^{\hat{h}}) \tag{4}$$

$$h_t = z_t \times h_{t-1} + (1 - z_t) \times \hat{h_t} \tag{5}$$

GRU has two gates, a reset gate r_t, and an update gate z_t. Intuitively, the reset gate determines how to combine the new input with the previous memory, and the update gate defines how much of the previous memory to keep around. We use Keras[2] GRNN implementation to setup our experiments. We note that GRU units are a concatenation of GRU layers in each task.

Attention layer - GRUs update their hidden state h(t) as they process a sequence and the final

[1]Data and system will be released upon the request.
[2]https://keras.io/

hidden state holds the summation of all other history information. Attention layer (Bahdanau et al., 2014) modifies this process such that representation of each hidden state is an output in each GRU unit to analyze whether this is an important feature for prediction.

Model Architecture - our model has an embedding layer of 300 dimensions using *fasttext* embedding, and 1024 dimensions using ELMo (Peters et al., 2018) embedding. *GRU* layer has 70 hidden unites. We have 3 perceptron layers with size 300. Last layer is a *softmax* layer to predict emotion tags. Textual information layers (explained in section 2.1) are concatenated with GRU layer as auxiliary layer. We utilize a dropout (Graves et al., 2013) layer after the first perceptron layer for regularization.

2.1 Textual Information

Sentiment and objective Information (SOI)- relativity of subjectivity and sentiment with emotion are well studied in the literature. To craft these features we use SentiwordNet (Baccianella et al., 2010), we create sentiment and subjective score per word in each sentences. SentiwordNet is the result of the automatic annotation of all the synsets of WORDNET according to the notions of *positivity*, *negativity*, and *neutrality*. Each synset *s* in WORDNET is associated to three numerical scores Pos(s), Neg(s), and Obj(s) which indicate how positive, negative, and objective (i.e., neutral) the terms contained in the synset are. Different senses of the same term may thus have different opinion-related properties. These scores are presented per sentence and their lengths are equal to the length of each sentence. In case that the score is not available, we used a fixed score 0.001.

Emotion Lexicon feature (emo)- presence of emotion words is the first flag for a sentence to be emotional. We use NRC Emotion Lexicon (Mohammad and Turney, 2013) with 8 emotion tags (*e.i.* joy, trust, anticipation, surprise, anger, fear, sadness, disgust). We demonstrate the presence of emotion words as an 8 dimension feature, presenting all 8 emotion categories of the NRC lexicon. Each feature represent one emotion category, where 0.001 [3] indicates of absent of the emotion and 1 indicates the presence of the emotion. The advantage of this feature is their portability in transferring emotion learning across genres.

2.2 Word Embedding

Using different word embedding or end to end models where word representation learned from local context create different results in emotion detection. We noted that pre-trained word embeddings need to be tuned with local context during our experiments or it causes the model to not converge. We experimented with different word embedding methods such as *word2vec*, *GloVe* (Pennington et al., 2014), *fasttext* (Mikolov et al., 2018), and *ELMo*. Among these methods *fasttext* and *ELMo* create better results.

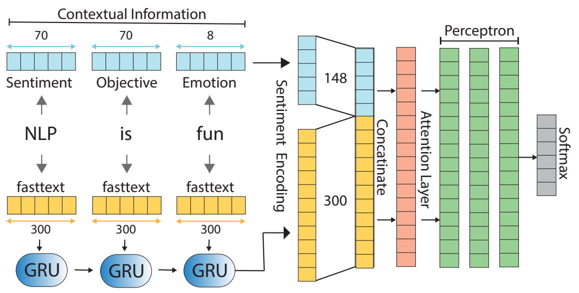

Figure 1: GRU-Attention neural net architecture. In this model framework, context information are features generated from SentiWordNet and emotion lexicon. We use fasttext to show the embedding layer (we use ELMo too, but we do not show it in here). Features are presented to GRU and attention layer and the output of attention layer is sent to 3 perceptron layer. Last layer is a softmax layer to predict emotion labels. Model without contextual info, exclude the contextual info input, which we do not show in the architecture.

3 Experimental Setup

We split *MULTI* dataset into 80%,10%,10% for train, dev, and test, respectively. We use AIT and EmoContext (data for this task) split as it is given by SemEval 2018 and semEval 2019. We describe these data sets in details in the next section. All experiments are implemented using Keras [4] and Tensorflow [5] in the back-end.

3.1 Data

We used three different emotion corpora in our experiments. Our corpora are as follows: a)

[3]empirically we observed that 0 is not a good initial value in neural net.

[4]https://keras.io/
[5]https://www.tensorflow.org/

A multigenre corpus created by (Tafreshi and Diab, 2018) with following genres: *emotional blog posts*, collected by (Aman and Szpakowicz, 2007), *headlines* data set from SemEval 2007-task 14 (Strapparava and Mihalcea, 2007), *movie review* data set (Pang and Lee, 2005) originally collected from Rotten tomatoes [6] for sentiment analysis and it is among the benchmark sets for this task. We refer to this multigenre set as (MULTI), b) SemEval-2018 Affect in Tweets data set (Mohammad et al., 2018) (AIT) with most popular emotion tags: *anger*, *fear*, *joy*, and *sadness*, c) the data set that is given for this task, which is 3-turn conversation data. From these data sets we only used the emotion tags *happy*, *sad*, and *angry*. We used tag *no-emotion* from MULTI data set as *others* tag. Data statistics are shown in figures 2, 3, 4 .

Data pre-processing - we tokenize all the data. For tweets we replace all the URLs, image URLs, hashtags, @users with specific anchors. Based on the popularity of each emoticon per each emotion tag, we replace them with the corresponding emotion tag. We normalized all the repeated characters, finally caps words are replaced with lower case but marked as caps words.

3.2 Training the Models

We have input size of 70 for sentence length, sentiment, and objective features and emotion lexicon feature has size 8. All these features are explained in section 2.1 and are concatenated with GRU layer as auxiliary (input) layer. Attention comes next after GRU and have size 70. We select dropout of size 0.2. We select 30 epochs in each experiment, however, training is stopped earlier if 2 consecutive larger loss values are seen on evaluation of dev set. We use Adam (Kingma and Ba, 2014) optimizer with a learning rate 0.001. We use dropout with rates 0.2. The loss function is a categorical-cross-entropy function. We use a mini batch (Cotter et al., 2011) of size 32. All hyper-parameter values are selected empirically. We run each experiment 5 times with random initialization and report the mean score over these 5 runs. In section 4 we describe how we choose the hyper-parameters values.

[6]https://www.rottentomatoes.com/

Data set	#train	#dev	#test	total
MULTI	13776	1722	1722	17220
AIT	6839	887	4072	11798
EmoContext	30160	2755	5510	38425

Table 1: Data statistics illustrating the distributions of the train, dev, and test sets across different data sets.

baseline- in each sentence we tagged every emotional word using NRC emotion lexicon (Mohammad and Turney, 2013), if any emotion has majority occurrence we pick that emotion tag as sentence emotion tag, when all emotion tags happen only once we randomly choose among them, when there is no emotional word we tag the sentence as *others*. We only use the portion of the emotion lexicon that covers the tags in the task (*i.e.* happy, sad, and angry).

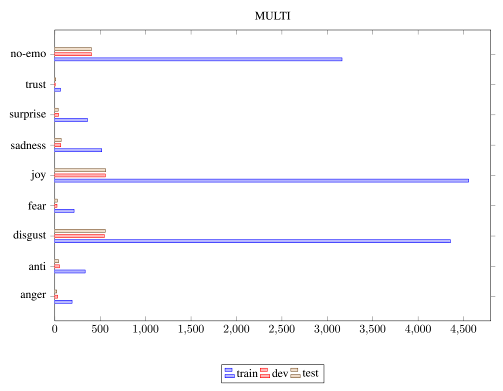

Figure 2: MULTI data set - train, dev, test data statistic

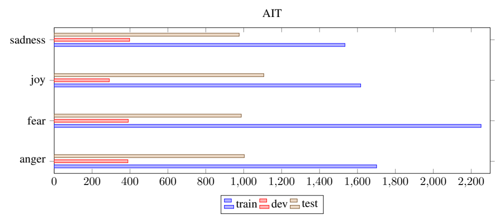

Figure 3: AIT data set - train, dev, test data statistic

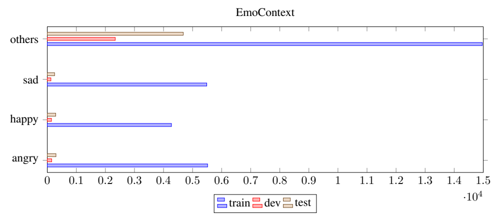

Figure 4: EmoContext data set - train, dev, test data statistic

Methods/Data set	**EmoContext**				
	pr.	re.	f.	acc.	sp./#epo.
Baseline	-	-	46.20	46.20	n.a.
GRU-att-fasttext	88.12	81.24	83.44	80.84	103/14
GRU-att-fasttext+F	88.27	84.47	85.27	82.07	321/8
GRU-att-ELMo	88.50	82.65	83.05	82.65	310/20
GRU-att-ELMo+F	**88.61**	**84.34**	**85.54**	**83.62**	960/28
Context Results(emotion only)	54.28	57.93	56.04	-	960/28

Table 2: Results on the *EmoContext* test sets. We report the mean score over 5 runs. Standard deviations in score are around 0.8. The experiments are demonstrating different embedding (*i.e.* ELMo and fasttext), with features (F), which are *emo* and *SOI* explained in section 2.1

Emotion tags/Data set	**EmoContext**		
	pr.	re.	f.
happy	45.37	53.52	49.11
sad	57.92	55.60	56.73
angry	61.02	64.09	62.52

Table 3: Context results of each emotion tag.

4 Results and Analysis

The results indicates the impact of contextual information using different embeddings, which are different in feature representation. Results of class *happy* without contextual features has %44.16 by GRU-att-ELMo model, and %49.38 by GRU-att-ELMo+F.

We achieved the best results combining ELMo with contextual information, and achieve %85.54 f-score overall, including class *others*. In this task we achieved %56.04 f-score overall for emotion classes, which indicates our model needs to improve the identification of emotion. Table 3 shows our model performance on each emotion tag. The results show a low performance of the model for emotion tag *happy*, which is due to our data being out of domain. Most of the confusion and errors are happened among the emotion categories, which suggest further investigation and improvement. We achieved %90.48, %60.10, %60.19, %49.38 f-score for class *others*, *angry*, *sad*, and *happy* respectfully.

Processing ELMo and attention is computationally very expensive, among our models GRU-att-ELMo+F has the longest training time and GRU-att-fasttext has the fastest training time. Results are shown in table 2 and table refemoresultss

5 Related Works

In semEval 2018 task-1, *Affect in Tweets* (Mohammad et al., 2018), 6 team reported results on sub-task E-c (emotion classification), mainly using neural net architectures, features and resources, and emotion lexicons. Among these works (Baziotis et al., 2018) proposed a Bi-LSTM architecture equipped with a multi-layer self attention mechanism, (Meisheri and Dey, 2018) their model learned the representation of each tweet using mixture of different embedding. in *WASSA 2017 Shared Task on Emotion Intensity* (Mohammad and Bravo-Marquez, 2017), among the proposed approaches, we can recognize teams who used different word embeddings: GloVe or word2vec (He et al., 2017; Duppada and Hiray, 2017) and exploit a neural net architecture such as LSTM (Goel et al., 2017; Akhtar et al., 2017), LSTM-CNN combinations (Köper et al., 2017; Zhang et al., 2017) and bi-directional versions (He et al., 2017) to predict emotion intensity. Similar approach is developed by (Gupta et al., 2017) using sentiment and LSTM architecture. Proper word embedding for emotion task is key, choosing the most efficient distance between vectors is crucial, the following studies explore solution sparsity related properties possibly including uniqueness (Shen and Mousavi, 2018; Mousavi and Shen, 2017) .

6 Conclusion and Future Direction

We combined several data sets with different annotation scheme and different genres and train an emotional deep model to classify emotion. Our results indicate that semantic and syntactic contextual features are beneficial to complex and state-of-the-art deep models for emotion detection and classification. We show that our model is able to classify non-emotion (others) with high accuracy. In future we want to improve our model to be able to distinguish between emotion classes in a more sufficient way. It is possible that hierarchical bi-directional GRU model can be beneficial, since these models compute history and future sequence while training the model.

Abstract

Recent advancements in Internet and Mobile infrastructure have resulted in the development of faster and efficient platforms of communication. These platforms include speech, facial and text-based conversational mediums. Majority of these are text-based messaging platforms. Development of *Chatbots* that automatically understand latent emotions in the textual message is a challenging task. In this paper, we present an automatic emotion detection system that aims to detect the emotion of a person textually conversing with a chatbot. We explore deep learning techniques such as CNN and LSTM based neural networks and outperformed the baseline score by 14%. The trained model and code are kept in public domain.

1 Introduction

In recent times, text has become a preferred mode of communication (Reporter, 2012; ORTUTAY, 2018) over phone/video calling or face-to-face communication. New challenges and opportunities accompany this change. Identifying sentiment from text has become a sought after research topic. Applications include detecting depression (Wang et al., 2013) or teaching empathy to chatbots (WILSON, 2016). These applications leverage NLP for extracting sentiments from text. On this line, SemEval Task 3: EmoContext (Chatterjee et al., 2019) challenges participants to identify Contextual Emotions in Text.

Challenges: The challenges with extracting sentiments from text are not only limited to the use of slang, sarcasm or multiple languages in a sentence. There is also a challenge which is presented by the use of non-standard acronyms specific to individuals and others which are present in the task's dataset 2.

*Equal Contribution

Existing work: For sentiment analysis, most of the previous year's submissions focused on neural networks (Nakov et al., 2016). Teams experimented with Recurrent Neural Network (RNN) (Yadav, 2016) as well as Convolutional Neural Network (CNN) based models (Ruder et al., 2016). However, some top ranking teams also used (Giorgis et al., 2016) classic machine learning models. Aiming for the best system, we started with classical machine learning algorithms like Support Vector Machine (SVM) and Logistic Regression (LR). Based on the findings from them we moved to complex models using Long Short-Term Memory (LSTM), and finally, we experimented with CNN in search for the right system.

Our contribution: In this paper, we present models to extract emotions from text. All our models are trained using only the dataset provided by EmoContext organizers. The evaluation metric set by the organizers is micro F1 score (**referred as score in rest of the paper**) on three {*Happy, Sad, Angry*} out of the four labels. We experimented by using simpler models like SVM, and Logistic regression but the score on dev set was below 0.45. We then worked with a CNN model and two LSTM based models where we were able to beat the baseline and achieve a maximum score of 0.667 on test set.

Outline: Section 2 describes the dataset and preprocessing steps. Section 3 presents model description and system information. In the next section (Section 4), we discuss experimental results and comparisons against state-of-the-art baselines. Towards the end, Section 5 and Section 6 conclude this work with current limitations and proposal for future extension.

2 Dataset

We used the dataset provided by Task 3 in SemEval 2019. This task is titled as *'EmoContext: Contextual Emotion Detection in Text'*. The dataset consists of textual dialogues i.e. a user utterance along with two turns of context. Each dialogue is labelled into several emotion classes: *Happy, Sad, Angry* or *Others*. Figure 1 shows an example dialogue.

Turn 1: N u
Turn 2: Im fine, and you?
Turn 3: I am fabulous 😎

Figure 1: Example textual dialogue from EmoContext dataset.

Table 1 shows the distribution of classes in the EmoContext dataset. The dataset is further subdivided into train, dev and test sets. In this work, we use training set for model training and dev set for validation and hyper-parameter tuning.

	Others	**Happy**	**Sad**	**Angry**
Train	14948	4243	5463	5506
Dev	2338	142	125	150
Test	4677	284	250	298

Table 1: Dataset statistics.

Preprocessing: We leverage two pretrained word embedding: (i) GloVe (Pennington et al., 2014) and (ii) sentiment specific word embedding (SSWE) (Tang et al., 2014). However, several classes of words are not present in these embeddings. We list these classes below:

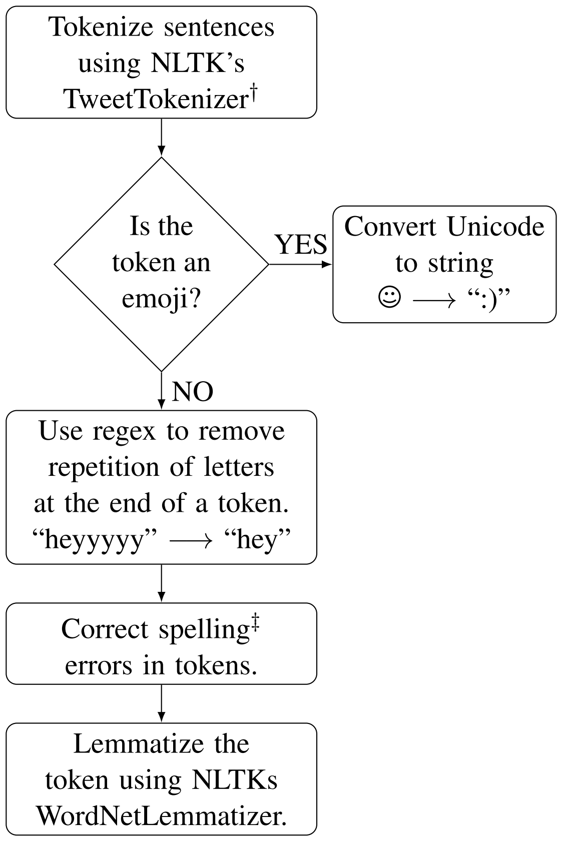
- **Emojis:** 😎, 😇, etc.
- **Elongated words:** Wowwww, noooo, etc.
- **Misspelled words:** ofcorse, activ, doin, etc.
- **Non-English words:** Chalo, kyun, etc.

We follow a standard preprocessing pipeline to address the above limitations. Figure 2 describes the dataset preprocessing pipeline.

By using the dataset preprocessing pipeline, we reduced the number of words not found in GloVe embedding from *4154* to *813* and in SSWE from *3188* to *1089*.

[†]NLTK Library (Bird et al., 2009)

[‡]For spell check we the used the following PyPI package - pypi.org/project/pyspellchecker/.



Tokenize sentences using NLTK's TweetTokenizer†
Is the token an emoji?
YES
Convert Unicode to string ☺ ⟶ ":)"
NO
Use regex to remove repetition of letters at the end of a token. "heyyyyy" ⟶ "hey"
Correct spelling‡ errors in tokens.
Lemmatize the token using NLTKs WordNetLemmatizer.

Figure 2: Data processing pipeline.

3 Experiments

We experiment with several classification systems. In the following subsections we first explain the classical ML based models followed by Deep Neural Network based models.

3.1 Classical Machine Learning Methods

We learn[§] two classical ML models, (i) Support Vector Machine (SVM) and (ii) Logistic Regression (LR). The input consists a single feature vector formed by combining all sentences (turns). We term this combination of sentences as *'Dialogue'*.

We create feature vector by averaging over d dimensional GloVe representations of all the words present in the dialogue. Apart from standard averaging, we also experimented with tf-idf weighted averaging. The dialogue vector construction from tf-idf averaging scheme is described below:

$$Vector_{dialogue} = \frac{\Sigma_{i=1}^{N}(\text{tf-idf}_{w_i} \times GloVe_{w_i})}{N}$$

[§]We leverage the Scikit-learn (Pedregosa et al., 2011) implementation.

Here, N is the total number of tokens in a sentence and w_i is the i^{th} token in the dialogue. Empirically, we found that, standard averaging shows better prediction accuracy than tf-idf weighted averaging.

3.2 Deep Neural Networks

In this subsection, we describe three deep neural architectures that provide better prediction accuracy than classical ML models.

3.2.1 Convolution Neural Network (CNN)

We explore a CNN model analogous to (Kim, 2014) for classification. Figure 3 describes our CNN architecture. The model consists of an embedding layer, two convolution layers, a max pooling layer, a hidden layer, and a softmax layer. For each dialogue, the input to this model is a sequence of token indices. Input sequences are padded with zeros so that each sequence has equal length n.

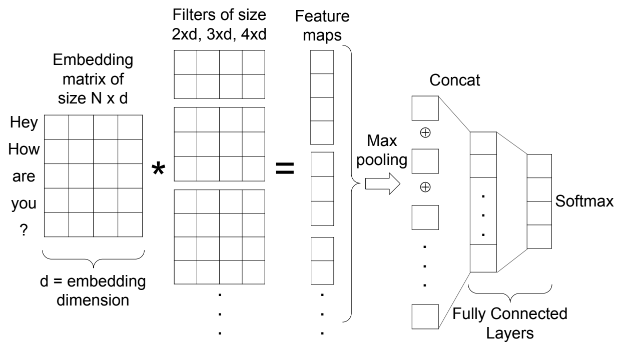


Figure 3: Architecture of the CNN model.

The embedding layer maps the input sequence to a matrix of shape $n \times d$, where n represents n^{th} word in the dialogue and d represents dimensions of the embedding. Rows of the matrix correspond to the GloVe embedding of corresponding words in the sequence. A zero vector represents words which are not present in the embedding.

At the convolution layer, filters of shape $m \times d$ slide over the input matrix to create feature maps of length $n - m + 1$. Here, m is the 'region size'. For each region size, we use k filters. Thus, the total number of feature maps is $m \times k$. We use two convolution layers, one after the other.

Next, we apply a max-pooling operation over each feature map to get a vector of length $m \times k$. At the end, we add a hidden layer followed by a softmax layer to obtain probabilities for classification. We used Keras for this model.

3.2.2 Long Short-Term Memory-I (LSTM-I)

We experiment with two Long Short-term Memory (Hochreiter and Schmidhuber, 1997) based approaches. In the first approach, we use an architecture similar to (Gupta et al., 2017) Here, similar to the CNN model, the input contains an entire dialogue. We experiment with two embedding layers, one with SSWE embeddings, and the other with GloVe embeddings. Figure 4 presents detailed description. Gupta et al. showed that SSWE embeddings capture sentiment information and GloVe embeddings capture semantic information in the continuous representation of words. Similar to the CNN model, here also, we input the word indices of dialogue. We pad input sequences with zeros so that each sequence has length n.

The architecture consists of two LSTM layers after each embedding layer. The LSTM layer outputs a vector of shape 128×1. Further, concatenation of these output vectors results a vector of shape 256×1. In the end, we have a hidden layer followed by a softmax layer. The output from the softmax layer is a vector of shape 4×1 which refers to class probabilities for the four classes. We used Keras for this model.

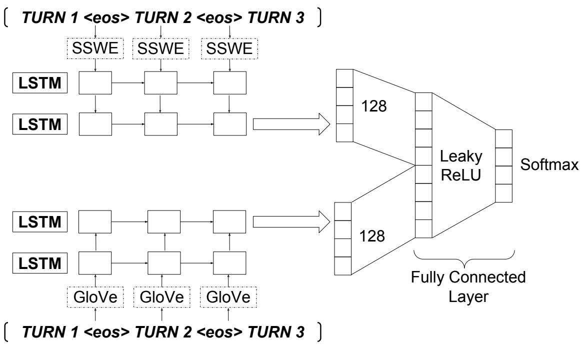

Figure 4: LSTM-I architecture.

3.2.3 Long Short-Term Memory-II (LSTM-II)

In the second approach, we use the architecture shown in Figure 5. This model consists of embedding layers, LSTM layers, a dense layer and a softmax layer. Here, the entire dialogue is not passed at once. Turn 1 is passed through an embedding layer which is followed by an LSTM layer. The output is a vector of shape 256×1. Turn 2 is also passed through an embedding layer which is followed by an LSTM layer. The output from Turn 2 is concatenated with the output of Turn 1 to form a vector of shape 512×1. The concatenated vector is passed through a dense layer which reduces the vector to 256×1. Turn 3 is passed through an embedding layer which is followed by an LSTM layer. The output from Turn 3 is concatenated with the reduced output of Turn 1 & 2, and the resultant vector has shape 512×1. The resultant vector is passed through a dense layer and then a softmax layer to find the probability distribution across different classes. We used Pytorch for this model.

The motivation of this architecture was derived from the Task's focus to identify the emotion of Turn 3. Hence, this architecture gives more weight to Turn 3 while making a prediction and conditions the result on Turn 1 & 2 by concatenating their output vectors. The concatenated vector of Turn 1 & 2 accounts for the context of the conversation.

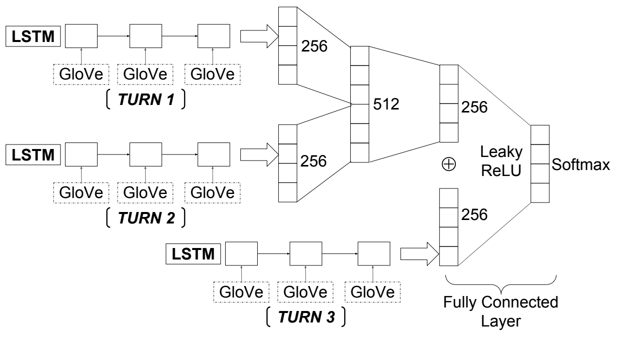

Figure 5: LSTM-II architecture.

4 Results

In Table 2, we report the performance of all the models described in the previous section. We train each model multiple (=5) times and compute the mean of scores.

Algorithm	$Score_{dev}$	$Score_{test}$
SVM	0.46	0.41
LR	0.44	0.40
SVM (tf-idf weighted averaging)	0.42	0.38
LR (tf-idf weighted averaging)	0.37	0.34
CNN	0.632	0.612
LSTM-I	0.677	**0.667**
LSTM-II	**0.684**	0.661

Table 2: Model performance on dev & test dataset.

SVM and Logistic Regression models did not yield very good results. We attribute this to the dialogue features that we use for the models. Tf-idf weighted average of GloVe vectors performed worse than the simple average of vectors. Hand-crafted features might have performed better than our current implementation. Neural network based models had very good results, CNN performed better than classical ML models but lagged behind LSTM based models. On the test set, our LSTM-I model performed slightly better than LSTM-II model.

Hyper-parameter selection for CNN was difficult, and we restricted to LSTM for the Phase 2 (i.e. test phase). We also noticed that the LSTM model was overfitting early in the training process (4-5 epochs) and that was a challenge when searching for optimal hyper-parameters. We used grid search to find the right set of hyper-parameters for our models. We grid searched over dropout (Srivastava et al., 2014), number of LSTM layers, learning rate and number of epochs. In case of the CNN model, number of filters was an extra hyper-parameter. We used Nvidia GeForce GTX 1080 for training our models.

5 Conclusion

In this paper, we experimented with multiple machine learning models. We see that LSTM and CNN models perform far better than classical ML methods. In phase-1 of the competition (dev dataset), we were able to achieve a score of 0.71, when the scoreboard leader had 0.77. But in phase-2 (test dataset), our best score was only 0.634, when the scoreboard leader had 0.79. After phase-2 ended, we experimented more with hyper-parameters and achieved an increase in scores on the test-set (mentioned in Table 2).

Full code for the paper can be found on GitHub*.

6 Future Work

Our scores on the test dataset suggest room for improvement. Now we are narrowing down to transfer learning where the starting point for our model will be a pre-trained network on a similar task. Our assumption is, this will help in better convergence on EmoContext dataset given the dataset size is not too large.

Abstract

This paper describes our approach to solve *Semeval task 3: EmoContext*; where, given a textual dialogue, i.e., a user utterance along with two turns of context, we have to classify the emotion associated with the utterance as one of the following emotion classes: *Happy, Sad, Angry* or *Others*. To solve this problem, we experiment with different deep learning models ranging from simple LSTM to relatively more complex attention with Bi-LSTM model. We also experiment with word embeddings such as ConceptNet along with word embeddings generated from bi-directional LSTM taking input characters. We fine tune different parameters and hyper-parameters associated with each of our model and report the micro precision, micro recall and micro F1-score for each model. We identify the Bi-LSTM model, along with the input word embedding taken as the concatenation of the embeddings generated from the bidirectional character LSTM and ConceptNet embedding, as the best performing model with a highest micro-F1 score over the test set as 0.7261.

1 Introduction

In recent years, with the increase in the popularity of social media platforms, a significant amount of unstructured social media content (posts, tweets, messages etc.) has become available to the research community. People use social media as a platform to share their opinions, emotions, thoughts etc. This information has a huge potential to serve as a commercial catalyst to the business of companies and organizations, e.g., knowing the opinion of people about a product or a service could help the company to do betterment of their product or service according to the desire of the online consumers. In similar lines, emotions from the peoples' comments/opinion can help us to model the future popularity of the product or the service. Further, knowing public emotions about different events can help political parties to set their agenda for elections. Thus mining of opinions and emotions has a lot of practical relevance. Even prior to the social media era, emotion detection had achieved significant attention of psychologists and linguistics. An elaborate discussion of emotion as a research topic is presented in the next section.

In this paper, we describe our system and the models, with which, we achieved significant performance improvement over the SemEval baseline for task 3. The task is described in (Chatterjee et al., 2019), where, given a textual dialogue, i.e., a user utterance along with two turns of context, we have to classify the emotion associated with the utterance into one of the following emotion classes: *Happy, Sad, Angry* or *Others*. To solve this problem, we experiment with different deep learning models ranging from simple LSTMs to more complex attention based Bi-LSTM models. We also experiment with different word embeddings such as ConceptNet along with word embeddings generated from bi-directional character LSTMs. Our best model gives a micro F1 of 0.7261 on the test set released by the organizers.

2 Related works:

From the last decades of the previous century, emotion as a topic of research has captured the attention of many scientists and researches from different sub-fields of computer science and psychology. While prior to the current century, researches tried to capture emotions from acoustic signals (Murray and Arnott, 1993; Banse and Scherer, 1996) and facial expressions (Ekman and Friesen, 1971; Ekman, 1993; Ekman et al., 1987), in the current century, due to the emergence of

Internet and social media, expression and detection of emotion through/from texts and social media, has grabbed significant attention (Alm et al., 2005; Fragopanagos and Taylor, 2005; Binali et al., 2010; Dini and Bittar, 2016; Canales and Martínez-Barco, 2014; Seyeditabari et al., 2018) of researchers. The whole literature around emotion can be broadly divided into two categories (1) theoretical studies and (ii) computational studies.

Theoretical studies: The theoretical studies include searching answers for whether facial expressions of emotion are universal (Ekman and Friesen, 1971), searching for cross-cultural agreement in the judgment of facial expression (Ekman et al., 1987), studying the acoustic profile of vocal emotion expression (Banse and Scherer, 1996) etc. An exploratory discussion of the literature detailing human vocal emotion and its principal findings are presented in (Murray and Arnott, 1993). Application of the literature to the construction of a system capable of producing synthetic speech with emotion has also been discussed. A brief description of how emotion is processed in our brain is discussed in (LeDoux, 2000).

Computational studies: From last two decades detecting and analysis of emotion in texts and social media content has grabbed significant attention of computational linguists and social scientists. (Litman and Forbes-Riley, 2004) determine the utility of speech and lexical features for predicting student emotions in computer-human spoken tutoring dialogues. They develop an annotated corpora that mark each student dialogue for negative, neutral, positive and mixed emotions. Then they extract acoustic-prosodic features from the speech signal, and lexical items from the transcribed or recognized speech and apply machine learning approaches to detect the emotions. In the same year, (Busso et al., 2004) came up with an analysis of emotion recognition techniques, using facial expressions, speech and multimodal information etc. They conclude that the system based on facial expression gives better performance than the system based on just acoustic information for the emotions considered. Sentiment classification seeks to identify a piece of text according to its authors general feeling toward their subject, be it positive or negative. Traditional machine learning techniques have been applied to this problem with reasonable success, but they have been shown to work well only when there is a good match between the training and test data with respect to the topic. (Read, 2005) use emoticons to reduce dependency in machine learning techniques for sentiment classification. (Wiebe et al., 2005) came up with a corpus having an annotation of opinions, emotions, sentiments, speculations, evaluations and other private states in the language of 10000 lines. In the second half of the last decade several studies came up that analyze and detect (Fragopanagos and Taylor, 2005; Binali et al., 2010; Hancock et al., 2007; Strapparava and Mihalcea, 2008) emotion from the text using machine learning techniques of the text context. Detection of emotion over social media content (Yassine and Hajj, 2010; Pak and Paroubek, 2010; Gupta et al., 2010) and electronic media content (Neviarouskaya et al., 2007; Yang et al., 2007) started to become popular during this period. Emotion cause detection (Chen et al., 2010) introduce another interesting problem in this period. In the current decade many problems in this domain have been introduced like emotion detection in code-switching texts (Wang et al., 2015), metaphor detection with topic transition, emotion and cognition in context (Jang et al., 2016), sentence and clause level emotion annotation and detection (Tafreshi and Diab, 2018), detecting emotion in social media contents (Roberts et al., 2012; Liew, 2014), detecting emotion in multilingual contexts (Das, 2011) etc. to name a few. Several corpora have been introduced having an annotation of emotions and other associated things such as emotion over multi-genre corpus (Tafreshi and Diab, 2018), emotion corpus of multi-party conversations (Hsu et al., 2018), a fine-grained emotion corpus for sentiment analysis (Liew et al., 2016), a dataset of emotion annotated tweets to understand the interaction between affect categories (Mohammad and Kiritchenko, 2018) etc. to name few. Simultaneously, methodological novelty in emotion detection is also an important contribution by researchers in the recent times; works like emotion detection by GRUs (Abdul-Mageed and Ungar, 2017), representation mapping (Buechel and Hahn, 2018), hybrid neural networks (Li et al., 2016) etc. are a few such latest techniques. A detail description of different hidden challenges present in emotion detection over social media content is present in (Dini and Bittar, 2016). Few survey papers (Canales and Martínez-Barco, 2014; Seyeditabari et al., 2018) describing different emotion analysis and detection methods adopted in past years also came up during this period.

3 Dataset and preprocesing

3.1 Dataset

The dataset consists of three parts, (i) training data, (ii) development data (dev set), and (iii) test data. The training dataset consists of 30k conversations, where each conversation contains three turns of user utterances. The dev set and the test set contains 2754 and 5508 conversations respectively. These have been collected and annotated by the organisers. All of the conversations are classified into four classes, 'angry', 'sad', 'happy' and 'others'. Training data consists of about 5k samples each from 'angry', 'sad', 'happy' class, and 15k samples from 'others' class, whereas, both dev and test sets have a real-life distribution, which is about 4% each of 'angry', 'sad', 'happy' class and the rest is 'others' class.

3.2 Preprocessing

Before feeding the conversations to our model, we perform the following operations on the text:

- The three turns of the conversation are joined to form a single sentence; also if there are multiple instances of punctuation, then we keep only a single instance. The joined utterance contains the conversations in the same order as that is given in the data set.

- Each emoji is replaced by its respective English translation. Example: ':-)' is replaced by 'happy'.

- All the possible English contractions are replaced by their expanded forms. for example: 'don't' is converted 'do not'.

- We use Ekphrasis toolkit (Baziotis et al., 2017) to normalize the occurrence of the URL, e-mail, percent, money, phone, user, time, date, and number in the comments. For example, URLs are replaced by 'url', and all occurrences of @someone are replaced by 'user'.

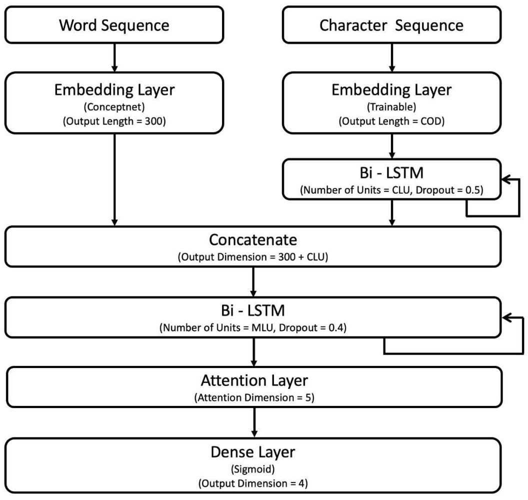

Figure 1: Overall schematic architecture of our system.

- Finally, we use NLTK Wordnet lemmatizer (Loper and Bird, 2002) to lemmatize the words to their roots.

4 System description

Our overall system is illustrated in Figure 1. We run different variants of our system by changing associated parameters, hyper-parameters and layers. For input, we consider a variety of options, which include (i) creating word embeddings using a Bi-LSTM trained on the character sequence of the sentence/utterance, (ii) using a pre-trained word embedding, i.e., Conceptnet, and (iii) concatenating (i) and (ii). From the architecture point of view our systems can be categorized into three types – (i) simple LSTM model, where an LSTM layer is considered instead of a Bi-LSTM layer (see figure 1) with no attention, i.e., the final hidden vector of LSTM layer is fed to the dense layer bypassing the attention layer (ii) simple Bi-LSTM model, where no attention layer is present, i.e., the final hidden vector of Bi-LSTM layer is fed to the dense layer by-passing the attention layer in figure 1, and (iii) Bi-LSTM model + attention, where we keep the attention layer active as shown in figure 1. We use the python module keras for our implementation.

5 Models and results

As previously stated, we experiment with different variants of the model. In this section, we discuss some of the top performing models and their performance. The results for different sys-

Model Type	Acc_μ	Pre_μ	Rec_μ	$F1_\mu$	$F1_{test}$
LSTM + Conceptnet	0.90	0.88	0.90	0.89	0.6825
Bi-LSTM + ConceptNet	0.90	0.86	0.91	0.88	0.6686
BiLSTM + (char embed. + Conceptnet)	0.90	0.88	0.89	0.89	**0.7261**
Bi-LSTM + (character embed. + Conceptnet) + no emojis	0.90	0.88	0.90	0.89	0.6418
Attentive Bi-LSTM + character embedding + Conceptnet	0.89	0.88	0.88	0.88	0.6900

Table 1: Results of different models; accuracy (Acc_μ), micro-precision (Pre_μ), micro-recall (Rec_μ) and micro-F1 score ($F1_\mu$) over the training data for five-fold cross validation; $F1_{test}$ is the micro-F1 score over the test set released by the organisers.

tems and their description are as shown in Table 1. We report two types of results (i) performance over training set which we obtain through five-fold cross-validation and (ii) performance over test data as reported by SemEval organizers. A short description of the model variants and their results are given below.

1. The first two models present in Table 1, as the name suggests, contains a layer of LSTM (1st model) and Bi-LSTM (2nd model). Sequence of words padded to a fixed length is given as input to this layer. The input sequence is then converted to an embedding vector with the help of pre-trained embedding matrices. We tried various pre-trained embedding matrices such as GloVe, fastText, ConceptNet and Google word2vec, out of which for Conceptnet we get best results. The outcome of LSTM/Bi-LSTM is given as input to the final dense layer which contains four nodes with sigmoid activation function for four emotions.

2. In the next model, we append character embeddings to the Conceptnet embeddings. This model produces the best performance over the test set, i.e., micro F1 score over the test set is 0.7261 as released by the organizers. The input to this model is a 2-D vector of words with characters in the second dimension.

3. The fourth model is the same as the previous model but emotion words (words which replaced emojis) are removed. As we can infer from the table this choice though did not affect the performance over the training set, the test set performance is significantly affected.

4. Finally, in the attentive Bi-LSTM model, we switch on the attention layer. Other parameters are kept the same as the third model model.

6 Conclusion

In this paper, we present a neural network based model to detect emotions from textual conversations. The usage of pre-trained embedding, Conceptnet gives a huge boost to the performance of our system. The performance reported in our paper could further be improved by implementing a better prepossessing pipeline and using more advanced RNN models. Furthermore, the dataset provided had a huge imbalance among different classes, therefore sampling among classes could result in increased performance. On the other hand, studying emotion in social media text can be linked further to the popularity of a product, service etc. which might be linked to financial interests of organizations. Further, how users expressing a particular predominant emotion interact with other users could be another line of future study.

King Saud University
Saudi Arabia
nourah_swaidan@yahoo.com, menai@ksu.edu.sa

Abstract

In this paper, we present the model submitted to the SemEval-2019 Task 3 competition: contextual emotion detection in text "EmoContext". We propose a model that hybridizes automatically extracted features and human engineered features to capture the representation of a textual conversation from different perspectives. The proposed model utilizes a fast gated-recurrent-unit backed by CuDNN (CuDNNGRU), and a convolutional neural network (CNN) to automatically extract features. The human engineered features take the term frequency-inverse document frequency (TF-IDF) of semantic meaning and mood tags extracted from SinticNet. For the classification, a dense neural network (DNN) is used with a sigmoid activation function. The model achieved a micro-F1 score of 0.6717 on the test dataset.

1 Introduction

Emotion recognition in text refers to the task of automatically assigning an emotion to a text selected from a set of predefined emotion labels. The SemEval-2019 competition (Chatterjee et al., 2019b) provides a textual dialogue and asks to classify the emotion as one of the emotion labels: happy, sad, and angry or others.

Previous research shows that emotion recognition has been performed on different types of text, including fairy tales[1] (Alm et al., 2005), news headlines[2] (Strapparava and Mihalcea, 2007), blog posts[3] (Aman and Szpakowicz, 2007), and tweets[4] (Mohammad et al., 2018). Whether a text expresses a single emotion or multiple emotions, it is challenging to recognize implicit emotions, which requires natural language understanding (NLU). Recognizing emotions in textual conversation increases difficulty by adding a dialogue format. Understanding emotions in textual conversation will further boost the research on NLU.

In this paper, we present an emotion recognition model that hybridizes human engineered features and automatically extracted features. For the human engineered features, we opted for calculating the term frequency-inverse document frequency (TF-IDF) of semantic meaning and mood tags retrieved from SenticNet. For the automatically extracted features, we explored two deep neural networks, a fast gated-recurrent-unit backed by CuDNN (CuDNNGRU) and convolutional neural networks (CNN). The classification is performed by a dense neural network (DNN).

The remainder of this paper is organized as follows. Section 2 describes the task corpus. Section 3 presents the proposed emotion recognition model. Section 4 presents the experimental results, and the main conclusions and future work are presented in Section 5.

2 Corpus

The organizers of the competition split the corpus into three datasets: a training dataset with 30160 instances, a development dataset with 2755 instances, and a test dataset with 5509 instances. The corpus was in a (.txt) format and contained five columns. The first column held the ID of the instances. The second, third and fourth columns held a conversation between two individuals. The first individual started the conversation then it was the second individuals turn, then the turn returned to the first individual. The fifth column held the emotion labels of the third turn in the conversation. The emotion label was either happy, sad, angry, or others. The distribution of the emotion

labels differed between the training, development and test datasets. The training data consisted of approximately 5000 instances each of happy, sad, and angry labels, and 15000 instances of the others label. The development and the test datasets had 4% each of happy, sad, and angry labels and the rest was for the label others. During the competition, the development dataset and the test dataset were released without the label column. The full development dataset was released when the final evaluation on the test dataset started. The full test dataset was released after the end of the competition.

3 Proposed Model

In this section, we present the submitted emotion recognition model. Figure 1 shows an overview of the model.

3.1 Preprocessing

The conversation style was informal and similar to a social media style of writing. Therefore, we utilized the ekphrasis[5] (Baziotis et al., 2017) tool. Ekphrasis was developed as part of the text processing pipeline for SemEval-2017 Task 4, sentiment analysis in Twitter. The preprocessing steps include Twitter-specific tokenization, unpack contractions, spell correction, word normalization, word annotation, word segmentation (for splitting hashtags), and replacing emoticons with suitable keywords.

We also grouped the most popular emojis into four classes, which matched the corpus emotion labels. With the use of regular expressions, we replaced the emoji with a keyword that represented the group the emoji belonged to. Then, we performed stopword removal and lemmatization with the use of the natural language toolkit[6] (NLTK).

[5]https://github.com/cbaziotis/ekphrasis
[6]https://www.nltk.org

3.2 Automatically Extracted Features

We utilized different deep neural networks, from the Keras[7] deep learning library, to enhance the representation of the text. However, we did not utilize any pretrained embeddings.

After text preprocessing, we split the text based on the conversation turns into turn 1 (T1), turn 2 (T2) and turn 3 (T3). An embedding matrix was generated for each turn of the conversation. Then, we applied BatchNormalization. These embeddings were used in two parallel submodels.

Submodel 1 in Figure 2, shows that each embedding matrix formed an input to a separate CuDNNGRU. The outputs of the three CuDNNGRUs were concatenated, and global max-pooling was performed. A dropout of value 0.1 was added to help avoid overfitting. Finally, the output was fed into two dense neural networks (DNN) with 50 units and a rectified linear unit (ReLU) activation function.

Submodel 2 in Figure 3, shows that each embedding matrix formed an input to a separate CNN with a sigmoid activation function. The number of filters of the first two CNNs was 100, but the third one had 300 filters, and the kernel size was five in all three CNNs. Next, global max-pooling was performed on the output of each CNN. Finally, the outputs were concatenated and fed into two DNNs with 100 units and a ReLU activation function.

3.3 Human Engineered Features

We took the conversation as a whole and extracted the following features:

- The TF-IDF of the Mood tags: SenticNet[8] (Cambria et al., 2018) was used to retrieve the mood tag of each word in the dataset. Then, every word was replaced by its mood tag. If a word had no mood tag, then it was deleted. Finally, the TF-IDF was calculated using the scikit-learn[9] library.

- The TF-IDF of the semantic meaning: SenticNet[8] was used to retrieve the semantic meaning of each word in the dataset. Then, the word was replaced by its semantic meaning. Finally, the TF-IDF was calculated using the scikit-learn[8] library.

Happy	0.5306	0.7324	0.6154
Sad	0.6780	0.7160	0.6965
Micro Average	0.6098	0.7476	0.6717

Table 4: Performance results on the test dataset using both automatically extracted features and human engineered features.

Submodel 3 in Figure 4, was responsible for training the human engineered features. Each of the TF-IDF features was trained with a DNN with 100 units and a ReLU activation function. Then, the outputs were concatenated and fed into two DNNs with 50 units and a ReLU activation function.

3.4 Emotion Classification

The three submodels were concatenated and fed into two DNNs with 50 units and a ReLU activation function. Then, a dropout of value 0.1 was used. Finally, a DNN with four units and a sigmoid activation function was added as an output layer for the classification of the emotions.

4 Experiments

The code was implemented in Python. We used the following libraries: NLTK[6], scikit-learn[9], and Keras[7] deep learning library run on a GPU, with the TensorFlow[10] backend.

We found the best hyper-parameters by evaluating on the development dataset. We trained with a batch size of 32, for two epochs with Adam optimization and 0.0005 as a learning rate. Tables 1 and 2 show the performance results obtained on the development dataset when only the automatically extracted features, and the human engineered features were used, respectively. They show that automatically extracted features clearly lead to the best microaverage performance results (Precision=0.5398, Recall=0.7962, F1=0.6434) in comparison to those obtained with the human engineered features only (Precision=0.3858, Recall=0.6403, F1=0.4815).

Table 3 presents the microaverage results obtained with the proposed model on the development dataset when both kinds of features were used altogether. The model achieved its best precision and F1 results (precision=0.6014, F1=0.6852) and the same recall obtained with only the automatically extracted features (Recall=0.7962). These performance results demonstrate the effectiveness of the proposed model. It scored above the baseline (Chatterjee et al., 2019a) on the test dataset. Table 4 presents the microaverage results obtained (Precision=0.6098, Recall=0.7476, F1=0.6717).

5 Conclusion

In this paper, we proposed a model to address emotion recognition in textual conversation based on using automatically extracted features and human engineered features. The usefulness of the model was demonstrated by the experimental results obtained in terms of precision, recall, and F1 measures. In the future, we plan to investigate the impact of other features on the performance of the model, including affect lexicons and pretrained embedding models.

Abstract

This paper addresses the problem of modeling textual conversations and detecting emotions. Our proposed model makes use of 1) deep transfer learning rather than the classical shallow methods of word embedding; 2) self-attention mechanisms to focus on the most important parts of the texts and 3) turn-based conversational modeling for classifying the emotions. Our model was evaluated on the data provided by the SemEval-2019 shared task on contextual emotion detection in text. The model shows very competitive results.

1 Introduction

Emotional intelligence has played a significant role in many application in recent years (Krakovsky, 2018). It is one of the essential abilities to move from narrow to general human-like intelligence. Being able to recognize expressions of human emotion such as interest, distress, and pleasure in communication is vital for helping machines choose more helpful and less aggravating behavior. Human emotions are a mental state that can be sensed and hence recognized in many sources such as visual features in images or videos (Boubenna and Lee, 2018), as textual semantics and sentiments in texts (Calefato et al., 2017) or even patterns in EEG brain signals (Jenke et al., 2014). With the increasing number of messaging platforms and with the growing demand of customer chat bot applications, detecting the emotional state in conversations becomes highly important for more personalized and human-like conversations (Zhou et al., 2018).

This paper addresses the problem of modeling a conversation that comes with multiple turns for detecting and classifying emotions. The proposed model makes use of transfer learning through the universal language modeling that is composed of consecutive layers of Bi-directional Long Term Short Term Memory (Bi-LSTM) units. These layers are learned first in sequence-to-sequence fashion on a general text and then fine-tuned to a specific target task. The model also makes use of an attention mechanism in order to focus on the most important parts of each text turn. Finally, the proposed classifier models the changing of the emotional state of a specific user across turns.

The rest of the paper is organized as follows. In Section 2, the related work is introduced. Then, we present a quick overview of the task and the datasets in Section 3. Section 4 describes the proposed model architecture, some variants and hyperparameters settings. The experiments and results are presented in Section 5. Section 6 concludes the study.

2 Related Work

Transfer learning or domain adaptation has been widely used in machine learning especially in the era of deep neural networks (Goodfellow et al., 2016). In natural language processing (NLP), this is done through Language Modeling (LM). Through this step, the model aims to predict a word given some context. This is considered as a vital and important basics in most of NLP applications. Not only because it tries to understand the long-term dependencies and hierarchical structure of the text but also for its open and free resources. LM is considered as unsupervised learning process which needs only corpus of unlabeled text. The problem is that LMs get overfitted to small datasets and suffer catastrophic forgetting when fine-tuned with a classifier. Compared to Computer Vision (CV), NLP models are typically more shallow and thus require different fine-tuning methods. The developing of the Universal Language Model Fine-tuning

(ULMFiT) (Howard and Ruder, 2018) is considered like moving from shallow to deep pre-training word representation. This idea has been proved to achieve CV-like transfer learning for many NLP tasks. ULMFiT makes use of the state-of-the-art AWD-LSTM (Average stochastic gradient descent - Weighted Dropout) language model (Merity et al., 2018). Weight-dropped LSTM is a strategy that uses a DropConnect (Wan et al., 2013) mask on the hidden-to-hidden weight matrices, as a means to prevent overfitting.

On the other hand, one of the recent trend in deep learning models is the attention Mechanism (Young et al., 2018). Attention in neural networks are inspired from the visual attention mechanism found in humans. The main principle is being able to focus on a certain region of an image with "high resolution" while perceiving the surrounding image in "low resolution", and then adjusting the focal point over time. This is why the early applications for attention were in the field of image recognition and computer vision (Larochelle and Hinton, 2010). In NLP, most competitive neural sequence transduction models have an encoder-decoder structure (Vaswani et al., 2017). A limitation of these architectures is that it encodes the input sequence to a fixed length internal representation. This cause the results going worse performance for very long input sequences. Simply, attention tries to overcome this limitation by guiding the network to learn where to pay close attention in the input sequence. Neural Machine Translation (NMT) is one of the early birds that make use of attention mechanism (Bahdanau et al., 2014). It has recently been applied to other problems like sentiment analysis (Ma et al., 2018) and emotional classification (Majumder et al., 2018).

3 Data

The datasets are collections of labeled conversations (Chatterjee et al., 2019b). Each conversation is a three turn talk between two persons. The conversation labels correspond to the emotional state of the last turn. Conversations are manually classified into three emotional states for *happy*, *sad*, *angry* and one additional class for *others*. In general, released datasets are highly imbalanced and contains about 4% for each emotion in the validation (development) set and final test set. Table 1 shows the number of conversations examples and emotions provided in the official released datasets.

Dataset	Data size	Happy	Sad	Angry
Training	30160	5191	6357	6027
Validation (Dev)	2755	180	151	182
Testing	5509	369	308	324

Table 1: Used datasets.

4 Proposed Models

4.1 Model Architecture

In figure 1, we present our proposed model architecture. The model consists of two main steps: encoder and classifier. We used a linear decoder to learn the language model encoder as we will discuss later. This decoder is replaced by the classifier layers. The input conversations come in turns of three. After tokenization, we concatenate the conversation text but keep track of each turn boundaries. The overall conversation is inputted to the encoder. The encoder is a normal embedding layer followed by AWD-LSTM block. This uses three stacked different size Bi-LSTM units trained by ASGD (Average Stochastic Gradient Descent) and managed dropout between LSTM units to prevent overfitting. The conversation encoded output has the form of $C_{Enc} = [T^1_{Enc} \oplus T^2_{Enc} \oplus T^3_{Enc}]$ where T^i is the ith turn in the conversation and $\oplus$ denotes a concatenation operation and $T^i_{Enc} = \{T^i_1, T^i_2, \ldots, T^i_{N_i}\}$. The sequence length of turn i is denoted by N_i. The size of T^i_j is the final encoding of the j's sequence item of turn i.

For classification, the proposed model pays close attention to the first and last turns. The reasons behind this are that the problem is to classify the emotion of the last turn. Also, the effect of the middle turn appear implicitly on the encoding of the last turn as we used Bi-LSTM encoding on the concatenated conversation. In addition to these, tracking the difference between the first and the last turn of the same person may be beneficial in modeling the semantic and emotional changes. So, we apply self-attention mechanism followed by an average pooling to get turn-based representation of the conversation. The attention scores for the ith turn S^i is given by:

$$S^i = Softmax\{W_i.T^i_{Enc}\} \qquad (1)$$

Where W_i is the weight of the attention layer of the i^{th} turn and S^i has the form of $S^i = \{S^i_1, S^i_2, ..., S^i_{N_i}\}$. The output of the attention layer is the scoring of the encoded turn sequence $O^i =$

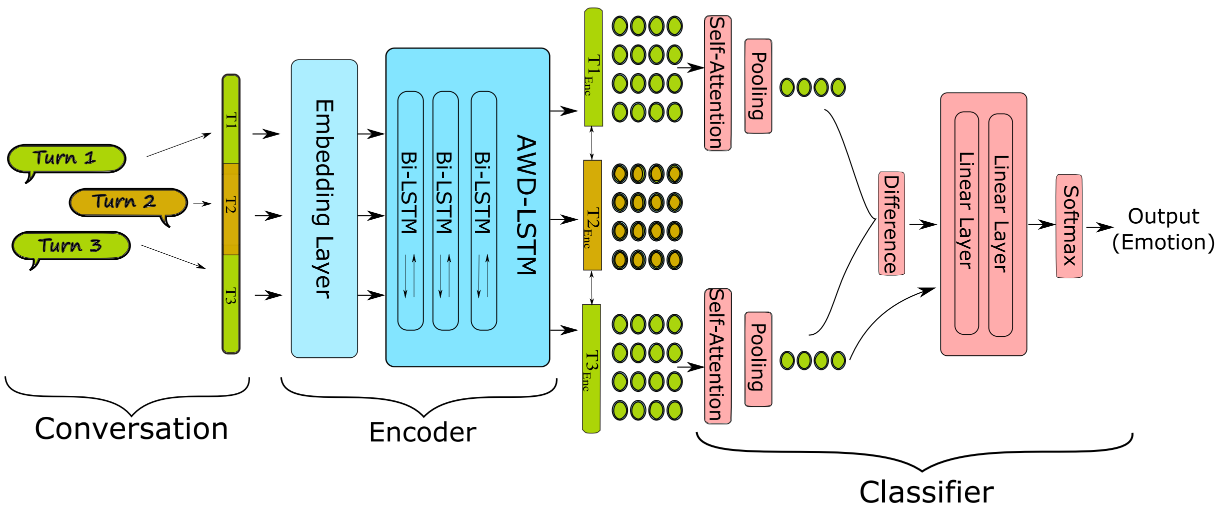

Figure 1: Proposed model architecture (*Model-A*).

$\{o_1^i, o_2^i, \ldots, o_{N_i}^i\}$ which has the same length as the turn sequence and is given by $O^i = S^i \odot T^i_{Enc}$ where $\odot$ is the element-wise multiplication. The difference of the pooled scored output of O^1 and O^3 is computed as O_{diff}. The Input of the linear block is X_{in} is formed by:

$$X_{in} = [O_{\text{diff}} \oplus O^3_{\text{pool}}] \quad (2)$$

The fully connected linear block consist of two different sized dense layers followed by a Softmax to determine the target emotion of the conversation.

4.2 Training Procedures

Training the overall models comes into three main steps: 1) The LM is randomly initialized and then trained by stacking a linear decoder in top of the encoder. The LM is trained on a general-domain corpus. This helps the model to get the general features of the language. 2) The same full LM after training is used as an initialization to be fine-tuned using the data of the target task (conversation text). In this step we limit the vocabulary of the LM to the frequent words (repeated more tan twice) of target task. 3) We keep the encoder and replace the decoder with the classifier and both are fine-tuned on the target task.

For training the language model, we used the Wikitext-103 dataset (Merity et al., 2016). We train the model on the forward and backward LMs for both the general-domain and task specific datasets. Both LMs -backward and forward- are used to build two versions of the same proposed architecture. The final decision is the ensemble of both. Our code is released at https://github.com/WaleedRagheb/Attentive-Emocontext.

4.3 Model Variations

In addition to the model - *Model-A* - described by Figure 1, we tried five different variants.

The first variant -(*Model-B*)- is formed by bypassing the self attention layer. This will pass the output of the encoder directly to the average pooling layer such that $X^B_{\text{in}} = [T_{\text{diff}} \oplus T^3_{\text{pool}}]$ where T_{diff} is the difference between the first and third pooled encoded turns of the conversations.

-(*Model-C*)- is to input a pooled condensed representation to the whole conversation C_{pool} rather than the last turn to the linear layer block. In this case: $X^C_{\text{in}} = [O_{\text{diff}} \oplus C_{\text{pool}}]$. We also studied two versions of the basic model where only one input is used $X^D_{\text{in}} = O_{\text{diff}}$ -(*Model-D*)- and $X^E_{\text{in}} = O^3_{\text{pool}}$ -(*Model-E*). In these two variants, we just change the size of the first linear layer.

Also, we apply the forward direction LM and classifier only without ensemble them with the backward direction and keep the same basic architecture -(*Model-F*).

4.4 Hyperparameters

We use the same set of hyperparameters across all model variants. For training and fine-tuning the LM, we use the same set of hyperparameter of AWD-LSTM proposed by (Merity et al., 2018) replacing the LSTM with Bi-LSTM. For classifier, we used masked self-attention layers and average pooling. For the linear block, we used hidden linear layer of size 100 and apply dropout of 0.4. We

Table 2: Test set results of the basic proposed model and it's variants.

used Adam optimizer (Dozat and Manning, 2017) with $\beta_1 = 0.8$ and $\beta_2 = 0.99$. The base learning rate is 0.01. We used the same batch size used in training LMs but we create each batch using weight random sampling. We used the same weights (0.4 for each emotion). We train the classifier on training set for 30 epochs and select the best model on validation set to get the final model.

5 Results & Discussions

The results of the test set for different variants of the model for each emotion is shown in table 2. The table shows the value of precision (P), recall (R) and F1 measure for each emotion and the micro-F1 for all three emotional classes. The micro-F1 scores are the official metrics used in this task. *Model-A* gives the best performance F1 for each emotion and the overall micro-F1 score. However some variants of this model give better recall or precision values for different emotions, *Model-A* compromise between these values to give the best F1 for each emotion. Removing the self-attention layer in the classifier -*Model-B*- degraded the results. Also, inputting a condensed representation of the all conversation rather than the last turn -*Model-C*- did not improve the results. Even modeling the turns difference only -*Model-D*- gives better results over *Model-C*. These proves empirically the importance of the last turn in the classification performance. This is clear for *Model-E* where the classifier is learned only by inputting the last turn of the conversation. Ensemble the forward and backward models was more useful than using the forward model only -*Model-F*.

Comparing the results for different emotions and different models, we notice the low performance in detecting happy emotion. This validate the same conclusion of Chatterjee et.al in (2019a). The model shows a significant improvement over the EmoContext organizer baseline (F1: 0.5868). Also, comparing to other participants in the same task with the same datasets, the proposed model gives competitive performance and ranked 11th out of more than 150 participants. The proposed model can be used to model multi-turn and multi-parties conversations. It can be used also to track the emotional changes in long conversations.

6 Conclusions

In this paper, we present a new model used for Semeval-2019 Task-3 (Chatterjee et al., 2019b). The proposed model makes use of deep transfer learning rather than the shallow models for language modeling. The model pays close attention to the first and the last turns written by the same person in 3-turn conversations. The classifier uses self-attention layers and the overall model does not use any special emotional lexicons or feature engineering steps. The results of the model and it's variants show a competitive results compared to the organizers baseline and other participants. Our best model gives micro-F1 score of 0.7582. The model can be applied to other emotional and sentiment classification problems and can be modified to accept external attention signals and emotional specific word embedding.

MILAB at SemEval-2019 Task 3: Multi-View Turn-by-Turn Model for Context-Aware Sentiment Analysis

Yoonhyung Lee, Yanghoon Kim, and Kyomin Jung
Seoul National University, Seoul, Korea
{cpi1234, ad26kr, kjung}@snu.ac.kr

Abstract

This paper describes our system for SemEval-2019 Task 3: EmoContext, which aims to predict the emotion of the third utterance considering two preceding utterances in a dialogue. To address this challenge of predicting the emotion considering its context, we propose a Multi-View Turn-by-Turn (MVTT) model. Firstly, MVTT model generates vectors from each utterance using two encoders: word-level Bi-GRU encoder (WLE) and character-level CNN encoder (CLE). Then, MVTT grasps contextual information by combining the vectors and predict the emotion with the contextual information. We conduct experiments on the effect of vector encoding and vector combination. Our final MVTT model achieved 0.7634 microaveraged F1 score.

1 Introduction

Sentiment analysis is a task of identifying emotional information from text materials and has been studied by various research fields since it can be applied to many applications such as public survey and market analysis. However, most studies in sentiment analysis have only focused on a single sentence (Socher et al., 2011) or a single document (Pang and Lee, 2005). It is still hard to predict the emotion of a sentence with extra contextual information because the emotion can be understood differently depending on its context. SemEval-2019 Task 3: EmoContext (Chatterjee et al., 2019) provides a dataset of dialogues which consist of three utterances between two users (Figure 1). Participants are required to predict the emotion of the third utterance among ‘Happy’, ‘Sad’, ‘Angry’, and ‘Others’, considering its context of two preceding utterances.

In this paper, we propose a Multi-View Turn-by-Turn (MVTT) model which encodes each utterance separately and combines the encoded vectors to get the contextual information. MVTT model first generates vectors from each utterance with two encoders: word-level Bi-GRU encoder (WLE) and character-level CNN encoder (CLE). The two-encoder strategy makes MVTT model more robust to the noisy texts which have a lot of typos and abbreviations. Then, MVTT extracts contextual information by combining the vectors and makes a prediction. We compare the MVTT model with some variants focusing on utterance vector encoding and utterance vector combination methods with microaveraged F1 score (F1) which is the main evaluation metric.

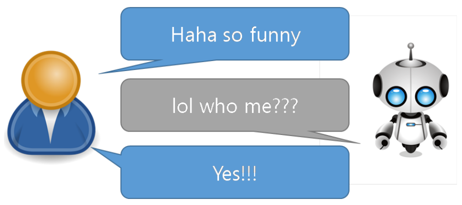

Figure 1: An example of a dialogue between two users.

This paper is organized as follows: Section 2 describes MVTT model architecture in detail. Section 3 describes dataset and various methods that we use to reflect the dataset’s characteristics to our training. Section 4 compares our results of MVTT model and other variants, and Section 5 outlines our conclusions.

2 System Description

This section describes our Multi-View Turn-by-Turn (MVTT) model which consists of two encoders: word-level Bi-GRU encoder (WLE) and character-level CNN encoder (CLE), which make our model more robust to noisy data. First, MVTT generates utterance vectors from each utterance using the encoders. Then, to understand the contextual information, MVTT combines the vectors into context-aware dialogue vectors and makes a

prediction using the context-aware dialogue vectors.

In this section, we first describe how each encoder generates the utterance vectors from each utterance and how MVTT combines the vectors into the context-aware dialogue vectors in detail.

2.1 Word-level Bi-GRU encoder

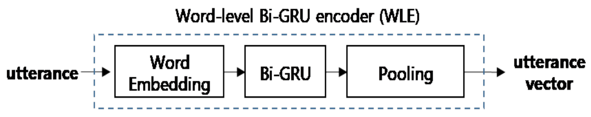

Figure 3: Word-level Bi-GRU encoder.

Word-level Bi-GRU encoder (WLE) takes an utterance as a sequence of word tokens $\{w_1, w_2, ..., w_N\}$. The tokens are fed into an embedding layer which is initialized with Glove word-embedding (Pennington et al., 2014) trained with a large twitter corpus. Then the embedded tokens are fed into the Bi-GRU encoder to get an utterance vector by max-pooling its hidden states over time.

WLE allows the model to benefit from pre-trained Glove word-embedding which have abundant information in syntactic and semantic word relationships. Also, MVTT benefits a lot from Bi-GRU encoder (Cho et al., 2014): (a) MVTT model can understand an text contextually with previous word information using Bi-GRU's gating mechanism; (b) by reading an text in two opposite ways, MVTT model can extract contextually more informative information. This is especially beneficial for MVTT to understand contextual meaning of a dialogue from each utterance.

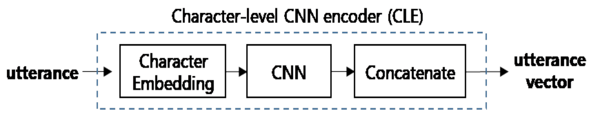

Figure 4: Character-level CNN encoder.

2.2 Character-level CNN encoder

Character-level CNN encoder (CLE) takes an input as a sequence of character tokens $\{c_1, c_2, ..., c_N\}$. The tokens are fed into a randomly initialized embedding layer, and then the embedded tokens are fed into the CNN encoder (Kim, 2014) to get an utterance vector.

Since it is impossible to consider all words in a word-level encoding, vocabulary consisting of 15k words is pre-defined based on word frequency and the other words are considered as out of vocabulary (OOV) tokens. Therefore, if the model only depends on WLE to extract features from a sequence of word tokens, a significant proportion of words will be tokenized as the OOV tokens when the texts are noisy. As a result, the model can't sufficiently utilize the benefit from pre-trained word-embedding. However, since the CNN encoder helps extract the local features from a sequence of character tokens, CLE enables our model to speculate the meaning of the text has some typos.

2.3 Multi-View Turn-by-Turn encoding

Multi-View Turn-by-Turn encoding is a method of generating utterance vectors from each utterance first and then combining the vectors into context-aware dialogue vectors. MVTT makes a prediction by encoding each utterance and combining them using concatenation and feed-forward neural network (FNN) as follows:

$$w13 = FNN([w1; w3])$$

$$w123 = FNN([w13; w2])$$

$$c13 = FNN([c1; c3])$$

$$c123 = FNN([c13; c2])$$

$$pred = FNN([w123; c123])$$

where $w1, w2, w3$ are the utterance vectors from each utterance generated by WLE and $c1, c2, c3$ are the utterance vectors from each utterance generated by CLE.

Since the first and third utterances are written by the same user, they are more informative in predicting the emotion of the third utterance. Therefore, by processing each utterance separately and combining them as above, the model can understand the context while maintaining the important emotional information.

2.4 Binary relevance classification

Binary relevance classification is a classification scheme to independently train binary classifiers for each label. It has usually been used for multi-label classification tasks and we apply the method to our task. In our system, we build three identical classifiers for 'Happy', 'Sad', 'Angry' classes and independently train them to output probabilities of each class. Then, we take the emotion with the highest probability as a class prediction, otherwise, if all the probabilities don't exceed 50%, take 'Others' as a predicted class.

3 Experiments

SemEval-2019 Task 3: EmoContext provided dialogue dataset consisting of three utterances written by two users and each sample is labeled among 'Happy', 'Sad', 'Angry' and 'Others'. In this section, we describe the dataset and some implementation details.

3.1 Datasets

The provided dialogue dataset is split into training, validation and test sets. Table 1 shows the label distribution of each data split. As Table 1 indicates, there are large differences in class label distributions among data splits and it is important to consider the differences in configuring our system.

Data split	Happy	Sad	Angry	Others
training	4243	5463	5506	14948
validation	142	125	150	2338
test	284	250	290	4677

Table 1: The statistics for the number of labels of each split.

3.2 Implementation details

We optimize our model using Adam optimizer (Kingma and Ba, 2014) and learning rate is set to 0.0015. We use Bi-GRU with 256 hidden units and CNN filters with window sizes of [3, 5, 9], 64 feature maps each. All FNN have 256 hidden units with $tanh$ activation function except for the last FNN classifier with $sigmoid$ function.

3.3 Pre-processing

In this task, we pre-process the utterances as described in Figure 5. We first lowercase all texts and replace abbreviations with their original forms as many as possible to make the best use of Glove word-embedding. Next, we unify emojis that have similar meanings into one specific emoji to help our model to learn emoji embeddings.

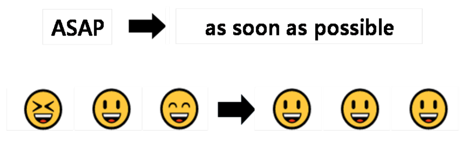

Figure 5: Text pre-processing.

3.4 Label smoothing

Label smoothing is a method to relax our confidence on the labels by using lower target values like 0.7 instead of 1. In the test set, almost all samples belong to the "Others" class with only a small percentage of examples belonging to the "Happy", "Sad", or "Angry" classes. Therefore, if we train each classifier for each emotion with label smoothing, we can prevent the model from predicting a emotion with excessive confidence and make the model be more likely to predict the emotions as 'Others'.

4 Results

In this section, we compare the performance of our MVTT model with some variants of our model. Since our model mainly consists of WLE and CLE, we try to investigate how our model benefits from both encoders. Further, we found that different combination methods of utterance vectors make a great difference in model evaluation. All of the results below are experimental results on the test set. MVTT outperforms all other variants and achieved 0.7634 microaveraged f1 score.

4.1 Ablation test on sentence embeddings

Our MVTT model utilizes the features of WLE and CLE. As is shown in Table 2, the model takes more advantage from WLE than CLE since the WLE utilizes the pre-trained word-embedding vectors trained on large twitter corpus which have abundant information in syntactic and semantic word relationships in the corpus. However, when we use both encoders, our MVTT model outperforms both models that use only one encoder. This results from the fact that CLE gives robustness to our model because it takes an input as a sequence of character tokens and extracts the local features from it.

Model	F1(H)	F1(S)	F1(A)	F1μ
WLE	0.7227	0.7680	0.7638	0.7515
CLE	0.6975	**0.7860**	0.7089	0.7270
MVTT	**0.7273**	0.7853	**0.7767**	**0.7634**

Table 2: Performance comparison among WLE, CLE and MVTT.

4.2 Impact of Turn-by-Turn encoding

Considering the characteristic of the given task, we find that the way to combine features from each utterance of a dialog is crucial. We tried several different combination methods, especially in the order of combination, to find out which setting has the most explainable structure with the best performance. We here list some variants with comparably better performance:

- C123: We simply concatenate $w1\,(c1)$, $w2\,(c2)$, $w3\,(c3)$ and feed it into a FNN to generate context-aware dialogue vectors.
- C12_3: Firstly concatenate $w1\,(c1)$, $w2\,(c2)$ and feed it into a FNN, and then concatenate the output and $w3\,(c3)$ and feed it into another FNN to generate context-aware dialogue vectors.
- C13_2 (MVTT): Firstly concatenate $w1\,(c1)$, $w3\,(c3)$ and feed it into a FNN, and then concatenate the output and $w2\,(c2)$ and feed it into another FNN to generate context-aware dialogue vectors.
- Submission: Ensemble of C123, C12_3, C13_2 models with various hyper parameters

Model	F1(H)	F1(S)	F1(A)	F1μ
C123	0.7119	0.7798	0.7602	0.7502
C12_3	0.7029	0.7674	0.7524	0.7406
Submission	0.7236	**0.7860**	0.7656	0.7581
MVTT	**0.7273**	0.7853	**0.7767**	**0.7634**

Table 3: The effect of vector combination on performance.

Table 3 shows the results of MVTT and some variants which combine the utterance vectors in other ways. As is shown in Table 3, our utterance vector combination method enables our model to understand both the emotional and contextual information. Since it is likely that a person's emotion is maintained through a 3-turn dialogue, combining the utterance vectors by user first and then making a prediction is beneficial to understand the context while maintaining emotional information.

5 Conclusion

In this paper, we propose a Multi-View Turn-by-Turn model (MVTT) for SemEval-2019 Task 3: EmoContext. Our goal was to predict the emotion of the third utterance in a dialogue consisting of three utterances. Firstly, MVTT model generates utterance vectors from each utterance using two encoders: word-level Bi-GRU encoder and character-level CNN encoder. The encoders make MVTT model more robust to the noisy texts. Then, MVTT combines the vectors to understand both the emotional and contextual meanings. We evaluated our MVTT model and its variants, focusing on utterance vector encoding and utterance vector combination. Our final MVTT model achieved 0.7634 microaveraged f1 score.

Abstract

When reading "I don't want to talk to you any more", we might interpret this as either an angry or a sad emotion in the absence of context. Often, the utterances are shorter, and given a short utterance like "Me too!", it is difficult to interpret the emotion without context. The lack of prosodic or visual information makes it a challenging problem to detect such emotions only with text. However, using contextual information in the dialogue is gaining importance to provide a context-aware recognition of linguistic features such as emotion, dialogue act, sentiment etc. The SemEval 2019 Task 3 EmoContext competition provides a dataset of three-turn dialogues labeled with the three emotion classes, i.e. *Happy*, *Sad* and *Angry*, and in addition with *Others* as none of the aforementioned emotion classes. We develop an ensemble of the recurrent neural model with character- and word-level features as an input to solve this problem. The system performs quite well, achieving a microaveraged F1 score (F1µ) of 0.7212 for the three emotion classes.

1 Introduction

Humans might interpret text wrongly when reading sentences in the absence of context, so machines might too. When reading the following utterance,

```
Why don't you ever text me?
```

it is hard to interpret the emotion where it can be either a sad or an angry emotion (Chatterjee et al., 2019; Gupta et al., 2017). The problem becomes even harder when there are ambiguous utterances, for example, the following utterance:

```
Me too!
```

one cannot really interpret the emotion behind such an utterance in the absence of context. See Table 1 where the utterance "Me too!" is used in many emotional contexts such as *sad*, *angry*, and *happy* and also in the class *"others"* where none of aforementioned emotions is present.

Analyzing the emotion or sentiment of text provides the opinion cues expressed by the user. Such cues could assist computers to make better decisions to help users (Kang and Park, 2014) or to prevent potentially dangerous situations (O'Dea et al., 2015; Mohammad and Bravo-Marquez, 2017; Sailunaz et al., 2018). Character-level deep neural networks have recently showed outstanding results on text understanding tasks such as machine translation and text classification (Zhang et al., 2015; Kalchbrenner and Blunsom, 2013).

Usually, the utterances are short and contain mis-spelt words, emoticons, and hashtags, especially in the textual conversation. Hence, using character-level language representations can theoretically capture the notion of such texts. On the other hand, the EmoContext dataset is collected from the social media, and so the character language model used in our experiments is also trained on such a corpus (Radford et al., 2017).

We propose a system that encapsulates character- and word-level features and is modelled with recurrent and convolution neural networks (Lakomkin et al., 2017). We used our recently developed models for the context-based dialogue act recognition (Bothe et al., 2018). Our final model for EmoContext is an ensemble average of the intermediate neural layers, ended with a fully connected layer to classify the contextual emotions. The system performs quite well and we ranked on the public leaderboard (MoonGrad team) on CodaLab[1] in the top 35% of the systems (at the time of writing this paper Feb 2019) achieving the microaveraged F1 score (F1µ) of 0.7212 for the three emotion classes.

Table 2: EmoContext Data Distribution; first row represents the total number of conversations in dataset.

2 Approach

The final model used for the submission to the EmoContext challenge is shown in Figure 1. It is an average ensemble of four variants of neural networks. *Net1* and *Net2* use the input from a pre-trained character language model; *Net3* and *Net4* use GloVe word embeddings as input. All models are trained with Adam optimizer at a learning rate of 0.001 (Kingma and Ba, 2014).

The dataset provided by the EmoContext organizers consists of the 3-turn dialogues from Twitter, where *turn1* is a tweet from user 1; *turn2* is a response from user 2 to that tweet, and *turn3* is a back response to user 2 (Gupta et al., 2017). The data distribution is presented in Table 2. We do not perform any special pre-processing except converting all the data into plain text.

2.1 Character-level RNN Model

The character-level utterance representations are encoded with the pre-trained recurrent neural network model[2] which contains a single multiplicative long short-term memory (mLSTM) (Krause et al., 2016) layer with 4,096 hidden units, trained on ∼80 million Amazon product reviews as a character-level language model (Radford et al., 2017). *Net1* and *Net2* are fed the last vector (LM) and the average vector (AV) of the mLSTM respectively. It is shown in (Lakomkin et al., 2017) that the AV contains effective features for emotion detection. The character-level RNN models (*Net1* and *Net2*) are identical and consist of two stacked bidirectional LSTMs (BiLSTM) followed by an average layer over the sequences computed by final BiLSTM.

2.2 Word-level RNN and RCNN Model

The word embeddings are used to encode the utterances. We use pre-trained GloVe embeddings (Pennington et al., 2014) trained on Twitter[3] with 200d embedding dimension. The average length of the utterances is 4.88 (i.e. ∼5 words/utterance on average) and about 99.37% utterances are under or equal to 20 words. Therefore, we set 20 words as a maximum length of the utterances. *Net3* is stacked with two levels of BiLSTM plus the average layer while *Net4* consists of a convolutional neural network (Conv). Conv in *Net4* over the embedding layer captures the meaningful features followed by a max pooling layer (max), with the kernel size of 5 with 64 filters and all the kernel weights matrix initialized with Glorot uniform initializer (Glorot et al., 2011; Kim, 2014; Kalchbrenner and Blunsom, 2013). The max pooling layer of pool size 4 is used in this setup, the output dimensions are shown in Figure 1. We build a recurrent-convolutional neural network (RCNN) model by cascading the stack of LSTMs and the average layer to model the context.

2.3 Ensemble Model

The overall model is developed in such a way that the outputs of all the networks (*Net1*, *Net2*, *Net3*, and *Net4*) are averaged and a fully connected layer (FCL) is used with *softmax* function over the four given classes. The complete model is trained end-to-end so that, given a set of three turns as an input, the model classifies the emotion labels.

[3]https://nlp.stanford.edu/projects/glove/

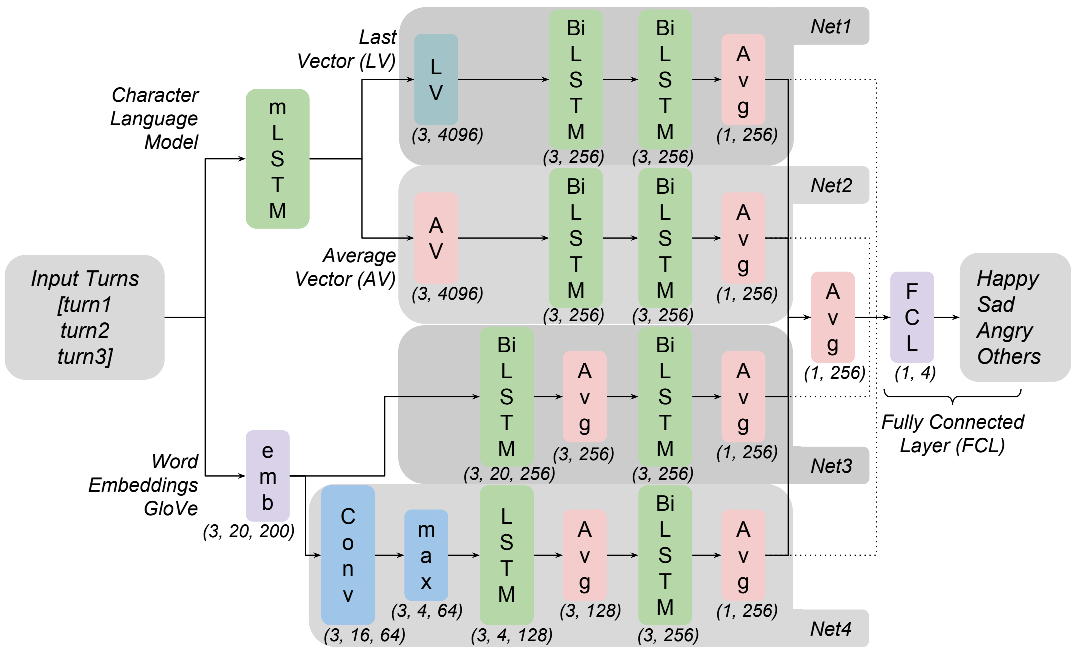

Figure 1: The overall architecture of the contextual emotion detection.

Models	F1µ
Baseline model (organizers)	0.5838
Our proposed model	**0.7212**
happy	0.6893
sad	0.7485
angry	0.7287

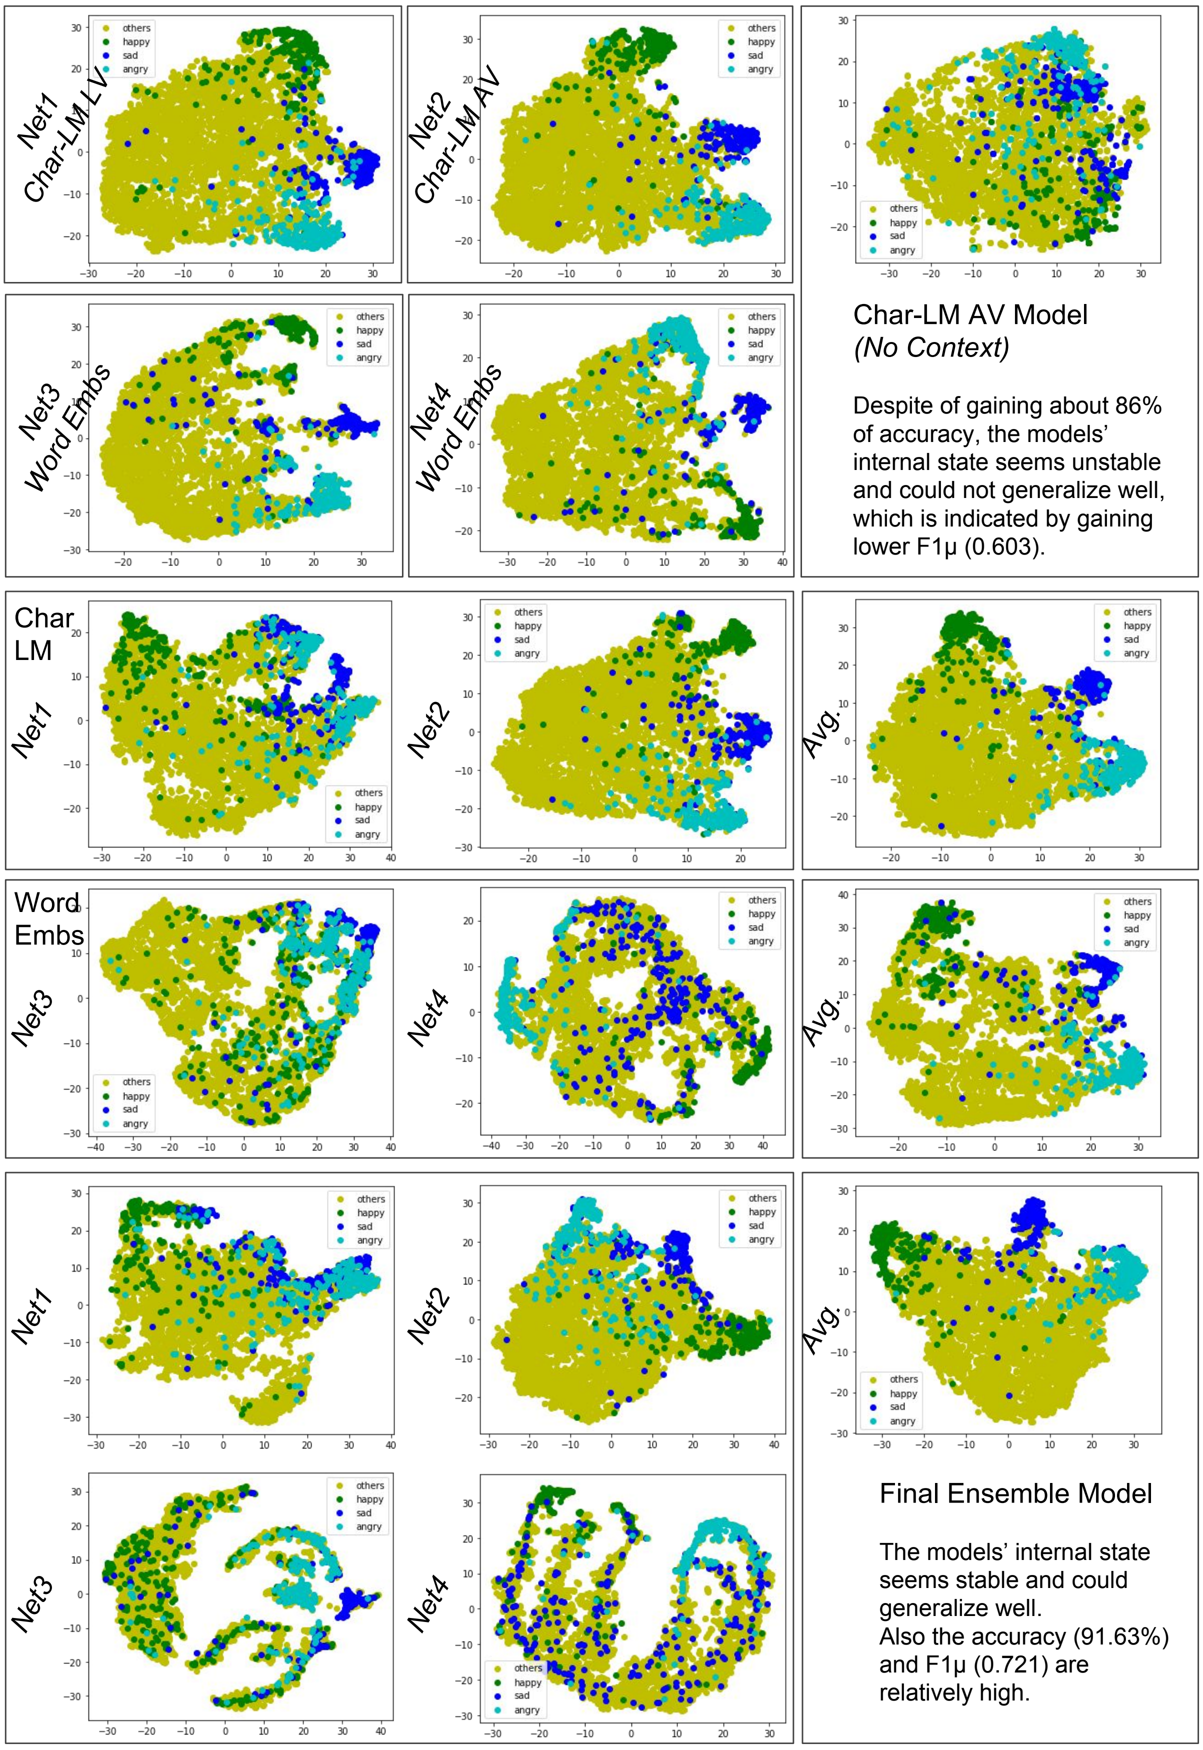
Table 3: Result as microaveraged F1 score (F1µ) compared to baseline and F1 score for each emotion.

3 Experiments and Results

The final submitted result to the challenge is shown in Table 3. The metric used for the challenge is the microaveraged F1 score (F1µ) for the three emotion classes, i.e. *Happy*, *Sad* and *Angry*. Our model performance was able compete quite well with the participating teams in the challenge. The main goal to present these experiments is to explore the features used for contextual emotion detection. For the comparison of different language features (character and word), we consider calculating the accuracy over all four classes, in addition to F1µ. The experimental setup developed and each network is tested individually and in an ensemble way. The results are reported in Table 4. When the models train individually, the output of the model being trained is directly connected to the FCL as shown in dotted line in Figure 1. From the results, it is clear that the average vector Char-LM AV Model outperforms the four individual networks. As this model performs well, we also train a single FCL to see the effect of the absence of context. The ensemble models, Char-LM Models (*Net1* and *Net2*) and Word Embs Models (*Net3* and *Net4*) show a clearer pick up on accuracy than individuals. The final ensemble model clearly improves the overall performance. However, we also ensemble the output predictions of all the networks trained individually, and average them at the end. Such ensembling is also effective for the overall improvement in the performance.

Models	Acc (%)	F1µ
Char-LM LV Model (*Net1*)	88.12	0.655
Char-LM AV Model (*Net2*)	89.87	0.694
Char-LM AV Model (*No Context*)	86.25	0.603
Word Embs Model (*Net3*)	88.27	0.665
Word Embs Model (*Net4*)	88.80	0.653
Char-LM Models (*Net1* and *Net2*)	89.59	0.688
Word Embs Models (*Net3* and *Net4*)	87.91	0.692
Final Ensemble Model	**91.63**	**0.721**
Avg. Ensemble Model *(outputs of individual nets)*	**91.71**	**0.721**

Table 4: Results comparing our experimental setups.



Char-LM AV Model
(No Context)

Despite of gaining about 86% of accuracy, the models' internal state seems unstable and could not generalize well, which is indicated by gaining lower F1µ (0.603).

Final Ensemble Model

The models' internal state seems stable and could generalize well.
Also the accuracy (91.63%) and F1µ (0.721) are relatively high.

Figure 2: Clustering the intermediate representations of different networks and their average (Avg.) ensembled representations. EmoContext test data is used to generate these representations.

In Figure 2, we demonstrate the intermediate representations taken at the last average layers of the networks on test data and plotted against four classes. We use t-SNE algorithm that converts multi-dimensional (in our case 256) to 2-dimensional arrays. We can notice that the *Net2* Char-LM AV model is quite consistent while other models are a bit unstable in clustering for the given emotions classes. For the final ensemble model, surprisingly, word models become too cluttered, but still contribute to the improvement.

4 Conclusion

The contextual emotion detection is a crucial step towards conversational analysis where emotion can aid the natural language understanding in socio-linguistic studies. Especially in the absence of facial expression and prosodic features, context becomes an important asset for emotion detection in the text. As we can see from the results our model could compete and provide insight to explore different feature representations. The ensemble modelling and transfer learning are effective tools for such a challenging task, specifically, when the given data is small and the labels are not balanced over all the samples.

paragag@microsoft.com

Anshuman Suri[*]
Microsoft
ansuri@microsoft.com

Abstract

Existing Machine Learning techniques yield close to human performance on text-based classification tasks. However, the presence of multi-modal noise in chat data such as emoticons, slang, spelling mistakes, code-mixed data, etc. makes existing deep-learning solutions perform poorly. The inability of deep-learning systems to robustly capture these covariates puts a cap on their performance. We propose **NELEC** : **Ne**ural and **Le**xical **C**ombiner, a system which elegantly combines textual and deep-learning based methods for sentiment classification. We evaluate our system as part of the third task of 'Contextual Emotion Detection in Text' as part of SemEval-2019 (Chatterjee et al., 2019b). Our system performs significantly better than the baseline, as well as our deep-learning model benchmarks. It achieved a micro-averaged F_1 score of 0.7765, ranking 3^{rd} on the test-set leader-board. Our code is available at https://github.com/iamgroot42/nelec

1 Introduction

Sentiment analysis of textual data: Twitter data (Kouloumpis et al., 2011; Pak and Paroubek, 2010), movie reviews (Thet et al., 2010), and product reviews (Pang et al., 2008), is perhaps the most extensively explored problem, with a plethora of research to tackle it. Novel systems utilise deep learning architectures to achieve near-human performance on clean, well-formatted data. However, sentiment classification of chat data is significantly challenging. The presence of spelling errors, slang, emoticons, code-mixing, style of writing and abbreviations makes it significantly harder for existing deep-learning models to work on such data.

[*]Equal contribution, order determined by coin toss

Literature dealing with this problem comprises a wide range of approaches: from hand-crafted features to end-to-end deep-learning methods. Some rule-learning based methods use keyword-based analysis (Ko and Seo, 2000) and part-of-speech tagging (Agarwal et al., 2011). These procedures require extensive human-involvement for identifying keywords and designing rules and are thus not scalable.

Non-neural machine-learning methods utilize feature extraction algorithms like n-grams and Tf-Idf vectors, coupled with classification algorithms like Naive Bayes (Pang et al., 2002), Decision Trees (Bilal et al., 2016), SVM (Moraes et al., 2013). These approaches perform significantly better than rule-based approaches but fail to capture context well, since they ignore the order of words in text sequences.

Statistic	Train	Dev	Test
Emojis (%)	17.6	11.1	12.5
OOV (%)	3.7	4.9	4.9
OOV(processed) (%)	2.1	1.5	1.8
Avg.Length	13.6	12.7	12.7
Avg.Length(processed)	15.7	15.3	15.2
Happy emotion (%)	14.1	5.2	5.2
Sad emotion (%)	18.1	4.5	4.5
Angry emotion (%)	18.3	5.4	5.4

Table 1: Some statistics for the given training, development and test sets.

Neural, deep-learning based approaches use architectures such as variations of recurrent models: GRU (Chung et al., 2014), LSTM (Hochreiter and Schmidhuber, 1997), BiLSTM (Schuster and Paliwal, 1997) and Convolutional models (Mundra et al., 2017), performing significantly better than other machine-learning techniques. Their ability to generalise and capture context over long se-

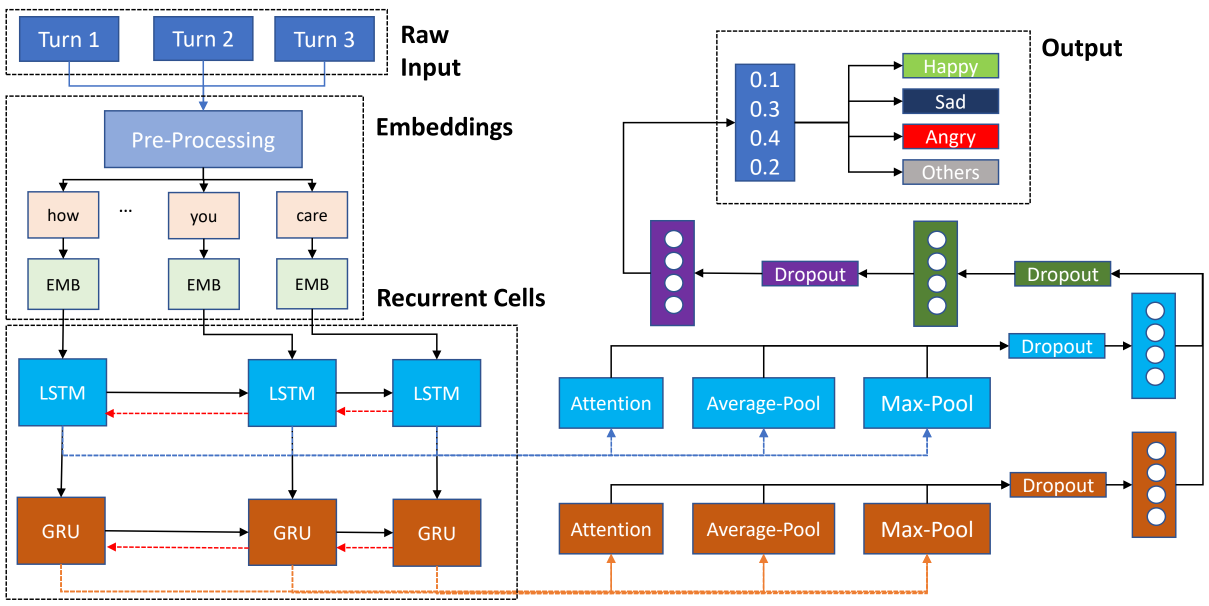

Figure 1: System diagram of the Deep-Learning model described in Section 2.1.

quences makes them a popular choice for text classification tasks.

We propose **NELEC**, a novel system specifically designed for sentiment classification. We combine lexical and neural features for sentiment classification, followed by class-specific thresholds for better labelling. Our system yields an F_1 score of 0.7765 on the test-set of Task 3 of SemEval 2019.

2 System Description

2.1 Deep Learning Model

We experiment with a two-layer, recurrent, deep-learning model with skip connections, bidirectional cells and attention (Figure 1). We trained our model for 100 epochs with Cyclic Learning Rate (Smith, 2017) scheduling. This model outperforms the baseline by a significant margin. An in-depth analysis of the cases where it fails reveals its shortcomings (along with that of a deep-learning model in general): it is not robust to misspellings and cannot capture the meaning of out-of-vocabulary words robustly. Even though pre-trained embeddings are available for most words, the context with which they are used in chat may vary from the corpora they were trained on, thus lowering their usability.

2.2 NELEC : Neural and Lexical Combiner

Since neural features have a lot of shortcomings, we shift our focus to lexical features. Using a combination of both lexical (n-gram features, etc.) and neural features (scores from neural classifiers), we trained a standard Light-GBM (Ke et al., 2017) Model for 100 iterations, with feature sub-sampling of 0.7 and data sub-sampling of 0.7 using bagging with a frequency of 1.0. We use $10^{-2} * \|weights\|_2$ as regularization. We also experimented with a logistic regression model, but it had a significant drop in performance for the 'happy' and 'angry' classes (Table 2). The total number of features used is 9270, out of which 9189 are sparse. The features we use in our model are described in the sections below:

2.2.1 Turn Wise Word *n*-Grams

Word level bi-grams and tri-grams (skip 1). These help capture patterns like “am happy” and automatically handles unseen data such as ”am very happy” or ”am so happy” because of the skip word. We take the term frequencies of these n-Grams as features. Word Grams not|good, hate, no|one had the highest feature gains.

2.2.2 Turn Wise Char *n*-Grams

Character level bi-grams and tri-grams. This feature helps capture character-level trends such as “haha” (and its variants), as well as emoticons. It helps with misspellings and makes the system robust to variants of several words like “haha”. h|a|h, w|o|w had one of the highest feature gains.

2.2.3 Valence Arousal Dominance

We used Valence-Arousal-Dominance data (Mohammad, 2018) in the following manner:

1. Mean of Valence and Arousal values, along with turn-wise Maximum Dominance value for all words. Turn 3 Arousal for maximum dominant word had the highest feature gain.

2. Turn-wise mean of Valence, Arousal and Dominance values.

2.2.4 Emotion Intensity

We use EmoLex (Mohammad and Turney, 2010), which associates words to eight emotions and two sentiments. For each turn, we obtain the number of words having specific emotions and sentiment and use it as a feature.

Model	F_1			
	happy	sad	angry	μ_{avg}
Without Data Pre-Processing				
Deep	.5863	.5977	.6485	.6123
NELEC	.7382	.8047	.7873	**.7765**
Logistic	.6712	.7642	.7151	.7154
Baseline	.5461	.6149	.5945	.5861
With Data Pre-Processing				
Deep	.5710	.6630	.7350	.6651
NELEC	.7324	.8015	.7878	**.7736**
Logistic	.6782	.7680	.7120	.7177
Baseline	.5797	.5973	.6241	.6024

Table 2: Class-wise and micro-averaged F_1 scores for NELEC, our deep-learning model and existing baseline.

2.2.5 Neural Features

We used scores obtained by utilizing available pre-trained classifiers features:

1. Scores obtained by running conversations through a Sentiment Classifier trained on Twitter Data using SSWE embeddings (Tang et al., 2014).

2. Signals from Adult and Offensive Classifiers (Yenala et al., 2017), obtained via the Text Moderation API by Microsoft Cognitive Services. As observed in Table 2, this helps in 'Anger' detection. [1]

[1]https://docs.microsoft.com/en-in/azure/cognitive-services/content-moderator/text-moderation-api

2.3 Lexical Count Features

Lastly, we used certain count features such as the number of interrogation marks, exclamation marks, uppercase letters, the total number of words and letters for each turn. These features were observed to be very helpful while detecting anger and happiness.

3 Data Preparation

The training, development and test sets consist of 30160, 2755 and 5509 examples respectively. The final model is trained on the combined training and development set. For each instance, one of four class labels: {happy, angry, sad, other}, is provided. Table 1 provides some statistics for the given dataset.

We concatenate all three turns per conversation. For the Deep-Learning approach, a special $\langle eos \rangle$ token is inserted in between these turn-conversations.

3.1 Pre-processing for NELEC

1. **Lemmatization**: Contrary to intuition, using lemmatization decreased the final performance of our model. Further analysis suggests that emotion is highly sensitive to exact words: information captured by the word "hate" and "hated" are very different, even though a lemmatization system would reduce them to the same word, and similarly for "happy" versus "happiest". Using lemmatization drops the system's F_1 score by 0.0092.

2. **WordNet for Synonyms**: We also tried using synonyms for nouns using the Wordnet Graph (Miller, 1998). However, a similar issue plagues this approach. For instance "dog", "doggie" and "puppy" are all synonyms, but they do not express the same kind of emotion: words like "puppy" convey much more positive emotion. Using Wordnet drops the system's F_1 score by 0.0023.

3. **Normalization**: We try word tokenization and normalization by removing diacritics, numbers, stop-words, question marks etc. However, this also drops the F_1 score by 0.0046.

Character n-gram features can handle lemmatization as well as misspellings for most of the cases without discarding any additional information. Finally, we only lower-cased the sentences.

Feature Dropped	Features (#)	$F1_{\mu avg}$	Angry F_1	Sad F_1	Happy F_1	$F1_{\mu avg}$ gain
Word n-grams	4565	.7355	.7373	.7723	.6995	.0410
Character n-grams	4624	.6067	.6271	.6168	.5749	**.1698**
Valence-Arousal	15	.7444	.7125	.7426	.7160	.0321
Word-emotion Classifier	30	.7537	.7584	.7739	.7301	.0228
Pre-Built Classifier	9	.7524	.7373	.7756	.7481	.0241
Lexical Count Features	27	.7654	.7751	.8015	.7217	.0111
Turn 1 (All Features)	2578	.7417	.7173	.7716	.7106	.0348
Turn 2 (All Features)	3873	.7642	.7719	.8015	.7217	.0123
Turn 1 & 2 (All Features)	6451	.7191	.7304	.7539	.6750	.0574

Table 3: Micro-averaged F_1 scores when all features apart from these (per row) are dropped. F_1 gain here refers to the gain when using the feature mentioned, as opposed to dropping it.

3.2 Pre-processing for Deep-Learning based Approach

We use pre-trained GloVe (Pennington et al., 2014) embeddings. Some observations are:

- **Emoticons**: Around 15% of all conversations includes at least one emoticon. We use embeddings from a pre-trained emoji2vec (Eisner et al., 2016) model to handle emoticons.
- **Words with repeated characters**: This trend is common for chat-data. For example, “heelloo”, “ookayy”. We design specific regular expressions to handle such variations.
- **Abbreviations and slang**: tokens such as “idk”, “irl” are converted to their full forms.

4 Experiments

To ascertain the novelty of our system, we report both class-wise and micro-averaged F_1 scores on the test set. We also compare our performance with the benchmarks provided by the contest organizers (Chatterjee et al., 2019a).

As mentioned in Section 3.2, data pre-processing on deep-learning models leads to significant performance gains, while leading to a drop in performance when using **NELEC**. **NELEC** outperforms both the baseline and our deep model by a considerable margin (Table 2).

4.1 Ablation Study

To analyze the usefulness of all features used by **NELEC**, we perform hold-one-out experiments on its features (Section 2.2). Results are reported in Table 3. There is a noticeable gain for most of the features, with character n-grams observing the maximum gain among them all.

One of the most intriguing patterns observed is the ease with which they detect sad emotion and an equal difficulty in detecting happiness.

- Words like “haha” and “okay” have several forms which all convey different magnitudes of emotion. While lemmatising such words, there is a significant loss of information.
- Most of the conversations labelled sad have easy-to-recognize signals such as negative emoticons, keywords like “lonely”, which make detection easy. On the other hand, differentiating *happy* and *others* is non-trivial.
- Not using the second turn, along with its associated features, leads to a negligible drop in F_1 performance. This observation highlights the importance of the first user (in data) in analyzing sentiment. Moreover, we can utilize this information to make the feature set even smaller, making the model smaller and faster.

5 Conclusion

We propose a deep neural architecture to solve the problem of emotion detection in conversations from chat data. Although it outperforms the existing baseline, its performance is not satisfactory. To better capture lexical features and make the model robust to misspellings, abbreviations, emoticons, etc., we propose **NELEC**, a **Ne**ural and **Le**xical **C**ombiner. Our model utilises lexical features, along with signals from pre-trained neural models for sentiment and adult-offensive classification to boost performance. Our system performs at par with the existing state of the art, yielding a micro-averaged F_1 score of 0.7765 on the test set, ranking 3^{rd} on the test-set leader-board.

Abstract

In this paper, we present our system submission for the EmoContext, the third task of the SemEval 2019 workshop. Our solution is a hierarchical recurrent neural network with ELMo embeddings and regularization through dropout and Gaussian noise. We have mainly experimented with two main model architectures: simple and hierarchical LSTM network. We have also examined ensembling of the models and various variants of an ensemble. We have achieved microF1 score of 0.7481, which is significantly higher than baseline and currently the 19th best submission.

1 Introduction

Sentiment analysis has a long and successful history in the context of natural language processing. As with the majority of the problems in this domain, we have seen a gradual shift towards solutions based on neural models. Nowadays, such models can be readily used as a part of a larger solution, for example to analyse communication on social networks.

Then, perhaps unsurprisingly, the EmoContext task (Chatterjee et al., 2019b) with its format is highly evocative of the social networks. That is, it consists of conversational triplets, where the task is to correctly guess the emotion category of the last conversational turn.

Over the years, there was a number of different sentiment analysis and recognition competitions, workshops and shared tasks (Klinger et al., 2018; Rosenthal et al., 2017), however the conversational nature of the data is not common.

Our system is based on the recurrent neural networks, both simple and hierarchical architectures. We have experimented with various techniques and hyper-parameters, such as regularization, class weights, embeddings, strength of dropout and added noise. Finally, we have improved our results by creating an ensemble, with various voting methods and sample reweighing.

2 Approach

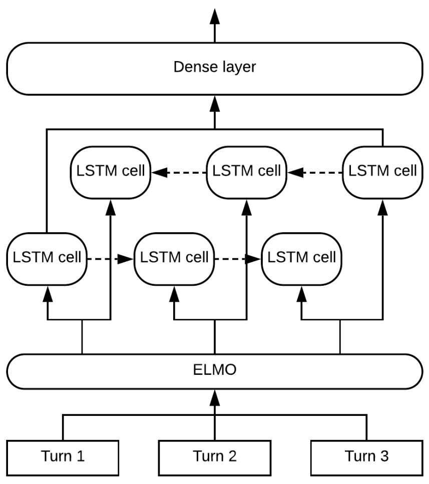
The first step in any natural language processing system is to preprocess the input data so it can be easily understood by the system. Since preprocessing was the major part of our previous work (Pecar et al., 2018), we have decided to prioritize work on the model instead. Nevertheless, we need to do some kind of preprocessing, hence we used the readily available Ekphrasis (Baziotis et al., 2017) tool.

We have experimented with both standard GloVe embeddings (Pennington et al., 2014) and more sophisticated ELMo embeddings (Peters et al., 2018). The improvements contextual embeddings, like ELMo, can bring are already well known and there is little need for additional comparisons, however the model that uses standard embeddings is considerably faster and hence more useful for quick experiments. Since training ELMo can be quite time consuming and resource intense, we have opted for pretrained models that are part of the AllenNLP library (Gardner et al., 2017).

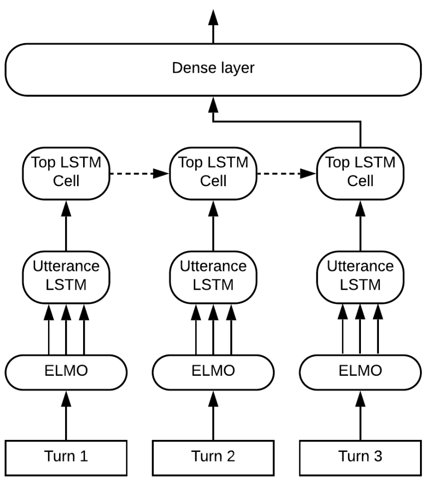
It should be noted that the character sensitive nature of the ELMo embeddings should help with typos, which were not fixed by preprocessing, and other similar errors.

2.1 Model

We have experimented with two main model variants. First model variant uses a simple bi-directional LSTM encoder (Hochreiter and Schmidhuber, 1997), second variant uses a hierarchical encoder, both can be seen in the figure 1. In both cases, the encoders are followed by dense



a) Simple encoder model.



b) Hierarchical encoder model.

Figure 1: Architecture of the main model variants.

layer which outputs probability distribution of labels.

Simple encoder works on concatenated utterances, utterances are part of a single string separated by semicolon. During the development we have also ran several runs only on the last utterance.

Hierachical model consists of two different encoders, at the utterance level and on the dialog level. This is fairly common practice in the dialog system domain (Serban et al., 2016). The utterance encoder is a bi-directional LSTM which encodes utterances into their representations. This utterance representation is then sent to the dialog encoder, which is a uni-directional LSTM.

Much of our model was dictated by a lack of GPU memory [1], we had to prioritize what to include in the model. Fully-connected layer as a dialog encoder, separate encoder for each turn, dense layer as a top encoder and attention mechanisms, did not achieve significantly better results and in some cases resulted in insufficient memory.

In the end, we had better results with the simpler, larger model rather than with the more complex, smaller model.

2.2 Training

We have opted to use Adam optimizer due to its far better performance on the hierarchical model where stochastic gradient descent did not perform up to our expectations.

[1]We used a single RTX 2070 with 8GB of memory

To properly regularize the model we have used the dropout (Srivastava et al., 2014) combined with the gaussian noise applied to word embeddings. Since we did not use multi-layer LSTMs we did not apply dropout in any other place in the model.

In the case of ensembles, we scheduled 90% reduction of the learning rate at the third epoch. This was done in the hopes of achieving less variance in the performance of various runs. Since a single model is trained considerably faster than an entire ensemble, we did not schedule learning rate change, as we were able to pick the best model or average from a variety of runs.

The class imbalance in the dataset, both for the train, validation and test set, was an issue we had to deal with. We have opted for class reweighing instead of a weighted sampling, due to ease of implementation. We have experimented with various weight setups.

2.3 Ensemble

To improve our results and help with significant variance in performance of different experiment runs, we have used an ensemble of multiple models. It should be noted that they are the exact same model, trained several times.

We have experimented both with voting through summation of the probabilities and with stacked classifier on top of the ensemble results. Stacked classifier is a single dense layer with the rectified linear activation and softmax. As input it takes a tensor of shape *(batch_size, ensem-*

Model	Size	Input data	Embeddings	MicroF1

Table 3: Effect of different class weight setups.

*ble_size*num_labels)* and outputs a tensor of shape *(batch_size, num_labels)*.

To ensure that the single models in the ensemble will specialize on different samples, we have included the option for sample weight rebalance, based on their performance on the already trained models. However, error in the code caused that the rebalance calculation took into account only the last model and that the sample weights were gradually rising for the latter models in an ensemble. This was fixed only after the submissions were closed.

3 Evaluation

In this section, we cover metrics used, our experiments and analysis of our results. All results in this sections are achieved on the test set.

For evaluation we have modified code that is the part of the starter kit (Chatterjee et al., 2019a). Out of all metrics this function calculates we have primarily used microF1 score, which is the score reported in all our tables.

3.1 Results

In our experiments, we have explored a variety of different models, setups, ensembling approaches and effects of class weights. If not specified otherwise, models are using categorical crossentropy and following parameters:

- batch size: 32
- gaussian noise after embedding layer: 0.5 for simple, 3 for the hierarchical model
- dropout after embedding layer: 0.5 for simple, 0.6 for the hierarchical model

Class	Precision	Recall	F1
Angry	0.6948	0.8020	0.7445
Happy	0.7303	0.6866	0.7078
Sad	0.7687	0.8240	0.7954
Micro Average	0.7281	0.7692	0.7481

Table 4: Summary of the best submission.

Our first set of experiments are targeted at the model architecture and the effect of the used embeddings, results can be seen in table 1. In this table, all results are an average of three different runs. Unsurprisingly, the most significant effect is from the type of embeddings used. The effect of the rest of the factors seems to be in this order: model/input and size. At least for the ELMo embeddings, hierarchical models universally outperformed simple models. For the GloVe embeddings there is no clear separation, however the differences are rather small and if we averaged from more experiment runs a distinction could appear. The model that takes only the last turn into account was last when compared with the same embeddings, however we expected a more pronounced difference.

The next batch of experiments examines setup of our ensembles as seen in the table 2. In these experiments each row represent a single run of the entire ensemble. The combined score is the score of the ensemble after voting, in the parentheses we see change in respect to the max and average of the constituent models. Since the flawed reweighing does not seem to have a significant effect we have decided to left these experiments in. The experiment with asterisk, done after the submissions were closed, was run with the rebalancing fixed and while it shows second best improvement it is hard to tell if this is just a noise or a real effect. The most significant finding of this batch is that the stacked classifier performed rather poorly compared to the summation. For the stacked classifier, in two cases out of three, the combined score is actually worse than the best model in an ensemble.

Lastly, we have taken a look at the effect of different class weights, which can be seen in table 3, where the first column signifies distribution resulting from the given reweighing. We have experimented with ignoring others class due to the way the evaluation is done. The effect of such rebalancing is that all of the samples belonging to the ’others’ class is classified as one of the other classes, which causes extremely high recall. Since the test set distribution is closer to the distribution of the train set than to the balanced dataset, trying to reweigh the data to obtain a balanced dataset[2] is worse than doing nothing. The best results are obtained when the reweighed distribution is the same as the test set, even though score is not averaged over the ’others’ class.

Detailed summary of our best submission can be seen in the table 4.

4 Conclusion

In this paper, we have presented our models and experiments for emotion detection in conversational triples. We have also discussed results, various setups and model variants.

The bulk of our work was focused on simple vs. hierarchical models. We observed that the hierarchical model outperformed simple model. Additionally, simple model with only the last turn of conversation was only slightly worse than the model with the entire context.

We managed to improve our results by using an ensemble of multiple instances of the same model. During our experiments summation method of result combination proved to be superior to using stacked classifier. Interestingly, the stacked classifier could be perhaps a way to adapt model to different class distribution.

Our efforts were hindered by insufficient amount of memory on our GPU, thus we could not include every feature we wanted into our model. Perhaps, using GPU with more memory available, we could achieve slightly better results.

The source code of our system is available at GitHub [3].

Abstract

Sentiment analysis (SA) in texts is a well-studied Natural Language Processing task, which in nowadays gains popularity due to the explosion of social media, and the subsequent accumulation of huge amounts of related data. However, capturing emotional states and the sentiment polarity of written excerpts requires knowledge on the events triggering them. Towards this goal, we present a computational end-to-end context-aware SA methodology, which was competed in the context of the SemEval-2019 / EmoContext task (Task 3). The proposed system is founded on the combination of two neural architectures, a deep recurrent neural network, structured by an attentive Bidirectional LSTM, and a deep dense network (DNN). The system achieved 0.745 micro f1-score, and ranked 26/165 (top 20%) teams among the official task submissions.

1 Introduction and Related Work

One of the most challenging fields of Natural Language Processing (NLP) and Computational Linguistics is Sentiment Analysis (SA) that aims towards the automated extraction of a writer's sentiment or emotion as conveyed in text excerpts (Liu, 2015). Relevant efforts focus on tracking the sentiment polarity of single utterances, which in most of the cases is loaded with a lot of subjectivity and a degree of vagueness (Thelwall et al., 2010). Contemporary research in the field utilizes data from social media resources (e.g., Facebook, Twitter) as well as other short text references. However, users of social media tend to violate common grammar and vocabulary rules and even use various figurative language forms to communicate their message. In such situations, the sentiment polarity underlying the literal content of the conveyed concept may significantly differ from its figurative context, making SA tasks even more puzzling (Patra et al., 2016). Evidently, single turn text lacks in detecting sentiment polarity on sarcastic and ironic expressions (Potamias et al., 2019), as already indicatd in the relevant SemEval-2014 Task-9 *Sentiment Analysis in Twitter* (Sara et al., 2014). As sentiment reflects the emotion behind customer engagement, SA finds its realization in automated customer aware services (Kurniawati et al., 2013). A lot of research has already been devoted on capturing the sentiment polarity of contextual conversations of various utterances. Most of the relevant studies utilize single turn texts from topic related sources (e.g., Twitter). Hand-crafted and sentiment-oriented features, indicative of emotion polarity, are utilized to represent respective excerpt cases. The formed data were used as input to various traditional machine learning classifiers (e.g. SVM, Random Forests etc.) or deep learning architectures (e.g. recurrent neural networks, CNNs) in order to induce analytical models that are able to capture the underlying sentiment content of passages (Singh et al., 2018; Jianqiang et al., 2018; Hangya and Farkas, 2017).

The work presented in this study considers the recognition of the three fundamental emotions, Happy, Sad and Angry, specified in the SemEval-2019 / EmoContext task (Task 3), as a context sensitive task. In order to capture emotional categories, we settled two-layered bidirectional LSTM units that share weights over three embedded utterances resembling a siamese like architecture (Mueller and Thyagarajan, 2016). Pretrained word embeddings were utilized, Standford GloVe (Pennington et al., 2014), in order to represent single turn text input, resulting into an attentive and context-aware model. We also extended word embeddings with appropriate handling of emojis, utilizing the pretrained emoji2vec vectors (Eisner et al., 2016), and sentiment lexicons, NCR and DepecheMood (Mohammad and Turney, 2013), resulting into an enhanced representation of single turn text cases. The overall complex presents a combined neural architecture to serve SA tasks.

2 Experimental Setup: Data & Preprocessing

The SemEval-2019 / EmoContext shared task (Task 3) targets the emotion classification of user utterances in three classes, namely Happy, Sad, Angry and Other (Chatterjee et al., 2019). It provides a 33K training textual dialogue dataset in the form of three contextual turns. The distribution of data demands the elaboration of techniques that are able to cope with class imbalances in order to capture correctly the less frequent emotions, i.e., Happy, Sad and Angry (13%, 17%, 17% and 53% for Happy, Sad, Angry and Other, respectively). To handle imbalance among classes we applied a penalty weight to the loss function, proportional to the respective class frequencies.

Given that the provided data do not contain any Twitter-specific informative sign, such as hashtags and user mentions, we tried to keep the preprocessing step as simple as possible. Thus, we replaced repeated emojis and punctuation with single ones, and substituted slang abbreviations to their full expression (e.g. “bcz” is substituted by “because”).

3 System Overview

The proposed emotion analysis methodology is composed by (i) the formulation of the suitable representation schemes for the input data, and (ii) the implementation of an elaborative deep neural network architecture to map these schemes to their associated labels and the appropriate neural layers.

3.1 Embedding Layer

Word Embeddings tend to become a necessary component of deep learning approaches, with the mapping of single dimensional words to their dense vector encodings to be a critical part of the job (Mikolov et al., 2013). Vector representations are exhaustively trained on large corpora to capture the semantic content of each word. One of the most utilized vector representation is offered by Standford GloVe pretrained word vectors. However, GloVe vectors do not handle one of the most important factors in sentiment analysis, the emojis. To expand their capabilities, we append GloVe embeddings with pretrained emoji2vec, as proposed by Eisner et al. (2016). In addition, we utilized 23 extra features to enhance our pretrained word embeddings. Specifically, we elaborated 13 mood-oriented emotions, provided by the DepecheMood lexicon, as proposed by Staiano and Guerini (2014), in order to capture words mood intentions, as well as 10 NRC emotion relation scores. The utility of emotion scores is manifested in various studies (Mohammad and Turney, 2013; Kiritchenko et al., 2014). The enhancement led to a dense 323 dimensions vector representation for each word (300d-GloVe + 13d-DepecheMood emotions + 10d-NRC sentiment scores), which after re-normalization fed a recurrent neural network.

3.2 Bidirectional LSTMs and Siamese Network Architecture

In the recent years, deep learning models and in particular convolutional neural network (CNN) architectures, have become a popular and a favorable choice for several artificial intelligence tasks. However, the recurrent nature of textual data implies the need for architectures that are able to capture data of sequential nature information, which CNNs are unable to manage. To cope with the recurrent nature of textual data as well as with the sentiment contradictions that may occur in both text directions we utilize a bidirectional LSTM network architecture. In particular, we used three bidirectional LSTMs (Hochreiter and Schmidhuber, 1997) in a siamese like architecture (Bromley et al., 1994) in order to map all turns into the same vector space (Figure 1). To determine the sentiment impact of the last utterance, given the previous two, we introduce bidirectional LSTM hidden states, for each time-step and utterance. The hidden states are calculated using the same weights for each input.

3.3 Attention layer

To focus on the most significant time-sample, an attention layer (Bahdanau et al., 2014) is added on top of the regular LSTMs in order to capture and assign an importance attention factor to the hidden states, forming the so-called attentive vector $\vec{s}$:

$$r_t = tanh(W_h h_t + b_t) \quad (1)$$

$$a_t = \frac{e^{r_t}}{\sum_{j=0}^{T} e^{r_t}}, \quad \sum_{t=1}^{n} a_t = 1 \quad (2)$$

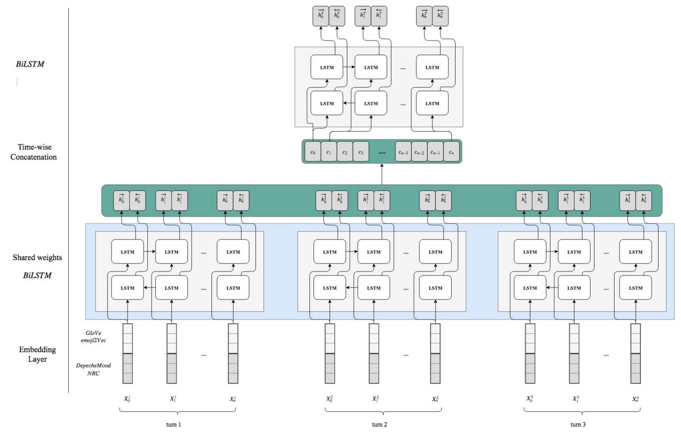

Figure 1: Siamese alike architecture, containing two layers of bidirectional LSTMs.

$$\vec{s} = \sum_{t=0}^{T} a_t h_t \tag{3}$$

where W_h and b_t are the LSTM model weights, to be optimized during training.

3.4 Dense network

To unfold and map the devised feature set we implemented a four-layered deep dense neural network, equiped with unigram and bigram Tf-idf weights of each utterance. Each neuron is activated by a ReLu function, and the final layer is concatenated with the attentive vector as defined in sub-section 3.3.

3.5 Proposed method

As already mentioned, we utilize two different and combined schemes to represent and train processed data, (i) an embedded matrix that feeds the Embeddings layer (as described in sub-section 3.1), and (ii) a uni/bi-gram Tf-idf training schema to be processed by the a layered dense DNN. In addition, the Embedding layer is connected with a siamese like bidirectional LSTM architecture, containing 164 units each. As shown in Figure 2, on top of the shared weighted LSTMs we add another bidirectional LSTM layer, also containing 164 units. To boost LSTM performance, we apply an attention mechanism on top of it, concluding to an attentive vector, as described in sub-section 3.3. We will refer to this subnetwork as *S-LSTM*, which includes the siamese like layers extended with an attentive mechanism. The Tf-idf features, as extracted for each conversation turn, are mapped onto two-layered dense neural networks containing 84 neurons each, with a ReLu non-linear activation function. The output of these layers is then concatenated and followed by another dense 84-neuron layer, creating a vector $\vec{d}$. We refer to this dense sub-network as *F-DNN*. The output vectors, $\vec{s}$ and $\vec{d}$, from the respective *S-LSTM* and *F-DNN* sub-networks are then concatenated and feed a final softmax activated dense network. The whole setup presents a combination of different and heterogeneous deep learning models.

3.6 Training

To train our model we adopted several regularization techniques to prevent overfitting. Therefore, we applied Dropout (Srivastava et al., 2014) to randomly deactivate neurons during forward training pass. We empirically set dropout parameters to 0.3 for every model layer, as well as recurrent connections of LSTM units (Gal and Ghahramani, 2016). In addition, we utilized L_2 regularization penalty loss function to every LSTM unit exceeding weight limits. Finally, we apply early-stopping technique to terminate training when loss on the development phase stop decreasing. To optimize our network we adopted Adam optimizer (Kingma and Ba, 2014) using cross entropy loss.

4 Results

Our proposed system achieved a micro f1-score ($\mathbf{f1}_{\mu}$) of 0.743, ranked the 26th in the SemEval 2019 EmoContext task. Results are presented in Table 1 and compared with different approaches. EmoContext organisers proposed a baseline classifier (referred as Baseline) that exhibits a f1-score of 0.587(Chatterjee et al., 2019). In Table 1, we compare the proposed method with the *S-LSTM* and *F-DNN* implementations, described in 3.4 and 3.5, respectively. Moreover, we present results for the SS-BED system, proposed by Gupta et al.

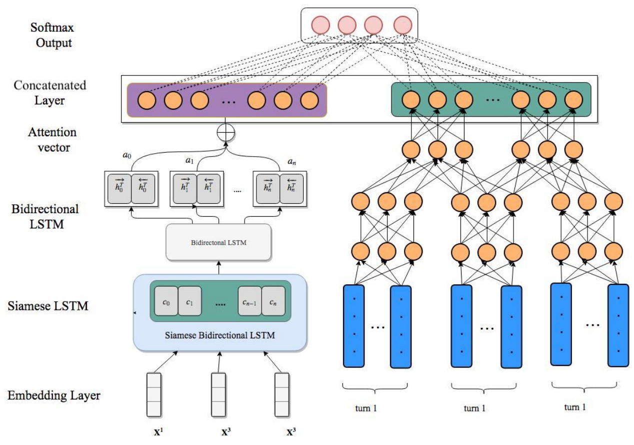

Figure 2: **Proposed Method**. the left model (S-LSTM) is composed by two LSTM layers followed by an attentive mechanism; the right model (F-DNN) is composed by two dense layers for each utterance followed by two additional dense layers

(2017). Compared with the other approaches, the proposed method exhibits a significantly higher f1-score for the Happy and Angry classes, 0.71 and 0.75, respectively. SS-BED system achieves a better performance for the Sad class (0.81) but it exhibits a poor performance for the Happy class (0.59).

To assess the importance of emoji embeddings and of the introduced mood and emotion feature sets which appended GloVe embeddings (G), we conducted additional experiments retaning the same siamese neural architecture (S-LSTM). In each experiment we extended GloVe embeddings with a respective feature set, i.e., the emoji2vec embeddings (E), the 13 DepecheMood (D) mood intensions, and the 10 NRC emotion relations (N). Compared to the S-LSTM$_G$ neural classifier, the use of additional embedding sets improve slightly the $f1_\mu$ performance, with the utilization of the emoji embeddings to achieve the highest increase (S-LSTM$_{G+E}$, from 0.67 to 0.70). But their yield remains lower compared to the respective architecture where all embedding sets are utilised (S-LSTM$_{all}$, 0.72).

In summary, the results demonstrate the superiority of the proposed method over all other approaches, and signifies its ability to succeed stable results over the different sentiment classes.

5 Conclusion

In this study we implemented a combination of two different representations and respective training schemes for the input data. First, we extended pretrained GloVe embedding vectors with emojis and appended 23 additional emotional features. In addition, we developed an S-LSTM model, containing a siamese alike bidirectional LSTM architecture with its output to feed another bidirectional LSTM layer followed by an attention layer. Furthermore, we transformed input data by their Tf-idf weight representations in order to feed a dense deep neural network (F-DNN).

System	**f1**$_{Happy}$	**f1**$_{Sad}$	**f1**$_{Angry}$	**f1**$_\mu$
Baseline	-	-	-	0.58
SS-BED	0.59	**0.81**	0.74	0.71
F-DNN	0.70	0.68	0.73	0.70
S-LSTM$_{all}$	0.69	0.76	0.71	0.72
S-LSTM$_G$	0.67	0.69	0.65	0.67
S-LSTM$_{G+E}$	0.65	0.71	0.74	0.70
S-LSTM$_{G+D}$	0.68	0.68	0.71	0.69
S-LSTM$_{G+N}$	0.66	0.71	0.68	0.68
Proposed	**0.71**	0.77	**0.75**	**0.74**

Table 1: Comparison results: Proposed method vs. other approaches (**f1**$_\mu$ refer to the f1-micro metric)

All model features are appropriately mapped and concatenated in order to feed the final dense softmax layer. Comparative results demonstrate the superiority of the proposed method over other approaches and single network models, as well as its robustness with regard the stability of performance over different emotional classes. Thus we could state that the proposed methodology defines an end-to-end solution on sentiment analysis and classification tasks, suited for imbalanced data, with the ability as well, to cope with huge amounts of data.

Abstract

In this paper we present our model on the task of emotion detection in textual conversations in SemEval-2019. Our model extends the Recurrent Convolutional Neural Network (RCNN) by using external fine-tuned word representations and DeepMoji sentence representations. We also explored several other competitive pre-trained word and sentence representations including ELMo, BERT and InferSent but found inferior performance. In addition, we conducted extensive sensitivity analysis, which empirically shows that our model is relatively robust to hyper-parameters. Our model requires no handcrafted features or emotion lexicons but achieved good performance with a micro-F1 score of 0.7463.

1 Introduction

Emotions are psychological and physiological states generated in humans in reaction to internal or external events. Messages in human conversations inherently convey emotions. With the rise of social media platforms such as Twitter, as well as chatbots such as Amazon Alexa, there is an emerging need for machines to understand human emotions in conversations, which has a wide range of applications such as opinion analysis in customer support (Devillers et al., 2002) and providing emotion-aware responses (Zhong et al., 2019). SemEval-2019 Task 3: EmoContext (Chatterjee et al., 2019b) is designed to promote research in this task.

This task is to detect emotions in textual conversations. Each conversation is composed of three turns of utterances and the objective is to detect the emotion of the last utterance given the first two utterances as the context. The emotions in this classification task include happy, sad, angry and others, adapted from the well-known Ekman's six basic emotions: anger, disgust, fear, happiness, sadness, and surprise (Ekman, 1992). The evaluation criteria is micro-averaged F1 score since the data is extremely unbalanced, as shown in Table 1.

In recent years, pre-trained word and sentence representations achieved very competitive performance in many NLP tasks, e.g., fine-tuned word embeddings using distant training (Cliche, 2017) and tweet sentence representations DeepMoji (Felbo et al., 2017) on sentiment analysis, and contextualized word representations BERT (Devlin et al., 2018) on 11 NLP tasks. Motivated by these successes, in this task we explored different word and sentence representations. We then fed these representations into a Recurrent Convolutional Neural Network (RCNN) (Lai et al., 2015) for classification. RCNN includes a Long short-term memory (LSTM) network (Hochreiter and Schmidhuber, 1997) to capture word ordering information and a max-pooling layer (Scherer et al., 2010) to learn discriminative features. We also experimented LSTM and CNN in our preliminary analysis but achieved worse performance as compared to RCNN. Our final system adopted fine-tuned word embeddings and DeepMoji as our choices of word and sentence representations, respectively, due to their superior performance on the validation dataset. The code is publicly available at Github[1].

2 Related Work

Emotion detection in textual conversations is an under-explored research task. The majority of existing works focused on the multi-modality settings (Devillers et al., 2002; Hazarika et al., 2018; Majumder et al., 2019). Chatterjee et al. (2019a) is one of the early works on the textual modality that first collected the dataset used in this task and then

Table 1: Total number of conversations and their distributions over each emotion class for each dataset split. Average number of tokens per utterance for each dataset split are also reported.

proposed an LSTM model with both semantic and sentiment embeddings to classify emotions. This task is also closely related to sentiment analysis (Pang et al., 2008) where the opinions of a piece of text is to be identified. One major difference between them is that this task detects emotions only on the last portion of a piece of text and the rest is treated as context.

Our model leverages pre-trained word and sentence representations. There is a research trend on word and sentence embeddings after the invention of Word2Vec (Mikolov et al., 2013). Cliche (2017) fine-tuned word embeddings using CNN-based sentiment classification model and distant training (Go et al., 2009). Peters et al. (2018) proposed a contextualized word embedding named ELMo to incorporate context information and solve the polysemy issues in conventional word embeddings. Devlin et al. (2018) proposed another contextualized word embedding named BERT by extending the context to both directions and training on the masked language modelling task. Kiros et al. (2015) proposed a sentence-level representation named SkipThought, which shares similar ideas to Word2Vec but operates on sentence level. Conneau et al. (2017) proposed InferSent by learning sentence representations on natural language inference tasks. Felbo et al. (2017) proposed DeepMoji by learning tweet sentence representations in the emoji classification task using 1246 million tweets and distant training.

Our RCNN model is closely related to neural network based sentiment analysis models. Two of the most popular models are LSTMs and CNNs. LSTM-based models can capture the word ordering information and have achieved the state-of-the-art performance on many sentiment analysis datasets (Gray et al., 2017; Liu et al., 2018; Howard and Ruder, 2018). CNN-based models can capture local dependencies, discriminative features, and are parallelizable for efficient computation (Kim, 2014; Johnson and Zhang, 2017).

3 System Description

In this section we describe our data preprocessing procedures and illustrate how we leverage pre-trained word and sentence representations in our RCNN model. The overall architecture is depicted in Figure 1.

3.1 Data Preprocessing

We concatenated three utterances as one sentence, separated by EOS tokens. We used the tokenizer from Spacy[2] for tokenization. We removed training sentences that have more than 75 tokens. We removed duplicate punctuations and spaces. We kept all remaining tokens in the training dataset as the vocabulary.

3.2 Pre-trained Word Representation

We fine-tuned the word embeddings obtained from (Baziotis et al., 2017), which has an embedding size of 100 and is pre-trained on 330M English Twitter messages using Glove (Pennington et al., 2014). The fine-tuning is conducted on the binary sentiment classification task using the basic CNN model (Kim, 2014) on 1.6 million tweets (Go et al., 2009). These tweets are labelled with positive and negative sentiments. Fine-tuning on these tweets introduces sentiment-discriminative features to word embeddings (Cliche, 2017). The CNN model has kernel sizes of 1, 2, and 3. Each kernel size has 300 filters. During fine-tuning, the embedding layer is first frozen for one epoch and then unfrozen for another three epochs.

3.3 Pre-trained Sentence Representation

We adopted DeepMoji (Felbo et al., 2017) as the sentence representations in our model. Each sentence will be encoded into a vector of size 2304. DeepMoji is trained on the 64-class emoji classification task using 1246 million tweets. Since emoji reflects emotions and sentiments, DeepMoji is an ideal model to provide emotion-discriminative sentence representations. We also

[2]https://spacy.io/

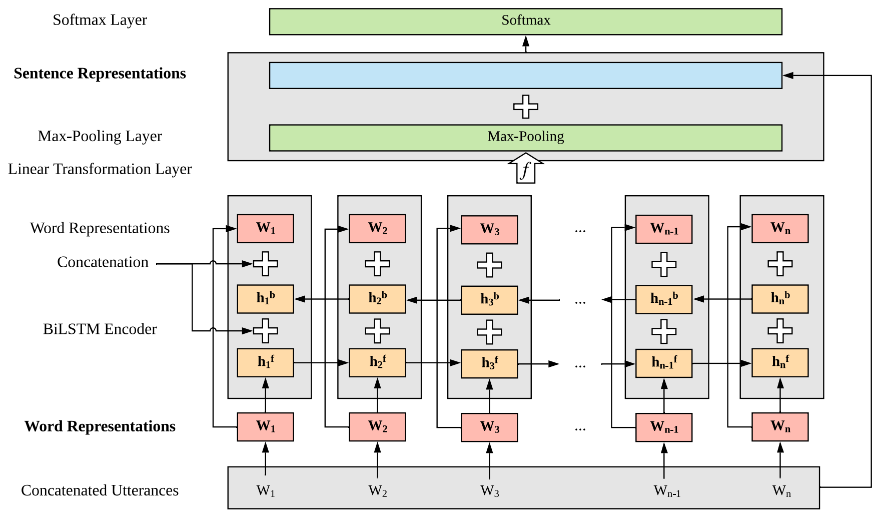

Figure 1: Overall architecture of our proposed model.

explored InferSent (Conneau et al., 2017), another sentence representation model with competitive performance on sentence classification and information retrieval tasks (Perone et al., 2018).

3.4 RCNN

As shown in Figure 1, we fed word and sentence representations into a RCNN model. The RCNN model mainly comprises of a two-layer Bidirectional LSTM (BiLSTM), a linear transformation layer and a max-pooling layer. At the embedding layer, each sentence is transformed to a sequence of word embeddings W_i of size 100 using our pre-trained word representations, where $i = 1, 2, ..., n$, and n is the number of tokens in the concatenated utterance. The BiLSTM encodes these word embeddings into hidden states h_i^f, h_i^b in both forward and backward directions, respectively, where each direction has a hidden size of 200. The hidden states in both directions are concatenated together, along with the word representations W_i to form a vector of size 500. A linear transformation is then applied to project the resulted vector into a vector of size 200, followed by a max-pooling layer to extract discriminative sentence features. Finally, the DeepMoji sentence representation is concatenated with the pooled vector to form a final sentence representation of size 2504, followed by a softmax layer for classification.

3.5 Training

We train our model on the training dataset and fine-tune on the validation dataset based on the micro-F1 score. Since the dataset is highly unbalanced, we use weighted cross-entropy loss for optimization, where the weights are the ratio of validation dataset label distribution to training dataset label distribution, followed by a normalization to ensure that the sum of weights is 1. We use Adam (Kingma and Ba, 2014) optimizer with a learning rate of 0.0005 and batch size of 64. We clip the norm of gradients to 5. We trained our model 6 epochs. The learning rate is annealed by a factor of 0.2 every epoch after epoch 5. We also freeze the embedding for the first two epochs. We use dropout rate of 0.5 in BiLSTM and 0.7 in linear layers. The model is implemented in PyTorch.

4 Result Analysis

In this section we explored different word and sentence representations and compared their performance on the test set. We also conducted sensitivity analysis for our model hyper-parameters. All results are averaged across 5 different seeds. It is worth noting that the settings with the best test scores in the analysis below are not exactly the same as our best system on the leaderboard since our best system is fine-tuned on the validation dataset, which do not guarantee to produce the best test results.

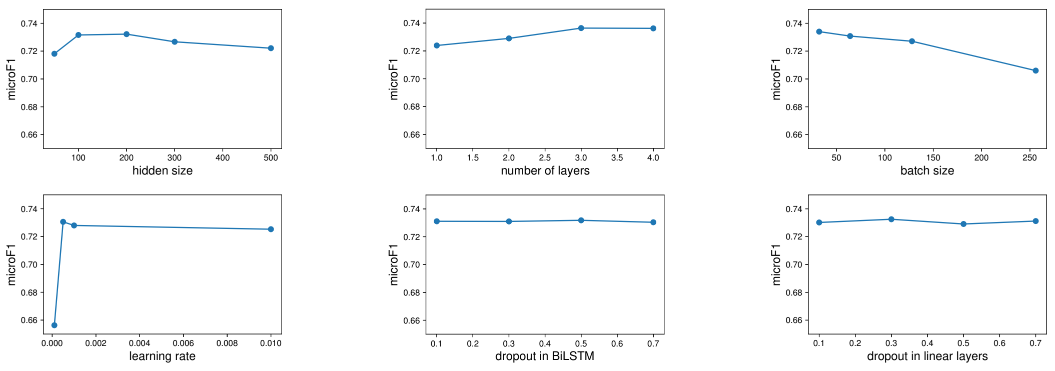

Figure 2: Sensitivity analysis on model hyper-parameters.

Word Representation	micro-F1
Original Glove	0.7250
Pre-trained Glove	0.7279
Fine-tuned Glove	0.7339
ELMo	0.6990
BERT	0.6656

Table 2: Micro-F1 score on the test set using different word representations.

Sentence Representation	micro-F1
None	0.7194
InferSent (GloVe)	0.7259
InferSent (fastText)	0.7277
DeepMoji	0.7299
DeepMoji + InferSent (GloVe)	0.7298
DeepMoji + InferSent (fastText)	0.7344

Table 3: Micro-F1 score on the test set using different sentence representations.

We explored the original GloVe embedding trained on 27B tweet tokens[3], pre-trained GloVe embedding[4], our fine-tuned GloVe embedding, ELMo embedding and BERT embedding. The results are shown in Table 2. Fine-tuned GloVe embedding performs noticeably better than the original GloVe embedding and the pre-trained GloVe embedding. Surprisingly, contextualized embeddings such as ELMo and BERT perform worse than the original GloVe embedding. Possible reasons for their inferior performance are 1) they are fixed during training, which may hinder the overall optimization. 2) they have large embedding size, which can easily cause overfitting.

We explored no sentence embedding, InferSent trained on GloVe, InferSent trained on fastText, and DeepMoji. The results are shown in Table 3. It is clear that sentence representations improved model performance significantly. In particular, DeepMoji achieves the best performance for single sentence representation. InferSent trained on fastText consistently performs better than InferSent trained on GloVe. In addition, concatenating two sentence representations together further improved model performance.

We conducted sensitivity analysis on our model hyper-parameters: hidden size, number of layers in BiLSTM, batch size, learning rate, dropout in BiLSTM and dropout in linear layers. The results are depicted in Figure 2. Our model is relatively robust to hyper-parameters except for the learning rate. When learning rate is around 0.0001 or smaller, the model is unable to be trained effectively.

5 Conclusion

In this paper we presented our model on the task of emotion detection in textual conversations in SemEval-2019. We explored different word and sentence representations in the RCNN model and achieved competitive results. Our result analysis indicate that both pre-trained word and sentence representations help improve the performance of RCNN. However, currently popular contextualized word representations such as ELMo and BERT produced inferior results.

Abstract

This paper presents the system in SemEval-2019 Task 3, "EmoContext: Contextual Emotion Detection in Text". We propose a deep learning architecture with bidirectional LSTM networks, augmented with an emotion-oriented attention network that is capable of extracting emotion information from an utterance. Experimental results show that our model outperforms its variants and the baseline. Overall, this system has achieved 75.57% for the microaveraged F1 score.

1 Introduction

With the rapid development of social media platforms like Twitter, a huge number of textual dialogues has increasingly emerged. It is a challenge for chat bots to generate responses based on user emotions which can avoid inappropriate conversations. Emotion detection in text (Chatterjee et al., 2019) is a research area within Natural Language Processing which is aim to detect the emotion of user expressed in text.

Many techniques have been proposed, Wang et al.,Hasan et al.,Liew and Turtle used feature engineering to extract features manually. In this area, deep learning-based approches have performed well in recent years. Some methods (Wöllmer et al., 2010; Metallinou et al., 2012; Poria et al., 2017; Chernykh et al., 2017) used recurrent neural network to model the sequence of utterances for emotion detection. However, those models did not highlight the emotion-related parts. We use attention mechanism to locate the parts expressing emotions in the utterance.

The Task3 in Semeval-2019 is to detect contextual emotions in text. For this task, we propose a deep learning approach which is a combination of Long Short-Term Memory network and attention mechanism.

The rest of the paper is organized as follows: Section 2 provides system overview. Section 3 describes our approach in detail. Our experiment is discussed in Section 4. We conclude our work in Section 5.

*These authors have contributed equally to this work.

2 System Overview

2.1 Text Preprocessing and Word Embedding

We use word embeddings as input to the model. Word embeddings are distributed vector presentations of words (Mikolov et al., 2013), capturing their syntactic and semantic information. A good word embedding can get a better classification performance. After comparison, we find that the effect of the GloVe (Pennington et al., 2014) is the best, but when we turn the word into a word vector, we find a lot of cases that are out of vocabulary(oov). In view of that, we preprocess the data as follows:

- The emoji used in the chat can better express human emotions, so we turn them into corresponding emotion words and add them to the sentence, which not only solves the oov, but also increases the emotion information in the sentence
- Several emoticons are replaced by the tokens "happy", "sad", "angry"
- All words are lowercased

2.2 Long Short-Term Memory

LSTM is a special form of threshold RNN (Hochreiter and Schmidhuber, 1997), which is designed to deal with sequential data by sharing its internal weights across the sequence. Different from the structure of RNN, LSTM has three gates:

an input gate i_t, a forget gate f_t, an output gate o_t and a memory cell c_t. Their effect is to allow the network to store and retrieve information over long periods of time.

In our approach, we use the bidirectional LSTM model to better capture the contextual information in sentences. Schuster and Paliwal shows that the bidirectional structure has better performance in classification experiments. In order to better handle the relations among the utterances of a dialogue, we use the bc-LSTM architecture(Poria et al., 2017) to process the dialogue-level classification. The architecture preserves the sequential order of utterances when constructing the dialogue representation.

2.3 Attention Mechanism

The attention mechanism was originally applied to image recognition (Itti and Koch, 2001; Mnih et al., 2014), mimicking the focus of the eye moving on different objects when the person viewed the image. Similarly, when people read an article, their attention to each part of the text is different. The attention mechanism imitates human behavior, giving each feature different weights. With the weight of a feature being greater, the contribution of this to current recognition becomes greater. Neural networks with attention mechanism have been applied in many tasks of NLP, including machine translation (Bahdanau et al., 2014; Luong et al., 2015) text summarization (Rush et al., 2015) text classification (Yang et al., 2016) sentiment classification (Chen et al., 2016) and stance classification (Du et al., 2017).

When learning the representations of text sequences, word embeddings are the most effective intermediate representations for capturing semantic information. We embed the classification label and word into the same semantic space, and then construct the semantic relatedness of them according to the similarity of word embeddings. Our model obtains the attention weights of the words through the emotion-oriented attention network, which highlights the emotion words, thus improving the performance of the emotion classification.

3 Model Description

Our model has two steps as follows: 1. Extract the features of each utterance in the dialogue 2. Construct the representation of the dialogue by the features of three utterances for emotion classification.

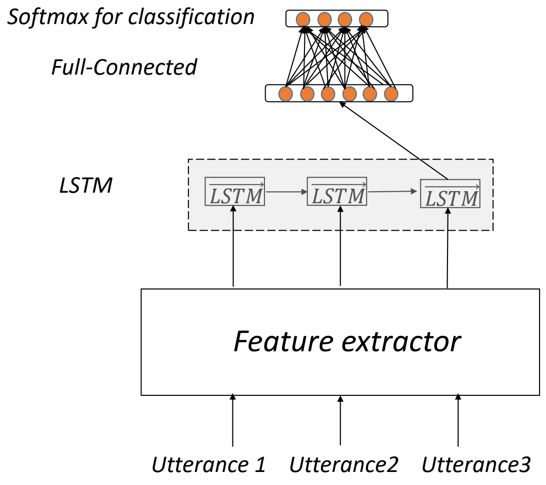

Figure 1: Architecture for emotion classification.

In the feature extraction step: the embedding of each utterance is fed into the BiLSTM layer to construct the word representation of each word; meanwhile we obtain the attention weight of the corresponding word by the emotion-oriented attention network. We use the inner product of them to represent the word, and then feed it into the BiLSTM layer. Finally, we get the representation of each utterance after the pooling operation(Fig. 2).

In the classification step: the features of the three utterances obtained from the previous step are fed into the LSTM layer as timing information for emotion classification(Fig. 1).

3.1 Embedding Layer

An input sequence $\boldsymbol{X}$ of length T is composed of word tokens: $\boldsymbol{X} = \{x_1, ..., x_T\}$. Each token x_t is replaced with the corresponding vocabulary index $V(t)$. The embedding layer transforms the token into vector $e_t \in \mathbb{R}^d$ which is selected from the embedding matrix E according to the index, where d is the dimensionality of the embedding space.

In order to highlight the emotion words in the sequence, we append the word embedding vector of "emotion" to the embedding of each word in original text. The emotion-augmented embedding of a word t is the concatenation of the embedding vector e_t and the emotion representation e_z,

$$e_t^z = e_t \| e_z \qquad (1)$$

where $\|$ denotes the concatenation operation, and then the dimention of e_t^z is $2d$.

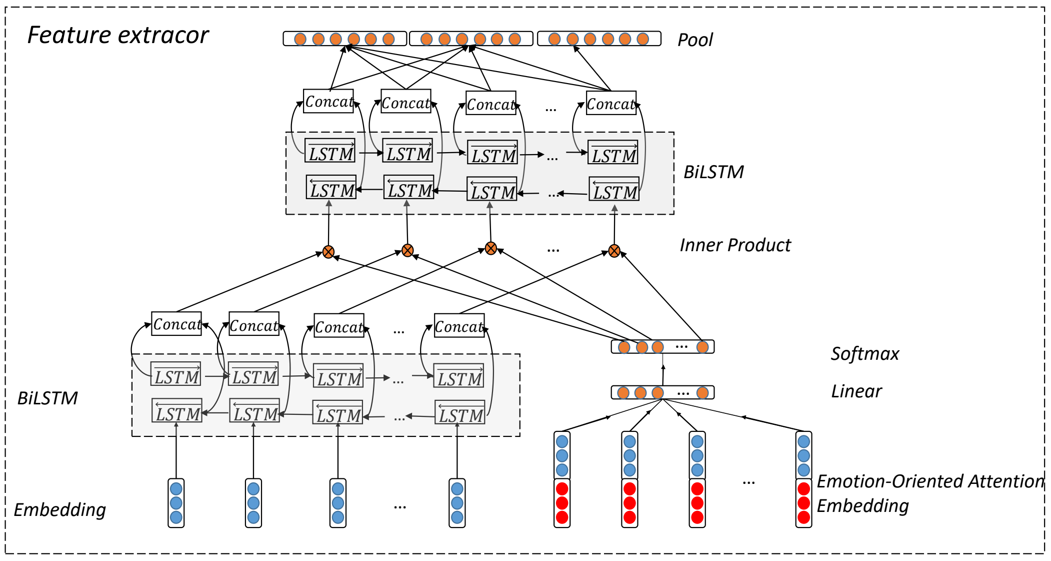

Figure 2: Feature extractor of an utterance with emotion-oriented attention network.

3.2 BiLSTM Layer

The LSTM reads the sequence $\boldsymbol{X}$ only in one direction. We use a bidirectional LSTM to get annotations of words by summarizing the contextual information from both directions. A bidirectional LSTM consists of a forward LSTM $\overrightarrow{f}$ that reads the sentence from x_1 to x_T and a backward LSTM $\overleftarrow{f}$ that reads the sentence from x_T to x_1. We obtain the annotation h_t for each word x_t, by concatenating the forward hidden state $\overrightarrow{h}_t$ and the backward one $\overleftarrow{h}_t$,

$$h_t = \overrightarrow{h}_t \| \overleftarrow{h}_t \tag{2}$$

3.3 Emotion-Oriented Attention Network

In the task, the emotion words in the conversation are vital for classification, which cannot be captured by the BiLSTM. In order to highlight the emotion-related words in the utterance, we design an attention mechanism which increases the weight of the important words on the basis of the BiLSTM and contributes more to the classification decision.

We apply a linear layer to convert the emotion-augmented embedding of a word e_t^z to a scalar value u_t, and then get a normalized importance weight α_t through a softmax function. This weight is producted with the word representation h_t to get a weighted word representation v_t for each word.

$$u_t = W_u e_t^z + b_u \tag{3}$$

$$\alpha_t = \frac{e^{u_t}}{\sum_{i=1}^{T} e^{u_i}} \tag{4}$$

$$v_t = \alpha_t h_t \tag{5}$$

3.4 Pooling Layer

From the idea of network in network, we use global maxpooling, global averagepooling and last tensor for the matrix f output of the BiLSTM layer. Maxpooling can get the most important features of all features (Scherer et al., 2010). Averagepooling can get the most common features of all features. The last tensor output $\bar{l}$ of the matrix f can obtain the semantic information of the sentence in forward and backward through BiLSTM.

The utterance representation z is obtained by the concatenation of the max vector $\overline{m}$, the average vector $\bar{a}$ and the last vector $\bar{l}$.

$$z = \overline{m} \| \bar{a} \| \bar{l} \tag{6}$$

3.5 Emotion Classification

We use the three utterance representations obtained by feature extractor shown in Figure 2 to construct the dialogue representation. The three utterance representations $[z_1, z_2, z_3]$ are fed into the LSTM, and the last time-step hidden state h_3 of the LSTM is regarded as the dialogue representation r. We pass it to a fully-connected network with a softmax activation function. This layer obtains a normalized four-dimensional vector through the nonlinear transformation function of the input vector.

$$p = \mathrm{softmax}(W_f h_3 + b_f) \tag{7}$$

where W_f and b_f are the weights and bias terms of the fully-connected layer.

4 Evaluation

4.1 Data

The datasets are provided by Semeval-2019 Task 3. Table 1 gives an overview of the datasets. All the conversations are collected from twitter. The conversations consist of user 1's tweet, user 2's response to the tweet and user 1's response to user2. The label is the emotion of the third turn that human judges mark after considering the context of three rounds of dialogue.

Dataset	Happy	Sad	Angry	Others	Total
Training	4243	5463	5506	14948	30160
Validation	425	547	551	1495	3018
Test	284	250	298	4677	5509

Table 1: Datasets for Semeval-2019 Task 3.

4.2 Experiments

The model is implemented using Keras 2.0 (Chollet et al., 2017). We experiment with Stanford's GloVe 300 dimensional word embeddings trained on 840 billion words from Common Crawl. Our model is trained with Adam Optimizer (Kingma and Ba, 2014) with initial learning rate of 0.001 and batch size of 64. We use BiLSTMs with hidden state size 256, with dropout rate 0.5 on the first BiLSTM layer and dropout rate 0.3 on the second one to prevent our neural network from overfitting (Srivastava et al., 2014).

In our task, the size of samples for each class is not balanced, which will result in the model tending to be biased toward the majority class with poor accuracy for the minority class. For this, we adjust the parameter 'class_weight' to weight the loss function of each class during training. This can be useful to tell the model to "pay more attention" to samples from an under-represented class. In this case, we set the parameter 'class_weight' (Happy : 2, Sad : 1, Angry : 1, Others : 4)

4.3 Result and Analysis

In order to evaluate the effect of the emotion-oriented attention network and the balanced class weights, we compare our approach with its variants and the baseline.

Variant1: The variant does not adjust the parameter 'class_weight'.

Variant2: The variant changes the emotion-oriented attention network with the attention machanism used in (Yang et al., 2016)

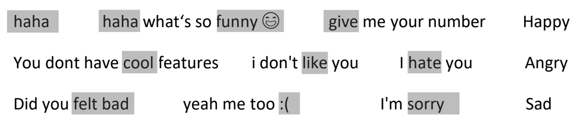
Variant3: The variant removes the emotion-oriented attention network from the model.

model	Happy	Sad	Angry	MicroF1
Baseline	0.5461	0.6149	0.5945	0.5861
Variant1	0.7082	0.7574	0.7175	0.7264
Variant2	0.6967	0.7683	0.7375	0.7330
Variant3	0.7051	**0.8113**	0.7182	0.7423
Our Model	**0.7138**	0.8088	**0.7500**	**0.7557**

Table 2: Performance of our system and its variants.

Table 2 shows that our model outperforms the other variants which are all above the baseline 0.5861 for the micro-averaged F1 score. Variant3 has the best performance on 'Sad' class and our model has the best performance on two classes and micro-averaged F1 score.

To validate that our model has the ability to capture the emotion-related parts of an utterance, we visualize the weights of attention for the following three dialogues. Figure 3 shows that the emotion words are highlighted in the dialogues, such as 'Haha', 'funny', 'cool', 'like', 'hate', 'felt', 'bad', 'SORRY', but the model also highlights some trivial words, such as 'Give'.



haha	haha what's so funny 😊	give me your number	Happy
You dont have cool features	i don't like you	I hate you	Angry
Did you felt bad	yeah me too :(	I'm sorry	Sad

Figure 3: Visualization of attention of examples.

5 Conclusion

In this paper, we proposed an emotion-oriented neural attention network for Semeval-2019 Task 3. The network use the attention mechanism to select the emotion-related parts in the utterances. The classification performance of our model is better than its variants and the baseline. Meanwhile, the visualization shows that the model has captured more decision-making information in the dialogue.

Abstract

This paper describes our linear SVM system for emotion classification from conversational dialogue, entered in SemEval2019 Task 3. We used off-the-shelf tools coupled with feature engineering and parameter tuning to create a simple, interpretable, yet high-performing, classification model. Our system achieves a micro F1 score of 0.7357, which is 92% of the top score for the competition, demonstrating that "shallow" classification approaches can perform well when coupled with detailed feature selection and statistical analysis.

1 Introduction

Sentiment analysis from textual data is a well-studied topic, however the particular problem of inferring the emotional context of text-based *conversations* is relatively little-studied. With the increasing abundance of conversational text-based datasets, particularly from social media, there is increasing interest in studying such datasets across a wide range of domains, from unsolicited opinion polling (Cody et al., 2015) to mental health monitoring (Miner et al., 2016). Highly sophisticated systems for emotion detection on conversational data exist (Gupta et al., 2017), however these may not be appropriate for researchers in other fields, and it is desirable to develop *interpretable* models where the informative features can be readily interpreted and measures of confidence can be assigned to individual predictions.

Our aim in entering SemEval2019 therefore was to build a high-performing model using only off-the-shelf tools and some feature engineering, without resorting to deep neural network architectures or overly sophisticated approaches. This model only uses linear Support Vector Machines (SVMs) (Hastie et al., 2009) and feature engineering using the Natural Language Toolkit (NLTK) (Bird et al., 2009). These relatively "shallow" (as opposed to "deep") approaches to classification from text have been used, for example, in event prediction from social media data (Tuke et al., 2018). Despite its simplicity, our system performed very well, achieving a maximum score in the top 22% of all submissions.

2 Task

The task for Semeval 2019 Task 3 is classifying the correct emotion (`happy`, `angry`, `sad` or `others`) on a 3-turn text communication dialogue (Chatterjee et al., 2019). Table 1 shows an example conversation.

Turn 1	You are funny
Turn 2	LOL I know that :p
Turn 3	=)
Label	Happy

Table 1: A example of the 3-turn text dialogue.

The Training dataset contained 5 columns:

- ID: a unique number to identify each training sample;
- Turn 1: the first turn in the 3-turn conversation, written by User A;
- Turn 2: a reply to Turn 1 by User B;
- Turn 3: reply to Turn 2, written again by User A;
- Label: the human-judged label of emotion of Turn 3 based on the conversation for the given training sample. It is always one of the four labels: `happy`, `sad`, `angry` and `others`.

The organisers provided three datasets:

- `Training` contains 30,160 examples with the correct labels and approximately 50% `others`;
- `Dev` contains 2,755 examples with correct labels (approximately 88% `others`);
- `Test` contains 5,509 examples without labels, but participants are told that the split is approximately the same as the `Dev` set, i.e., ≈88% `others`.

This last piece of information given by the organisers regarding the balance of the `Test` set will be critial to our system described below, as we will employ a *post hoc* class balancing technique to match these proportions.

Evaluation is performed using the micro-averaged F1 score for the three emotion classes i.e. `happy`, `sad` and `angry` on the `Test` set.

3 Proposed System

Figure 1 shows an overview of our system, which we describe below in detail.

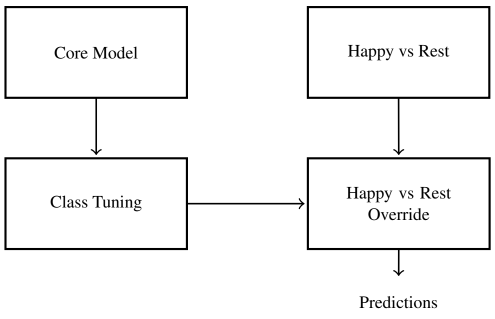

Figure 1: Model pipeline. Our core SVM model performs well for the `sad` and `angry` classes, but underestimates the `happy` class. The "Happy vs Rest" override classifier therefore is designed to achieve high accuracy on this class specifically.

3.1 Feature Engineering

Given a 3-turn text conversation between two users, our system only relied on Turns 1 and 3 while discarding Turn 2 altogether. This was motivated by the insight that the label for each conversation was "the human judged label of *Emotion of Turn 3* based on the conversation" (from the competition website, emphasis ours). This means the overall emotional context of the conversation is dictated by the *reaction* of User A to the chatbot User B's response to A's initial post in Turn 1. Therefore, we hypothesised that the most informative features regarding the emotional context would come from User A's text (with Turn 3 likely to be more informative than Turn 1), and that Turn 2 would largely degrade the impact of these features. This was borne out by experimentation, where inclusion of features from Turn 2 only ever decreased the score compared with models using only data from Turn 1 and Turn 3. Table 2 shows the results of our experiments using different combinations of turns in terms of F1 score.

Turns 1 and 3 were then tokenized using the NLTK Tweet Tokenizer with additional rules[1] to handle symbols, and odd tokens.

These tokens were then scanned for negation words such as {`'not'`, `'isnt'`, `'no'`, `'dont'`} and combined with the next neighbouring token to create one new token. For example, the sentence: `'not happy jane'` tokenized turns into `'not'`, `'happy'`, `'jane'` finally combining negations turns into `'not_happy'`, `'jane'`.

Next the tokens were turn-encoded, meaning each token is prepended with `'1_'` or `'3_'` based on which turn the token was extracted from. For example, tokens from Turn 1 {`'you'`, `'are'`, `'funny'`} are prepended to {`'1_you'`, `'1_are'`, `'1_funny'`}, while Turn 3 tokens {`'=)'`} turn into {`'3_=)'`}.

3.2 Feature selection using TFIDF

The previous section constructs all the tokens found in the `Training`, `Dev` and `Test` data. We then use only the vocabulary found in the intersection of all the datasets. This was done because features which do not appear in the test set have no predictive power on that set. We found in practice that including these features did not improve the scores obtained by our system.

The term frequency inverse document frequency (TFIDF) score was then computed for each term per label basis. The token importance score is computed using the highest TFIDF score for that token across classes minus the second highest. In this manner the importance score used was a measure of a feature's ability to discriminate between classes. Experimentation on the `Dev` set showed that this produced better results than filtering based on, for example, the highest TFIDF score across classes. Figure 2 shows the top 10

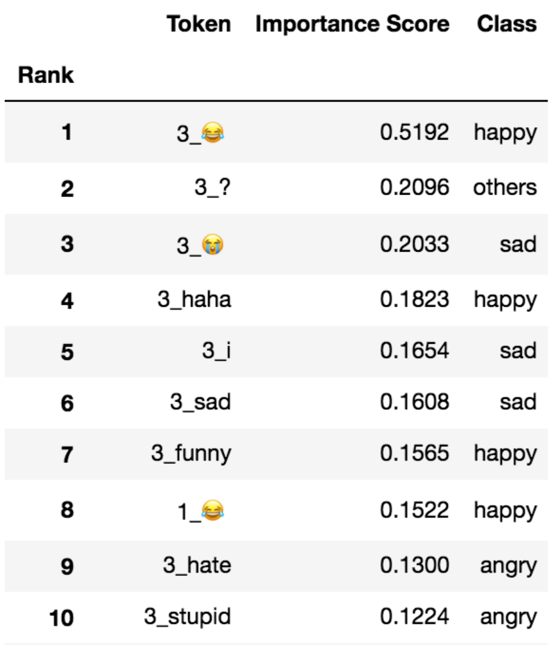
[1]https://github.com/andrew-ai/EmoContext2019/blob/master/tokenzie.py

features based on the importance scores.

A cutoff importance score was experimentally selected to further filter down the vocabulary to use only the most informative tokens and avoid overfitting (see Figure 3).

We note that the system is robust to variations in this parameter above a certain threshold – as shown in Figure 3, while the F1 score varies greatly for cutoff values between 0 and 0.005, above 0.005 the F1 score varies only between 0.720 and 0.725.

The features were then one-hot encoded as our final transformation.



Rank	Token	Importance Score	Class
1	3_😂	0.5192	happy
2	3_?	0.2096	others
3	3_😭	0.2033	sad
4	3_haha	0.1823	happy
5	3_i	0.1654	sad
6	3_sad	0.1608	sad
7	3_funny	0.1565	happy
8	1_😂	0.1522	happy
9	3_hate	0.1300	angry
10	3_stupid	0.1224	angry

Figure 2: Top 10 features based on the importance score computed and their associated labels.

3.3 Model pipeline: Core Model

The sklearn Linear Support Vector Classifier (LinearSVC) was used as our classifier. We used a gridsearch strategy with a simple hold out set (`Training` set to train and `Dev` set to validate) to tune the best performing hyper parameters based on F1 score for the `Training` and `Dev` datasets. We used sklearn's default LinearSVC parameters, except for the cost penalty (C) which we tuned and set to $C = 0.3$.

3.4 Model pipeline: Class tuning

Once the core model and model parameters were well tuned, we further tuned the predictions output by the system. Each class of predictions was

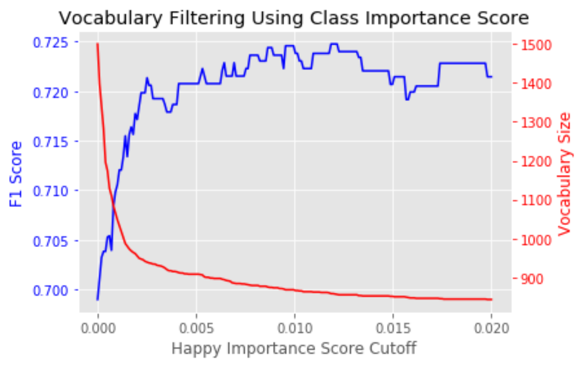


Figure 3: F1 score and vocabulary size as a function of the happy importance score cutoff. The importance scores for the `angry`, `sad` and `others` classes was set to 0.001 from prior tuning. Tuning individually on the `happy` importance score was performed due to it being the weakest classification class and in the end, 0.007 was chosen, which was a local max.

ranked and the least confident predictions based on sklearn's LinearSVC decision_function were shifted to the `others` class. Shifting the classes to have `angry` $\approx$ 5%, `happy` $\approx$ 4.5% and `sad` $\approx$ 4% maximised our F1 score. The results of these experiments are shown in Table 2. We note that this relies on the observation that the `Dev` and `Test` sets have approximately the same class-wise distributions, which of course may not hold true if the model is to be used in other contexts.

3.5 Model pipeline: Happy vs Rest override

This model tended to under-predict the `happy` class in terms of precision and recall, therefore an additional model was built to boost classifications within this class. A Happy vs Rest classifier was trained, using the same LinearSVC model and parameters but this time trained on the Training data relabeled as *'happy'* or *'rest'* (`angry`, `sad`, `others`).

After the Core Model predictions and the class tuning, the Happy vs Rest predictions were compared and the most confident predictions based on a confidence threshold was used to override the Core Models predictions. This threshold was chosen by ranking the predictions from the Happy vs Rest classifier in decreasing order of confidence, and converting the top n most confident predictions to `happy` over this threshold. In this case, all predictions from the Happy vs Rest linearSVC decision function with a signed distance over -0.6 were converted. Here the threshold was chosen by inspection of where the predictions appeared to change from being correct to dubious.

This allowed a more focused model to boost `happy` predictions that the Core Model had missed.

4 Results

Table 2 shows the results of all the system variants described in Section 3. The best overall micro F1 score achieved by our system was 0.735719, or 92.4% of the overall top score in the competition. This placed us in the top 22% of all submissions, and resulted in a final ranking of 37th place.

We note that for each variant of the model, using only Turn 1 + Turn 3 consistently improved the F1 score over using all turns. Adding the Happy vs Rest classifier boosted the `happy` predictions from: Precision = 0.7490, Recall = 0.6514, F1 = 0.6968 to Precision = 0.7368, Recall = 0.6901, F1 = 0.7127. This boosted our overall micro F1 score from 0.729352 to 0.735719. While not shown in Table 2, our *post hoc* class balancing of the final predictions to match the proportions in the `Dev` set was consistently also beneficial in improving our model, as shown in Figure 3.

	T123	T13
NCB	0.7155	0.7188
CB	0.7255	0.7294
NCB + HvR	0.7175	0.7198
CB + HvR	0.7294	**0.7357**

Table 2: Experimental results for system variants where: *T123* = Turn 1 + Turn 2 + Turn 3, *T13* = Turn 1 + Turn 3, *NCB* = No class balancing, CB = Class balancing against test set, *HvR* = With Happy vs Rest override. Note that in each case using using T13 improves over using T123.

Figure 4 shows a confusion matrix for predictions made by our system. In general, the worst misclassifications made by our system were predictions of the `others` class when the correct label was one of the other emotions (or vice versa), rather than misclassifications between emotions, which were negligible.

Figure 5 shows the top 5 "mistakes" – where our system was highly confident in its prediction, but turned out to be wrong. All of these top mislabels were when we incorrectly predicted an emotional class (`angry`, `happy`, `sad`) rather than `others`, and generally when the text contained emojis.

	angry	happy	others	sad
angry	212	0	85	1
happy	0	188	95	1
others	57	65	4514	41
sad	6	2	65	177

Figure 4: Confusion matrix of misclassifications by our system.

	turn1	turn2	turn3	pred_label	true_label
2198	I didn't get the joke 😂 😅	what joke?	You said it was gonna be funny	happy	others
615	But why? funny	I find it funny 😆 😤	I am looking funny	happy	others
4853	No one's brain at least	There was a knock on the change room door	I didn't lock it, left it open so no one needs...	sad	others
5284	😂 😂 😂 😂 I should have talked to you earlier	I forget you're a model 😂 just work it off lat...	😂 😂 😂 😂	happy	others
606	😂 😂 😂 😂 😂 thanks for compliment	😑 for what?	Smile😂 😂	happy	others

Figure 5: Top misclassifications by our system. All errors were when the correct label was "others" but our system predicted an emotion.

5 Conclusion

That our system performed so well using such a simple approach was very satisfying, and demonstrates that high-quality emotion detection is achievable by practitioners across a range of disciplines. Future work using this system will investigate a longitudinal study of long-term changes in the emotional context of conversations conducted over online social network platforms.

Abstract

In this paper we present our submission for SemEval-2019 Task 3: EmoContext. The task consisted of classifying a textual dialogue into one of four emotion classes: happy, sad, angry or others. Our approach tried to improve on multiple aspects, preprocessing with an emphasis on spell-checking and ensembling with four different models: Bi-directional contextual LSTM (**BC-LSTM**), categorical Bi-LSTM (**CAT-LSTM**), binary convolutional Bi-LSTM (**BIN-LSTM**) and Gated Recurrent Unit (**GRU**). On the leader-board, we submitted two systems that obtained a micro F1 score ($F1\mu$) of **0.711** and **0.712**. After the competition, we merged our two systems with ensembling, which achieved a $F1\mu$ of **0.7324** on the test dataset.

1 Introduction

Rapid progress in natural language processing with the rise of deep learning has brought increasing attention on tasks such as text classification and sentiment analysis. Most of the work in that field was made using social media due to the large amount of data available. The task addressed in this paper focuses on emotion detection within conversations from social media. The key point is that we need to take into account multiple speakers and capture a global emotion out of their conversation. It becomes a challenge when facing different users who each have a different way to express their emotions depending on their personalities. In a dialogue, users have an initial emotional state, and their mood will shift as the dialogue goes on. Therefore, the task of labelling a turn-based conversation with the right emotion is even more challenging.

State of the art approaches consist of using language models (Vaswani et al., 2017) to pre-train the model on the general NLP task of language modeling before fine-tuning on specific tasks like classification or translation. The language model approach used by **ULMFiT** (Howard and Ruder, 2018), **ELMO** (Peters et al., 2018) and **BERT** (Devlin et al., 2018) was especially successful for this kind of tasks. For the specific task of emotion classification in textual conversation, Gupta et al. (2017) achieved a $F1\mu$ score of 0.7134 on the same dataset, using an architecture based on **LSTM**. For sentiment analysis, other successful approaches also used **Bi-LSTM** (Baziotis et al., 2017b) as well as transfer learning (Daval-Frerot et al., 2018).

In this paper, we present two sub-systems that are composed of four deep-learning models (using **Bi-LSTM**, **GRU** and **CNN**). Those two sub-systems competed independently at SemEval-2019 Task 3 (Chatterjee et al., 2019). After the final evaluation, we merged both sub-systems, taking advantage of ensemble learning. The rest of the paper is organized as follows. Part 2 gives an overview of our approach. Our preprocessing methods, the description of our models, and our ensembling approach are all described in Part 3. Part 4 shows the obtained results and in Part 5, we give a conclusion with remarks for future works.

2 Overview

Our four models are: **CAT-LSTM**, **BIN-LSTM**, **BC-LSTM** and **GRU**. We decided to use four different model architecture, two different preprocessing and two different word embeddings. We built very diverse models in order to maximize the effect of ensembling on our system. **CAT-LSTM** and **BIN-LSTM** share the exact same preprocessing and embeddings, while **BC-LSTM** and **GRU** use the same embeddings but slightly different preprocessing methods.

3 Proposed System

3.1 Text Preprocessing

We used two different preprocessing methods. However, both preprocessing share the same normalization (all words are lower cases and numbers, links, emails and dates were replaced by special tags). String emoticons are transformed into Emojis before tokenization (':)' becomes 😃).

3.1.1 CAT-LSTM and BIN-LSTM

Here, the preprocessing used was motivated by the fact that the dataset comes from social media, meaning the writing style contains improper use of grammar, misspellings, emoticons and slang. Because of that we used the *ekphrasis*[1] (Baziotis et al., 2017a) library which was made specifically for preprocessing text from social networks. This tool performs tokenization, word normalization, word segmentation and spell correction. Here, we didn't take into account the fact that our inputs are turned based and instead we added a special token `<eos>` in-between each turn of the dialogues which we then concatenated together. We also improved **spellchecking** with this method. Indeed, we realized that 8.8% of our vocabulary consisted of words that weren't part of our word embeddings because they were misspelled, even after preprocessing with *ekphrasis*. Obvious spelling errors like *angru* instead of *angry* were still present. In order to solve this problem we used a spellchecking library named *autocorrect*[2] after preprocessing with *ekphrasis* which decreased to 3.4% the number of unknown words from our vocabulary.

3.1.2 BC-LSTM and GRU

Here, for the normalization, specials tags (numbers, links, emails and dates) were removed. We did the **spellchecking** ourselves with the most common mistakes (e.g: *waht* becomes *what*). This makes the conversation cleaner and easier to understand while leaving a part of natural since most of the words are not corrected (e.g: *nooo* stay *nooo* instead of just *no* since it has a stronger meaning). Notice that for our **GRU** model, we concatenated the three input turns to make it simpler for the **GRU** to process but for our **BC-LSTM**, we made separate layers to process each turns.

[1] https://github.com/cbaziotis/ekphrasis

[2] https://github.com/phatpiglet/autocorrect

3.2 Pre-Trained Word Embeddings

Word embeddings are dense vectors representing semantic meaning for each word of the vocabulary. We used pre-trained word embeddings to initialize the weights of our embedding layers. **CAT-LSTM** and **BIN-LSTM** used *Datastories* embeddings [3], while **BC-LSTM** and **GRU** used our own pre-trained word embeddings.

3.2.1 CAT-LSTM and BIN-LSTM

The weights we used for the embedding matrix of these models were the same as Baziotis et al. (2017b), pre-trained on 330 millions of english tweets messages posted from 12/2012 to 07/2016 with GloVe.

3.2.2 BC-LSTM and GRU

For these models, each word is represented by a vector of 312 dimensions which are obtained by the concatenation of the following features :

- *Word2Vec* (Mikolov et al., 2013) - We created our vector representations of words using *Word2Vec* networks trained with skip-gram and negative sampling on 30 millions of english tweets messages posted from 01/2017 to 06/2017. This word embeddings are 300 dimensional.

- *Affect Intensity Lexicons* (Mohammad and Turney, 2013) - 6,000 entries for four basic emotions: anger, fear, joy, and sadness. Considering fear as other, it adds 4 dimensions

- *Emolex* (Novak et al., 2015) - The NRC Emolex is a list of words and their associations with eight emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust). We transformed fear, anticipation, trust, surprise and disgust into the class 'others' with a vector of 4 dimensions (joy, anger, sad, others)

- *Emoji Emotion* [4] - List of emoji rated by polarity. The polarity was hand classified (by one person) based on the names of these emoji. The contained emoji are the faces defined by Unicode

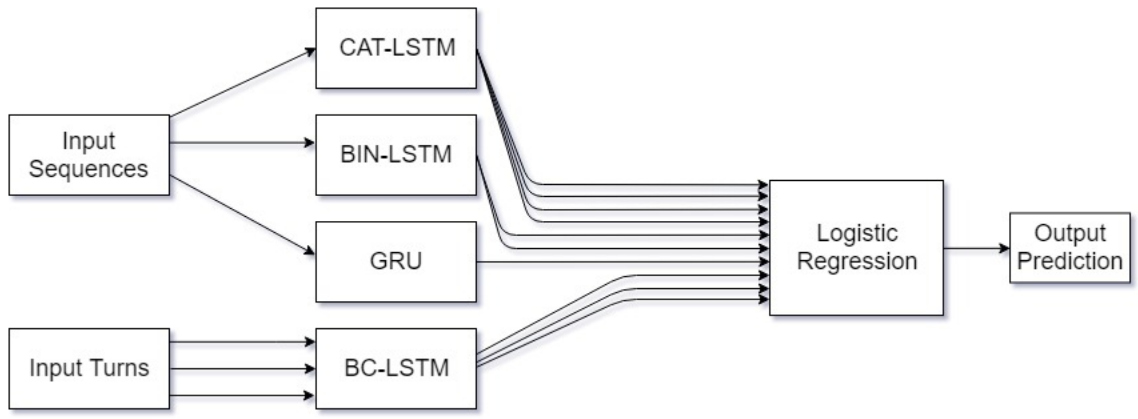

Figure 1: Ensembling method.

3.3 Models Description

We used Bi-directional Long Short-Term Memory networks (*B-LSTM*) in every model except the **GRU**. Every model used *Adam* optimizer and *crossentropy* [5] as the loss function.

3.3.1 CAT-LSTM Model

The core of the network is composed of two sets of *B-LSTM* as in Baziotis et al. (2017a). The input layer is composed of an embedding layer of size 300, followed by a dropout layer (0.4) directly after the embedding layer to help regularizing by showing slightly different sequences every epochs. Each *B-LSTM* layer consist of 150 units with recurrent dropout (0.5) and regular dropout (0.5). *B-LSTM* layers reads each sequence two times in different order, forward (from left to right) and backward (from right to left) which helps to capture the context of the sentence. The output layer is a dense layer followed by a softmax.

3.3.2 BIN-LSTM Model

With the previous model (**CAT-LSTM**), we realized most of our errors came from confusion between the class ’others’ and the rest (angry, happy and sad). Which might be because the training set is slightly unbalanced (15k others, 5.5k angry, 5.4k happy, 4.2k sad). Because of that we decided to train a model specifically on binary classification between the class ’others’ and the rest. That way we could use ensembling to help our categorical model to differentiate between the two categories. For this binary model, we kept a similar architecture as **CAT-LSTM**. However, we added a convolution 1D and a maxpool before the first *B-LSTM* layer to train faster. Since our input is a one-dimensional sequence of words, it makes sense to use a one-dimensional convolution right after the embedding layer in order to capture meaningful context about our sequence while reducing its size. We kept most spatial information by using a kernel size of 5 so that we take every group of 5 adjacent words into account. After the convolution, we used a one-dimensional maxpool layer of size 5 in order to reduce the input size. With this new architecture we were able to train a second model more focused on separating ’others’ class from the rest of the emotion classes while increasing our training speed by 80%.

[5]We used *categorical crossentropy* except for the binary (**BIN-LSTM**) model which used *binary crossentropy*

3.3.3 BC-LSTM Model

We used the **BC-LSTM** architecture introduced in Poria et al. (2017). **BC-LSTM** (Bidirectional Contextual LSTM) is a model for context-dependent sentiment analysis and emotion recognition. For this model we treated each turn inputs in separate parallel layers before concatenating the results. Hence, we have 3 parallel embedding layers with our pre-trained embeddings, which then go through 3 parallel bidirectional LSTM layers of 300 units. Each of those *B-LSTM* have a Dropout of 0.5. After that, we stack each *B-LSTM* layer. We then have a fully-connected layer with 4 units, that will give us probabilities for each emotion class. This model was particularly useful to detect happy, sad, and others emotions so we only keep those 3 probabilities.

3.3.4 GRU Model

The **GRU** model (Cho et al., 2014) allowed us to discriminate the angry class. The first layer is made using our pre-trained embeddings to process the concatenated text input. We added a dropout of 0.5. Then, the output of our embedding goes through a *GRU* layer of 128 units. On top of our *GRU*, we added a fully-connected layer of 32 units with relu as the activation function. A Dropout of 0.2 was added after this layer.

3.4 Ensembling

As stated before, we trained each model individually, hence giving us multiple sets of predictions for each input sample. We used all of those probabilities to train a logistic regression. We stack all 10 predictions (4 from **CAT-LSTM**, 2 from **BIN-LSTM**, 1 from **GRU** and 3 from **BC-LSTM**) to a create a new training sample associated with the corresponding true label of the sample, as shown in Figure 1. This way, we take each of our models into account and the logistic regression takes care of weighting the importance of our models. Since our four models are very diverse, they all contribute to the final prediction.

4 Results and Analysis

When evaluating each group of model separately, we found that they were correct on different samples even if the $F1\mu$ score is almost the same. Table 1 illustrate the performances of our systems on the test set. We can see that the class 'happy' gave our models the most trouble. Which might be because it is the smallest class in the dataset. Ensembling had a little impact on this emotion compared to 'angry' and 'sad'. Our final system achieves an $F1\mu$ score of **0.7324**.

Emotion / Models	Angry	Happy	Sad	$F1\mu$
CAT-LSTM+ BIN-LSTM	0.719	0.678	0.734	0.711
GRU+ BC-LSTM	0.722	0.673	0.739	0.712
Model ensembling	0.744	0.689	0.766	**0.7324**

Table 1: $F1\mu$ score on the test set for each model.

Note that [**CAT-LSTM + BIN-LSTM**] and [**GRU + BC-LSTM**] were submitted independently for the final submission. However, both systems were combined in **model ensembling** after the competition ended which significantly improved our final score.

5 Conclusion

In this paper, we proposed to use ensemble learning for sentiment analysis in conversations (SemEval2019 Task 3). Using various neural networks structures such as **B-LSTM**, parallel **B-LSTM**, **GRU** and **CNN**, ensemble learning takes advantage of this diversity of approach to make a prediction for our emotions classes (angry, happy, sad or others). Each model was trained separately on the given corpus. Then, we trained a logistic regression with the probabilities given by our four deep learning models in order to make the final predictions for each conversations. Our ensembling system achieved a $F1\mu$ score of **0.7324** on the final testing set, after the competition ended.

Improvements could be made by gathering more models. A properly fine-tuned language model (for instance using ULMFiT) or LSTM with attention mechanism could improve our current system. Future work will consist of finding better ensembling methods and working with language models pre-trained on larger corpus of data.

Sentim at SemEval-2019 Task 3: Convolutional Neural Networks For Sentiment in Conversations

Jacob Anderson
Sentim LLC, USA
papers@sentimllc.com

Abstract

In this work convolutional neural networks were used in order to determine the sentiment in a conversational setting. This paper's contributions include a method for handling any sized input and a method for breaking down the conversation into separate parts for easier processing. Finally, clustering was shown to improve results and that such a model for handling sentiment in conversations is both fast and accurate.

1 Introduction

The model for this paper was created for Task 3 of SemEval 2019, EmoContext (Chatterjee et al., 2019). The basic idea of the task is to classify the emotion (as "angry", "sad", "happy", or "others") that someone is expressing in the third turn of a three part conversation, given the previous two turns as context.

The dominant approach in many natural language tasks is to use recurrent neural networks or convolutional neural networks (CNN) (Conneau et al., 2016). For classification tasks, recurrent neural networks have a natural advantage because of their ability to take in any size input and output a fixed size output. This ability allows for greater generalization as no data is removed nor added in order for the inputs to match in length. While CNN's can also support input of any size, they lack the ability to generate a fixed size output from any sized input. In text classification tasks, this often means that the input is fixed in size in order for the output to also have a fixed size.

This work expands upon a previous work (Anderson, 2018), a way of using CNN's for classification to allow for any sized input length without adding or removing data. That work was expanded upon in this paper by making it simpler, using it in a different setting, and applying a new method to compensate for the previous model's deficiencies.

2 Model Description

The overall architecture of this model can be broken into two parts: the language understanding model and the emotion prediction model. The language understanding model takes in each part of the conversation and processes it separately in order to produce a latent vector representing the network's understanding of that part of the conversation. Then, the emotion prediction model takes all of the latent vectors from the language understanding model and combines them in order to make a prediction for what the emotion is.

More specifically, the language understanding model takes in the first and third turns of each conversation[1], processes them separately, and returns a respective understanding vector of size 128 for each input. The emotion model then concatenates those vectors to make one vector of size 256 and then processes that output through a small fully connected network in order to predict the emotional content.

The model was designed using Tensorflow (Abadi et al., 2015) and Keras (Chollet et al., 2015) and was trained using a Google Colab GPU.

2.1 Language Understanding Model

The idea behind the language understanding model (Figure 1) is to take in each part of the conversation separately and process them into a fixed size vector representing a machine understanding of the input text. In order to accomplish this, the input conversation was first embedded into a subword embedding using the byte-paired encoding provided by Heinzerling and Strube (2018) and SentencePiece (Kudo and Richardson, 2018). The subword embedding used a base vocabulary size of 10,000 with a vector size of 100. This em-

[1]The second turn was not used during my training because it was found empirically to make the results worse.

bedding was further extended with random vectors during data preprocessing to include emojis and other unique characters not found in the original vocabulary.

Output

Figure 1: The language understanding model.

A specialized convolutional stack was used in order to process the embeddings. The first layer of the stack was a convolutional layer with linear activation in order to set up the initial size of the input. This was followed by a stack of seven residual dilated convolutional layers (Figure 2) with relu activation. The number of layers was chosen so that the final layer would have a receptive field large enough to be able to see the whole input.

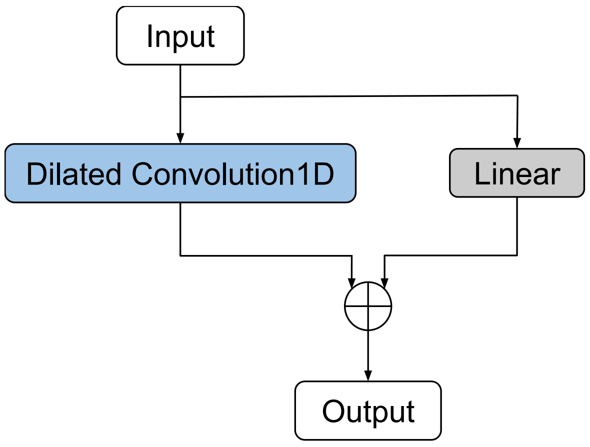

Figure 2: A residual dilated convolution, without skip connections.

One more convolutional layer was used with a linear activation function and the “same” padding method. This layer was originally added to increase the number of filters, but after a grid search was performed to determine the optimal hyperparameters, this layer was left in as a way to do any necessary linear transformations on the latent vector. Note that all convolutional layers in the final version had a kernel size of 2 and 300 filters. Additionally, the padding method varied depending on the experiment. See the “Experiments and Results” section for more information on that topic.

The convolutional stack was followed by a global max pool layer to bring the network down to a constant size, and then an FC Layer. The idea of this last FC layer is to allow for any fine tuning of the language understanding model as necessary and to compensate for the max pool layer’s inability to provide perfect information.

2.2 Emotion Prediction Model

The purpose of the emotion prediction model (Figure 3) is to predict the emotion given the latent vectors representing the conversation. The emotion prediction model starts off with the concatenation all of the language understanding outputs. This is then fed through one fully connected layer of size 256 with sigmoid activation, followed by the final prediction fully connected layer of size 4, also with sigmoid activation.

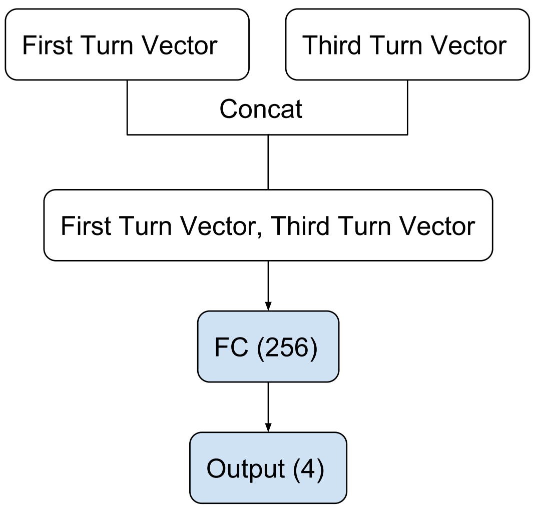

Figure 3: The layout of the emotion prediction model.

2.3 Training and Loss Functions

The network is end to end trainable without having to train the networks separately. Triplet loss was used (with triplets chosen via the all anchor-positive method) from Schroff et al. (2015) to cluster similarly labeled data together for the language understanding model, and softmax cross entropy loss was used for the emotion prediction model. The models were trained using the Adam (Kingma and Ba, 2014) optimization method with a learning rate of .001.

The loss function can be written as

$$L = T(a_s, p_s, n_s) + T(a_e, p_e, n_e) + S(labels, logits)$$

Where $T(anchor, positive, negative)$ is the triplet loss and $S(labels, logits)$ is the softmax cross entropy loss given the true labels and logit predictions from the emotion prediction model. Additionally, a_s, p_s, n_s are the anchor, positive, and negative examples corresponding to the first turn and a_e, p_e, n_e are the anchor, positive, and negative examples corresponding to the last turn respectively.

To further clarify, each first turn text in the batch was matched against every other first turn text so that they (the anchor) would be closer to similarly labeled data (positive examples) and farther away from every other category of data (the negative examples). The same thing was done for the last turn of the conversation. The first turn was specifically not clustered to be close to both first turn and last turn labels in order to preserve any contextual information that could be available in the first turn of a conversation versus the last turn.

An interesting thing to note is the time taken to train the model. Perhaps due to using the clustering loss and the softmax cross entropy loss simultaneously, the fast speed of training residual convolutions, or the small size of the dataset, the model always finished training within 7 minutes (or 9 epochs). Any more than that would never improve the micro f1 score and would start overfitting. Furthermore, roughly twenty percent of the time the model would show the best results within 1.5 minutes (or 2 epochs).

In one experiment, the networks were trained using just softmax cross entropy loss, but the networks never improved beyond the initial prediction of always pick the “others” class. This could be because of wrong hyperparameters (the same model was used as the one with the clustering loss), didn’t train for long enough (one model was trained for 24 hours (or 1755 epochs over the training data)), or didn’t try enough random restarts (10 restarts were attempted in this paper). Regardless of the case, this shows that using the clustering loss helped the network find the right solutions faster and with less hyperparameter tuning than just using the softmax cross entropy loss.

3 Experiments and Results

The experiments for this paper were all run on the dataset provided by the EmoContext organizers. The main dataset contains roughly 30,000 conversations, while the test dataset contains roughly 2,750, and the final evaluation dataset contains about 5,500. The order of each conversation goes Person A, Person B, then Person A again for all of the datasets.

Model Type	**Micro F1 Score**
118 network ensemble	.7295
Same padding ensemble	.7262
Causal padding ensemble	.7357
Best single model	.7255
2nd best single model	.707
Ensemble of micro f1 $>.7$	.7366
Ensemble of micro f1 $>.71$	.7386
Emoji replacement model	.7386

Table 1: Micro f1 score on the final evaluation set for each of my submissions.

The first submission on the evaluation dataset was an ensemble of 118 networks. In total, the 118 networks came from 100 different training cycles: 50 runs using causal padding as the padding method in the dilated residual convolutional stack, and 50 runs using the "same" padding method. Each run was trained against the full dataset for nine epochs and tested against the test dataset, so the checkpoints chosen were the ones that performed the best on the test dataset. The remaining 18 networks came from checkpoints that were not the best checkpoint of the training run but still had a micro f1 score above 0.7 on the test set.

To compare two different convolutional padding methods, an ensemble of all networks using "same" padding (56 in total), and an ensemble of all causal padding runs (62 in total) was submitted. While the causal padding models performed better on average, the difference was not significant. Two non-ensemble runs were submitted - one of which was the best run of all 100 runs (which happened to be a causal padding model) and the other of which was the second best run of all 100 runs (which happened to be a "same" padding model).

The sixth submission was an ensemble where every network in the ensemble had to have a micro f1 score of .7 or higher and the seventh submission was an ensemble where every network had to have a micro f1 score of .71 or higher respectively.

Unsurprisingly, the ensemble methods ourperform the best single model runs on micro f1 score. Interestingly though, the 118 network ensemble performed worse than the causal padding ensemble. This could represent opposing learning biases present in "casual" versus "same" padding types. That is, instead of the two different types of models agreeing with each other and removing bad predictions, the two models instead mostly disagree over certain portions of the data, leading to larger uncertainty and therefore lower overall performance.

A rule based model was also tested where every conversation was labeled based on whether or not it contained an emoji. More specifically, for every conversation the first and third turns of the text were concatenated and then if that had a happy emoji it was labeled happy, if it had a sad emoji it was labeled sad, if it had an angry emoji it was labeled angry, and if it didn't have any of those emojis then it was labeled using the output of the seventh submission. This model is interesting because applying the algorithm changed zero labels from the seventh submission. This means that the network learned the different emojis and used them in order to predict the emotion. This also agrees with the intuition that emojis should represent how a user is feeling (or perhaps that the dataset was created or biased by this idea). To see all of the results, view Table 1.

Submitter	**F1 Score**
1st Place	.7959
2nd Place	.7947
3rd Place	.7765
My Best	**.7386**
Median	.6947
Average	.6605

Table 2: Micro f1 score of the first, second, and third place submissions as well as the average and median scores of all submissions as compared to my best submission.

To see a comparison to other people's submissions in the competition, view Table 2. Additionally, I show the micro f1 score as well as the f1 score for the happy, angry, and sad labels for a few of my models in Table 3.

Model	**F1**	**Angry**	**Happy**	**Sad**
BSM	.7255	.7382	.6718	.7653
f1 >.7	.7366	.7481	.6812	.7803
f1 >.71	.7386	.7536	.6790	.7818

Table 3: Micro f1 score as well as the f1 score for the angry, happy, and sad labels. Best single model is abbreviated as BSM, as well as the ensemble of all models that scored higher than a certain f1 score as f1 >score.

4 Conclusion

A language understanding model and an emotion prediction model was trained in an end to end fashion for understanding and predicting the emotions of conversations. The previous work was adapted in order to leverage the ability to use any sized inputs with convolutional neural networks, and showed that such a model can be fast and accurate. Finally, it was shown that augmenting language learning using clustering loss can help augment training and improve results.

Abstract

Detecting emotions in textual conversation is a challenging problem in absence of nonverbal cues typically associated with emotion, like facial expression or voice modulations. However, more and more users are using message platforms such as WhatsApp or telegram. For this reason, it is important to develop systems capable of understanding human emotions in textual conversations. In this paper, we carried out different systems to analyze the emotions of textual dialogue from SemEval-2019 Task 3: EmoContext for English language. Our main contribution is the integration of emotional and sentimental features in the classification using the SVM algorithm.

1 Introduction

Emotions seem to govern our daily lives since most of our decisions are guided by our mood. They are complex and that is why they have been studied in many areas over time. Given the importance to develop systems to be able to mimic functioning of the human brain, emotions have attracted the attention in the field of affective computing (Thilmany, 2007).

To our knowledge, there are not many works that focus on studying how emotions are reflected verbally. However, studying emotions on text messaging platforms such as WhatsApp, Facebook Messenger or Telegram is important as more and more users are using them to share their experiences and emotions.

Currently, detecting emotions in instant messaging has multiple applications in different fields (Gupta et al., 2017; Yadollahi et al., 2017; Hakak et al., 2017), such as businesses intelligence to increase customer satisfaction knowing their preferences, social media to alert users if they are going to post an offensive tweet or psychology to detect some disorders like anorexia, anxiety or stress.

In this paper, we present the different systems we developed as part of our participation in SemEval-2019 Task 3: Contextual Emotion Detection in Text (EmoContext) (Chatterjee et al., 2019b). It is an emotion classification task. Given a textual dialogue along with two turns of context, its consists of classify the emotion of user utterance as one of the emotion classes: Happy, Sad, Angry or Others.

The rest of the paper is structured as follows. In Section 2 we explain the data used in our methods. Section 3 introduces the lexical resources used for this work. Section 4 presents the details of the proposed systems. In Section 5, we discuss the analysis and evaluation results for our system. We conclude in Section 6 with remarks and future work.

2 Data

To run our experiments, we used the English datasets provided by the organizers in SemEval19 Task 3 : EmoContext (Chatterjee et al., 2019b). The datasets containing 3-turn conversations along with their emotion class labels (Happy, Sad, Angry, Others) provided by human judges. The Turn 1 contains the first turn in the three turn conversation, written by User 1. The turn 2 contains the second turn, which is a reply to the first turn in conversation and it is written by User 2 and finally, the turn 3 contains the last turn, which is a reply to the second turn in the conversation, which is written by User 1.

During pre-evaluation period, we trained our models on the train set, and evaluated our different approaches on the dev set. During evaluation period, we trained our models on the train and dev sets, and tested the model on the test set. Table 1 shows the number of 3-turn conversations used in our experiments in English.

Dataset	train	dev	test
Happy	4,243	142	284
Sad	5,463	125	250
Angry	5,506	150	298
Others	14,948	2,338	4,677
Total	30,160	2,755	5,509

Table 1: Number of 3-turn conversations per EmoContext dataset

3 Resources

For the development of the task, we used different lexicons that we explain in detail below.

NRC Affect Intensity Lexicon (Mohammad, 2017). It has almost 6,000 entries in English. Each of them has an intensity score associated to one of the following basic emotions: anger, fear, sadness and joy. The scores range from 0 to 1, where 1 indicates that the word has a high association to the emotion and 0 that the word has a low association to the emotion.

NRC Word-Emotion Association Lexicon (EmoLex) (Mohammad and Turney, 2010). This lexicon has a list of English words associated to one or more of the following emotions: anger, fear, anticipation, trust, surprise, sadness and joy.

VADER (Valence Aware Dictionary and sEntiment Reasoner) (Gilbert, 2014). The VADER sentiment lexicon is a rule-based sentiment analysis tool. This is sensitive both the polarity and the intensity of sentiments expressed in social media contexts, and is also generally applicable to sentiment analysis in other domains. VADER has been validated by multiple independent human judges. The tool returns four values: positive, negative, neutral and compound. The first three scores represent the proportion of text that falls in these categories. The compound score is computed by summing the valence scores of each word in the lexicon, adjusted according to the rules, and then normalized to be between -1 (most extreme negative) and +1 (most extreme positive).

4 System Description

In this section, we describe the systems developed for the EmoContext task. During our experiments, the scikit-learn machine learning in Python library (Pedregosa et al., 2011) was used for benchmarking.

4.1 Data Preprocessing

In first place, we preprocessed the corpus of conversations provided by the organizers. We applied the following preprocessing steps: the documents were tokenized using NLTK Tweet Tokenizer[1] and all letters were converted to lower-case.

4.2 Feature Extractor

Converting sentences into feature vectors is a focal task of supervised learning based sentiment analysis method. Therefore, the features we chose in our system can be divided into three parts: statistic features, morphological features and lexical features.

- **Statistic features**. We employed the feature that usually perform well in text classification: Term Frecuency (TF) taking into account unigrams and bigrams.

- **Morphological features**. We employed Part-of-speech tagging (PoS). For each sentence, we obtain a vector associated with the part of speech recognized in each word of the sentence.

- **Lexical features**. As we explained in Section 3, we used three lexicons obtained different features in the following way:

  1. **NRC Affect Intensity**. We checked the presence of lexicon terms in the sentence and then we computed the sum of the intensity value of the words of the sentence grouping them by the emotional category (*fear*, *sadness*, *anger* and *joy*). Therefore, we obtained a vector of four values (four emotions) for each sentence. Each value of intensity is normalized $\hat{i}_e$ applying the following equation:

  $$\hat{i}_e = \frac{i_e}{\sum_e i_e}$$

  Where $e = \{\text{fear, sadness, anger, joy}\}$ and i_e is equal to value of intensity per emotion. Note that the components of the normalized vector add up to 1, and each of them is a positive number between 0 and 1.

[1]https://www.nltk.org/api/nltk.tokenize.html

2. **Emolex**. We identified the presence of lexicon terms in the sentence and we assigned 1 as confidence value (CV). Then, we summed the CV of the words whose emotion is the same obtaining a vector of emotions for each sentence. As a result, we obtained a vector of eight values (eight emotions). Each value $\hat{v}_e$ is normalized following the next equation:

$$\hat{v}_e = \frac{CV_e}{\sum_e CV_e}$$

Where e = {anger, fear, anticipation, trust, surprise, sadness and joy} and CV_e is equal to confidence value per emotion. Note that the components of the normalized vector add up to 1, and each of them is a positive number between 0 and 1.

3. **VaderSentiment**. We use the sentiment.vader module[2] provided by the Natural Language Toolkit (NLTK). With this module, we analyze each sentence and we obtained a vector of four scores: negative sentiment, positive sentiment, neutral sentiment and compound polarity.

4.3 Classifier

The concatenation of the features described before are applied for the classification using the SVM algorithm. We selected the Linear SVM formulation, known as C-SVC and the value of the C parameter was 1.0.

5 Experiments and analysis of results

During the pre-evaluation phase we carried out several experiments and the best experiments were taken into account for the evaluation phase. The architecture of the different systems can be seen in Figure 1 and are described below:

- **Basic system (BS)**. For this experiment, we have combined the 3-turn conversations of the corpus in a text string separated by spaces. For example, for turn 1: ”Hahah i loved it” , turn 2: ”Yay! Glad you loved it X3” and turn 3: ”You always make us happy”, the final sentence is ”Hahah i loved it Yay! Glad you loved it X3 You always make us happy”. Then, each sentence is represented as a vector of unigrams and bigrams choosing the TF weighting scheme and it is used as feature for the classification using the SVM algorithm.

- **Basic system with turn 1 and 2 (BS-2)**. This experiment is similar to the previous one. However, we have only taken into account the first and last conversation turns because analyzing the training data, we realized that the second conversation turn is not useful for the classification as it does not provide representative information. For example, for turn 1: ”Hahah i loved it” , turn 2: ”Yay! Glad you loved it X3” and turn 3: ”You always make us happy”, the final sentence is ”Hahah i loved it You always make us happy”. We notice that the emotion is the same (happy) as if we consider the three turns.

- **System with features (SF)**. In this system, also we have only taken into account the first and last conversation turns. With these turns of conversations, we have tested several combinations with the lexical resources during the development phase and we chose the best combination for the evaluation phase. The best combination is the set of the vector of NRC (four values), the vector of Emolex (eight values) and the vector of VaderSentiment (four values) explained in Subsection 4.2. Therefore, the union of the best lexical features and the TF of the two conversation turns are used as features to perform the classification with the selected SVM algorithm.

Table 4: System test results per user in EmoContext task.

systems in EmoContext task is the microaveraged F1 score (F1μ) for the three emotion classes (Happy, Sad and Angry). This metric is calculated between the real classes and the predicted classes. The results of our participation in the task can be seen in Tables 2 and 3.

In relation to our results, during the pre-evaluation phase and evaluation phase, we noticed that 1 and 3 conversation turns performed better the classification due to the reason that the 2 conversation turn is usually a contradiction or a question of the 1-turn. In Tables 2 and 3 we can observed that the BS-2 experiments outperformed the BS experiments. According to the classification per emotion, we may note different issues. On the one hand, the use of lexical features (SF experiment) improve about 2% of F1 with respect to the BS-2 experiment in the dev set. Nevertheless, this is not the case in the test set. On the other hand, the Happy emotion class perform worse than other emotion classes in both datasets, as it happens in other works (Chatterjee et al., 2019a; Gupta et al., 2017). Besides, if we observed the SF experiment in test set, we can see that the emotional features do not help to improve the classification because there are some words like “love” or “cool” whose assigned emotion is Happy class but in the 3-turn conversation of test set have been marked as Others class by the judges. Finally, in Table 4 we can observe our official position in the competition. We are ranked 92 out of 165 participating teams and our system outperforms the baseline system provided by the organizers of the task.

6 Conclusions and Future Work

In this paper, we present different systems to predict the emotion of user in a textual dialogue along with two turns of context. To carry out the task, we have developed three different systems. The first two are base systems, combining different turns of conversation and in the last system we decided to incorporate lexical features from sentiment and emotional resources.

In the future, we plan to continue working in emotion classification tasks because we have observed that the participation in this tasks is very high and this shows the interest by the scientific community in solving this type of tasks. Efforts will also be made to include more contextual information and to explore other multiple classifier methods.

Abstract

We present several techniques to tackle the mismatch in class distributions between training and test data in the Contextual Emotion Detection task of SemEval 2019, by extending the existing methods for class imbalance problem. Reducing the distance between the distribution of prediction and ground truth, they consistently show positive effects on the performance. Also we propose a novel neural architecture which utilizes representation of overall context as well as of each utterance. The combination of the methods and the models achieved micro F1 score of about 0.766 on the final evaluation.

1 Introduction

A new task whose goal is to predict the emotion of the last speaker given a sequence of text messages has been designed, and coined Contextual Emotion Detection (EmoContext; Chatterjee et al., 2019).

Though predicting the emotion of a single utterance or sentence, *i.e.* emotion detection, is a well-discussed subject in natural language understanding literature, EmoContext has several novel challenges. Firstly, the class distribution of training data is significantly different from that of the test data. Consequently, a model trained on the training data might not perform well on the test data. There have been efforts made to address the problem of learning from training data sets that have imbalanced class distribution, i.e. the class imbalance problem (Chawla et al., 2004; Buda et al., 2018). However, they are not applicable to our case, since the imbalance appears only in the test data while the training data can be viewed to be balanced.

We extend the existing methods of addressing the class imbalance problem to be applicable for more general cases where the distributions of the collected training data differ from those of the real population or the data at test time, under the assumption that the validation set is organized carefully to reflect the practical distribution. From experiments and analyses, we show that the proposed methods reduce the difference between two distributions and as a result improve the performance of the model.

The additional challenge we have to consider arises from the fact that utterances having identical surface form may have different meanings due to sarcasm, irony, or etc.. Thus a model should track the emotional transitions within a dialogue. To grasp the context of utterances, we propose a semi-hierarchical encoder structure. Lastly, the texts contain lots of non-standard words, *e*.g. emoticons and emojis. This makes it difficult to exploit typical pre-trained embeddings such as GloVe (Pennington et al., 2014). Therefore, we adopt pre-trained embeddings which are specialized for handling non-standard words. We show that the proposed model largely outperforms the baseline of task organizers by experiments.

2 Related Work

2.1 Contextual Emotion Detection

EmoContext is a emotion classification data set composed of 3-turn textual conversations. The goal of the data set is to classify the emotion in the last utterance of each example given the context. The label set consists of 4 classes: 'happy', 'sad', 'angry' and 'others'. In the training data set, there are about 50% of 'others' class examples and 50% of emotional (happy, sad, angry) examples, which can be viewed as well-balanced. On the other hand, only 15% of examples in the test and the validation data set are labeled as emotional, reflecting the real-life frequency. For more details, refer to Chatterjee et al. (2019).

2.2 Class Imbalance Problem

When some classes have the significantly higher number of examples than other classes in a training set, the data is said to have an imbalanced class distribution (Buda et al., 2018). This makes it difficult to learn from the data set using machine learning approaches (Batista et al., 2004; Mazurowski et al., 2008), since the learned models can be biased to majority classes easily, which results in poor performance (Wang et al., 2016). We give a brief explanation of methods to solve this problem.

Sampling: This type of methods deals with the problem by manipulating the data itself to make the resulting data distribution balanced. The simplest versions are *random oversampling* and *random undersampling*. The former randomly duplicates examples from the minority classes and the latter randomly removes instances from the majority classes (Mollineda et al., 2007).

Thresholding: This method moves the decision threshold after training phase, changing the output class probabilities. Typically, this can be done by simply dividing the output probability for each class by its estimated prior probability (Richard and Lippmann, 1991; Buda et al., 2018).

Cost-Sensitive Learning: This assigns different misclassification cost for each class and applies the cost in various ways, *e.g.* output of the network, learning rate or loss function. For multi-class classification tasks, the simplest form of the cost-sensitive learning is to introduce weights to the cross entropy loss (Han, 2017; Lin et al., 2018):

$$L = -\frac{1}{N}\sum_{i=1}^{N}\sum_{c=1}^{K} w^c y_i^c \ln p(c|x_i), \qquad (1)$$

where N and K denote the total number of examples and classes respectively, $p(c|x_i)$ the predicted probability of i-th example x_i belonging to class c, y_i^c the ground truth label which is 0 or 1, and w^c a class dependent weighting factor. Recent work suggests to use the inverse ratio of each class, *i.e.* $w^c = \frac{N}{N_c}$, where N_c is the number of examples belonging to class c (Wu et al., 2018; Aurelio et al., 2019).

Ensemble: The term ensemble usually refers to a collection of classifiers that are minor variants of the same classifier to boost the performance. This is also successfully applied to the class imbalance problem (Sun et al., 2007; Seiffert et al., 2010), by replacing the resampling procedure in the bagging algorithm with oversampling or undersampling (Galar et al., 2012).

3 Methods for Mismatch Problem

3.1 Sampling

In our case, it is not possible to make the distinction between majority and minority classes; even if the 'others' class is the most prevalent in the training data, the ratio is less than that of the test data. To address this issue, the random minority oversampling technique should be modified, since it assumes that the class imbalance appears only in the training data set. Accordingly, we apply random oversampling or random undersampling to make the distribution of the training data similar to that of the validation data.

3.2 Thresholding

The basic thresholding method mentioned in §2.2 is not sufficient for our case, since we should additionally *bias* the model output distribution to match the test time distribution, not only correcting the imbalance in the training data. When p_r is a probability of training time and p_s is that of validation time, we multiply the predicted probability by the estimated class ratio from validation set as below:

$$\begin{aligned} y_c(x) = p(c|x) &\approx \frac{\boldsymbol{p_s(c)}}{p_r(c)} \cdot p_r(c|x) \\ &= \frac{\boldsymbol{p_s(c)}}{p_r(c)} \cdot \frac{p_r(c)\cdot p_r(x|c)}{p_r(x)} \qquad (2) \\ &= \frac{\boldsymbol{p_s(c)}\cdot p_r(x|c)}{p_r(x)}, \end{aligned}$$

where $p(c) = \frac{N_c}{N}$.

3.3 Cost-Sensitive Learning

The weighted cross entropy loss, described in Eq. (1), can be used for our case, as long as the weights are carefully chosen. Although the reciprocal of class ratio is helpful for learning balanced prediction (Wu et al., 2018), the target distribution between classes is not uniform for our task. Also, the misclassification cost of 'others' class should be larger than those of emotional classes, because the model tends to predict it less than the actual. Therefore, it is reasonable to modify w^c by multiplying the estimated ratio of each class for test time, *i.e.* $w^c = \frac{N^r}{N_c^r} \cdot \frac{N_c^s}{N^s}$, where N^r and N^s denote

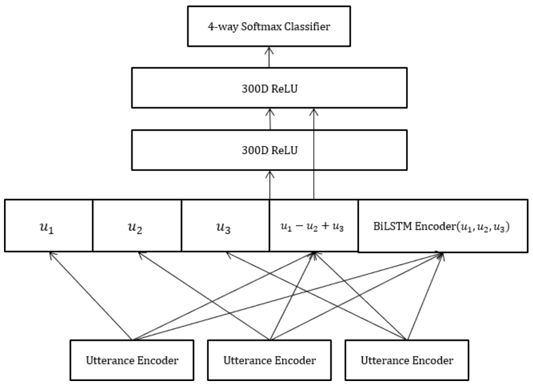

Figure 1: Overall Architecture

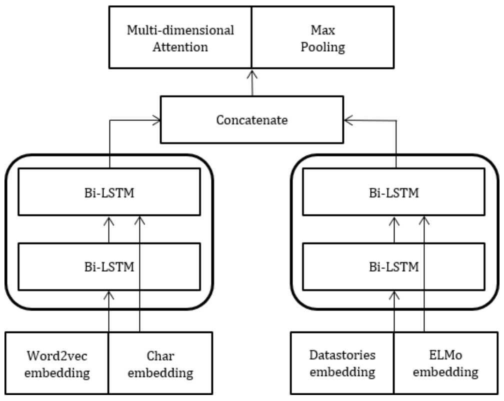

Figure 2: Utterance Encoder

the number of instances in training and validation data set respectively. This corresponds to the term introduced in Eq. (2), as $\frac{N^r}{N^r_c} \cdot \frac{N^s_c}{N^s} = \frac{p_s(c)}{p_r(c)}$. The difference between them is that thresholding utilizes the term in inference phase after training is finished, while weighted cross entropy loss includes it from the training time.

3.4 Ensemble

We combined bagging-based ensemble with sampling techniques represented in §3.1. In addition, we compared ensembles of randomly initialized classifiers using other methods (*i.e.* thresholding and cost-sensitive learning).

4 Model and Training Details[1]

4.1 Overall Architecture

We propose a semi-hierarchical structure to capture the context as well as the meaning of each single utterance. Fig. 1 depicts the overall architecture. Each single utterance representation u_m is encoded by Utterance Encoder described in Fig. 2. In addition, we introduce another bi-directional LSTM (BiLSTM) encoder for higher level representation which receives the outputs of utterance encoder as its inputs. The representation of all context is generated by the concatenation of u_1, u_2, u_3, $u_1 - u_2 + u_3$ and the output of this encoder. Then it is fed to the two 300-dimensional (300D) hidden layers with $ReLU$ activation with shortcut connections and a $softmax$ output layer.

4.2 Utterance Encoder

The proposed utterance encoder has two types of shortcut-stacked bi-directional long short-term memory (BiLSTM) encoder (Nie and Bansal, 2017) to fully exploit four types of lexicon level representations. The first encoder utilizes pre-trained word2vec (Mikolov et al., 2013) embeddings concatenated with trainable embeddings from a character level convolutional neural network (CNN). We also added emoji2vec (Eisner et al., 2016) embeddings to word2vec to map emoji symbols to the same space. The other encoder receives concatenated representations of pre-trained datastories (Baziotis et al., 2017) embeddings and contextualized represenations from ELMo (Peters et al., 2018).

The results from the two stacked BiLSTM encoder are concatenated. We use the multi-dimensional source2token self-attention of Shen et al. (2018) and max pooling to integrate contextualized word level representations to a single utterance representation, as in Im and Cho (2017).

4.3 Training Details

We use 300D Google News word2vec[2] embeddings and 300D pre-trained emoji2vec.[3] Datastories vectors[4] which were pre-trained on a big collection of Twitter messages using GloVe are also 300D. The dimension of character embeddings is fixed to 15, and it is fed to a CNN where the filter sizes are 1, 3, and 5 and the number of feature map for each is 100, thus a 300D vector is generated for each word as a result. To guarantee the same size for ELMo embeddings, a 300D position-wise feed-forward network is applied above them. The hidden states of all the BiLSTMs for each direc-

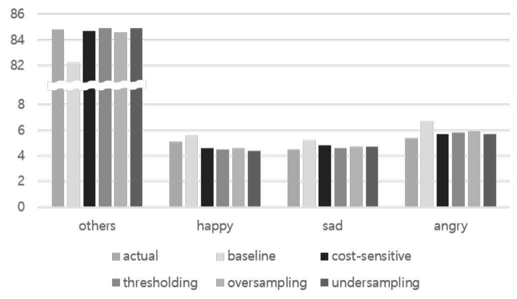

Figure 3: Class distributions on test data. Actual is from the ground truth labels and the others are from the predicted labels by each model. These are the averages of 10 results with random initialization.

tion are 150D and the number of layers is 2.

Our model is trained using the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 and a batch size 64. We clip the norm of gradients to make it smaller than 3. Dropout (Srivastava et al., 2014) technique is applied to word embeddings with $p = 0.1$. We chose the best model based on a micro F1 score on the validation set.

5 Experiments

5.1 Effects of mismatch in class distributions

Fig. 3 shows that the class distribution of predictions from the baseline model without any methods applied is substantially different from that of the actual test data. On the other hand, when the proposed methods are applied, the gap becomes much smaller. From this result, we conjecture that the difference in output distributions could be a reason for poor performance of the baseline compared to the proposed methods, as presented in Table 1.

5.2 Single model methods

Table 1 shows the accuracy and micro F1 scores of variants of our methods and baselines on the test set. We report the mean and standard deviation of 10 experimental runs (with the same hyperparameters) for each methods. And all the models were chosen based on their performance on the validation set.

The reported results show that proposed methods except undersampling are effective for enhancing both accuracy and F1 score. This means that alleviating the difference of class distribution is the key factor for the higher performance. In the case of undersampling, since the total size of training data decreases, the model seems to fail to capture the general semantics. The result is consistent with Buda et al. (2018), where the undersampling solely does not bring a performance gain for deep learning models. On the other hand, in our experiments, thresholding and cost-sensitive learning were the most effective approaches when a single model is used.

Approach	**Acc**	(±)	**F1**	(±)
Baseline (organizers)	-	-	.587	-
Baseline (ours)	.914	.005	.726	.008
Oversampling	.922	.004	.733	.012
Undersampling	.919	.006	.719	.013
Thresholding	**.924**	.002	.738	.010
Cost-Sensitive	.924	.004	**.739**	.010

Table 1: Comparison of single model approaches on the test set.

Approach	**Acc**	**F1**
Baseline (ours)	.921	.743
Oversampling	.930	**.758**
Undersampling	.930	.753
Thresholding	.930	.752
Cost-Sensitive	**.931**	.757
Mixed (submitted)	**.933**	**.766**

Table 2: Comparison of ensemble approaches on the test set. 10 models were used for each ensemble result.

5.3 Ensemble methods

Table 2 reports the comparison of ensemble models. The results show that our methods consistently outperform the baseline. We can see that ensemble with bagging has a great effect on refining class distribution, and in this time, undersampling also showed a good performance. Overall, for ensemble methods, oversampling and cost-sensitive learning performed best. The version we submitted to the leaderboard was the ensemble of different methods selected by their performance on validation set, and achieved the official result of 0.766.

6 Conclusion

In this paper, we proposed several methods for alleviating the problems caused by difference in class distributions between training data and test data. We demonstrated that these methods have positive effects on the result performance. We also presented a novel semi-hierarchical neural architecture that effectively exploits the context and the utterance representation. For future work, we plan to conduct more systematic experiments on other data sets to generalize our results.

SSN_NLP at SemEval-2019 Task 3: Contextual Emotion Identification from Textual Conversation using Seq2Seq Deep Neural Network

B. Senthil Kumar, D. Thenmozhi, Chandrabose Aravindan, S. Srinethe
Department of CSE, SSN College of Engineering, India
{senthil,theni_d,aravindanc}@ssn.edu.in
srinethe16108@cse.ssn.edu.in

Abstract

Emotion identification is a process of identifying the emotions automatically from text, speech or images. Emotion identification from textual conversations is a challenging problem due to absence of gestures, vocal intonation and facial expressions. It enables conversational agents, chat bots and messengers to detect and report the emotions to the user instantly for a healthy conversation by avoiding emotional cues and miscommunications. We have adopted a Seq2Seq deep neural network to identify the emotions present in the text sequences. Several layers namely embedding layer, encoding-decoding layer, softmax layer and a loss layer are used to map the sequences from textual conversations to the emotions namely Angry, Happy, Sad and Others. We have evaluated our approach on the EmoContext@SemEval2019 dataset and we have obtained the micro-averaged F1 scores as 0.595 and 0.6568 for the pre-evaluation dataset and final evaluation test set respectively. Our approach improved the base line score by 7% for final evaluation test set.

1 Introduction

Emotion identification is a process of identifying the emotions automatically from different modalities. Several research work have been presented on detecting emotions from text (Rao, 2016; Abdul-Mageed and Ungar, 2017; Samy et al., 2018; Al-Balooshi et al., 2018; Gaind et al., 2019), speech (Arias et al., 2014; Amer et al., 2014; Lim et al., 2016), images (Shan et al., 2009; Ko, 2018; Ayvaz et al., 2017; Faria et al., 2017; Mohammadpour et al., 2017) and video (Matsuda et al., 2018; Hossain and Muhammad, 2019; Kahou et al., 2016). Emotion understanding from video may be easier by analyzing the body language, speech variations and facial expressions. However, identification of emotions from textual conversations is a challenging problem due to absence of above factors. Emotions in text are not only identified by its cue words such as *happy, good, bore, hurt, hate* and *fun*, but also the presence of interjections (e.g. "whoops"), emoticons (e.g. ":)"), idiomatic expressions (e.g. "am in cloud nine"), metaphors (e.g. "sending clouds") and other descriptors mark the existence of emotions in the conversational text. Recently, the growth of text messaging applications for communications require emotion detection from conversation transcripts. This helps conversational agents, chat bots and messengers to avoid emotional cues and miscommunications by detecting the emotions during conversation. EmoContext@SemEval2019 shared task (Chatterjee et al., 2019) goal is to encourage more research in the field of contextual emotion detection in textual conversations. The shared task focuses on identifying emotions namely Angry, Happy, Sad and Others from conversation with three turns. Since, emotion detection is a classification problem, research works have been carried out by using machine learning with lexical features (Sharma et al., 2017) and deep learning with deep neural network (Phan et al., 2016) and convolutional neural network (Zahiri and Choi, 2018) to detect the emotions from text. However, we have adopted Seq2Seq deep neural network for detecting the emotions from textual conversations which include sequence of phrases. This paper elaborates our Seq2Seq approach for identifying emotions from text sequences.

2 Related Work

This section reviews the research work reported for emotion detection from text / tweets (Perikos and Hatzilygeroudis, 2013; Rao, 2016; Abdul-Mageed and Ungar, 2017; Samy et al., 2018; Al-Balooshi et al., 2018; Gaind et al., 2019) and text conversations (Phan et al., 2016; Sharma et al., 2017; Zahiri and Choi, 2018).

Sharma et al. (2017) proposed a methodology to create a lexicon - a vocabulary consisting of positive and negative expressions. This lexicon is used to assign an emotional value which is derived from a fuzzy set function. Gaind et al. (2019) classified twitter text into emotion by using textual and syntactic features with SMO and decision tree classifiers. The tweets are annotated manually by Liew and Turtle (2016) with 28 fine-grained emotion categories and experimented with different machine learning algorithms. Results show that SVM and BayesNet classifiers produce consistently good performance for fine-grained emotion classification. Phan et al. (2016) developed an emotion lexicon from WordNet. The conversation utterances are mapped to the lexicons and 22 features are extracted using rule-based algorithm. They used fully connected deep neural network to train and classify the emotions. TF-IDF with handcrafted NLP features were used by Al-Balooshi et al. (2018) in logistic regression, XGBClassifier and CNN+LSTM for emotion classification. The authors found that the logistic regression performed better than the deep neural network model. All the models discussed above considered the fine-grained emotion categories and used the twitter data to create a manually annotated corpus. These models used the rule-based or machine learning based algorithms to classify the emotion category.

A new C-GRU (Context-aware Gated Recurrent Units) a variant of LSTM was proposed by Samy et al. (2018) which extracts the contextual information (topics) from tweets and uses them as an extra layer to determine sentiments conveyed by the tweet. The topic vectors resembling an image are fed to CNN to learn the contextual information. Abdul-Mageed and Ungar (2017) built a very large dataset with 24 fine-grained types of emotions and classified the emotions using gated RNN. Instead of using basic CNN, a new recurrent sequential CNN is used by Zahiri and Choi (2018). They proposed several sequence-based convolution neural network (SCNN) models with attention to facilitate sequential dependencies among utterances. All the models discussed above show that the emotion prediction can be handled using variants of deep neural network such as C-GRU, G-RNN and Sequential-CNN. The commonality between the above models are the variations of RNN or LSTM. This motivated us to use the Sequence-to-Sequence (Seq2Seq) model which consists of stacked LSTMs to predic the emotion labels conditioned on the given utterance sequences.

3 Data and Preprocessing

We have used the dataset provided by EmoContext@SemEval2019 shared task in our approach. The dataset consists of training set, development set and test set with 30160, 2755 and 5509 instances respectively. The dataset contains sequence id, text sequences with three turns which include user utterance along with the context, followed by emotion class label. The task is to label the user utterance as one of emotion class: happy, sad, angry or others. The textual sequences contain many short words. In preprocessing, these words are replaced with original or full word. We resort to build a look-up table which replace ''m', with 'am', ''re' with 'are', ''ere' with 'were', 'n't' with 'not', ''ll' with 'will', ''d' with 'would', 'what's' with 'what is' and 'it's' with 'it is'. The sequences are converted to lower case. Also, the three turns/sentences are delimited with "eos" in the input sequences.

4 Methodology

Seq2Seq model is the most popular model in learning the target sequence conditioned on the source sequence. The Seq2Seq model is adopted to map the sequences of n words with a target label (n:1 mapping). This model has an embedding layer, an encoder, a decoder and a projection layer as shown in Figure 1.

Once the dialogue sentences are preprocessed, the first three turns of each instance are considered as the input sequences w_1, w_2,..,w_n, and the corresponding label e is considered as the target sequence. For example, the given instance "13 Bad Bad bad! That's the bad kind of bad. I have no gf sad" is converted into input sequence "bad eos bad bad that is the bad kind of bad eos i have no gf" and target label "sad". The input sequences and the target label are converted into its corresponding word embeddings by the embedding layer. The vector representation for each word is derived at embedding layer by choosing a fixed vocabulary of size V for input sequences and target labels.

Now, the encoder which uses Bi-LSTM, encode these embeddings into a fixed vector representa-

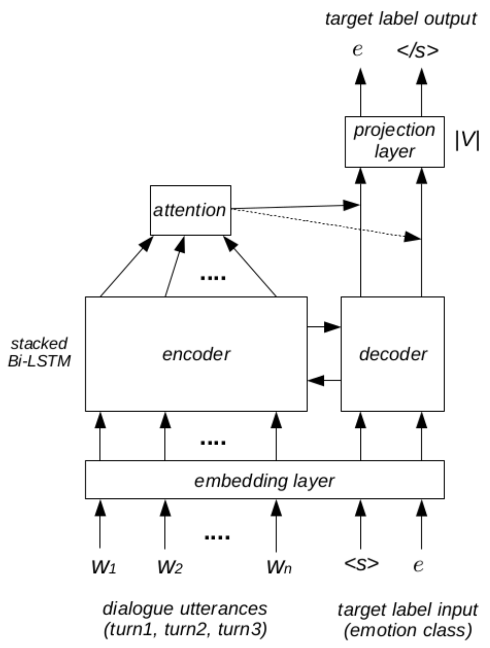

Figure 1: System Architecture

tion s which also represents the summary of input sequences. Once the source sequences are encoded, the last hidden state of the encoder is used to initialize the decoder. The projection layer is fed with the tensors of the target output label. Given the hidden state h_t , the decoder predicts the label e_t. However, h_t and e_t are conditioned on the previous output e_{t-1} and on the summary s of the input sequence. The projection layer is a dense matrix to turn the top hidden states of decoder to logit vectors of dimension V. Given the logit values, the training loss is easily minimized by using standard SGD optimizer with a learning rate. The model is also trained with the attention mechanism, which computes the attention weight by comparing the current decoder hidden state with all encoder states. The detailed description of working principle about Seq2Seq model is described in (Sutskever et al., 2014).

We have adopted Neural Machine Translation[1] code to implement our Seq2Seq deep neural network. Several variations have been implemented by varying the number of layers, units and attention mechanisms. It is evident from the earlier experiments (Sutskever et al., 2014; Thenmozhi et al., 2018) that bi-directional LSTM performs better for short text sequences. Hence, we have used it for encoding and decoding processes. The models were trained for 30000 steps with drop out of 0.2. We have utilized two attention wrappers namely Normed_Bahdanau (NB) (Sutskever et al., 2014; Bahdanau et al., 2014) and Scaled_Luong (SL) (Luong et al., 2015, 2017).

Since, the model was developed using deep learning technique, it does not require much of linguistic features such as stemming, case normalization and PoS in identifying the emotion cue words. These linguistic phenomena could be captured by the encoder RNNs in sequence-to-sequence (Seq2Seq) model. The other statistical features such as the word frequency are also not considered as input to the model, because the presence of particular cue alone does not guarantee to detect emotions in the text.

5 Results

Our approach is evaluated on EmoContext@SemEval2019 data set. During development, we have implemented our variations with and without end of sentence (EOS) delimiter. We have built the models using entire training set (No_split) and train-validation splits (TV_split). 27160 and 3000 instances from training data were considered as training and validation set in TV_split. The performance was measured in terms of micro-averaged F1 score (F1μ) for the three emotion classes namely Angry, Happy and Sad.

We have submitted eleven runs for EmoContext@SemEval2019 shared task on pre-evaluation dataset. The results obtained for pre-evaluation dataset are given in Table 1.

We observe from Table 1 that Normed_Bahdanau attention mechanism performs better than Scaled_Luong. Model building

Table 3: Class-wise F1 Score for Final Evaluation Test Data.

with TV_split performs better than the model without split. The incorporation of delimiter text EOS also improved the performance of our approach. Further, the performance degrades with the increase in number of layers. Thus, 2 layered LSTM with TVsplit, EOS delimiter and Normed_Bahdanau attention mechanism perform better on the pre-evaluation dataset of EmoContext@SemEval2019 and this architecture is considered for evaluating the final-evaluation test set. The final evaluation submissions are based upon the variations in TV_split ratio and the number of units as 16, 32, 64, 128 and 256. For TV_split_1, the development set (2755 instances) given by EmoContext@SemEval2019 was considered as a validation set. The other two TV_splits are by keeping the validation set as 1/5 (TV_split_2) and 1/3 (TV_split_3) of training set. The results of our submissions on final evaluation test data are given in Table 2. It is observed from Table 2 that 64U_TV_split_1 model outperforms all the other models with 0.656752 F1μ score. This score is higher than the base line score with 7% improvement. Table 3 shows the class-wise performance of our models on final evaluation set. Our models perform better for Angry class than the other two classes namely Happy and Sad.

6 Conclusion

We have adopted a Seq2Seq deep neural network to identify the emotions present in the text sequences. Our approach is evaluated on the EmoContext@SemEval2019 dataset. The input sequences are pre-processed by replacing the short hand notations and by introducing a delimiter string. The sequence is vectorized using word embeddings and given to bi-directional LSTM for encoding and decoding. We have implemented several variations by changing the parameters namely, number of layers, units, attention wrappers, with and without delimiter string and train-validation split. The performance is measured using micro-averaged F1 score on three emotion class labels namely Angry, Happy and Sad. Our experiments on development set show that 2 layered LSTM with Normed_Bahdanau attention mechanism with delimiter string and train-validation split performs better than all the other variations. Three variations of train-validation split ratio were experimented on final evaluation test data by varying the number of units with the best parameter values that are learnt during the development phase. 64U_TV_split_1 model performs better than all the other runs we have submitted to the task. This model shows 7% improvement than the base line on final evaluation test set. Our Seq2Seq model can be improved further by incorporating the soft attention mechanism which uses joint distribution between attention and output layer (Shankar et al., 2018).

Abstract

Emotion detection from user-generated contents is growing in importance in the area of natural language processing. The approach we proposed for the EmoContext task is based on the combination of a CNN and an LSTM using a concatenation of word embeddings. A stack of convolutional neural networks (CNN) is used for capturing the hierarchical hidden relations among embedding features. Meanwhile, a long short-term memory network (LSTM) is used for capturing information shared among words of the sentence. Each conversation has been formalized as a list of word embeddings, in particular during experimental runs pre-trained Glove and Google word embeddings have been evaluated. Surface lexical features have been also considered, but they have been demonstrated to be not usefully for the classification in this specific task. The final system configuration achieved a micro F1 score of 0.7089. The python code of the system is fully available at `https://github.com/marcopoli/EmoContext2019`.

1 Introduction

The task of emotion detection from a text is growing in importance as a consequence of a large number of possible applications in personalized systems. This task can be considered as part of the sentiment analysis process also if it differs about the information collected. Sentiment Analysis aims to detect the polarity (positive, negative or neutral) about a topic of discussion or a specific aspect. On the contrary, Emotion Detection aims to associate an emotional label to textual content to explicitly understand what is the emotional state of the user while writing it. The final user behaviors are strongly influenced by the emotional state which she is in. Following the studies of Ekman (Ekman et al., 1987), Plutchik (Plutchik, 1990), Parrot (Parrott and Sabini, 1990), and Frijda (Frijda and Mesquita, 1994) some emotions can be considered "basics" and consequently more important than others during everyday decisions. Their identification is, therefore, one crucial aspect for applications in commerce, public health, disaster management, and trend analysis (consumer understanding). In the research area of emotion detection and sentiment analysis, many challenges are organized every for overcoming the state-of-the-art results. *SemEval* [1] is one of the most famous among them and it provides a large amount of data every year useful for supporting the research about the topic and commonly considered as state-of-the-art. Recently the best results are obtained by machine learning approaches (Colneriĉ and Demsar, 2018) based on recurrent neural networks (long short-term memory network) (Li and Qian, 2016; Wöllmer et al., 2010). These algorithms have quickly become the standard approach for solving the Emotion detection task placing great emphasis on the strategies used for formalizing the training data (Levy et al., 2015; Goldberg and Levy, 2014) and for optimizing hyper-parameters of the algorithms (Vilalta and Drissi, 2002).

2 Background and Related Work

Machine learning, and more recently deep learning algorithms, have been demonstrated to be the best option when approaching classification tasks of contents in natural language (Collobert and Weston, 2008). Example of state-of-the-art results have been achieved for hate speech detection (Zhang et al., 2018), part-of-speech tagging (Blevins et al., 2018) and name entity recognition (Chiu and Nichols, 2016; Chen et al., 2018).

Typical emotion detection systems work mostly with features directly extracted from text (Kao

[1] `http://alt.qcri.org/semeval2019/`

et al., 2009). A simple vector-space strategy can often be sufficient for resolving easier tasks, but it suffers from sparsity and lack of generalization. In (Bengio et al., 2003) the author exposes the concept of word embedding summarized as a ”learned distributed feature vector to represent similarity between words”. This concept has been exploited by Mikolov (Mikolov et al., 2013b) through word2vec, a tool for implementing work embeddings through two standard approaches: skip-gram (Guthrie et al., 2006) and CBOW (Mikolov et al., 2013a). An alternative word embedding representation is described in (Pennington et al., 2014) as Glove trained on global word-word co-occurrence counts and able to use statistics for producing a word vector space with meaningful sub-structure. However, the use of word embeddings enriched with surface lexical features is common in sentiment classification algorithms. The relevance of these features is supported by Mohammad et al. (Mohammad et al., 2013) that produced the top ranked system at SemEval-2013 and SemEval-2014 for sentiment classification of Tweets using emotional lexicons. Moreover, word and character n-grams, number of URL, mentions, hashtags, punctuations, word and document lengths, capitalization, and more are often used for improving the classification performances (Shojaee et al., 2013). A support for a correct classification is also provided by lexical resources used for look up the sentiment of words in sentences. Linguistic features include syntactic information such as Part of Speech (PoS) which can provide relevant information for formalizing the syntactical form of the sentence. These aspects have been considered in our final classification system in order to provide a robust and updated tool for emotion detection from Tweets.

3 The EmoContext task at SemEval 2019

The EmoContext task at SemEval 2019 (Chatterjee et al., 2019) [2] aims to understand the emotion of the last turn expressed by a short dialog composed of three turns extracted from social media. The training set is composed of 30k records annotated with three main emotions: Happy, Sad, Angry and the ’other’ class that includes all other not annotated emotions following a data distribution of respectively 5k, 5k, 5k, 15k. The test set is composed by 5509 records, 2,95% of the total ’Happy’ , 2,68% about ’Sad’, and 3,15% of ’Angry’ records. The tuning of the systems has been performed over a ”dev set” composed by 2755 records with a class distribution similar to the one of the test set. Evaluation has been performed by calculating micro-averaged F1 score ($\mu F1$) for the three emotion classes, i.e. Happy, Sad and Angry.

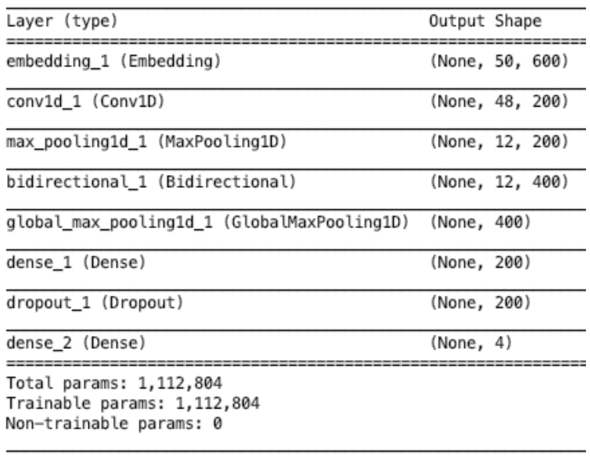
4 Classification model

The model of emotion understanding applied in this study is based on the synergy between two deep learning classification approaches: the convolutional neural networks (LeCun et al., 1989) (CNN) and the long-short-term memory networks (LSTM) (Hochreiter and Schmidhuber, 1997).

The conjunct use of a CNN and an LSTM has been demonstrated to be very efficient with textual data (Chiu and Nichols, 2016; Ordóñez and Roggen, 2016). Fig. 1 shows the complete stack of the classification model for emotion understanding. Data are provided as the input of the model through a word embedding layer. Each n-gram of the record has been mapped into a k-dimensional word embedding vector. The dimension of the word embedding is different for each strategy of encoding evaluated, and the length of the record has been truncated at max 50 tokens. Words not found in the embedding dictionary have been encoded using a randomly selected word. The output of the previous layer has been provided to a 1D convolution layer with 200 filters and a kernel of size 3x3. The activation function used is the rectified linear unit function (’ReLU’) (Nair and Hinton, 2010). The output has been downsampled by a max pooling layer using a pool size of 4 along the number of tokens. The output of dimension 12x200 has been passed as input of a Bidirectional LSTM layer based, as for the CNN, on the ReLU activation function. The difference with a classic LSTM layer is the ability to find correlation among words in both the directions. In order to ’flatten’ the results, we used a max pooling strategy for considering only the highest value obtained for each slot and each direction. The resultant 1x400 vector has been provided to a dense layer without activation function with the purpose to reduce the dimensionality of the vector obtained. Finally, another dense layer with a soft-max activation function has been applied for estimating the probability distribution of each of the four classes of the dataset. The model has



```

been trained using the categorical cross entropy loss function (Goodfellow et al., 2016) and Adam optimizer (Kingma and Ba, 2014).

5 Data processing

Each discussion in the dataset is provided as a set of three consecutive turns. We consider the dialog as a single textual content obtained concatenating the three turns into a single textual entity. Textual data have been processed for obtaining surface lexical features over the whole record. In particular, we calculate the following:

- **Statistics (RStat)**: number of tokens and characters; percent of uppercase characters and special tokens such as numbers, email, money, phone numbers, date and time, emoticons, stopwords, names, verbs, adverbs, pronoun; percent of punctuations including white spaces, exclamation points and word in a common words English dictionary [3];
- **Sentiment (RSent)**: the polarity of the record obtained through Stanford CoreNLP [4] and the percent of positive/negative words analyzed by TextBlob [5];

The textual record has been normalized before their transformation into word embeddings. We performed the correction of misspellings and the stripping of repeated characters using the Ekphrasis[6] python library. The record has been consequently tokenized using the TweetTokenizer of the ”nltk” suite [7] and when required for the word embedding lookup, they have been transformed into lower case. For each token we calculate, other extra features:

- **Statistics (TStat)**: percentage upper case characters; percentage repeated characters, before the text normalization;
- **Sentiment (TSent)**: sentiment of the token obtained using TextBlob;
- **Sentiment (TLex)**: part of speech; name entity label; is exclamation mark; is question mark; is a stopword; is in a dictionary of common English Words;

The transformation of each token in a word embedding has been performed using the following pre-trained resources:

- **Google word embeddings (GoEmb)**[8]: 300 dimensionality word2vec vectors, case sensitive, composed by a vocabulary of 3 millions words and phrases that they trained on roughly 100 billion words from a Google News dataset;
- **Glove (GLEmb)**:[9]: 300 dimensionality vectors, composed by a vocabulary of 2.2 millions words case sensitive trained on data crawled from generic web pages;
- **Sentiment140 positive (SentPosEmb) and negative (SentNegEmb)**: word embeddings created over the tweets annotated in the Sentiment140 dataset [10]. We used a word2vec skip-gram strategy over a window of 5 positions, 30 epochs and considering only words counted at least five times in the dataset. We produced two word embeddings (one for positive tweets and one for negative) of 100 dimensionality vectors each case sensitive;
- **Generic Tweets (GTEmb)**: word embeddings created over 1.1 million of generic tweets in English language. As previously, we used the skip-gram strategy over a window of 5 positions, 30 epochs min word count of 5 for obtained 300 dimensionality vectors case sensitive.

6 Experiments, discussion and results

We began to configure the proposed model pointing attention on the strategy to formalize records. We decided to train our model for 10 epochs for each run using a batches size equal to 64 on the *train* dataset and validating the model on the *dev* dataset. For each run, we vary the word embedding formalization. In Tab. 1 are shown the results that allow us to observe how the concatenation of Google pre-trained word embeddings (GoEmb) and the words embeddings obtained by general tweets (GTEmb) is the most promising for the classification task in term of micro F1. It is also important to note that the value of precision obtained by the concatenation of Glove pre-trained word embeddings (GLEmb) and the GTEmb set is the higher obtained but very unbalanced with the recall. This is a clear index of the instability of the model. The second step performed in this tuning phase has been the inclusion of surface lexical features about the records and every single token. In order to understand the influence of each set of lexical features on the final micro F1 score, we performed an ablation test. The results in Tab. 2 demonstrate that lexical features, in this specific classification task and dataset do not contribute positively to the final performances of the model. As a consequence of this observation, we decided to do not use them in our model.

Following the goal to make the model robust, we decided to train it for its final configuration also on data which comes from the dev set about the classes Happy, Sad and Angry. Then we trained the model again for 10 times on 100 epochs, with a batch size of 64 using GoEmb + GTEmb for data embeddings with a validation set of 20% of training data and an early stop when the micro F1 of the validation would overcome 0.75. We obtained three final models with micro F1 respectively of 0.7714, 0.8078 and 0.78163. We used these final models to classify the test set adopting a majority vote algorithm of the predictions. This strategy has allowed us to reach a final evaluation score of 0.7089 in the final task leader-board.

7 Conclusion

In this work, we proposed a robust emotion detection classifier based on the synergy of a CNN and an LSTM deep learning algorithm. The model has been evaluated with different data formalization and configurations for finding the one which better fits the data provided for the EmoContext task at SemEval-2019. Future work will include the evaluation of other model shapes and deep learning algorithms in order to increase the final performances of the system. Abstract

In this paper, we present our participation to the EmoContext shared task on detecting emotions in English textual conversations between a human and a chatbot. We propose four neural systems and combine them to further improve the results. We show that our neural ensemble systems can successfully distinguish three emotions (SAD, HAPPY, and ANGRY), and separate them from the rest (OTHERS) in a highly-imbalanced scenario. Our best system achieved a 0.77 F_1-score and was ranked fourth out of 165 submissions.

1 Introduction

Detecting emotions in text is a key task in many scenarios, such as social listening, personalised marketing, customer caring, or in building emotionally intelligent chat-bots: in this last case, the task complexity increases, since a bot's response might influence the user's emotion.

The EmoContext shared task (Chatterjee et al., 2019) was posed as a sequence classification task. Given a set of three conversational turns (human–bot–human), the goal is to predict the emotion of the third turn. The label space contains the emotions SAD, ANGRY and HAPPY, and the label OTHERS denoting anything else (emotional or non-emotional), as illustrated in Table 1.

In this paper, we present our approaches to EmoContext shared task, and describe our best system in details. Additionally, we show that: (a) this task is very difficult even for humans (Section 2.2); (b) for this task, neural approaches outperform a strong non-neural baseline (Section 4); (c) an ensemble of neural systems with different architectures significantly outperforms the best neural model in isolation (Section 4).

[*] The first four authors have contributed equally to this work and are ordered alphabetically.

2 Data

The data released by the organisers consist of English user-chatbot interactions occurring in an Indian chat room. An overview of the dataset is provided in Table 2. It can be seen that the label distribution is highly imbalanced, and different for the training set than for the development (dev) and test sets (a 14:18:18:50 distribution for the training set, and a 5:5:5:85 distribution for the dev and test sets). To overcome this issue we tested three strategies: (1) down-sampling the dataset to its smallest class; (2) up-sampling the emotion-related labels with an in-house dataset; and (3) up-sampling by duplicating a random portion of the dataset. None of these solutions worked, and therefore, we trained our best models using the data provided by the organisers.

2.1 Preprocessing

The language of this corpus presents many of the features of micro-blogging language: large use of contractions (e.g. *I'm gonna bother*), elongations (e.g. *a vacation tooooooo!*), non-standard use of punctuation (e.g. *gonna explain you later..!*), incorrect spelling (e.g. *U r*).

To properly handle this language, we build a simple preprocessing pipeline which consists of: (1) the NLTK `TweetTokenizer` (Bird and Loper, 2004); and (2) a normalisation strategy that reduces sparseness by lowercasing all the words and converting elongations like *looool* to *lol*. These steps are used in all the experiments. Some of our models use additional preprocessing described further in the text.

ID	TURN 1	TURN 2	TURN 3	LABEL
71	Not good	:(why not..?	Been sick for one week	SAD
78	I hate Siri and it's friends	if you hate them , they are not your friends then xD	Yeah and u r Siri's friend so I hate utoo	ANGRY
91	Now I'm doing my dinner	I can see you!	How can you see me??	OTHERS
140	How about you tired of life or just your day?	Aha I' happy today, thanks for asking	Wow great..!	HAPPY

Table 1: Examples from the training dataset.

CLASS	TRAIN	DEV	TEST
SAD	5463	125	250
HAPPY	4243	142	284
ANGRY	5506	150	298
OTHERS	14948	2338	4677
total	30160	2755	5509

Table 2: Distribution of classes.

2.2 Manual Validation

To check how difficult this task is, for a trained human annotator, and get an estimate of the expected upper limit for our classification models, we asked two fluent (but non-native) English speakers with previous annotation experience to label 300 randomly selected instances from the dev set. The annotators achieved the official F_1-score of 0.73 and 0.72 against the 'gold' labels, and a 0.71 F_1-score among themselves. The only observed misclassifications between "emotional" classes were those between SAD and ANGRY. The highest number of disagreements the annotators had was between the OTHERS and the "emotional" classes. This showed that: (1) the task is naturally difficult (the trained human annotators reach 0.73 F_1-score at the most); (2) the main problem is distinguishing between the OTHERS class and the "emotional" classes.

3 Experimental Setup

We first randomly selected two times 2754 instances from the official training set, maintaining the class ratio that was announced for the official dev and test sets (4:4:4:88) resulting in 110 instances for the SAD, ANGRY and HAPPY, and 2424 instances for the OTHERS class. These two datasets we refer to as intDev and intTest sets, while the rest of the training dataset we refer to as intTrain.

We train and tune our four neural models (Section 3.1) using intTrain and intDev sets, and test them on the intTest, and the official dev and test sets (in different phases of the competition). We further experiment with combining their softmax output per class probabilities (Section 3.2).

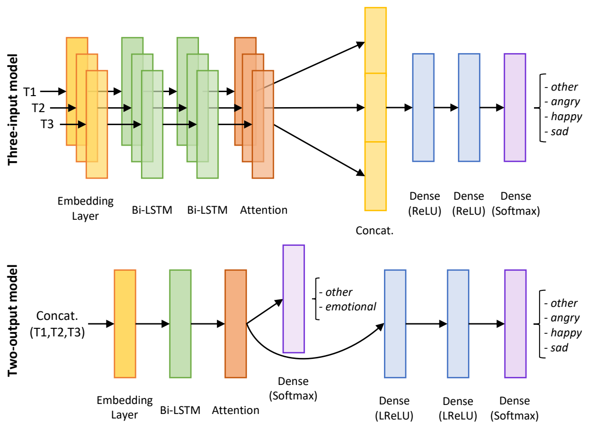

Figure 1: Model architectures for the three-input (IN3) and two-output (OUT2) models.

As a strong non-neural baseline we set up a linear SVM model with word and character n-grams (1-6) as features.[1]

3.1 Neural Models

We propose four neural network models that slightly differ on their objective.

3.1.1 Three-Input Model (IN3)

Having the three conversation turns (T1, T2, and T3), we explicitly represent the position of each sequence in the conversation by creating an input branch for each turn. The branches are identical and represent the text using word embeddings that feed a 2-layer bidirectional Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997). An attention mechanism (Yang et al., 2016) combines its hidden states. This architecture allows to independently process and attend to the most relevant parts of T1, T2, and T3. The information is later combined by a simple concatenation and few fully connected dense layers. The model architecture is shown in Figure 1.

We use a proprietary model © Symanto Research to obtain 300-dimensional word embeddings on the English Wikipedia. The performance

[1]For the implementation of the baseline we use `scikit-learn` (Pedregos et al., 2011). All the neural models are based on `Tensorflow` (Abadi et al., 2016), and for the ensemble models we use `Weka` (Hall et al., 2009).

of this representation is comparable with fastText (Bojanowski et al., 2017) but the resulting embedding model is fifty times lighter. We apply 10% dropout on the output of the embedding and concatenation layers, and layer normalisation (Ba et al., 2016) after the concatenation and before the output softmax.

3.1.2 Two-Output Model (OUT2)

Motivated by the findings of the manual validation (Section 2.2), we build this model in an attempt to ease the *emotional* vs. OTHERS classification. For this reason, we use a multi-task learning approach and add an auxiliary output whose label space conflated the ANGRY, HAPPY, and SAD labels into a single *emotional* one. We hypothesise that this approach is well suited to our unbalanced scenario, with the dominant OTHERS class.

The model architecture is similar to our three-input one (see Figure 1). However, the three conversational turns (T1, T2, and T3) are fed to the model as a single concatenated input, with additional tokens to mark the turn boundaries. The auxiliary output is connected to the output of the attention. This forces the attention weights to favour the *emotional* vs. OTHERS task.

We use the pretrained word embeddings described in Section 3.1.1. Our dense layers use the leaky version (LReLU) of the Rectified Linear Unit (ReLU) activation. In addition, we use the attention mechanism (He et al., 2017). Finally, we use the batch normalisation (Ioffe and Szegedy, 2015) to process the attention output.

3.1.3 Sentence-Encoder Model (USE)

As an exploration in transfer-learning, we build a simple feed-forward network together with a fine-tuned Universal Sentence Encoder (Cer et al., 2018). As input, we use the first (T1) and the last (T3) turn of the conversation, as we observed that adding the second turn (T2) leads to lower performances of this model.

3.1.4 BERT Model (BERT)

We fine-tune a BERT-base model (Devlin et al., 2018), modelling the problem as a sentence-pair classification problem: we use the first and the third conversational turn (T1 and T3) as the first and the second sentence respectively, completely ignoring the utterance by the bot (T2). We use this model in combination with a lexical normalisation system (van der Goot and van Noord, 2017).

We also built a neural model combining BERT, IN3, and OUT2, but it resulted in lower performance than any of those models separately, and is thus not presented here.

3.2 Ensemble Models

As we noticed that our neural systems have different strengths and weaknesses on the "emotional" classes (see Table 4), we combine them by using the softmax output probabilities of each class from all four models (16 features in total) and training several classification algorithms: Naïve Bayes (John and Langley, 1995), Logistic Regression (le Cessie and van Houwelingen, 1992), Support Vector Machines (Keerthi et al., 2001) with normalization (SVM-n) or standardization (SVM-s), JRip rule learner (Cohen, 1995), J48 (Quinlan, 1993), Random Forest (Breiman, 2001), and various meta-learners on top of them or their subsets.

The neural systems are trained and tuned on the intTrain and intDev sets, and their per class probabilities are obtained for the intTest, dev, and test sets. The ensemble models are then trained on the intTest+dev set and tested on the official test set. For this second classification stage, we thus have 5509 instances for training (intTest+dev) and 5509 for testing (the official test set).

4 Results

We evaluate our systems using precision (P) and recall (R) per each emotional class, and the micro F_1-score over the three "emotional" classes (the metric used by the task organisers for the official evaluation). The results for the baseline and the four neural systems are presented in Table 4. The results of the best ensemble models (trained on the per class probabilities of the four neural models) are presented in Table 5. We can notice that:

(1) Our best neural system (IN3) reaches .73 on the intTest set and .72 on the official test set.

(2) All our neural systems have a noticeably higher recall on the HAPPY and SAD classes on the intTest set than on the official dev and test sets.

(3) Our two best neural systems (IN3 and OUT2) have a noticeably lower precision on the HAPPY and SAD classes on the intTest set than on the official dev and test sets.

(4) Ensemble models reach .77 for three classification algorithms in the 10-fold cross-validation setup on the intTest+dev set, and that score is maintained on the official test set only by SVM.

Table 5: Results of our best ensemble models in a 10-fold cross-validation setup on intTest+dev (CV), and training on intTest+dev and testing on test set. Our best system submitted to the competition is marked in bold.

5 Error Analysis

The confusion matrix for our best system is given in Figure 2. The highest number of confusions is between the HAPPY and OTHERS classes, followed by confusions between the ANGRY and OTHERS.

Given the findings of our manual validation (Section 2.2), we performed an additional experiment. All instances for which our best system did not predict the gold label (355 instances), we presented to one of our annotators together with its gold and predicted labels (in random order), and asked him to choose the correct one, or assign a NOT SURE label. The annotator chose the label predicted by our system in 46% of the cases, the gold label in 39% of the cases, and in 15% of the cases the annotator was not sure. Several examples of instances for which the predicted label did not match the "gold" label are presented in Table 3.

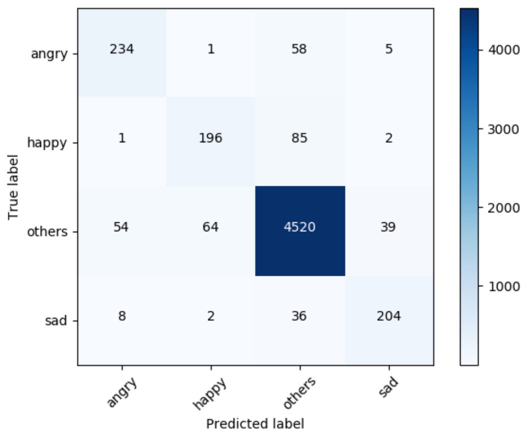

Figure 2: Confusion martix for the best model.

6 Conclusions

We presented our most successful approaches to the EmoContext shared task, with the goal of predicting the emotion (SAD, HAPPY, ANGRY, or OTHERS) in the third turn of a human–chatbot–human interaction, with an additional challenge of having a very unbalanced distribution of classes.

We showed that the task is difficult even for trained human annotators, and that our best neural systems can reach the human performance (.72 F-measure). Furthermore, we showed that a SVM classifier trained on the softmax output per class probabilities of four different neural systems can improve results scoring a .77 F_1-measure over the three emotional classes, and reaching thus the fourth place in the official competition.

Appendix A: Model Parameters

Three-input model parameters: 20k most frequent tokens per branch, maximum text length of 25, 1024 LSTM units per layer, 300-dimensional dense layers, batch size of 128, 15 training epochs, and the Adam weight optimization.

Two-output model parameters: 20k most frequent tokens, maximum text length of 100, 300 LSTM units, batch size of 128, dense layer sizes of 300 and 150 (respectively), 10 training epochs, and the Adam weight optimization.

TDBot at SemEval-2019 Task 3: Context Aware Emotion Detection Using A Conditioned Classification Approach

Sourabh Maity
Teradata India Pvt. Ltd.
Hyderabad, India
sourabh.maity@teradata.com

Abstract

This paper presents the system developed to detect the contextual emotion (*SemEval19 Task 3* (Chatterjee et al., 2019)) from conversational dialogue. The system models the fact that emotion of a dialogue depends on the context of the conversation and not independent. It uses multiple layers in the deep learning model where each layer *bootstraps* with the context of what has already been said in the conversation.

1 Introduction

Over the years, we are getting more and more comfortable in text based conversations over the web, leading to increased interest in emotion analysis. Such a conversation is no longer limited between humans, it is now mainstream to use chat bots at various domains, e.g., customer care, HR management, virtual doctor etc.
Needless to say that in a conversation human emotions needed to be handled with care and empathy. Due to this, the task of emotion detection is very important when our aim to use chat bots and voice assistants more effectively. It is more difficult when the conversation is text based, lack of facial expressions and voice modulations make detecting emotions in text a challenging problem (Gupta et al., 2017).
In this SemEval19 Task 3 there were total three turns of dialogues; *turn1* and *turn3* were spoken by one participant of the conversation and *turn2* was spoken by another participant as a reply of *turn1*. We are tasked to detect the emotion of *turn3*. So, *turn1* and *turn2* act as context for *turn3*. There are four different emotions in the data set, namely, *happy*, *sad*, *angry* and *others*. The problem is modeled as a four class classification problem where each of the emotions listed above is the target class.

2 System Description

2.1 Preprocessing

This section describes the preprocessing steps of the system. Few of the steps are standard; the steps are just mentioned and are not discussed in detail. Rather the steps which are critical for the performance in the task are discussed in detail. Standard steps are: converting all letters to lower case, removing numbers, removing white spaces, removing stop words, sparse terms and particular words. The most important preprocessing steps are:
Expanding abbreviations: In chat data there are infinite number of possible abbreviations or shorthand uses, most of which are not standard. Those abbreviations can not be left in the data set as is, because there are no embedding for those. In my system , it is chosen to expand the top 10% of such abbreviations and others are ignored. For this, I created a map of abbreviation to expansion manually by inspecting the data set.
Few examples: lol $\rightarrow$ laugh out loud, ur $\rightarrow$ you are etc.
Handling emojis: Emojis are the single most important piece of information in chat data. In most of the cases it is a huge clue about the emotion of the party in conservation. I had two options to handle emojis, one, to use some kind of embedding (Eisner et al., 2016) for emojis; two, convert emojis into text and then use word embedding. I chose to convert emojis into text; partly because of the robust performance of the word embeddings and partly because of lack of a proven quality embedding for emojis. Also, this conversion made the *weight of evidence* feature (see section 2.2.2) more effective.
Examples: 😄 $\rightarrow$ beaming face with smiling eyes, ☹ $\rightarrow$ sad face etc.
But, a conversion scheme shown in the above examples leads to infiltration of words like *face*, *with*. To avoid this, I created a list of stop-words

and removed those from the expanded text. With this modification the above examples will look like:
😁 $\rightarrow$ beaming smiling eyes, ☹ $\rightarrow$ sad.

2.2 Features

There were mainly two features, word embedding and weight of evidence. Each word in the conversation is embedded into a 300 dimensional embedding space and for each turn the weight of evidence is computed. I intentionally refrained myself from using any sentence encoder like BERT (Devlin et al., 2018) or ELMo (Peters et al., 2018), as I wanted to explore the lower level embedding of words rather than using sentence embeddings as back boxes.

2.2.1 Word Embeddings

In the system, word embeddings are created as an average of three word vectors, GloVe (Pennington et al., 2014), FastText (Bojanowski et al., 2016) and Paragram (John Wieting and Livescu, 2015). I used 300 dimensional word embeddings. The embedding vocabulary could cover ∼85% of the data set vocabulary (unique words in the data set) which in turn covered ∼97% of the entire text of the data set.

2.2.2 Weight of Evidence

Weight of evidence (WOE) is a measure of how much the evidence supports or undermines a hypothesis. Here the intention is to weigh the evidence of each word in determining the emotion of the conversation. WOE is defined as:

$$WOE_{word,event} = \ln \frac{\frac{N^{non-event}_{word}}{N^{totalnon-event}_{word}}}{\frac{N^{event}_{word}}{N^{totalevent}_{word}}}$$

where,
$N^{non-event}_{word}$: number of other class records that has the word
$N^{totalnon-event}_{word}$: total number of other class records
N^{event}_{word}: number of records of the class that has the word
$N^{totalevent}_{word}$: total number of records of the class

Top 1000 most common words for each of the emotion classes were collected and then their WOE is computed for each of the four emotion classes. In the example below the words are represented by four dimensional vector, those dimensions belong to the four emotion classes.

$WOE_{word,event}$	Word	
	`smiling`	`sad`
$WOE_{word,happy}$	0.9	0.2
$WOE_{word,sad}$	0.1	0.8
$WOE_{word,angry}$	0.2	0.1
$WOE_{word,others}$	0.6	0.5

Table 1: $WOE_{word,event}$ for words.

For each turn I add up the WOE vectors of the words in that turn. So, each turn also has a WOE embedding of four dimensions. This embedding is fed into the model as an auxiliary feature. When emojis were converted into text, the WOE vector of the words explaining an important emoji reflected the emotion nicely. Also, when an emoji is used multiple times, its effect is multiplied into the WOE embedding of the turn. For example, "😁 😁 😁 " in a turn produces the below WOE embedding:

$WOE_{word,event}$	turn = 😁😁😁
$WOE_{smiling,happy}$	2.7
$WOE_{smiling,sad}$	0.3
$WOE_{smiling,angry}$	0.6
$WOE_{smiling,others}$	1.8

Table 2: WOE embedding for turn "😁 😁 😁 ".

Please note that "😁 😁 😁 " was first converted into text as: beaming smiling eyes beaming smiling eyes beaming smiling eyes. In the above table WOE vector for the word "smiling" is shown. Similar exercise can be done for other words.

2.3 Deep Learning Model

Given the turns of a conversation, the target emotion label can be modeled in different ways. One, model the target label based on *turn3* only. Two, Consider all the turns as one single input of text (may be separated by EOS tokens) and from this learn the target label. But, none of the options are truly context aware. Construction of my model is based on the idea that every turn in a conversation builds on top of the previous turn. Also this task is treated as a multi-class classification problem where each emotion is treated as individual classes.
At the core of the system are three bi-directional

(Schuster and Paliwal, 1997) Gated Recurrent Unit (GRU) (Cho et al., 2014) layers, one each for the three turns in the conversation. Second and third layer are *derived* from their immediate previous layer. This is achieved by using the hidden states of a turn GRU layer to initialize the subsequent turn's GRU layer. Hence, when turn three layer starts with the hidden state of turn two layer which has already summarized the *context* of the ongoing conversation, it is building on top of the existing context. I see it as each layer is conditioned on the what has already been conversed before it. Used model is depicted in Figure 2. Then the additional features, i.e., the WOE values were introduced into the model by concatenating with the intermediate latent representation of the conversation.

2.3.1 Gated Recurrent Unit: GRU

A GRU unit (in Figure 1) can be represented by the following equations:

$$\begin{aligned} z_t &= \sigma\big(x_t U^z + h_{t-1} W^z\big) \\ r_t &= \sigma\big(x_t U^r + h_{t-1} W^r\big) \\ \tilde{h}_t &= \tanh\big(x_t U^h + (r_t * h_{t-1}) W^h\big) \\ h_t &= (1 - z_t) * h_{t-1} + z_t * \tilde{h}_t \end{aligned}$$

Here r is the reset gate, and z is the update gate. Intuitively, the reset gate determines how to combine the new input with the previous memory, and the update gate defines how much of the previous memory to keep. And h_t is the new hidden state.

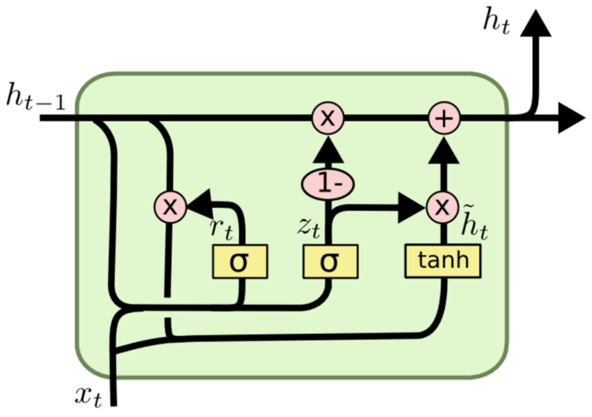

Figure 1: Gated Recurrent Unit. Figure adapted from (Olah, 2015).

2.3.2 Class Weights

The given data set is not well balanced (see Table 4 for details). To combat this issue I used $class\_weights$ for weighting the loss function, in a way it is to say the model which class to concentrate on. A *balanced* class weight is used to automatically adjust weights to be inversely proportional to class frequencies in the input training data. Weight of a class c_i is given by:

$$weight_{c_i} = \frac{n\_samples}{n\_class \times n\_samples_{c_i}}$$

Where,
$n\_samples$: total number of data sample
n_class: number of class present
$n\_samples_{c_i}$: number of samples of class c_i
The $class\_weights$ that were used are listed in Table 3.

class	$class\_weights$
$angry$	2.145
$happy$	0.841
sad	1.085
$others$	0.702

Table 3: $class\_weights$ for the input classes.

2.4 Data Description

We were provided 48544 data points to train our model. The class representations are shown in Table 4. It can be clearly seen that the data is highly imbalanced. This imbalance is handled by using weighted loss function and by fine tuning the model based on the micro-averaged f1 score (see section 2.5 for details).

Label	# data points
$angry$	5656
$happy$	14426
sad	11176
$others$	17286

Table 4: Class representation in training data.

2.5 Training Details

Data set is split (90 : 10) into train and validation. For class representation in the whole data set please see Table 4. In validation data generation, the proportion of class representation was kept similar to the data set. Table 5 shows the data split details.

I trained the model on the training data set and fine-tuned on the validation data set based on the

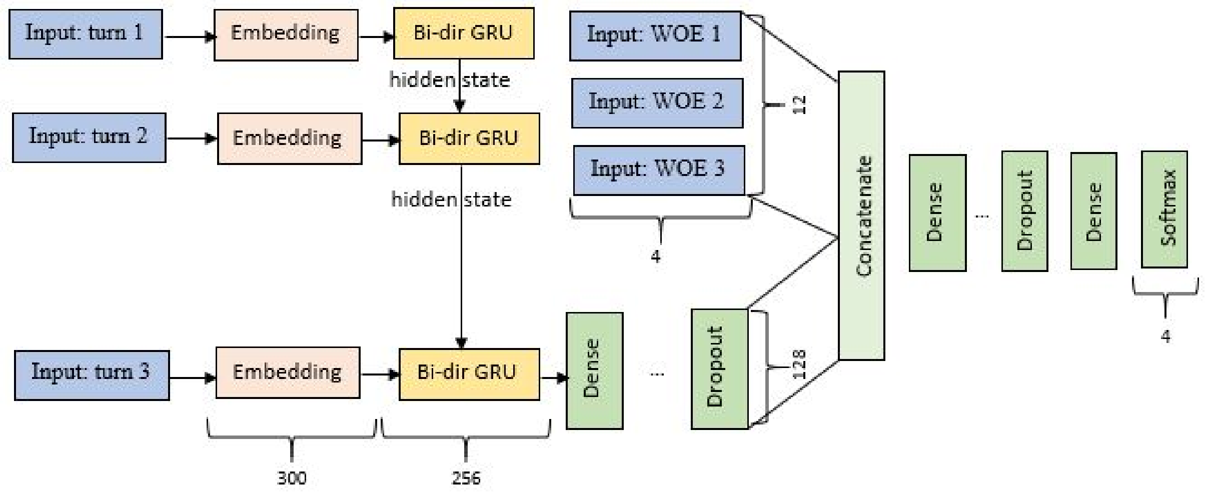

Figure 2: The deep learning model used in the system.

#Label	Training	Validation
#angry	5091	565
#happy	12983	1443
#sad	10058	1118
#others	15557	1729

Table 5: Class representation in training and validation data.

micro-F1 score. Since the data set is highly unbalanced, a weighted categorical cross-entropy loss is used, see Table 1 for the class weights. Adam (Kingma and Ba, 2015) optimizer is used with a learning rate of 0.001 and batch size of 128. Learning rate was decreased by 15% after each 3 epochs. Hidden state size of 256 is used for the bi-GRU gates. All the dense layers are of dimension 128 and a dropout of 0.5 is used for all of those.

3 Results

Here the detailed result of the system performance is presented. The performance shown in Table 6 is on the test data set.

label	precision	recall	f1-score	support
others	0.96	0.91	0.94	4677
happy	0.56	0.74	0.64	284
sad	0.61	0.80	0.69	250
angry	0.60	0.81	0.69	298

Table 6: System performance details

In the task the evaluation metric is micro-averaged F1 score only for the three emotion classes *happy*, *sad* and *angry*. Table 7 shows the confusion matrix of different classes.

label	*others*	*happy*	*sad*	*angry*
others	4246	162	119	150
happy	69	211	4	0
sad	36	3	200	11
angry	52	0	5	241

Table 7: Confusion matrix.

Precision and recall values for *happy*, *sad* and *angry* classes are 0.783653 and 0.589511 respectively. My system score is 0.6729 thereby beats the baseline (score 0.5868) convincingly.

4 Conclusion

With the system it is shown how to use the context information while detecting the emotion in a dialogue. Some guidelines about how to handle emojis is also laid out. While developing this system I realized the importance of pre-processing in conversational text data, or in general NLP related tasks; it can not be over emphasized.

Acknowledgments

I want to thank my mentors at Teradata, Ramesh Bhashyam and C Jaiprakash for the never ending support and to my teammates Lovlean Arora and Naveen TS for all the engaging discussions we had.
I want to apologize to my wife Samarpita, for all the weekend plans which were cancelled due to me working on TDBot. I promise to make up for those!

THU_NGN at SemEval-2019 Task 3: Dialog Emotion Classification using Attentional LSTM-CNN

Suyu Ge , Tao Qi , Chuhan Wu , Yongfeng Huang
Department of Electronic Engineering, Tsinghua University Beijing 100084, China
{gesy17,qit16,wuch15,yfhuang}@mails.tsinghua.edu.cn

Abstract

With the development of the Internet, dialog systems are widely used in online platforms to provide personalized services for their users. It is important to understand the emotions through conversations to improve the quality of dialog systems. To facilitate the researches on dialog emotion recognition, the SemEval-2019 Task 3 named EmoContext is proposed. This task aims to classify the emotions of user utterance along with two short turns of dialogues into four categories. In this paper, we propose an attentional LSTM-CNN model to participate in this shared task. We use a combination of convolutional neural networks and long-short term neural networks to capture both local and long-distance contextual information in conversations. In addition, we apply attention mechanism to recognize and attend to important words within conversations. Besides, we propose to use ensemble strategies by combing the variants of our model with different pre-trained word embeddings via weighted voting. Our model achieved 0.7542 micro-F1 score in the final test data, ranking 15th out of 165 teams.

1 Introduction

The analysis of emotions in dialog systems where limited number of words appear with strong semantic relations between them deserves special attention in domain of natural language processing (NLP) due to both interesting language novelties and wide future prospects (Gupta et al., 2017). By analyzing the emotions through conversations, service providers can design better chatting strategies according to users' emotion patterns, which can improve user experience. Therefore, SemEval-2019 task 3 (Chatterjee et al., 2019) aims to call for research in this field. Given a textual dialogue, i.e., a user utterance along with two turns of context, systems need to classify the emotion of user utterance into four emotion classes: happy, sad, angry or others.

The field of sentiment analysis has been extensively studied. For example, SemEval-2018 Task 2 (Barbieri et al., 2018) once called for the study on relevance between tweet texts and emojis. However, understanding textual conversations is challenging in absence of voice modulations and facial expressions, which participants at this task are asked to deal with. Apart from diminishing the negative impact caused by class size imbalance, ambiguity, misspellings and slang, their systems should mainly focus on capturing the intricate interplay between two turns of conversations.

Traditional sentiment analysis requires a lot of feature engineering, such as n-grams and features extracted from sentiment lexicons (Mohammad and Turney, 2013; Kiritchenko et al., 2014a), and then feed them into a classifier such as Support Vector Machines (SVM) (Bollen et al., 2011; Kiritchenko et al., 2014b). However, manual feature engineering usually needs a large amount of domain knowledge. With the rapid development and ambiguity of social dialogues, these feature engineering strategies fade gradually and begin to be supplanted by neural networks (Tang et al., 2015; İrsoy and Cardie, 2014; Wang et al., 2016), which usually take word embeddings as inputs to incorporate rich semantic and syntactic information (Collobert and Weston, 2008). However, dialog emotion analysis is still very challenging, since dialog conversations can be very noisy and informal. In addition, the emotions evoked by conversations are usually highly context-dependent.

In this work, we propose an end-to-end attentional LSTM-CNN network as a unified model without hand-crafted features. In our approach, we use a combination of LSTM and CNN to capture both local and long-distance information. We use attention mechanism to select important words to learn more informative word representations. In addition, we use a data balancing method by setting a cost-sensitive loss function for training.

Besides, we use ensemble strategies by using a combination of the variants of our model with different pre-trained word embeddings. Our model achieved 0.7542 micro-F1 score on the test set, and extensive experiments validate the effectiveness of our approach. The source code can be found in our repository on github.[1]

2 Our Approach

The framework of our attentional LSTM-CNN model is illustrated in Figure 1. Each layer of network is introduced from bottom to top in the following sections.

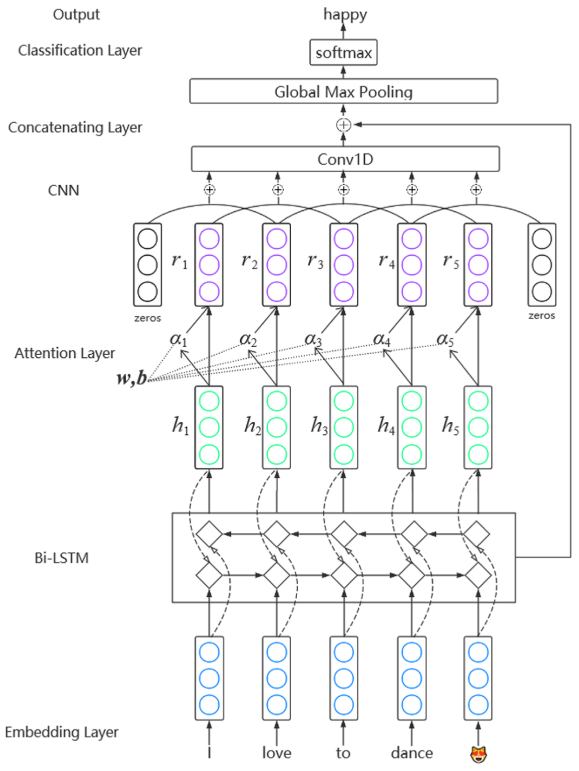

Figure 1: The architecture of our attentional LSTM-CNN model, the output is generated by soft voting ensemble after the softmax layer.

2.1 Word Embeddings

The first layer is a word embedding layer, which aims to convert the sequence of words in conversations into a low-dimensional vector sequence. We harness three types of pre-trained word embeddings, i.e., word2vec-twitter (Godin et al., 2015), pre-trained ekphrasis (Baziotis et al., 2017) vectors and GloVe (Pennington et al., 2014), to initialize the word embedding matrix.

[1]github.com/gesy17/Semeval2019-Task3-Emocontext

2.2 Bi-LSTM Layer

Considering the close relevance between two turns of dialogues, we use Bi-LSTM as encoder to capture abstract information from both directions. It consists of a forward LSTM $\overrightarrow{f}$ that encodes the sentence from $\boldsymbol{x_1}$ to $\boldsymbol{x_t}$ and a backward LSTM $\overleftarrow{f}$ that encodes the sentence backward. we concatenate the hidden representations in both directions, we get final representation of a word $\boldsymbol{x_i}$:

$$\boldsymbol{x_i} = \overleftarrow{\boldsymbol{x_i}} || \overrightarrow{\boldsymbol{x_i}} \quad \boldsymbol{x_i} \in \boldsymbol{R}^{2d}, \tag{1}$$

where $||$ denotes the concatenation operation and d is the size of each LSTM.

2.3 Attention Mechanism

An attention layer is incorporated after the Bi-LSTM layer to automatically select and attend to important words. The input of the attention layer is the hidden state vector $\boldsymbol{h_i}$ at each time step. The attention weight α_i for this time step can be computed as:

$$\boldsymbol{m_i} = \tanh \boldsymbol{h_i}, \tag{2}$$

$$\alpha_i = \boldsymbol{w}^T \boldsymbol{m_i} + b, \tag{3}$$

$$\alpha_i = \frac{\exp(\alpha_i)}{\sum_j exp(\alpha_j)}, \tag{4}$$

where w and b are the parameters of the attention layer. The output of attention layer at the i^{th} time step is:

$$\boldsymbol{r_i} = \alpha_i \boldsymbol{h_i} \tag{5}$$

2.4 CNN Layer

We use a convolutional neural network (CNN) to capture local contexts. Inspired by the residual connection for in ResNet (He et al., 2016), which combines the CNN outputs with original inputs to get better accuracy and shorter training time of deep CNN, we apply a merge layer to combine Bi-LSTM outputs and CNN outputs together. Our experiment proves that this structure can achieve a higher accuracy due to its full usage of both chronological information and local contextual information. Finally, max pooling is applied to the concatenated vectors to build conversation representations.

2.5 Emotion Classification

To make the final emotion prediction, we use a dense layer with softmax activation function to classify emotions. Considering the unbalanced data in both training set and testing set, we

	Happy	Sad	Angry	Average
Precision	0.7452	0.8117	0.7329	0.7598
Recall	0.6796	0.7760	0.7919	0.7488
F1	0.7109	0.7935	0.7613	0.7542

Table 1: Evaluation result on our final submission.

choose a cost-sensitive cross entropy loss function (Santos-Rodrguez et al., 2009) to modify the attention our model gives to different emotion categories. The loss function we use is formulated as:

$$\mathcal{L} = -\sum_{i=1}^{N} w_{y_i} y_i log(\hat{y}_i), \tag{6}$$

where N is the number of dialogue sentences, y_i is the emotion label of the i^{th} dialogue, $\hat{y}_i$ is the prediction score, and w_{y_i} is the loss weight of emotion label y_i. w_{y_i} is defined as $\frac{\sum_{k=1}^{C}\sqrt{N_k}}{\sqrt{N_{y_i}}}$, where C is the number of emotion categories and N_j is the number of texts with emotion label j. Consequently, this helps our model place higher weights towards infrequent emotion categories.

The last layer of our network utilizes a weighted soft voting ensemble method to fully take the advantage of different word embeddings. It should be mentioned that we design exactly the same network architecture with only word embeddings as slight differences. This soft voting method strengthens robustness and modifies our model to predict the class with the highest class probability.

3 Results and Analysis

3.1 Experimental settings

In our experiments, the word2vec-twitter embedding (Godin et al., 2015) was trained on 400 million microposts, which has a vocabulary of 3,039,345 words and 400-dimensional word representations. The Ekphrasis model leverages a collection of 330 million Twitter messages to generate word embeddings. It also uses GloVe as pretrained word vectors. Besides, a pre-processing pipeline is developed to enable users to get word vectors in a directly numerical form[2]. We also incorporate the GloVe embedding model and select the cased 300-dimension version[3] obtained by training on 2.2M data crawling from the Internet, containing 840B tokens in total.

[2]github.com/cbaziotis/ekphrasis
[3]nlp.stanford.edu/projects/glove

With word2vec-twitter embedding and GloVe embedding, we send raw texts to NLTK TweetTokenizer and randomly generate word vectors for all emojis and those out of vocabulary words appearing more than 3 times. Moreover, as to ekphrasis embedding, we use the pipeline provided by it. The pre-processing steps included in it are: Twitter-specic tokenization, spell correction, word normalization, word segmentation (for splitting hashtags) and word annotation.

In the experiment, we pertain the original dimension of the word embeddings and send them to a 400 dimension Bi-LSTM, adding to totally 800 dimension in LSTM layer. In the next CNN layer, the number of filters is 256, with filter length of 3. After each layer, we employ dropout with a drop rate of 0.2 to mitigate overfitting. Additionally, rmsprop (Tieleman and Hinton, 2012) is chosen as optimizer and Keras library (Chollet et al., 2015) is used for implementation.

3.2 Performance Evaluation

The final submission which scores micro $F1$ 75.42 is equipped with both the attention mechanism and weighted soft voting ensemble. The final result is shown in table 1, it suggests that our model performs relatively lower on happy emotion due to lack of training data and ambiguity. We evaluate parts of our network in the following paragraphs. The baseline we use is LSTM-CNN architecture(**LSTM-CNN**), baseline with concatenating layer is denoted as **LSTM-CNN+CL**. Upon this, attention mechanism is added, which is written as **LSTM-CNN+CL+AT**. Finally, a weighted soft voting is introduced, namely **LSTM-CNN+CL+AT+WE**. The result comparison is shown in table 2.

Concatenating Layer. By combining the outputs of Bi-LSTM and CNN layer, the model learns both local feature and long-term context, with the most obvious improvement in Word2vec-twitter, F1 score increasing from 0.7307 to 0.7483.

Attention Mechanism. Adding attention into network helps our network select those more essential words in the case of Ekphrasis and Glove word embeddings, but Word2vec-twitter witnesses a slight decline. This may be due to the randomness of out-of-vocabulary words and emoji word vectors. Overall speaking, attention benefits the study of word importance to some degree.

Weighted Soft Voting Ensemble. We place

	Word2vec-twitter	**Ekphrasis**	**GloVe**
LSTM-CNN	0.7307	0.7313	0.7429
LSTM-CNN+CL	**0.7483**	0.7355	0.7450
LSTM-CNN+CL+AT	0.7388	**0.7392**	**0.7460**
LSTM-CNN+CL+AT+WE		**0.7542**	

Table 2: Results on test data under various system framework.

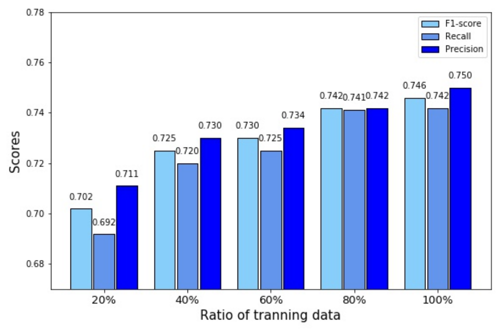

Figure 2: Influence of reducing training data on evaluation scores.

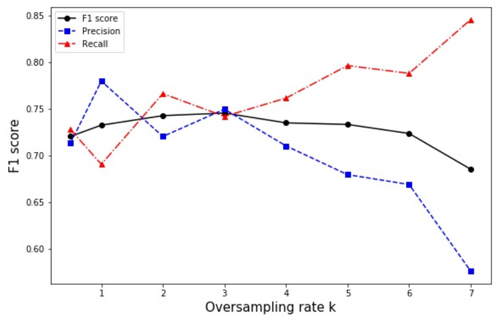

Figure 3: Influence of oversampling rate k on evaluation scores.

the highest weight on those showing good performances on dev dataset in our final submission. The significant improvement of F1 score at the bottom of table 2 indicates the power of ensemble. Results show that GloVe performs better than other two word embeddings, thus given more weight in practice. The result is ensembled from eight predictions , with the quantity we use of Word2vec-twitter, Ekphrasis, GloVe is respectively 2:3:3.

Quantity of training data. Since many methods in sentiment analysis rely heavily on high quality labeled data, we test our model with different reduction portion rate of training data. It can be seen in figure 2 that although there exists certain degree of performance reduction when the data amount is limited, our approach remain a F1 score of approximately 0.70 even with only 20% data, which proves that our approach can be widely applied to even when there exists shortage of labeled data.

Oversampling rate. The oversampling rate is defined to be the rate of loss weight between the class "others" and other three emotion categories. We officially set the oversampling rate k to be 3, meaning the loss weight rate between "others" and other three emotion categories is 3:1:1:1. To test the effectiveness of our choice of k, we select k to be in range from 0.5 to 7 and report the changes on F1 score, precision and recall in figure 3. It should be noticed that the scores are extremely unstable when $k < 2$, which may due to the sparsity of emotion labels in training data.

4 Conclusion

In this paper, we propose an attentional LSTM-CNN based neural network with concatenating layer for SemEval-2019 Task 3, i.e., predicting emotion categories of online dialogues. To strengthen robustness, weighted soft voting ensemble is exploited.

Abstract

In this paper, we describe our hierarchical ensemble system designed for the SemEval-2019 task3, *EmoContext*. In our system, three sets of classifiers are trained for different sub-targets and the predicted labels of these base classifiers are combined through three steps of voting to make the final prediction. Effective details for developing base classifiers are highlighted. Experiment results show that the ensemble approach manages to obtain better predictive performance in comparison with the base classifiers and our system has achieved the performance within the top 10 ranks in the final evaluation of *EmoContext*.

1 Introduction

Sentiment analysis is a task to identify the emotion conveyed by written language (Balahur et al., 2011; Lee et al., 2018). With the popularization of the Internet and instant message applications, text has become one of the most familiar media by which people express their ideas and communicate with each other. Automatic emotion classification can help people and robots better understand the messages or comments written by the others and make proper responses, which makes this study field increasingly important (Sun et al., 2018).

Deep learning approaches have achieved state-of-art performance in many recent studies of sentiment analysis (Rodrigues do Carmo et al., 2017). Gupta et al. (2017) used an LSTM-based model to identify the emotion in 3-turn conversations on Twitter. For emotion detection on TV show transcripts, a sequence-based convolutional neural network which can associate the information in the previous lines was designed by Zahiri and Choi (2017). Hazarika et al. (2018) proposed a conversational memory network based on both CNN (Lecun and Bengio, 1998) and gated recurrent unit (Chung et al., 2014) to recognize emotion in dyadic dialogue videos, featuring its ability to manipulate the information of different speakers. These studies focused on the architecture of the neural networks, but the optimization of the classification system based on the feature of the datasets are rarely discussed, which is crucial when dealing with specific real-world problems.

In this paper, we describe our approach to SemEval-2019 task3, *EmoContext* (Chatterjee et al., 2019), which aims to encourage more research of contextual emotion detection in textual conversation. Datasets of 3-turn conversations are provided and the participating systems are required to predict the contextual emotion of the last turn in the conversation: *Happy*, *Sad*, *Angry* or *Others*. The system performance is evaluated by the micro-averaged F1-score for *Angry*, *Happy*, and *Sad* (hereinafter referred to as *AHS*) on the given Test set. According to our observation of the dataset and single classifier's performance on it, we design a hierarchical ensemble classification system, which is composed of three sets of base classifiers, and three steps of voting to combine their predicted labels to make the final prediction. Our system has achieved F1-score of 0.7616 in the final evaluation, which is within the top 10 performances out of 165 participating systems.

This paper is organized as follows. In Section 2, our system and the strategies of training base classifiers are demonstrated. In Section 3, experiments are detailed and the evaluation results of our system and the base classifiers are presented and discussed. Conclusion is given in Section 4.

2 System Description

As we notice that the distinction among *AHS* and that between *Others* and *AHS* are significant, our system is designed to contain three sets of classifiers trained for different sub-targets and the pre-

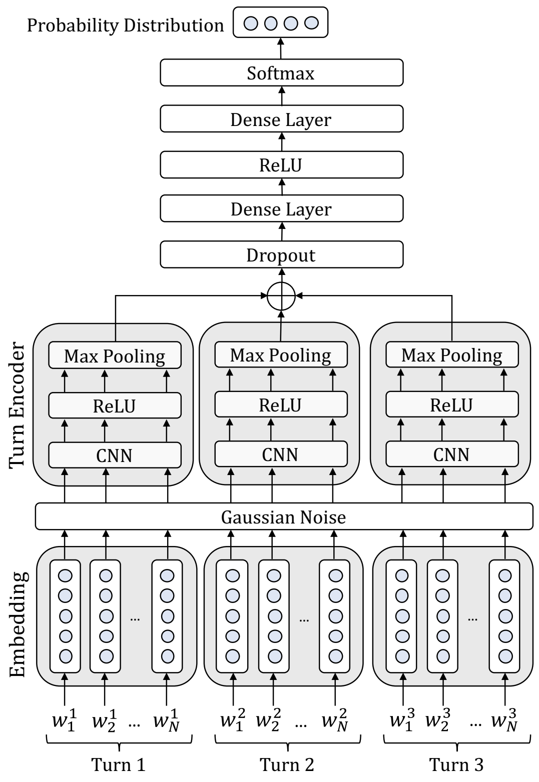

Figure 1: The architecture of the CNN-based classifiers in our system.

dicted emotion of a 3-turn conversation is obtained and refined through three steps of voting.

2.1 Classifier

Every base classifier in our system shares the same architecture (Fig 1). The input to the classifier is a 3-turn conversation represented as three sequences of tokens. An embedding layer is used to map the input to three sequences of vectors. Each turn is encoded to a vector individually by feeding its sequence of vectors into a CNN layer followed by a rectified linear unit (ReLU) and max pooling, as we notice that each turn's contribution to the prediction is different and the predictive clue to the contextual emotion can be captured within the turn. Three vectors are then obtained and concatenated as the feature vector of the 3-turn conversation. It is finally fed into a dense layer with a ReLU and another dense layer with softmax to get the probability distribution over all predicted classes.

2.2 Hierarchical Ensemble

Three steps of voting are designed (Algorithm 1) and a set of classifiers are trained for each step. For the first step, a set of four-emotion classifiers

Algorithm 1 Hierarchical ensemble

```
Input: the majority vote of Set A, $Label^A_{MV}$; the majority vote of Set B, $Label^B_{MV}$, and its voting count, $Count^B_{MV}$; the voting count for Others in Set C, $Count^C_{Others}$; two chosen thresholds, $thr_{II}$ and $thr_{III}$
Output: the predicted labels after each step of voting, $Label_I$, $Label_{II}$, $Label_{III}$;
 1: $Label_I \leftarrow Label^A_{MV}$;
 2: if $Label_I \neq Others$ & $Count^B_{MV} \geq thr_{II}$ then
 3:     $Label_{II} \leftarrow Label^A_{MV}$;
 4: else
 5:     $Label_{II} \leftarrow Label_I$;
 6: end if
 7: if $Count^C_{Others} >= thr_{III}$ then
 8:     $Label_{III} \leftarrow Others$;
 9: else
10:     $Label_{III} \leftarrow Label_{II}$;
11: end if
```

(hereinafter referred to as Set A) are trained on the given dataset and the original labels. For each test case, majority voting is applied to Set A to get the base predicted label, $Label^A_{MV}$. This set of predicted labels are hereinafter referred to as Prediction I.

For the second step, a set of three-emotion classifiers (hereinafter referred to as Set B) are trained only on the data of *AHS*. For each test case, majority voting is applied to Set B to get a new label $Label^B_{MV}$ and the predicted label for this case is changed to $Label^B_{MV}$ if $Label^A_{MV}$ is not *Others* and more than thr_{II} classifiers in Set B voted for $Label^B_{MV}$, by which the prediction for *AHS* is refined. This set of predicted labels are hereinafter referred to as Prediction II.

For the final step, a set of binary classifiers (hereinafter referred to as Set C) are trained on the given dataset but the labels for *AHS* are changed to *Not Others*. For each test case, we change its predicted label to *Others* if more than thr_{III} classifiers in Set C vote for *Others*, by which more *Others* samples are recalled. This set of predicted labels (hereinafter referred to as Prediction III) are used as the final prediction of our system.

2.3 Regularization

Common methods to alleviate the problem of overfitting are applied. Embedding layer is not fine-tuned. If this layer is tuned through training, the embedding space will be changed but the vectors of the tokens that exist only in the Test set are not adjusted, which may lead to wrong representations of these tokens. Gaussian noise is added after the embedding layer, by which the model is more robust when dealing with tokens of similar mean-

Turn 1	Turn 2	Turn 3	label
I live in uttra khand	ohh nice! love that place! ∧.∧	☺☺	happy
degreee	what degree & where?	sryyy i really got to goo	others

Table 1: Example training samples in Train set.

Dataset	Others	Happy	Sad	Angry
Train	14948	4243	5463	5506
Dev	2338	142	125	150
Test	4677	284	250	298

Table 2: Class distribution in each dataset.

ing. L2 regularization is applied to the weights of the stacked dense layers. Dropout (Srivastava et al., 2014) layer is added. Two more strategies are specifically highlighted.

- For each classifier, 90% of the training data is randomly selected for training and the 10% left for validation so that different information is captured. Although the evaluation metric is micro-averaged F1-score for *AHS*, for classifiers in Set A, the set of neural network weights that achieves the best micro-averaged precision on the validation set through the training process is chosen. As we notice that the precision is significantly sensitive to the class distribution and the task organizers have emphasized the difference between the class distributions of the provided datasets in advance, we need the precision of the base classifiers to be as high as possible.

- For each sample of the class *Others* in the training data, a new *Others* sample is created by randomly removing one token in one of the turns to simulate the situation when the user misspells a word and that misspelled token is not known to our embedding models. This is inspired by our observation that most of the *Others* samples in the training data still belong to *Others* even if one of the tokens is missing or misspelled. However, samples for *AHS* are not automatically generated in case a discriminative token is removed and a misleading sample will be made.

3 Experiments and Discussion

3.1 Data

Task organizers have released three datasets. Each sample in these datasets contains a 3-turn conversation(Table 1), in which Turn 1 was written by User 1, Turn 2 is User 2's reply to Turn 1 and Turn 3 is User 1's reply to Turn 2. The emotion label of Turn 3 is annotated for each conversation, which is one of the four emotions: *Angry*, *Happy*, *Sad*, and *Others*. Class distributions of these three datasets are shown in Table 2.

3.2 Preprocessing

We notice that the writing style of the conversations in the datasets resembles that of the tweets and comments on Twitter, featuring emoticons, informal usage of language, spelling errors and so on. Hence, we utilize the tweet processor, *ekphrasis*[1] (Baziotis et al., 2017). The preprocessing steps include (1) Twitter-specific tokenization, (2) spell correction, (3) word normalization for numbers and dates, (4) annotation for all-capital words, elongated words and repeated punctuations, (5) conversion of emoticons to emotion labels, through which each 3-turn conversation is converted to three sequences of tokens.

3.3 Word Embeddings

We deploy the pretrained embedding model provided by Baziotis et al. (2018) [2] (hereinafter called NtuaW2V) in our system, which contains 300-dimensional vectors trained on Twitter messages that are also preprocessed by *ekphrasis*. In addition, we tried another pretrained model provided by Mikolov et al. (2013) [3] (hereinafter called GoogleW2V), which contains 300-dimensional vectors trained on Google News dataset, in order to get an insight into the effect of different embedding models. The pretrained embeddings are used to initialize the embedding layer. For tokens that are not covered in the embedding model but occur in no less than two training samples, their embedding vectors are randomly initialized.

3.4 Implementation Details

Tensorflow (Abadi et al., 2016) is used to develop our models. For network optimization, we choose Adam algorithm (Kingma and Ba, 2014).

filter number of CNN	128
# of cells of the first dense layer	32
dropout keep prob.	0.5
l_2	0.2
initial learning rate	0.005
decay of learning rate	0.9
minibatch size	100

Table 3: Configuration of our system.

The configuration of our system and the hyper-parameters of the classifiers are shown in Table 3.

3.5 Results and Discussion

Table 4 shows the performance of our base classifier and its variants on the Test set. Note that **BASE** refers to the model trained as mentioned in Section 2 and **Prec**, **Rec**, and **F1** refer to the micro-averaged ones for *AHS*.

According to Table 4, adding automatically generated *Others* samples improves the accuracy, precision, and F1-score as more *Others* samples are correctly predicted but less *AHS* samples are recalled as the cost.

We also observe the performance difference when a different metric is used as the indicator for choosing the network weights, which is rarely discussed but the results show that the effect is significant. It is because of the remarkable difference between the class distributions of the training data and the Test set, which is emphasized by the task organizers.

On the other hand, the embedding models used to initialize the embedding layer are compared. Results show that using NtuaW2V achieves better F1-score while using GoogleW2V achieves the best precision but also the worst recall among the variants, which shows the importance of choosing suitable pretrained embedding models. The data on which the embedding model is trained and how the data are preprocessed should be the keys to it.

Table 5 and 6 illustrate the performance of our system after each step of voting. Results show that the first two steps bring slight improvement on all four metrics and the final step improves F1-score by raising the precision at the cost of the recall. The improvement also implies that, in comparison with Set A, classifiers in Set B are more effective to distinguish *AHS* samples and those in Set C are more precise to classify whether a sample belongs to *Others*. Although these classifier sets are all trained on the given dataset, Set B and Set C manage to work as a patch to Set A as they only focus on the simplified classification problems.

Classifier	Acc	Prec	Rec	F1

Table 5: Performance of our system after each step of voting on the Test set.

4 Conclusion and Future Work

In this paper, we present our system used for SemEval2019 Task3, *EmoContext*. This system is composed of three sets of CNN-based neural network models trained for four-emotion classification, *Angry-Happy-Sad* classification and *Others*-or-not classification respectively. Three steps of voting are used to combine the predicted labels of the base classifiers and make the final prediction. Experiment results show the ensemble approach manages to improve the performance in comparison with the base classifiers. Automatic generation of random *Others* samples is proven effective and the importance of choosing pretrained embedding models and picking the right metric as the indicator for choosing network weights is highlighted. In order to achieve a better result based on our system, improving the performance of the base classifier is crucial. The architecture of neural networks and the features used as the input should be the fields that worth further exploration.

Prediction	Others	Happy	Sad	Angry
I	0.9595	0.7153	0.7806	0.7671
II	0.9595	**0.7190**	0.7801	0.7704

Abstract

This paper presents our contextual emotion detection system in approaching the SemEval-2019 shared task 3: *EmoContext: Contextual Emotion Detection in Text*. This system cooperates with an emotion detection neural network method (Poria et al., 2017), emoji2vec (Eisner et al., 2016) embedding, word2vec embedding (Mikolov et al., 2013), and our proposed emoticon and emoji preprocessing method. The experimental results demonstrate the usefulness of our emoticon and emoji prepossessing method, and representations of emoticons and emoji contribute model's emotion detection.

1 Introduction

Social media and online text applications have been gaining popularity in recent years. Users post videos, pictures, and text to share their daily life as well as to communicate with others. This vast amount of multimodal data greatly facilitates various user analysis tasks such as sentiment analysis.

Emotion detection as part of sentiment analysis can be conducted with user's multimodal data such as facial expression and voice data in addition to text data. Therefore, emotion detection becomes a challenging problem when only textual data is available for extracting the contextual and sentiment features (Chatterjee et al., 2019). For example, without proper visual and voice data, ”Why did you not call me last night” may be classified as sad or angry without an appropriate understanding of context.

The SemEval-2019 shared task 3: *EmoContext: Contextual Emotion Detection in Text* is the task to detect an emotion of a three-turn conversation (Chatterjee et al., 2019). We can consider this task as contextual sentiment analysis, as it requires detecting the emotion of the third-turn conversation by comprehensively understanding the contextual relationship and sentiment features from both language and emotion-related symbols.

Emotion class	Distribution
others	50%
happy	14%
sad	18%
angry	18%

Table 1: Emotion class distribution in the training data set.

The task organizers provided a training set that consisted of 30,160 three-turn conversations. Meanwhile, as Table 1 shows, the emotion class distribution in the training data set was unbalanced: 50% of samples were from “others” class. The task organizers also mentioned about the real-life distribution of emotion class: 88% of data is classified as “others” (Chatterjee et al., 2019). We also observed that over 28% of conversations in the training data set contained emoticons or emoji; users use them along with text to express emotion in a conversation. These two observations challenge us to have a method that can learn emotion and contextual features from unbalanced training data and the emotion-related symbols (emoticons and emoji).

The rest of this paper is organized as follows: Section 2 introduces the related work to the task; Section 3 explains our method in detail; Section 4 illustrates the experiments and analyzes the experimental results; Section 5 concludes the paper and presents the future work.

2 Related Work

Natural language processing in social media as an emergent area has attracted a lot of attention (Poria et al., 2017), especially from the recent advances in applying neural network methods with pre-trained embeddings (Eisner et al., 2016).

To achieve generalization and robustness in social media sentiment analysis, pre-trained embeddings should contain the representations of not only words from natural language but also emotion-related symbols, such as emoticons and emoji (Eisner et al., 2016). Both pre-trained embeddings GloVe (Pennington et al., 2014) and word2vec (Mikolov et al., 2013) do not contain representations for emotion-related symbols, which restricts the performance of sentiment analysis in social media. Although pre-trained emoji2vec embedding contains Unicode emoji representation, not all emotion-related symbols are included, such as emoticons.

As emotion detection is a part of sentiment analysis, and the data from the task organizers contains emoticons and emoji for emotion expressions, we can utilize a neural network method with pre-trained embedding to solve this task. We also need to address the lack of representations of emotion-related symbols.

3 Method

We formalize the SemEval-2019 shared task 3 as an emotion classification problem. Our method performs as an emotion classifier that accepts a conversation containing three-turn textual utterances, and classifies the last utterance to one of four pre-defined emotion class (happy, sad, angry, and others).

Our method focuses on learning contextual relationships and extracting emotion features from three-turn conversations. Poria et al. (2017) presented an LSTM-based contextual sentiment analysis model: contextual LSTM network that captures inter-dependency and contextual relationship among utterances in a video. Their experimental results demonstrated that contextual features of utterances significantly boost the performance of sentiment analysis; therefore, we decided to use this model as the main component in our system.

Although pre-trained embeddings such as GloVe and word2vec are easy to access, both of them do not have representations for emoticons and emoji (Eisner et al., 2016). However, pre-trained emoji2vec embedding as a supplement to pre-trained Google news word2vec (Mikolov et al., 2013) contains 1,661 emoji symbols and is ready to be augmented in downstream natural language processing tasks for social media (Eisner et al., 2016). Thus, we decided to concatenate word2vec and emoji2vec in our method as word embedding.

3.1 Contextual LSTM Network

Since bi-directional contextual LSTM (bc-LSTM) performed the best in the experiments of Poria et al. (2017), we selected this variant of contextual LSTM as the main component.

bc-LSTM (Poria et al., 2017) consists of five layers: 1) embedding layer; 2) input layer; 3) LSTM layer; 4) dense layer; and 5) softmax layer. The embedding layer (shared across three utterances) converts utterances into distributed representations. The input layer is a shared bi-directional LSTM, accepting the output of each utterance from the embedding layer in a sequence. The LSTM layer is an uni-directional LSTM that uses concatenation of outputs of utterances from the input layer. The extracted contextual features from LSTM layer feed into a dense layer. Finally, the softmax layer predicts an output from the dense layer.

3.2 Emoticon and Emoji Pre-possessing

The emoticon and emoji pre-processing method removes sentiment ambiguity that emoji bring and solves the lack of representations of emoticons in pre-trained emoji2vec (Eisner et al., 2016) embedding.

Emoji Normalization Since emoji2vec does not learn context-dependent definitions of emoji (Eisner et al., 2016), a mixture and duplication of emoji within textual data in an utterance will add the complexity and ambiguity in an emotion expression.

We also noticed that appending emoji to the end of an utterance did not change its sentiment. Instead, this process splits an utterance into two parts: text part and emoji part, which guarantees the smooth emotion expression in each part.

Our emoji normalization reduces multiple instances of an emoji into one instance and append it to the end of its belonging utterance.

Emoticon to Emoji Mapping In addition to emoji, emoticons also play a vital role in expressing emotions. Thus, representations for emoticons are also important to our method.

Although emoji2vec does not contain a representation of an emoticon, an emoticon can be treated as a ”surface variation” of an emoji. Thus, we can use the same emoji2vec representation of

an emoji only if the emoticon is associated with the emoji. We built a dictionary to map an emoticon to its corresponding emoji (Figure 1). Containing 150 common emoticons, this dictionary can be used to replace emoticons to emoji.

3.3 System Description

Figure 2 shows an overview of our system: TokyoTech_NLP contextual emotion detection system (TNCED); our system consists of two phases: training and test phases. Both phases use the same pre-processing method. In the test phase, we use the contextual LSTM network classifier from the training phase to predict the emotion class on the test data.

4 Experiments

4.1 Data

We used the training data provided by the task organizers to train our model. For evaluation, we used the SemEval 2019 task 3 test data and micro F1 score and F1 score as metrics.

4.2 Experiment Setup

We used Keras (Chollet et al., 2015) and the code from the Github repository of bc-LSTM[1] to implement our TNCED system with the following settings: 128 LSTM dimensions; adam (Kingma and Ba, 2014) as an optimizer; 0.003 learning rate, 0.2 dropout, and 75 epochs. We used pre-trained Google word2vec (Mikolov et al., 2013) and pre-trained emoji2vec (Eisner et al., 2016) as embeddings.

4.3 Experiment Design

To evaluate the performance of *emoji normalization* and *emoticon to emoji mapping*, we used them to create following data set:

Data Set 1: For both training and test data, we first conducted *emoticon to emoji mapping*, and then performed punctuation normalization to reduce the number of repeated and frequently-used punctuation '?', '!', ',', '.' into one. We put a white space around the punctuation. Then, we applied *emoji normalization*.

Data Set 2: In addition to Data Set 1, we applied punctuation normalization to two frequently-used punctuation '_' and ':'; we only conducted *emoji normalization* in this data set. This data set was used in our submitted system for SemEval 2019 task 3.

Data Set 3: We did not apply any pre-processing in both training and test data.

We used these three data sets to train and test our system (TNCED), and calculated micro F1 score on the three emotion classes (happy, sad and angry) and F1 scores of happy, sad and angry classes.

4.4 Experimental Result

Table 2 shows micro F1 score and F1 scores of happy, sad, and angry classes obtained from the TNCED systems trained with different settings. The system with setting 1 (TNCED+Data Set 1) had the highest micro F1 score (0.7004) among the settings; it also achieved the highest F1 scores (0.746 and 0.709) in both sad and angry classes.

Compared with setting 3 (without any pre-processing), both settings 1 and 2 gained better F1 scores of three emotion classes as well as micro F1 scores, especially the setting 1 improved nearly 0.131 in F1 score of sad class and 0.071 in

micro F1 score. Compare to setting 2, *emoticon to emoji mapping* helped setting 1, improving 0.051 and 0.021 in F1 scores of sad and angry classes. These results indicate that our proposed emoticon and emoji pre-processing method helps the contextual LSTM network in understanding emotion expressions of emoticons and emoji.

5 Conclusion

In this paper, we described our system for SemEval-2019 shared task 3. This system consisted of the pre-processing method for emoticons and emoji, and bi-directional contextual LSTM network (Poria et al., 2017).

The proposed emoticon and emoji pre-processing method solves the lack of representations of emotion-related symbols (emoticons) in pre-trained embeddings, and removes the ambiguity in emotion expressions of emotion-related symbols. Experimental results demonstrate the usefulness of the emoticon and emoji pre-processing method by improving the representations of emoticons and emoji. It helped the neural network model to capture emotion expressions from emotion-related symbols.

A future direction of this work includes training embeddings to gather contextual definitions of all emotion-related symbols. Furthermore, we would like to explore other neural network architectures as well as retrieve more data to capture the nuance emotion in text.

Abstract

In this paper, we present a system description for implementing a sentiment analysis agent capable of interpreting the state of an interlocutor engaged in short three message conversations. We present the results and observations of our work and which parts could be further improved in the future.

1 Introduction

It is hard to understand emotions in textual conversations in the absence of voice modulations and facial expressions (Gupta et al., 2017). In sentiment analysis task researchers work on different levels of sentiment analysis: document (when are considered single topics documents), sentence (when single sentences are classified as positive, negative or neutral), entity or aspect (which deal with finding the aspects in the text and then classifying in respective aspect) (Liu, 2012).

Similar to sentiment analysis at sentence level, in last years tweets from Twitter were analyzed and classified (Zhang and Liu, 2017), (Kumar and Sebastian, 2012), (Mukherjee and Bhattacharyya, 2013) and (Singh and Husain, 2014). In the beginning, a binary classification was used, which linked opinions or opinions only to two classes: positive or negative. In (Pak and Paroubek, 2010) the authors proposed a model for classifying tweets in goals, positive and negative feelings using a classifier based on multinomial Naive Bayes to use features such as N-grams and tags POS (part- of-Speech). In (Parikh and Movassate, 2009) the authors have implemented two models, one based on the Naive Bayes bigrams model and one using Maximum Entropy to classify tweets. (Go et al., 2009) proposed a solution for analysing feelings on Twitter using distant supervision, the training data were tweets with emoticons, which are regarded as noise data. They built several well performing models using Naive Bayes, MaxEnt, and SVM. (Barbosa and Feng, 2010) have modeled an automated method to classify tweets using space features including retweets, hashtags, links, punctuation mark amazement in combination with words and POS features polarity. (Luo et al., 2013) have brought to light the difficulties that they encounter when they want to classify tweets. Spam and a variety of languages on Twitter make the task of identifying opinions very difficult.

In SemEval 2019, in Task 3, EmoContext: Contextual Emotion Detection in Text (Chatterjee et al., 2019), the organizers ask participants to classify users messages in one of four classes: *Happy*, *Sad*, *Angry* or *Others*. These are given in the context of another two previous messages. The textual dialogue is composed of short messages that appear to be from a chat conversation. In such a context, the users express their thoughts and ideas in a compact way. In this paper, we describe how we created one classifier to detect the sentiment of short messages such as tweets.

2 Related Work

2.1 Word Embeddings

In order to incorporate the meaning of the words in a software system that processes natural language, distributed representations of words in a vector space are used to achieve better results by grouping similar words.

Previous work (Mikolov et al., 2013) introduces two architectures *CBOW* (Continuous Bag-of-Words) and *Skip-gram model* for learning word representations using neural networks. The later is more efficient for small training data, generating better representations for the infrequent words (Naili et al., 2017).

When choosing the best representations for a certain training dataset, one can either use pre-trained word embeddings that were built using large general corpora or train their own embeddings on a specific corpus which is similar to the type of data the model will be working with. The advantage of the first approach is that the representations only need to add without any additional computational cost, meanwhile, the second one requires a large enough corpus that can lead to meaningful representations that can capture both syntactic and semantic regularities. While vectors like Word2Vec, GloVe (Global Vectors for Word Representation) or fastText capture the most frequent semantic meaning of the words, training new representation on social media data can bring a number of advantages such as embedding the specific informal language that is used on these platforms and comprising numerous words that might not be very frequent in general corpora (Rotari et al., 2017) and (Flescan-Lovin-Arseni et al., 2017).

3 System Architecture

In this section we will present the systems developed for the EmoContext task.

3.1 Data Pipeline

Starting off, a critical characteristic in our architecture was the ease of configuration of different parameters of our system. We want our system to require little additional work and troubleshooting when changing, adding or removing pre-processing, feature extractions or post-processing techniques.

As seen in Figure 1, the system can take any configuration and order of pre-processing, feature extraction and post-process methods as well as a model to be fed the data.

Since a lot of small changes would sometimes occur on the later stages of the pipeline, we implemented an auto-save feature in all components of the system which will simply use the cached processed data up to the point of the last modified step in the pipeline.

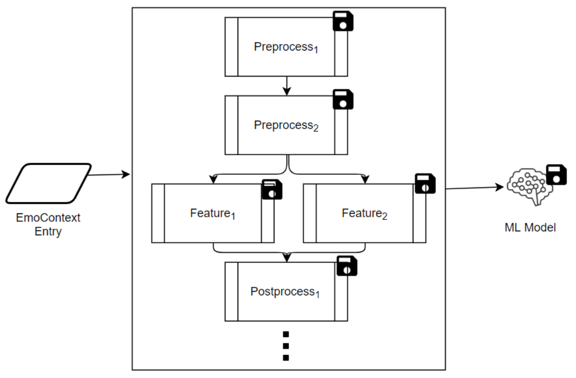

Figure 1: Pipeline structure

3.2 Data Processing

The dataset in from EmoContext task presented some clear challenges. Since we had to learn the expected sentiment of one of the interlocutors from a relatively small amount of text it was of utmost importance to remove noise from the data with minimal loss of potentially useful information. With such small amount of data (≈ 4 words per message) in each column, we decided to concatenate all three messages in every entry in order to be able to infer more information from it.

3.3 Pre-processing Stage

In the pre-processing stage, we implemented a number of steps progressively remove noise such as non utf-8 encoded symbols or random punctuation or characters, from which no important information could be extracted, using regex rewriting rules. After which we transform all misspelled words to the closest correct English word (closest in terms of Hamming distance) while some words would be transformed wrongly, the system performed better when using the "corrected" dataset.

We considered emoticons to be important in determining the sentiment state of the communicating parties, as such we identified as many standard use emoticons. With these emoticons, we analyzed the distribution of where they appear. For example: ":)" appeared predominantly in entries labeled "happy". Using these we replaced each emoticon with the keywords: "happyemoticon", "angryemoticon", "angryemoticon" and "otheremoticon" respectively.

In terms of the actual noise reducing rewriting rules:

- Eliminating any elongated series of characters greater than two, to a size of two;
- Reducing any repetition of English symbols or punctuation marks to just one, since it would not lead to any loss of information but it will remove noise;
- Removal of spaces between punctuation marks;
- Removal of any number with more than one decimal;
- Rewriting Unicode characters into utf-8 equivalents or complete removals when not possible;
- Isolated characters get deleted;
- Deletion of ASCII emoticons.

We have observed that this combination of preprocesses leads to the best results, without eliminating too much or leaving too much noise. Extensive empirical experimentation was done to assert the performance of various combinations of preprocesses and parameters.

We have to keep in mind, that before applying these modifications the average length of the concatenated messages is around 12 words, afterward, it became around 10.

3.4 Feature Selection

For the actual features we wanted to use in our system, we have attempted a number of syntactic features we thought of extracting.

All of these features proved to be either not helpful in the aid of the model performance or detrimental in the sense that it left any model we attempted prone to overfitting, such as getting stuck in the local maxima of classifying all instances as ”others”.

As such, we chose to use embeddings as our only form of feature selection. We have tried to utilize pre-trained embeddings offered online such as GloVe, FastText and Word2vec.

Sadly, all of the embeddings we have attempted to incorporate into the system produced weaker results compared to training the embedding from scratch on the data.

For this, we tokenized the data and padded it to have 200 elements per list. Even though these vectors were trained on a relatively small corpus, due to the high usage of jargon, rare abbreviations and bad grammar which made our dataset very much different compared to the corpus used by any of the above mentioned pre-trained word embeddings this was most likely the cause of improved performance when our own embedding even though the corpus is extremely small compared to what would be required to create a good embedding.

3.5 Model

In constructing our machine learning model, we chose to use artificial neural networks with the use of the ”Keras” python library[1].

For the actual model of the system, we have made use of very simple and small architectures since any attempt of creating a deeper or wider artificial neural network models resulted in drastic overfitting. Even with other overfitting alleviating techniques such as regularization, dropout and batch normalization we had to stick to a shallow architecture. We suspect this is due to the fact that we trained our embedding on such a small dataset, perhaps if more similar data can be collected and a more general word vector is created, overfitting would also be reduced. As such, the model we are presenting does not suffer from overfitting but it is relatively shallow.

Table 1: Submission metrics

4 Results

Using that simple model and an extensive meta-parameter tuning we were able to reach an average micro F1 score of 0.6895, this being the last submission we were able to upload during the workshop. See Table 1 for complete metrics of this submission, calculated by training the model 5 times, to factor in for randomness of shuffled data and weight initialization (all runs had comparably similar results).

We noticed that the greatest difficulty our system faces is correctly classifying instances belonging to the ”happy” class. As such, we should look into what data pre-processing we could use in order to decrease the high number of false-negatives.

Another potential improvement would be to add weights to the loss function based on the proficiency we observe the system to exhibit on each type of entry.

Applying the pre-processing we described previously we managed to boost that result to average micro F1 of 0.7362.

Both of these models were trained using a K-fold cross-validation with four splits and a batch size of 64.

What we observed time and time again, the main issue we faced was overfitting of the training data, as we can see when looking at the progression on the validation data, see Figure 3.

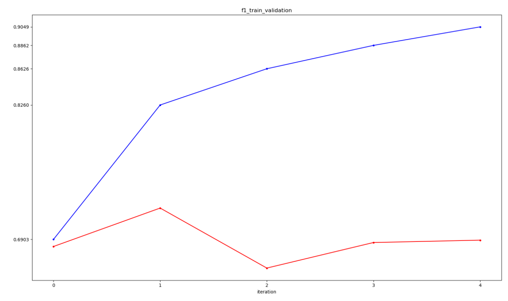

Figure 3: Training / Validation F1 - red validation data set, blue train data set

5 Conclusions

This paper presents the system developed by our group for the EmoContext task. The architecture of the system includes data processing, feature selection, and machine learning model. The results are promising, but they also expose the need for more experiments that should be done in this field in the next period.

For the future, we believe a CNN approach could prove fruitful. As well as a different or deeper network and configuration while using a similar pre-processing process which we believe is the main contributor to our relatively successful result.

Another direction worth investigating would be a Mixture of Experts approach, using various variations of the system even if they prove sub-optimal individually, such as *The currently proposed system*; *A system using a pre-trained embedding*; *Three sub-systems each trained to only classify one of the classes*; *A system with three input layers, one for each message reply, removing the concatenation of the text pre-processing*; *A system which only looks at the emoticons present in the text.*

Abstract

This paper describes our approach to the emotion detection of Twitter textual conversations based on deep learning. We analyze the syntax, abbreviations, and informal-writing of Twitter; and perform perfect data preprocessing on the data to convert them to normative text. We apply a multi-step ensemble strategy to solve the problem of extremely unbalanced data in the training set. This is achieved by taking the GloVe and ELMo word vectors as input into a combination model with four different deep neural networks. The experimental results from the development dataset demonstrate that the proposed model exhibits a strong generalization ability. For evaluation on the test dataset, we integrated the results using the stacking ensemble learning approach and achieved competitive results. According to the final official review, the results of our model achieved micro-F_1 score of about 0.7588 on the final evaluation.

1 Introduction

Over the past 10 years, short microblogging communication methods, such as Tweets and Weibo, have been widely adopted. Numerous emotions exist in the dialogue of texts, and there is great commercial value for the detection of such emotions. For example, in the customer service field, the feedback time limit is divided according to the emotion.

Text conversation emotion detection is a challenging issue without facial expressions and mood information being available. Moreover, the data of sadness, anger, and happiness in the current context, as well as the extremely unbalanced scale, natural language ambiguity, and rapidly growing online language, further exacerbate the challenges of sentiment detection.

In this paper, we describe our work on SemEval 2019 Task 3, EmoContext: Contextual Emotion Detection in Text (Chatterjee et al., 2019). The main challenge of the task lies in imbalanced data distribution. Previously proposed methods for solving data imbalance include over-sampling, under-sampling (Weiss, 2004), and Synthetic Minority Oversampling Technique (SMOTE) (Chawla et al., 2002). over-sampling is copying from a smaller number of categories, which may lead to over-fitting. Under-sampling discards potentially useful information, which can degrade the performance of the classifier (Drummond et al., 2003). SMOTE is down-sampling first, and then integration. We propose a multi-step integration approach similar to SMOTE for this task to alleviate the data imbalance problem. In the first step, we use five-fold cross-validation to train five sub-neural networks with different data distributions. Thereafter, soft-voting is used for integrating the results from these sub-neural networks. Soft-voting integration is applied because it not only alleviates the problem of unstable prediction results caused by data imbalance, but also improves the effective prediction accuracy of the single model. The second step of stacking integration further enhances the global effective prediction accuracy. The experimental results indicate that the proposed model alleviates the problem of data imbalance and significantly improves the effective prediction accuracy.

The remainder of this paper is organized as follows. In section 2, we describe the system architecture. Section 3 explains the data processing and parameter tuning. The conclusions and future work are presented in Section 4.

2 System Architecture

The data with the label *others* comprise 49.56% of the training set. The model trained by the conventional method exhibits a poor generalization a-

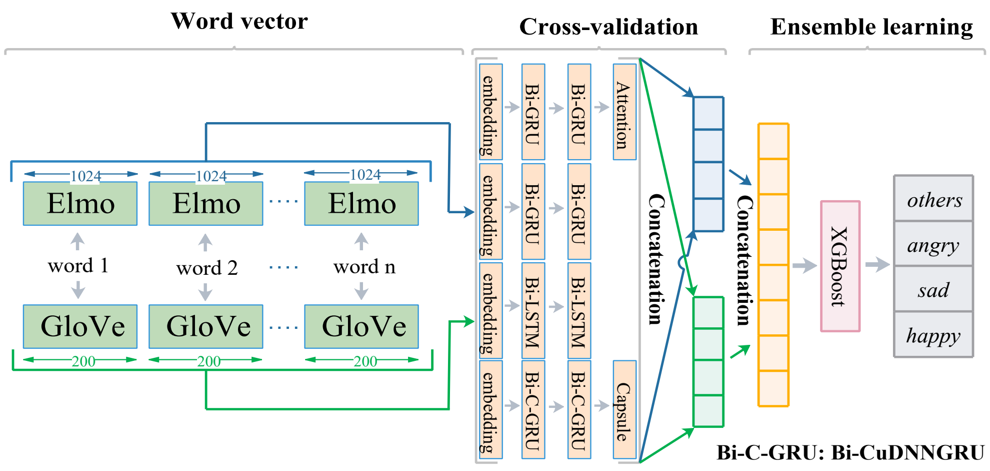

Figure 1: System architecture.

bility and is prone to over-fitting. Sampling verification may alleviate the problem of data imbalance (He and Garcia, 2008). In order to enable the model to learn the data characteristics of small samples, we use five-fold cross-validation to verify the model and test its robustness. The system architecture is illustrated in Figure 1.

2.1 Embedding

We use a GloVe (Pennington et al., 2014) pre-trained word vector: the Twitter 200-dimensional word vector. GloVe is a word representation tool based on the count base and overall statistics. It expresses a word as a vector of real numbers, and captures the semantic properties of words, such as similarity and analogy. Meanwhile, the ELMo algorithm (Peters et al., 2018) is used to train word vectors. ELMo simulates not only the complex features of vocabulary use, but also the changes in these usages in different language contexts. To train the ELMo word vector, we use the aforementioned processed text as input, including both the training and development set. The text is processed into a lookup table, and the words are passed into the ELMo algorithm one by one to generate a 1024-dimensional word vector.

For the feature extraction step, we use Keras (Francois and Chollet, 2015) to convert the text into a vector form of the word embeddings.

2.2 Model

Conventionally, the deep learning model is used in the natural language processing field. We use four superior-performance model components. By combining two different word embedding models, we obtain eight different models. We use four deep learning models, namely LSTM (Hochreiter and Schmidhuber, 1997; Mikolov, 2010), GRU (Cho et al., 2014), Capsule-Net (Sabour et al., 2017; Zhao et al., 2018), and Self-Attention (Luong et al., 2015).

We use Dropout (Salakhutdinov et al., 2014) to aid with improved model convergence. Finally, at each model output, we output the four predicted categories of probabilities, instead of the predicted results.

2.3 Ensemble Learning

According to the dataset characteristics, we design a multi-step ensemble neural network for the four-category emotion detection task.

The first step of integration consists of randomly dividing the entire dataset into 5-folds. In each round, four folds are used for training and the remaining fold is used to validate the model. Moreover, the model is used to predict the development and test sets. We use softmax activation function to get the probability distribution. At the end of the 5-fold cross-validation, five predicted probability values of train set, development set and test set are obtained. We apply a soft-voting mechanism to integrate the prediction probability on five predicted probability of development and test sets. The second step of integration involves combining different word vectors (GloVe and ELMo) with different models. The results of the first step of multiple models are horizontally concatenated as input for the second step of integration. The parameters are tuned and the predicted results are output.

Codes are publicly available at https://github.com/L-Maybe/SemEval-2019-task3-EmoContext

	others	*angry*	*sad*	*happy*
Training	0.4956	0.1826	0.1811	0.1407
Development	0.8486	0.0544	0.0454	0.0515

Table 1: Percentage of categories in dataset.

In the final integration phase, we use the XG-Boost (Chen and Guestrin, 2016) toolkit, which utilizes CPU multithreading for parallelism and exhibits strong classification performance. Furthermore, the toolkit can set different weights for unbalanced datasets, which is the most important reason for its use as the final predictive classifier. Following the ensemble learning of the soft-voting in the first step, we obtain eight groups of classification probability values. Owing to the different inputs, the final outputs of the four models differ, which meets the requirements of integrated learning. We horizontally concatenate the eight sets of probability prediction values into a new feature matrix and use the XGBoost tool to learn the new feature matrix to obtain the final prediction result.

3 Experiments and Results

3.1 Datastes and Official Evaluation Metrics

Datasets were provided by SemEval 2019 Task 3, EmoContext: Contextual Emotion Detection in Text (Chatterjee et al., 2019). The participants were asked to predict the emotions of a three-turn conversation. The task considered three emotion classes, namely *happy*, *sad*, and *angry*, along with an *others* category. The number of training and development sets was 30160 and 2755, respectively. The categories of the training and development sets are displayed in Table 1. Owing to the imbalance of the training set data, the official evaluation matrics is the micro-average F_1-score.

3.2 Preprocessing

For the data preprocessing, cleaning, and tokenization, as well as for most of the training sets, we used the Python Scikit-learn (Pedregosa et al., 2013) and Ekphrasis (Baziotis et al., 2017; Gimpel et al., 2011). The data is different from regular text, with substantial amounts of irregular grammar, logograms, and abbreviations, among others. Moreover, the emojis in text have an influence on the emotions detection. We studied the abbreviations of the text, determined the comparison table of abbreviations and words, and added English abbreviations to the abbreviated words. Moreover, the special emojis in text were counted, and a comparison table of expressions and corresponding explanations was generated. The processing steps are as follows:

- Process multiple consecutive punctuation points or emojis in a text into a punctuation or emoji.
- Splice the dialogue into a single text, and segment each round of dialogue with ’<eos>’.
- Use regular expressions to convert English mis-spelled words with similar rules into the correct words (for example, convert ’goooooood’ to ’good’, and ’yesssss’ to ’yes’).
- Use the Ekphrasis tool to segment texts. This tool is used to separate special emoticons (for example, convert ’:-(’ to ’unhappy face’, and ’:)’ to ’smiley face’), which is effective for the next step of expression processing.
- Traverse the word segmentation and comparison table one by one, replacing logograms, abbreviations, and emojis (for example, ’ ☹’ to ’unhappy face’ and convert ’☺’ to ’smiley face’,).

3.3 Parameter Optimization

In order to search the optimal parameters for each model, we used the Scikit-Learn toolkit to perform a grid search on the training set. In the single model tuning phase, we output the probability value of the four classifications and then performed integration. We used the micro-averaged F_1-score to evaluate the results of the soft-voting and to tune the optimal parameters.

After adjusting the single model parameters, we obtain the eight best performing models. As the training set was randomly scrambled, the training set for each cross-validation differs. Therefore, in the final integration, eight models will be run together, and the results of the eight models will be integrated to obtain the predicted results. The classifier for integrated learning is XGBoost, which uses the grid search method in Scikit-Learn to tune the optimal parameters. As the data to be learned are unbalanced, cross-validation is used to adjust the parameters. This step is applied to the training and development sets, and finally predicts the test set results.

Embeding	Dataset	Micro-Average-F_1(%)			
		Attention GRU	Capsule-Net	LSTM	GRU
GloVe	Dev	69.81	70.16	68.76	66.27
	Test	71.26	70.24	69.05	69.43
ELMo	Dev	71.36	70.18	70.32	70.12
	Test	70.04	70.95	70.92	70.1
Ensemble	Dev	76.05			
	Test	75.88			

Table 2: Final submission of development sets and tests.

	Precision	*Recall*	F_1
happy	0.717	0.687	0.701
sad	0.802	0.824	0.813
angry	0.720	0.0.819	0.766

Table 3: The result for each emotion class of test dataset.

The parameters are described as follows: model 1 and model 2 are two layers of LSTM and GRU respectively. Then there is the Dropout layer, and finally the softmax function is used to output the probability value. Model 3 and model 4 add the Attention layer and the Capsule-Net layer respectively after the stacked bidirectional GRU. The output is the same as model 1 or 2. The dropout in the GRU component is 0.25. The hidden dimension using the GloVe word vector is 120 while using the ELMO word vector is 400.The optimizer is rmsprop with a learning rate of 0.3. The loss function is categorical cross-entropy. The bacth size of model is 256. The Routings is 5 of Capsule-Net while the number of capsule is 10 and the capsule dimension is 32.

The super parameters of XGBoost are as follows: the learning rate is 0.09, the estimators are 18, the maximum depth is 4, gamma is 1.7, subsample is 0.15, colsample_bytree is 0.75, reg_alpha is 0.01, and seed is 6.

3.4 Results and Analysis

The proposed system is trained on the EmoContext training set. There are eight models, and each single model is trained using five-fold cross-validation combined with a soft-voting method. The stacking integration algorithm is used to output the final predicted results. The results of the development and test sets are presented in Table 2. the result for each emotion class of test dataset in Table 3.

It is worth noting that the results of developing the ELMo word vector on the set are significantly superior to the results of the GloVe word vector. We did not discard the GloVe word vector, and the results are not ineffective. Moreover, the performance will be improved by integrating multiple different models. Based on the results of the test set, the GloVe word vector results will be superior to those of the development set in the final prediction. In the overall comparison of the test set and development set results, the model offers a strong generalization ability.

Following the ensemble learning, our final result is 75.88%. Throughout the experiment, we found that, although we used cross-validation and applied a soft-voting mechanism, the experimental results were not very stable, the main reason for which is that the data were not balanced.

4 Conlusion

Our system won 10th place in SemEval-2019 Task 3, EmoContext: Contextual Emotion Detection in Text. The main challenge for this task was data imbalance. We achieved a competitive result using a multi-step ensemble neural network. The use of cross-validation in a single model mitigates the effects of data imbalance. A soft-voting mechanism was incorporated into the process to improve the model stability further. The results of the eight models were integrated using stacking integration. According to the final official review, our system is certainly effective. In future work, we will study how to enable the model to learn more features and improve our proposed model in the case of data imbalance.

Abstract

In the age of emerging volume of microblog platforms, especially twitter, hate speech propagation is now of great concern. However, due to the brevity of tweets and informal user generated contents, detecting and analyzing hate speech on twitter is a formidable task. In this paper, we present our approach for detecting hate speech in tweets defined in the SemEval-2019 Task 5. Our team KDEHatEval employs different neural network models including multi-kernel convolution (MKC), nested LSTMs (NLSTMs), and multi-layer perceptron (MLP) in a unified architecture. Moreover, we utilize the state-of-the-art pre-trained sentence embedding models including DeepMoji, InferSent, and BERT for effective tweet representation. We analyze the performance of our method and demonstrate the contribution of each component of our architecture.

1 Introduction

Nowadays, microblog platforms such as twitter has become the most popular communication medium among the people due to its convenient feature for sharing views, opinions, breaking news, and ideas. Besides its robust communication feature, it has facilitated the evil-minded people to propagate anti-social behavior including online harassment, cyber-bullying, and hate speech.

Hate speech is commonly defined as any communication that disparages a person or a group on the basis of some characteristics such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristics (Basile et al., 2019). Given the massive amount of user-generated contents on the microblog, the problem of detecting, and therefore possibly limit the hate speech diffusion, is becoming fundamental, for instance for fighting against misogyny and xenophobia.

To address the challenges of hate speech detection in microblog platforms, Basile et al. (2019) proposed a multilingual detection of hate speech (HatEval) in twitter, task 5 at SemEval-2019. The task features two specific different targets including immigrants and women and focuses on two related subtasks.

Task A defines a two-class (or binary) classification problem where a system needs to predict whether a tweet in English or Spanish with a given target (women or immigrants) is hateful or not hateful. Whereas task B defines the aggressive behavior and target classification problem. A system first classifies a hateful tweet as aggressive or not aggressive, and then identify the target harassed as the individual or generic (i.e., single human or group). In this paper, we only focus on the English tweets for both task A and B.

The rest of the paper is structured as follows: **Section 2** provides a brief overview of prior research. In **Section 3**, we introduce our proposed neural network model. **Section 4** includes experiments and evaluations as well as the analysis of our proposed method. Some concluded remarks and future directions of our work are described in **Section 5**.

2 Related Work

Early studies on hate speech detection focused mainly on lexicon-based approaches (Kwok and Wang, 2013; Gitari et al., 2015). However, these approaches prone to failure for detecting hate speech in a microblogging platform where rare terms are evolving incessantly. Besides some researchers tackled the problem by employing feature (e.g., N-gram, TF-IDF) based supervised learning approach using SVM and Naive-Bayes classifier (Gaydhani et al., 2018; Unsvåg and Gambäck, 2018).

Proceedings of the 13th International Workshop on Semantic Evaluation (SemEval-2019), pages 365–370
Minneapolis, Minnesota, USA, June 6–7, 2019. ©2019 Association for Computational Linguistics

More recently several researchers tried to address the problem by using state-of-the-art neural network based models. Among several prominent works, Badjatiya et al. (2017) employed multiple deep learning architectures including CNNs, LSTMs, and fastText to learn semantic word embeddings for hate speech detection. Golem et al. (2018) utilized the combination of traditional shallow machine learning models and deep learning models for hate speech detection. Pitsilis et al. (2018) utilized the ensemble of recurrent neural network (RNN) classifiers and incorporated various features associated with user-related information. Zhang et al. (2018) introduced a new method by combining a convolutional neural network (CNN) and gated recurrent unit (GRU) models. Djuric et al. (2015) used the comment embeddings for detecting hate speech.

3 Proposed Framework

In this section, we describe the details of our proposed neural network model. The goal of our proposed approach is to detect whether a tweet is hateful or not as well as determine its aggressiveness and identify the target harassed as individual or generic. We consider each task as a binary classification problem as well as train and evaluate our model accordingly. Figure 1 depicts an overview of our proposed model.

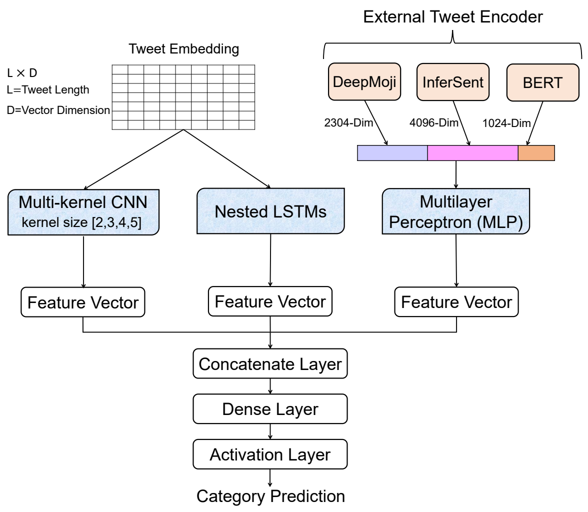

Figure 1: Proposed framework.

At first, we utilize a pre-trained word embedding model to obtain the high-quality distributed vector representations of tweets. Next, we apply the multi-kernel convolution (MKC) and nested LSTMs (NLSTMs) models to extract the higher-level feature sequences with sequential information from the tweet embeddings. Besides, we employ three different pre-trained tweet encoder models including DeepMoji, InferSent, and BERT to encode each tweet into 2304, 4096, and 1024-dimensional feature vector, respectively. These feature vectors are then combined and sent to a multi-layer perceptron (MLP) module. Finally, the generated output feature sequences from MKC, NLSTMs, and MLP are concatenated and fed into the fully-connected prediction module to determine the final category label. For the simplicity of discussion, we named our proposed neural network architecture as MKC-NLSTMs-MLP. Next, we describe each component elaborately.

3.1 Embedding Layer

Distributed representation of words known as word embedding is treated as one of the most popular representations of documents vocabulary due to its capability of capturing the context of a word within a document as well as estimating the semantic similarity and relation with other words (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017).

In our proposed framework, we utilize a pre-trained word embedding model based on fastText (Bojanowski et al., 2017) to obtain the high-quality distributed vector representations of tweets. The dimensionality of the embedding matrix will be $L \times D$, where L is the tweet length, and D is the word-vector dimension.

3.2 Multi-kernel Convolution

The convolution layers usually applied to extract the higher level features from the given input matrix. Since kernel sizes, i.e., the size of the convolution filters have a significant effect on performance, we apply filters with different sizes to get the different kinds of effective features. In our multi-kernel convolution, We perform the convolution on the input tweet's embedding matrix by using four different kernel sizes: 2, 3, 4, and 5. Some previous studies already demonstrated the effectiveness of multi-kernel convolution over the single one (Kim, 2014; Zhang and Wallace, 2015; Wang et al., 2017).

3.3 Nested LSTMs

In nested LSTMs (NLSTMs) (Moniz and Krueger, 2017), the LSTM memory cells have access to their inner memory, where they can selectively read and write relevant long-term information. While the value of the outer memory cell in the LSTM is estimated as $c_t^{outer} = f_t \odot c_{t-1} + i_t \odot g_t$, memory cells of the NLSTM use the concatenation $(f_t \odot c_{t-1}, i_t \odot g_t)$ as input to an inner LSTM (or NLSTM) memory cell, and set $c_t^{outer} = h_t^{inner}$. The inner memories of NLSTMs operate on longer time-scales and capture the context information from the input tweets effectively.

3.4 Pre-trained Models for Feature Encoding

In order to extract features for effective tweet representation, we utilize the three state-of-the-art pre-trained sentence embedding model including DeepMoji, BERT, and InferSent. In this section, we briefly describe these models.

DeepMoji: DeepMoji (Felbo et al., 2017) performs distant supervision on a dataset of 1246 million tweets comprising a more diverse set of noisy labels. DeepMoji uses an embedding layer of 256 dimensions to project each word of a tweet into a vector space. Two bidirectional LSTM layers with 1024 hidden units in each (512 in each direction) are applied to capture the context of each word. Finally, an attention layer takes all of these layers as input using skip-connections. We employ the representation vector of dimension 2304 obtained from the attention layer as the features.

BERT: BERT (Devlin et al., 2018) stands for Bidirectional Encoder Representations from Transformers, which is a new method of pre-training sentence representations. We employ the BERT-Large, Uncased model to encode each tweet into a 1024-dimensional feature vector.

InferSent: InferSent (Conneau et al., 2017) is a universal sentence embedding model trained using the supervised data of the Stanford Natural Language Inference (SNLI) datasets. We employ the InferSent model trained on fastText (Bojanowski et al., 2017) vectors to encode each tweet into a 4096-dimensional feature vector.

3.5 Multi-layer Perceptron

After extracting features from the pre-trained external tweet encoder model, we concatenate them and pass to a fully connected multi-layer perceptron (MLP) network.

A multilayer perceptron (MLP) (Pedregosa et al., 2011) is a feed-forward artificial neural network model that maps sets of input data onto a set of appropriate outputs. An MLP consists of multiple layers of nodes in a directed graph, with each layer fully connected to the next one. Except for the input nodes, each node is a neuron with a nonlinear activation function. MLP utilizes a supervised learning technique called back-propagation for training the network.

3.6 Prediction Module and Model Training

We concatenate the final tweet representation from the multi-kernel convolution (MKC) module, NLSTMs module, and MLP module and pass it to a fully connected softmax layer for category prediction. We consider cross-entropy as the loss function and train the model by minimizing the error, which is defined as:

$$E(x^{(i)}, y^{(i)}) = \sum_{j=1}^{k} 1\{y^{(i)} = j\} \log(y_j^{\sim(i)})$$

where $x^{(i)}$ is the training sample with its true label $y^{(i)}$. $y_j^{\sim(i)}$ is the estimated probability in $[0, 1]$ for each label j. $1\{condition\}$ is an indicator which is 1 if true and 0 otherwise. We use the stochastic gradient descent (SGD) to learn the model parameter and adopt the Adam optimizer (Kingma and Ba, 2014).

4 Experiments and Evaluations

4.1 Dataset Collection

The multilingual detection of hate speech (HatEval) task 5 at SemEval-2019 (Basile et al., 2019) provides a benchmark dataset to evaluate the performance of the participants' systems. The proposed task features two specific different targets including immigrants and women in a multilingual perspective, for Spanish and English. However, we only used the English dataset to evaluate our proposed system. The training, validation, and test set of the English dataset contains the 9000, 1000, and 2971 annotated tweets, respectively.

4.2 Model Configuration

In the following, we describe the set of parameters that we have used to design our proposed neural network model, MKC-NLSTMs-MLP. Our designed model was based on Tensorflow (Abadi et al., 2016) and trained on a GPU (Owens et al., 2008) to capture the benefit from the efficiency of parallel computation of tensors. We performed hyper-parameter optimization using a simple grid search. We used the 300-dimensional fastText embedding model pre-trained on Wikipedia with skip-gram (Bojanowski et al., 2017) to initialize the word embeddings in the embedding layer described in Section 3.1. For the multi-kernel convolution described in Section 3.2, we employed 4 different kernel sizes including (2,3,4,5), and the number of filters was set to 600. The nested LSTMs module contains 2 layers and multi-layer perceptron (MLP) module contains 3 fully-connected dense layers. We trained all models with 15 epochs with a batch size of 32 and an initial learning rate 0.001 by Adam optimizer. The MLP layers were dropped out with a probability of 0.02. $L2$ regularization with a factor of 0.01 was applied to the weights in the softmax layer. Unless otherwise stated, default settings were used for the other parameters.

4.3 Evaluation Measures

To evaluate the performance of the system, the organizers used different strategies and metrics for the task A and B (Basile et al., 2019). For the task A, standard evaluation metrics, including accuracy, precision, recall, and F1-score were applied to estimate the performance of a system. However, F1-score considered as the primary evaluation measure for this task.

For the task B, macro average $F1$-score of the hate speech (HS), target range (TR), and aggressiveness (AG) category and exact match ratio (EMR) of these categories are used as the evaluation measures. EMR considered as the primary evaluation measure for task B.

4.4 Experimental Results

We now evaluate the performance of our proposed method, MKC-NLSTMs-MLP, in this section. The summarized results for task A and task B are presented in Table 1 and Table 2, respectively.

At first, we presented the performance of our proposed method denoted by team name KDEHatEval as well as presenting the performance of randomly chosen top-ranked participated systems and

Team Name	Accuracy	Precision	Recall	F1-Score
KDEHatEval	0.493	0.633	0.555	0.440
Fermi	0.653	0.690	0.679	0.651
YNU_DYX	0.560	0.636	0.603	0.546
SINAI_DL	0.535	0.601	0.577	0.519
Hateminers	0.544	0.658	0.596	0.516
SVC Baseline	0.492	0.595	0.549	0.451
MFC Baseline	0.579	0.289	0.500	0.367

Table 1: (Task A) Our result with other selected teams.

Team Name	Avg. F1-Score	Exact Match Ratio (EMR)
KDEHatEval	0.559	0.324
MFC Baseline	0.421	0.580
CIC-1	0.551	0.568
SINAI_DL	0.611	0.384
Hateminers	0.589	0.357
SVC Baseline	0.578	0.308

Table 2: (Task B) Our result with other selected teams.

HatEval-2019 baselines. The organizers used the SVC (a linear support vector machine) and MFC (a trivial model that assigns the most frequent label, estimated on the training set) as the baseline system (Basile et al., 2019).

In order to estimate the effect of each component of our MKC-NLSTMs-MLP model, we performed the component ablation study. In this regard, we removed one component each time and repeated the experiment. The summarized experimental results of component ablation study for the task A are presented in Table 3.

Method	Accuracy	Precision	Recall	F1-Score
MKC-NLSTMs-MLP	0.493	0.633	0.555	0.440
−MKC	0.441	0.507	0.503	0.381
−NLSTMs	0.483	0.630	0.548	0.423
−MLP	0.495	0.636	0.557	0.443
−MKC−NLSTMs	0.458	0.507	0.505	0.431
−MKC−MLP	0.475	0.592	0.537	0.419
−NLSTMs−MLP	0.485	0.640	0.549	0.423

Table 3: (Task A) Ablation study of our proposed method.

From the results, it can be observed that when removing multi-kernel convolution (MKC) and nested LSTMs (NLSTMs) the overall F1 score decreased by 5.6% and 1.7%, respectively. However, when removing external tweet embedding with MLP module, the results increased by 0.3%. This observation deduced that in our current architecture, external pre-trained model features with MLP contributed negatively.

Besides, removing one component, we also perform ablation study by removing two components and present the results accordingly in Table 3. This analysis provides the overall performance of the individual component.

5 Conclusion

In this paper, we presented our approach to the SemEval-2019 Task 5: HatEval: Detection of hate speech. We tackled the problem by employing several deep learning techniques including multi-kernel convolution, nested LSTMs, and multi-layer perceptron in a unified architecture.

Though we have used the state-of-the-art techniques in our proposed approach, the overall performance is not satisfactory. The contribution of nested LSTMs (NLSTMs) is not significant while compared with the multi-kernel convolution (MKC). Regarding this, one possible solution will be used the MKC on top of NLSTMs. Moreover, we observed that the multi-layer perceptron (MLP) model trained with the concatenated features from the pre-trained sentence embedding models hurts the performance of our proposed architecture. We need to observe the ablation study of the sentence embedding models as well as modify the MLP architecture to mitigate this issue.

Therefore, there is much room left to improve the performance of our method presented in HatEval-2019 task. In the future, we have a plan to overcome these limitations by introducing several sophisticated techniques.

Abstract

In this paper, we present the results obtained using bi-directional long short-term memory (BiLSTM) with and without attention and Logistic Regression (LR) models for SemEval-2019 Task 5 titled ”HatEval: Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter”. This paper presents the results obtained for Subtask A for English language. The results of the BiLSTM and LR models are compared for two different types of preprocessing. One with no stemming performed and no stopwords removed. The other with stemming performed and stopwords removed. The BiLSTM model without attention performed the best for the first test, while the LR model with character n-grams performed the best for the second test. The BiLSTM model obtained an F1 score of 0.51 on the test set and obtained an official ranking of 8/71.

1 Introduction

Davidson et al. (2017) has defined hate speech as “language that is used to express hatred towards a targeted group or is intended to be derogatory, to humiliate, or to insult the members of the group.” Gambäck and Sikdar (2017), Badjatiya et al. (2017), Waseem (2016) and Waseem et al. (2017) have used the term hate speech to indicate tweets having racist or sexist comments. Social media is becoming a convenient medium to spread hate speech. Hate speech spread through social media has fueled riots in Myanmar [1], Sri Lanka [2], Charlottesville (USA) [3], and many other parts of the world. Thus, it is becoming increasingly important to detect and remove hate messages from the web. It is not possible to manually moderate the vast amount of text exchanged on the web. Developing automated systems to recognize hate speech is becoming crucially important. However, detecting hate speech in a text is more than just checking for the presence of hate words. Lexicon based approaches have not been very effective in hate speech detection (Nobata et al., 2016).

As part of the 13th workshop on semantic evaluation (SemEval-2019), shared task 5 defines two subtasks with regard to detection of hate speech against immigrants and women in Twitter (Basile et al., 2019). This task was conducted for tweets in English and Spanish language. In Subtask A, it is required to determine if a tweet, with a given target, is hateful or not. In Subtask B, it is required to determine if a given hateful tweet is aggressive or not and whether it targets an individual or a group.

2 Related Work

Nobata et al. (2016) studied the performance of different features such as character n-grams, word n-grams, word2vec, character2vec, etc. in detecting hate speech. A regression model was used in their study. Malmasi and Zampieri (2017) made a similar study to compare the performance of different features in detecting hate speech. Djuric et al. (2015) used paragraph embeddings for detecting hate speech. Wulczyn et al. (2017) worked on detecting insults in Wikipedia comments. Davidson et al. (2017) worked on detecting hate speech when hate words are not explicitly used in the text. Malmasi and Zampieri (2018) used ensemble method and combined 16 different base classifiers to detect hate speech. Serrà et al. (2017) used character-based Recurrent Neural Network (RNN) to study the use of out-of-vocabulary words in hate speech. Gao and Huang (2017) used BiLSTMs with attention mechanism

[2]https://qz.com/1223787/sri-lanka-shut-down-facebook-whatsapp-and-instagram-to-stop-anti-muslim-violence/

[3]https://psmag.com/social-justice/how-social-media-helped-organize-and-radicalize-americas-newest-white-supremacists

to detect hate speech. Pavlopoulos et al. (2017) used Convolutional Neural Network (CNN) and RNN with attention mechanism to moderate user comments. Sax (2016) compared the performance of several deep learning techniques, LR and Support Vector Machine (SVM) models in detecting hate speech.

3 Data

Table 1 below shows the proportion of positive and negative instances of hate speech in the train, development and test data sets. As can be seen, 42% of the instances in each of the data set are hate speech. The data collected in Gao et al. (2017) had only 0.6% hateful tweets. Nobata et al. (2016) found that only 5.9% of the online comments contained hate speech. The data sets used for this task, however, are quite balanced.

Type	Not Hate Speech	Hate Speech	Total
Train	5217 (58%)	3783 (42%)	9000
Dev	573 (57.3%)	427 (42.7%)	1000
Test	1718 (57.85%)	1252 (42.15%)	2970

Table 1: Data set statistics

The models used in our study were trained and validated using the train and development sets provided as part of this task. No other external data sets were used for training or validating. However, pre-trained GloVe [4] word vectors trained using 2 billion tweets were used as features for the two BiLSTM models. The 200-dimensional word vectors were used in our experiments.

4 Experimental Settings

4.1 Preprocessing

The preprocessing performed on the text includes the following -

1. All URLs, mentions and non-alphabetic characters were removed from the tweets.
2. The tweets were then converted to lowercase.
3. Stemming was performed using NLTK's Lancaster stemmer.
4. Stopwords were removed.
5. Tokenizer was used to convert each tweet into a sequence of integers by replacing each token by its index into the vocabulary. The tweet with the maximum length had 58 tokens (when stopwords were retained). This value is later used as the length of the input sequences to the Embedding layer of the BiLSTM models. So, tweets with length less than 58 were padded with zeros, so as to make all the tweets to be of the same length.

4.2 Models Used

In our study, we used a BiLSTM without attention, and a BiLSTM with attention and an LR model. The details of our models are provided below.

4.2.1 BiLSTM without attention mechanism

Figure 1 shows the architecture of the BiLSTM used in our study. Both the forward and backward Long Short-Term Memory (LSTM) layers of the bi-directional layer of this model consisted of 100 units. Pre-trained GloVe embeddings were used to train the model. An embedding layer was used to feed the word vectors to the BiLSTM layer. A dropout of 0.25 was applied to the input of LSTM and a dropout of 0.1 was used for the recurrent connections. The BiLSTM layer was set to return the hidden state for each timestep. Thus, the output shape of the BiLSTM layer was (None,58,200). A global max pooling layer was used on top of the BiLSTM layer. This resulted in an output of the shape (None,200). The output from the global max pooling layer was fed to a Dense layer having 100 units. The Rectified Linear Unit (ReLU) activation function was used for this Dense layer. The output of the Dense layer was of the shape (None,100). The output was passed through a dropout layer with the rate set to 0.25. The output from the dropout layer was then passed through another Dense layer having a single unit. The sigmoid activation function was used for this layer. The model was trained using the Adam optimizer. The loss function used was binary cross-entropy. The model was trained with a batch size set to 32. The hyperparameter values used for the model are summarized in Table 2.

4.2.2 BiLSTM with attention mechanism

This model is exactly the same as the model described in 4.2.1 except that the global max pooling layer was replaced with attention mechanism. The hyperparameter values for both the models were also same.

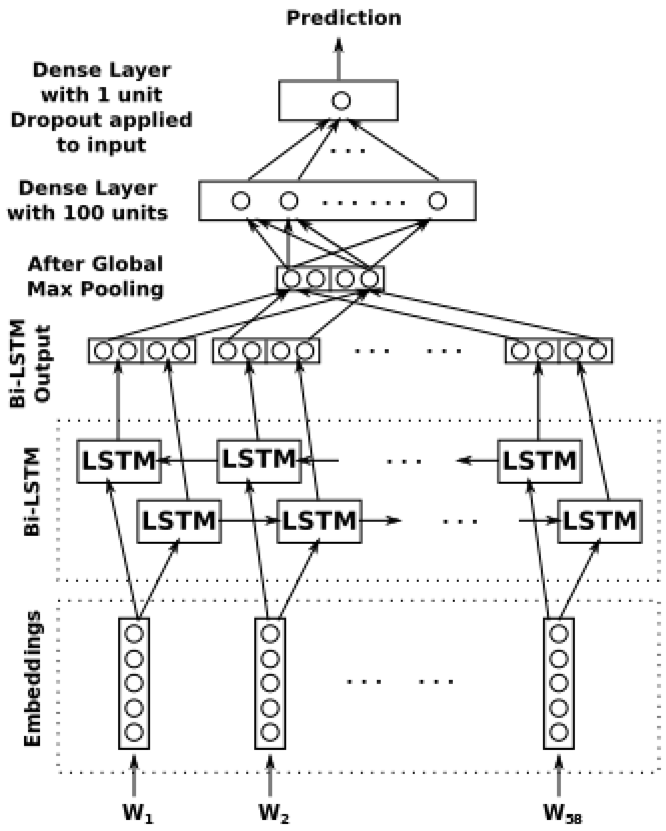

Figure 1: Architecture of the BiLSTM model used

Parameter	Value
Number of LSTM units	100
LSTM dropout	0.25
Recurrent dropout	0.10
Units in 1st Dense layer	100
Activation Function for 1st Dense layer	ReLU
Rate for dropout layer	0.25
Units in 2nd Dense layer	1
Activation Function for 2nd Dense layer	sigmoid
Optimizer	Adam
Loss Function	Binary cross-entropy

Table 2: Hyperparameters for the BiLSTM model

4.2.3 Logistic Regression

The third model we used was an LR model with L2 regularization. The class weight and C parameter were set to 'balanced' and 1.2 respectively. This model was trained with character n-grams (1 to 6), word n-grams (1 to 3), and a combination of both character and word n-grams. The hyperparameter values for the LR model were set as shown in Table 3.

5 Results & Discussions

The following tests were performed by us:

1. BiLSTM model trained using GloVe word embeddings as features.

2. BiLSTM model with attention mechanism trained using GloVe word embeddings as features.

3. LR model trained using character n-grams (1 to 6) only.

4. LR model trained using word n-grams (1 to 3) only.

5. LR model trained using both character and word n-grams concatenated together.

Parameter	Value
Regularization	L2
C	1.2
Class weight	balanced

Table 3: Hyperparameters for the LR model

Table 4 shows the results obtained by our models on the development set when stemming was not performed and stopwords were not removed. Table 5 shows the results when stemming was performed and stopwords were also removed.

Approach	Features	Acc	Prec	Rec	F1
BiLSTM	GloVe word embeddings	**0.748**	**0.749**	**0.748**	**0.748**
BiLSTM with attention	GloVe word embeddings	0.737	0.738	0.737	0.737
Logistic Regression	Char n-grams (1 to 6)	0.727	0.733	0.727	0.728

Logistic Regression	Char n-grams & Word n-grams	0.727	0.734	0.727	0.728

Table 4: Results of our models on Dev set of Task 5-Subtask A (No stemming + No Stopwords removed)

Approach	Features	Acc	Prec	Rec	F1
BiLSTM	GloVe word embeddings	0.674	0.699	0.674	0.675
BiLSTM with attention	GloVe word embeddings	0.698	0.698	0.698	0.689
Logistic Regression	Char n-grams (1 to 6)	**0.743**	**0.749**	**0.743**	**0.744**
Logistic Regression	Word n-grams (1 to 3)	0.727	0.731	0.727	0.728
Logistic Regression	Char n-grams & Word n-grams	0.739	0.746	0.739	0.740

Table 5: Results of our models on Dev set of Task 5-Subtask A (Stemming + Stopwords removed)

Approach	Accuracy	Precision	Recall	F1
SVC Baseline	0.49	0.60	0.55	0.45
MFC Baseline	**0.58**	0.29	0.50	0.37
BiLSTM	0.54	**0.64**	**0.59**	**0.51**
Best System	0.65	0.69	0.68	0.65

Table 6: Official results for Task 5-Subtask A

As can be seen from Table 4, the BiLSTM model without attention outperformed the other two models for all the metrics. However, the improvements achieved were not very significant compared to the other two models. It can also be seen that the choice of character or word n-grams did not make much difference to the performance of the LR model. Equivalent results were obtained for all the 3 tests performed using the LR model. This is surprising considering the fact that character n-grams usually performs better than word n-grams for text containing obfuscated words. Mehdad and Tetreault (2016) mentions that offenders often obfuscate the hate words in order to avoid detection by keyword-based filters. So, character n-gram features should have improved the performance of the model. One explanation for this observation could be the removal of numeric and special characters from the tweets during the data preprocessing stage. Numeric and special characters are used frequently used to obfuscate hate words. 'ass' replaced by 'a$$', 'slut' replaced by 's1ut' etc. are examples of such obfuscation. So, a test was performed without removing the numeric and special characters. However, no significant increase in the performance of character-based model was observed.

As can be seen from Table 5, the LR models performed better than the BiLSTM models when stemming was performed and stopwords were removed. The character n-gram based LR model performed the best for all the metrics considered.

The predictions obtained for the test set using the BiLSTM model without attention mechanism were submitted as the final predictions. The model that was trained with stopwords retained and stemming not performed was used to make the predictions on the test set. The official results obtained for the submission are shown in Table 6. Our official ranking is 8/71 in subtask A for the English language. As can be seen from the results, the MFC baseline had the best accuracy score. By labeling all the test instances with the most frequent label, the MFC baseline was able to obtain a better accuracy score. The MFC baseline achieved a better accuracy score at the cost of a low precision value. This resulted in a low F1 score for the baseline. Our BiLSTM model obtained a significantly higher F1 score compared to the MFC baseline. Our BiLSTM model outperformed the SVC baseline on all the metrics.

Table 7 shows the confusion matrices for the tests performed by retaining the stopwords and without performing stemming. The BiLSTM models were able to achieve better F1 score compared to the LR model by making better predictions for the benign class.

Table 8 shows the confusion matrices for the tests performed with stopwords removed and stemming performed. As can be seen, the BiLSTM models with attention and without attention show opposite tendencies. While the BiLSTM model without attention gets better in predicting the hate class, it becomes weaker in predicting the benign class. The opposite is true for the BiLSTM model with attention. The character n-gram based LR model gets better in predicting both the hate and benign classes.

6 Error Analysis

From the errors made by our system, it is evident that the model was not able to determine correctly if the hate words have really been used to express hate. For e.g., the following tweet from the test set is not a hate speech - "I can be a bitch and

	BiLSTM Predictions		**BiLSTM with Attention Predictions**		**LR (char) Predictions**		**LR (word) Predictions**		**LR (char+word) Predictions**	
	Not	**Hate**	**Not**	**Hate**	**Not**	**Hate**	**Not**	**Hate**	**Not**	**Hate**
Not	437	136	438	135	411	162	408	165	410	163
Hate	116	311	128	299	111	316	113	314	110	317

Table 7: Confusion Matrix (No Stemming + No stopword removed)

	BiLSTM Predictions		**BiLSTM with Attention Predictions**		**LR (char) Predictions**		**LR (word) Predictions**		**LR (char+word) Predictions**	
	Not	**Hate**	**Not**	**Hate**	**Not**	**Hate**	**Not**	**Hate**	**Not**	**Hate**
Not	345	228	476	97	421	152	418	155	416	157
Hate	98	329	205	222	105	322	118	309	104	323

Table 8: Confusion Matrix (Stemming + Stopwords removed)

an asshole but I will love you and care about you more than any other person you have met." Here, the speaker is attributing the word 'bitch' to himself/herself. So, the tweet cannot be a hate speech. However, our system wrongly classifies the tweet as a hate speech.

There have been many instances where our system wrongly classifies a tweet as hate speech just because of the mere presence of words such as 'bitch', '#buildthewall' etc. even when the tweet is not intended against women or immigrants. For e.g., the tweet 'He is a snake ass bitch. He is a fugly slut...' is a hate speech but it is not intended against women. But our system was not able to detect this and wrongly classifies it.

7 Conclusion

With hate speech in social media fomenting many riots in different parts of the world, it is becoming increasingly important to prevent their spread. While manual moderation is almost impossible, the need of the time is automated systems for their removal. The BiLSTM and logistic regression models used in this study have obtained some success compared to the baselines used. But there is much left to be desired. Hate words used in the benign sense and hate speech not directed at women and immigrants were wrongly getting classified. Contextual information and features such as part-of-speech (POS), dependency relations may help in classifying such instances correctly.

Amobee at SemEval-2019 Tasks 5 and 6: Multiple Choice CNN Over Contextual Embedding

Alon Rozental[*], **Dadi Biton**[*]
Amobee Inc., Tel Aviv, Israel
{alon.rozental,dadi.biton}@amobee.com

Abstract

This article describes Amobee's participation in "HatEval: Multilingual detection of hate speech against immigrants and women in Twitter" (task 5) and "OffensEval: Identifying and Categorizing Offensive Language in Social Media" (task 6). The goal of task 5 was to detect hate speech targeted to women and immigrants. The goal of task 6 was to identify and categorized offensive language in social media, and identify offense target. We present a novel type of convolutional neural network called "Multiple Choice CNN" (MC-CNN) that we used over our newly developed contextual embedding, Rozental et al. (2019)[1]. For both tasks we used this architecture and achieved 4th place out of 69 participants with an F_1 score of 0.53 in task 5, in task 6 achieved 2nd place (out of 75) in Sub-task B - automatic categorization of offense types (our model reached places 18/2/7 out of 103/75/65 for sub-tasks A, B and C respectively in task 6).

1 Introduction

Offensive language and hate speech identification are sub-fields of natural language processing that explores the automatic inference of offensive language and hate speech with its target from textual data. The motivation to explore these sub-fields is to possibly limit the hate speech and offensive language on user-generated content, particularly, on social media. One popular social media platform for researchers to study is Twitter, a social network website where people "tweet" short posts. Each post may contain URLs and/or mentions of other entities on twitter. Among these "tweets" we can find various opinions of people regarding political events, public figures, products, etc. Hence, Twitter data turned into one of the main data sources for both academia and industry. Its unique insights are relevant for business intelligence, marketing and e-governance. This data also benefits NLP tasks such as sentiment analysis, offensive language detection, topic extraction, etc.

Both the OffensEval 2019 task (Zampieri et al. (2019b)) and HatEval 2019 task are part of the SemEval-2019 workshop. OffensEval has 3 sub-tasks with over 65 groups who participate in each sub-task and HatEval has 2 sub-tasks with 69 groups.

Word embedding is one of the most popular representations of document vocabulary in low-dimensional vector. It is capable of capturing context of a word in a document, semantic and syntactic similarity, relation with other words, etc. For this work, word embedding was created with a model similar to Bidirectional Encoder Representations from Transformers (BERT), Devlin et al. (2018). BERT is a language representation model designed to pre-train deep bidirectional representations by jointly conditioning on both left and right context in all layers. As a result, the pre-trained BERT representations can be fine-tuned to create state-of-the-art models for a wide range of tasks, such as question answering and language inference, without substantial task-specific architecture modifications. Besides the word embedding, BERT generates a classification token, which can be used for text classification tasks.

This paper describes our system for the OffensEval 2019 and HatEval 2019 tasks, where our new contribution is the use of contextual embedding (modified BERT) together with an appropriate network architecture for such embeddings .

The paper is organized as follows: Section 2 describes the datasets we used and the pre-process

[*]These authors contributed equally to this work.

phase. Section 3 describes our system architecture and presents the MC-CNN. In section 4 we present the results of both tasks - the OffensEval and HatEval. Finally, in section 5 we review and conclude the system.

2 Data and Pre-Processing

We used Twitter Firehose dataset. We took a random sample of 50 million unique tweets using the Twitter Firehose service. The tweets were used to train language models and word embeddings; in the following, we will refer to this as the Tweets_50M dataset.

A modified language model, based on BERT, was trained using a large Tweets_50M dataset, containing 50 million unique tweets. We trained two models, one used to predict hate speech in posts (task 5) and the other used to predict offensive language in posts (task 6). The pre-process on the Tweets_50M dataset consists of replacing URLs and Twitter handles with special tokens and keeping only the first 80 sub-word tokens in each tweet (for our vocabulary over 99% of the tweets contain less than 80 tokens).

The language model we trained differs from Devlin et al. (2018) mainly by the addition of a latent variable that represents the topic of the tweet and the persona of the writer. The work on this model is still in progress and in this work we have used an early version of the model described in Rozental et al. (2019).

2.1 OffensEval

OffensEval 2019 is divided into three sub-tasks.

1. Sub-task A - Offensive language identification - identify whether a text contains any form of non-acceptable language (profanity) or a targeted offense.

2. Sub-task B - Automatic categorization of offense types - identify whether a text contains targeted or non-targeted profanity and swearing.

3. Sub-task C - Offense target identification - determine whether the target of the offensive text is an individual, group or other (e.g., an organization, a situation, an event, or an issue).

The official OffensEval task datasets, retrieved from social media (Twitter). Table 1 presents the label distribution for each sub-task. For further shared task description, data-sets and results regarding this task, see Zampieri et al. (2019a).

2.2 HatEval

HatEval 2019 is divided into two sub-tasks.

1. Sub-task A - Hate Speech Detection against Immigrants and Women: a two-class classification where systems have to predict whether a tweet in English with a given target (women or immigrants) is hateful or not hateful.

2. Sub-task B - Aggressive behavior and Target Classification: where systems are asked first to classify hateful tweets for English and Spanish (e.g., tweets where Hate Speech against women or immigrants has been identified) as aggressive or not aggressive, and second to identify the target harassed as individual or generic (i.e. single human or group). In this paper we will focus only on sub-task A as none of the participants overcame the baseline accuracy in sub-task B.

There were 69 groups who participated in sub-task A. Table 2 presents the label distribution in sub-

task A. For further shared task description, datasets and results regarding this task, see Basile et al. (2019). HatEval also included Spanish task which we didn't participate in.

3 Multiple Choice CNN

For both tasks, using our contextual word embedding, we tried several basic approaches - A feed forward network using the classification vector and an LSTM and simple CNNs Zhang and Wallace (2015) using the words vectors. These approaches overfitted very fast, even for straightforward unigram CNN with 1 filter, and their results were inferior to those obtained by similar models over a Twitter specific, Word2Vec based embedding, Mikolov et al. (2013); Rozental et al. (2018). The fast overfitting is due to the information contained in contextual embedding which was not reflected in Word2Vec based embedding.

In order to avoid overfitting and achieve better results we created the MC-CNN model. The motivation behind this model is to replace quantitative questions such as "how mad is the speaker?", where the result is believed to be represented by the activation of the corresponding filter, with multiple choice questions such as "what is the speaker - happy/sad/other?", where the number of choices denoted by the number of filters. By forcing the sum of the filter activations for each group to be equal to 1, we believe that we have acheived this effect.

The model that produced the best results is an ensemble of multiple MC-CNNs over our developed contextual embedding, described in figure 1. On top of our contextual embedding, we used four filter sizes - 1-4 sub-word token n-grams. For each filter size individual filters were divided into groups of 7 and a softmax activation applied on the output of each group. These outputs were concatenated and passed to a fully connected feed forward layer of size 10 with tanh activation before it yeiled the networks' prediction. To decrease the variance of the results, there were multiple duplications of this architecture, where the final prediction was the average of all the duplications' output.

4 Results

We chose to use this architecture for both tasks because we believe that the BERT model output contains most of the information about the tweet. The layers above, the MC-CNN and the fully connected layers, adapt it to the given task. We think that this model can be use for variety of NLP tasks in twitter data with the appropriate hyper-parameters tuning.

The results yielded from the architecture which was described in figure 1 for both tasks. We optimized the hyper-parameters to maximize the F_1score using categorical cross entropy loss. The tuned parameters were the activation function of the filters and the number of filters in the MC-CNNs, the size of the filter groups of the MC-CNN, and the hidden layer size. The best result were achieved with a sigmoid activation function on the filters, where the number of filters was 7 in each group. There were 10, 6, 4 and 2 filter groups for filter sizes of 1, 2, 3 and 4 respectively. The model with those hyper-parameters yielded the best results in both tasks.

At HatEval the model achieved an F_1score of 0.535. In table 3 there is the best result compared to two baselines- linear Support Vector Machine based on a TF-IDF representation (SVC), and a trivial model that assigns the most frequent label (MFC), according to the F_1score.

System	F1 (macro)	Accuracy
SVC baseline	0.451	0.492
MFC baseline	0.367	0.579
MC-CNN	**0.535**	**0.558**

Table 3: F_1Score And Accuracy Of MC-CNN Comparing To Baselines At HatEval.

At OffensEval the model achieved an F_1score of 0.787, 0.739 and 0.591 for sub-tasks A, B and C respectively. In table 4 there is the best result compared to the baseline for sub-tasks A, B and C respectively according to the F_1score.

5 Conclusion

In this paper we described the system Amobee developed for the HatEval and OffensEval tasks. It consists of our novel task specific contextual embedding and MC-CNNs with softmax activation. The use of social networks motivated us to train contextual embedding based on the Twitter dataset, and use the information learned in this language model to identify offensive language and hate speech in the text. Using MC-CNN helped overcome the overfitting caused by the embedding. In order to decrease the variance of the system we used duplications of this model and averaged the results. This system reached 4th place at the HateEval task with an F_1score of 0.535, and 2nd place at sub-task B in the OffensEval task, with an F_1score of 0.739. As we mentioned, we used an early version of a Twitter specific language model to achieve the above results. We plan to release the complete, fully trained version in the near future and test it for different NLP tasks- such as topic classification, sentiment analysis, etc.

Abstract

In recent years, the use of social media has increased incredibly. Social media permits Inter-net users a friendly platform to express their views and opinions. Along with these nice and distinct communication chances, it also allows bad things like usage of hate speech. Online automatic hate speech detection in various aspects is a significant scientific problem. This paper presents the Instituto Politécnico Nacional (Mexico) approach for the Semeval 2019 Task-5 [Hateval 2019] (Basile et al., 2019) competition for Multilingual Detection of Hate Speech on Twitter. The goal of this paper is to detect (A) Hate speech against immigrants and women, (B) Aggressive behavior and target classification, both for English and Spanish. In the proposed approach, we used a bag of words model with preprocessing (stemming and stop words removal). We submitted two different systems with names: (i) CIC-1 and (ii) CIC-2 for Hateval 2019 shared task. We used TF values in the first system and TF-IDF for the second system. The first system, CIC-1 got 2nd rank in subtask B for both English and Spanish languages with EMR score of 0.568 for English and 0.675 for Spanish. The second system, CIC-2 was ranked 4th in subtask A and 1st in subtask B for Spanish language with a macro-F1 score of 0.727 and EMR score of 0.705 respectively.

1 Introduction

The social media applications enable users to discover, create and share contents handily, without specific expertise. This remarkably boosted the amount of data generated by the users, within a process that some people call "democratization" of the web (Silva et al., 2016). Still, this liberty also permits for the publication of data, which is insulting and hurtful both regarding the ethics of democracy and the privileges of some categories of people – hate speech (HS). The Hate Speech (HS) term is defined in the literature as an expression *"that is abusive, insulting, intimidating, harassing, and incites to violence, hatred, or discrimination. It is directed against people by their race, ethnic origin, religion, gender, age, physical condition, disability, sexual orientation, political conviction, and so forth."* (Erjavec and Kovacic, 2012). HS has turned into the main issue for each sort of online website, where user-produced content comes into sight: from the comments on any post to live chatting in online games. Such material can isolate users and inflame violence (Allan, 2013). Website operators as Facebook, Twitter, and gaming companies like Runic Games recognize that hateful data are creating both practical and ethical issues and have attempted to demoralize them, causing changes in their platforms or strategies.

As stated by Pew[1], women experienced more sexualized forms of abuse than men. Platforms as Twitter are flopping in acting immediately against real-time misogyny and taking a lot of time to delete the hateful data[2]. The researchers began to concentrate on this problem and are building techniques to detect misogyny in real time (Fersini et al., 2018; Hewitt et al., 2016; Poland, 2016). Real-time HS about groups of people like asylum searchers and visitors is common all over the world, but it is rarely investigated.

In this article, we worked on the detection of (A) Hate speech against immigrants and women, (B) Aggressive behavior and target classification, both for English and Spanish languages at Hateval 2019. For this task, we submitted two systems with names: (i) CIC-1 and (ii) CIC-2. We used the bag-of-words model (plus stemming) with TF and TF-IDF as feature values and then we classified these vectors using various machine learning classifiers. We submitted two approaches (systems). Subtask A is ranked by macro-F1 score, whereas subtask B is ranked by EMR score. Our system CIC-1 got 2nd rank in subtask B for the both English (2nd out of 42 teams) and Spanish (2nd out of 25 teams) languages with EMR score of 0.568 for English; 0.675 for Spanish (accuracy score of 0.766 for English; 0.787 for Spanish). The second system, CIC-2 was ranked 4th (out of 39 teams) in subtask A and 1st (out of 23 teams) in subtask B for Spanish language with a macro-F1 score of 0.727 and EMR score of 0.705 respectively (accuracy score of 0.727 in subtask A; 0.791 for subtask B).

2 Related work

A wide range of work has been devoted to HS detection. Xu et al. (2012) applied sentiment analysis to classify bullying in tweets with the usage of Latent Dirichlet Allocation (LDA) topic models (Blei et al., 2003) to recognize related topics in these scripts.

HS detection has been improved by a diverse range of features such as n-grams (Nobata et al., 2016), character n-grams (Mehdad and Tetreault, 2016), paragraph embeddings (Nobata et al., 2016; Djuric et al., 2015) and average word embeddings. (Silva et al., 2016) proposed to detect target groups regarding their class and background on Twitter by looking for sentence structures like "I <intensity> hate <targeted group>".

Currently, interest is increasing in the identification of HS against women on the web (Ging et al., 2018). Initially, Hewitt (2016) worked on the identification of HS against women in social media. Fox (2015) observed that the reaction on hated contents posted against women by unknown and know accounts is different. In (Fox et al., 2015), the authors study the roles of anonymity and interactivity in response to sexist content posted on social media. They inferred that content from unknown account advances more prominent threatening sexism than the known ones.

3 Corpora and task description

Multilingual detection of hate speech on Twitter shared task at Hateval 2019 had two datasets for the English and Spanish language. We participated in both subtasks for both languages.

3.1 Corpora

Corpora for the training of the model consist of 9,000 labeled tweets, and the development dataset includes 1,000 unlabeled tweets. The English data set statistics of different labels is given in Table 1 and the Spanish statistics in Table 2. The corpora is manually labeled by different annotators according to three types:

- Hate speech (present vs not-present),
- Target range (whole group vs individual),
- Aggressiveness (present vs not-present).

We describe these types in the following section.

Type	Labels	Train	Dev
Hate Speech	Present (0)	2631	278
	Absent (1)	1838	222
Target Range	Whole group (0)	3352	363
	Individual (1)	1117	137
Aggres-siveness	Present (0)	2984	324
	Absent (1)	1485	176

Table 1: Spanish dataset statistics.

Type	Labels	Train	Dev
Hate Speech	Present (0)	3783	427
	Absent (1)	5217	573
Target Range	Whole group (0)	7659	781
	Individual (1)	1341	219
Aggres-siveness	Present (0)	1559	204
	Absent (1)	7441	796

Table 2: English dataset statistics.

3.2 Description of the subtasks

Subtask A: Hate speech detection against immigrants and women: it is a binary classification problem, where it is asked to predict if a specific piece of text (tweet) with a given target (women or immigrants) expresses hatred or not. The systems are evaluated using standard evaluation metrics, containing accuracy, precision, recall, and macro-F1 score. The submissions are ranked by macro-F1 score.

Subtask B: aggressive behavior and target classification: it is required to identify hatred text (tweet) (e.g., tweets, where there is HS against

Team	Task	Classifier	English	Rank$_{eng.}$	Spanish	Rank$_{spa.}$
CIC-1	A_{F1}	Logistic Regression	0.462	29 of 69	0.703	18 of 39
	B_{EMR}	Majority Voting	0.568	**2 of 41**	0.675	**2 of 23**
CIC-2	A_{F1}	MultinomialNB	0.494	14 of 69	0.727	**4 of 39**
	B_{EMR}	Classifiers Chain	0.314	19 of 41	0.705	**1 of 23**

Table 3: Our results of Hateval 2019 shared task with ranking for both subtasks A and B.

women or immigrants were marked before) as aggressive or not, and on the second place to recognize a harassing target, either the text (tweet) is against an individual or a group. The evaluation of subtask B was carried out using a partial match and exact match (Basile et al., 2019). The submissions are ranked by EMR score. A tweet must be identified exclusively in one of the following types:

1. **Hateful:** an expression with feelings of dislike, very unpleasant or filled with hatred.
2. **Target Range:** the tweet contains offensive messages intentionally sent to a particular individual or to a group.
3. **Aggressiveness:** it is based on the person's purpose to be aggressive, damaging, or even to provoke.

3.3 Baselines

The Hateval 2019 has set up two following baselines:

- **SVC baseline:** the SVC baseline is a linear Support Vector Machine (SVM) based on TF-IDF representation.
- **MFC baseline:** The MFC baseline is a trivial model that assigns the most frequent label (estimated on the training set) to all the instances in the test set.

4 Description of our approach

In this section, we describe the two submitted approaches (systems) considering the features and machines learning models used for this shared task.

4.1 Pre-processing

We performed pre-processing on raw tweets before feature extraction. Pre-processing helps in these kind of tasks (Markov et al., 2017). For both approaches we used stemming and stop words removal. In CIC-2 we additionally made the following steps:

- we removed HTML tags,
- punctuation marks are removed,
- special characters are removed, like "&", "$", "_", ", ", etc.

4.2 Features

The pre-processed text was used to generate the features for the machine learning (ML) algorithms. We used a well-known bag of words model, for example, (Sidorov, 2013; Sidorov, 2019). For the first system, we used TF and for the second system TF-IDF values.

4.3 Machine learning algorithms

In our two systems, we used four different classifiers for both subtasks A and B. In CIC-1: Subtask A: Logistic regression, subtask B: Majority voting. In CIC-2: Subtask A: Multinomial Naive Bayes, subtask B: Classifier chains. For all classifiers, we used available implementation in scikit-learn[3].

5 Results and analysis

Results of our both systems CIC-1 and CIC-2 are presented in Table 3, for both shared subtasks, i.e., A and B with our rank in Hateval 2019 competition. Table 3, subtask A ranked by macro-F1 and B by EMR, we used the following conventions. In the first column, "Team" refers to both different systems (CIC-1 and CIC-2) submitted for the shared task. "Task" represents two different subtasks A and B (A_{F1} means that scores of the subtask A are ranked by macro-F1 and B_{EMR} means that scores of the subtask B are ranked by EMR), see section 3.2. "Classifier" states different classifiers, which we used in this competition. "English" and "Spanish" indicate scores for English and Spanish respectively. "Rank$_{eng.}$" and "Rank$_{spa.}$" mean our team's rank in the competition in both subtasks.

The system CIC-1 got 2nd rank in subtask B for the both English and Spanish languages with EMR score of 0.568 for English; 0.675 for Spanish. We used majority voting classifier for both languages.

Table 7: Top 5 teams for subtask B - Spanish

The system CIC-2 CIC-2 ranked 4th in subtask A and 1st in subtask B for Spanish language with a macro-F1 score of 0.727 and EMR score of 0.705 respectively by using MultinomialNB classifier. It is clear that our system was able to get good results in subtask B (to classify aggressive behavior and target), but was not able to perform well in subtask A (to detect hate speech against immigrants and women) for English language, although we obtained the 2nd position in subtask A for Spanish language. For Spanish subtask B, we tried to reproduce SVM baseline as by organizers but we failed, our SVM baseline gave us 0.550 accuracy.

We made experiments without stop words removal and stemming, and accuracy, in this case, goes down by 2-3%. We discovered that imbalanced data was the main reason for poor performance on English for subtasks A and B. We noticed that most of the submitted systems achieved poor results on the subtask A.

6 Conclusion and future work

In this article, we described our approach to detect (1) Hate Speech Detection against immigrants and women; (2) aggressive behavior and target on the Twitter corpus. We submitted two different systems namely: (i) CIC-1 and (i) CIC-2. We used a bag of words model with TF and TF-IDF values. The vectors are then used as features for classifiers like MultinomialNB, Majority Voting, Logistic Regression, and Classifier Chains. Our CIC-1 system ranked 2nd in task B for both English and Spanish languages. Our system CIC-2 ranked 1st in task B for Spanish and 4th for the same language in task A.

In future work, we can consider embeddings with TF-IDF weighting (Arroyo-Fernández et al., 2019) and learning of document embeddings like in (Gómez-Adorno et al,. 2018). We also plan to consider syntactic n-grams (n-grams obtained by following paths in syntactic dependency trees) (Sidorov 2013; 2019).

We have also made the winning model public[4] for other researchers to use.

Abstract

This article describes the strategy submitted by the CiTIUS-COLE team to SemEval 2019 Task 5, a task which consists of binary classification where the system predicts whether a tweet in English or in Spanish is hateful against women or immigrants or not. The proposed strategy relies on combining linguistic features to improve the classifier's performance. More precisely, the method combines textual and lexical features, embedding words with the bag of words in Term Frequency-Inverse Document Frequency (TF-IDF) representation. The system performance reaches about 81% F1 when it is applied to the training dataset, but its F1 drops to 36% on the official test dataset for the English and 64% for the Spanish language concerning the hate speech class.

1 Introduction

Hate speech is usually defined as any communication that derogates a person or a group based on some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or another characteristic (Schmidt and Wiegand, 2017). The spread of the Internet and the increasing use of social networks has led people to have an increased willingness to express their opinions online. Despite the great benefits of using the Internet and particularly the social networks, the risk is that people are more likely to adopt aggressive behavior because of the anonymity provided by these environments. This contributes to the propagation of hate speech as well. Since this type of tendentious communication can be extremely harmful to society, governments and social network platforms can benefit from detection and prevention tools. The scientific study of hate speech, from a computer science point of view, is recent, and the number of studies in the field is low (Fortuna and Nunes, 2018). The goal of SemEval-2019 Task 5 as described in Basile et al. (2019) is Hate Speech detection in Twitter focused on two specific targets, women and immigrants. The task is organized in two related sub-tasks for each language (English and Spanish):

- TASK A - Hate Speech Detection against Immigrants and Women
- TASK B - Aggressive behavior and Target Classification.

In this article, we describe our proposed system for task A only. Our approach is mainly based on the generation of corpus-based dictionaries containing hate speech words which are used in addition to other linguistic features to improve the efficiency in detecting hate speech in both English and Spanish languages.

This paper is organized as follows. The method is described in Section 2. Experiments, results, and a discussion on them are presented in Section 3. Finally, conclusions are addressed in Section 4.

2 Method

We deal with the task by automatic classifiers composed of training data in a supervised strategy. The characteristics of tweets are encoded as features in vector representation. These vectors and the corresponding labels feed the classifiers.

2.1 Features

Linguistic features are the most important and influential factor in increasing the efficiency of classifiers for any task of text mining. Many studies examined the impact of these features in many tasks such as polarity classification (Almatarneh and Gamallo, 2018b, 2019). In this study, we included a number of linguistic features for the task of determining hate speech in tweets. The main linguistic features we will use and analyze are the following: N-grams, word embeddings, and lexical features.

2.1.1 TF-IDF features

We model texts by n-grams based on the occurrence of unigrams of words that occur in documents. The unigrams are very valuable elements to find very relevant expressions in the domain of interest. All terms are assigned a weight by TF-IDF which is computed in Equation 1:

$$tf/idf_{t,d} = (1 + log(tf_{t,d})) \times log(\frac{N}{df_t}), \quad (1)$$

where $tf_{t,d}$ is the term frequency of term t in document d. N stands for the the number of documents in the collection and, df_t represents the number of documents in the collection containing t. To transform the tweets into a matrix of TF-IDF features, we used *sklearn* feature extraction Python library.[1]

2.1.2 Doc2Vec

To represent the tweets, we make use of the *Doc2Vec* algorithm described in Le and Mikolov (2014). This neural-based model is efficient when you have to account for high-dimensional and sparse data (Le and Mikolov, 2014; Dai et al., 2015). Doc2vec learns corpus features using an unsupervised strategy and provides a fixed-length feature vector as output. The output is then fed into a machine learning classifier. We used a freely available implementation of the Doc2Vec algorithm included in gensim, [2] which is a free Python library. The implementation of the Doc2Vec algorithm requires the number of features to be returned (length of the vector). Thus, we performed a grid search over the fixed vector length 100 (Collobert et al., 2011; Mikolov et al., 2013a,b).

2.1.3 Lexical features

Lexical features consist of specific words identified as belonging to the class of hate speech. For instance, as word *bitch* can be associated with hate speech, it will be added to a specific dictionary containing words associated with hate speech. In addition, a weight is assigned to each word. The higher the weight the more intense the hate value of the word. We automatically built several weighted dictionaries from the annotated corpus:

- Dictionary of lexical words 295 English words and 262 Spanish words.
- Dictionary of hashtags: 1090 English hashtags and 201 Spanish hashtags.
- Dictionary of address references: 1661 English references and 1263 Spanish references.

We just considered words belonging to lexical categories, hence, only nouns, verbs, adjectives, and adverbs were selected. PoS tagging for English and Spanish was carried out with the multilingual toolkit LinguaKit (Gamallo et al., 2018).

The method to build the hate speech dictionaries is somehow inspired by that reported in Almatarneh and Gamallo (2018a, 2017) for very negative opinions. The hate speech score of a word, noted HS, is computed as follows:

$$HS(w) = \frac{freq_{total}(w)}{freq_{hs}(w)} \quad (2)$$

where $freq_{total}(w)$ is the number of occurrences of word w in the whole corpus, and $freq_{hs}(w)$ stands for the number of occurrences of the same word in the segments (tweets) annotated as hate speech. In addition to the hate speech score HS, it is also required to compute a threshold above which the word is considered hate speech. So, we compute the difference between the use of a word as hate speech and as not:

$$DIFF(w) = freq_{hs}(w) - freq_{-hs}(w) \quad (3)$$

where $freq_{-hs}(w)$ stands for the occurrences of w in segments that are not hate speech. To insert a word in the dictionary, the value of $DIFF(w)$ must be higher than a experimentally set threshold. In our experiments, this value was 5. So, in our dictionaries, we only selected those words (hashtags or references) with $DIFF$ values higher than 5. Finally, words were ranked by their HS score giving rise to weighted and ranked lexicons.

3 Experiments

The main datasets that were used for training and testing our model are described in Basile et al. (2019). This article describes the SemEval-2019 Shared Task 5 aimed at Hate Speech detection in Twitter.

Featuers	Hate			Not			Avg F1	Accuracy
	Prec.	Rec.	F1	Prec.	Rec.	F1		
TF-IDF	0.72	0.68	0.70	0.79	0.82	0.80	0.76	0.76
Doc2Vec	0.68	0.52	0.59	0.71	0.83	0.77	0.69	0.70
Lexicon	0.69	0.46	0.55	0.7	0.86	0.77	0.68	0.69
Doc2Vec + Lexicon	0.71	0.57	0.63	0.74	0.84	0.79	0.72	0.73
All	0.78	0.74	**0.76**	0.83	0.86	**0.84**	**0.81**	**0.81**

Table 2: Performance on the training dataset with different feature configurations of TF-IDF, Doc2Vec and lexicons for Spanish.

Featuers	Hate			Not			Avg F1	Accuracy
	Prec.	Rec.	F1	Prec.	Rec.	F1		
TF-IDF	0.75	0.7	0.72	0.78	0.83	0.80	0.77	0.77
Doc2Vec	0.57	0.11	0.18	0.58	0.94	0.72	0.49	0.58
Lexicon	0.82	0.66	0.73	0.78	0.89	0.83	0.79	0.79
Doc2Vec + Lexicon	0.82	0.68	0.74	0.78	0.89	0.83	0.79	0.80
TF-IDF + Lexicon	0.81	0.76	**0.78**	0.83	0.86	**0.85**	**0.82**	**0.82**

3.1 Development and training

As we considered that the size of the training collection provided by the organizers was not large enough, we made use of another available training data for the same task to build our lexicons.[3] The algorithm to build the lexicons has been described above in Subsection 2.1.3.

As far as the classification strategy is concerned, we decided to use *sklearn.svm.LinearSVC* for learning the classifiers.[4] Suport Vector Machine (SVM) proved to be the best strategy for detecting extreme opinions in previous work (Almatarneh and Gamallo, 2019)

The training dataset provided by the organizers of the shared task was used as a development corpus so as to learn the best feature configuration using 10-fold cross-validation.

Tables 1 and 2 shows the result of the experiments on the training corpus. In these tables, we depict the performance of all tested features in both English and Spanish Languages. The combination of all features (TF-IDF, Doc2Vec, and lexicons) gives the best performance for English. However, in Spanish the use of Doc2Vec made it lower the performance as the best F1 was achieved by just combining TF-IDF with lexical features.

3.2 Test

Taking into account the results shown in tables 1 and 2, we submitted two different model configurations for English and Spanish testing. More precisely, for English TASK A we used the combination of all features, whereas the Spanish model in TASK A was built by only combining lexical and TF-IDF features.

Unlike the experiments on the training dataset, our approach showed bad performance on the test dataset as Table 3 shows.

The poor scores in the English dataset are due to the strange behavior of our approach with the non-hate speech class of speech class. Recall on this class was merely 0.07 while on the target class reached 0.97.

4 Conclusions and Future Work

The approach we developed for the task of hate speech detection in English and Spanish is mainly based on the generation of lexicons containing hate speech words. Lexicons are used in addition to other linguistic features (TF-IDF and Doc2Vec) to improve the efficiency of a SVM classifier.

[3] https://github.com/ZeerakW/hatespeech/blob/master/NAACL_SRW_2016.csv

[4] https://scikit-learn.org/stable/modules/generated/sklearn.svm.LinearSVC.html

Table 3: Performance of our approach on the test dataset for English and Spanish languages

Featuers	Hate			Not			Avg F1	Accuracy
	Prec.	Rec.	F1	Prec.	Rec.	F1		
TASK A English	0.43	0.97	0.60	0.77	0.07	0.13	0.36	0.45
TASK A Spanish	0.59	0.54	0.56	0.70	0.74	0.72	0.64	0.66

Even if we obtained acceptable results in the development phase using the training corpus (more than 0.80 F1 score), the results achieved in the test phase were disappointing, especially for the English language.

In order to discover the problems underlying our overfitted model, a deep error analysis will be performed. Once released the dataset test, we will be able to analyze the contribution of each of the features used so that we can check if it was one of the lexicons that caused the low performance of our system.

In future work, our objective is to improve the basic method to build hate speech lexicons (and related topics) from annotated corpora in order to use them in both supervised and unsupervised strategies.

Abstract

Hate speech occurs more often than ever and polarizes society. To help counter this polarization, SemEval 2019 organizes a shared task called the Multilingual Detection of Hate. The first task (A) is to decide whether a given tweet contains hate against immigrants or women, in a multilingual perspective, for English and Spanish. In the second task (B), the system is also asked to classify the following subtasks: hateful tweets as aggressive or not aggressive, and to identify the target harassed as individual or generic. We evaluate multiple models, and finally combine them in an ensemble setting. This ensemble setting is built of five and three submodels for the English and Spanish task respectively. In the current setup it shows that using a bigger ensemble for English tweets performs mediocre, while a slightly smaller ensemble does work well for detecting hate speech in Spanish tweets. Our results on the test set for English show 0.378 macro F1 on task A and 0.553 macro F1 on task B. For Spanish the results are significantly higher, 0.701 macro F1 on task A and 0.734 macro F1 for task B.

1 Introduction

The increasing popularity of social media platforms such as Twitter for both personal and political communication has seen a well-acknowledged rise in the presence of toxic and abusive speech on these platforms (Kshirsagar et al., 2018). Although the terms of services on these platforms typically forbid hateful and harassing speech, the volume of data requires that ways are found to classify online content automatically. The problem of detecting, and therefore possibly limit the hate speech diffusion, is becoming fundamental (Nobata et al., 2016).

Previous work concerning hate speech against immigrants and women such as Olteanu et al. (2018) observed that extremist violence tends to lead to an increase in online hate speech, particularly on messages directly advocating violence. Also, Anzovino et al. (2018) contributed to the research field by (1) making a corpus of misogynous tweets, labelled from different perspective and (2) created an exploratory investigations on NLP features and ML models for detecting and classifying misogynistic language.

Basile et al. (2019) proposed a shared task on the Multilingual Detection of Hate, where participants have to detect hate speech against immigrants and women in Twitter, in a multilingual perspective, for English and Spanish. The task is divided in two related subtasks for both languages: a basic task about hate speech, and another one where fine-grained features of hateful contents will be investigated in order to understand how existing approaches may deal with the identification of especially dangerous forms of hate, for example those where the incitement is against an individual rather than against a group of people, and where an aggressive behavior of the author can be identified as a prominent feature of the expression of hate.

Within this experiment, Task A is a binary classification task where our system has to predict whether a tweet is hateful or not hateful. For Task B, our system has to decide whether a tweet is aggressive or not aggressive, and whether that tweet targets an individual or generic group, to elaborate, a single human or group of people.

The paper is structures as follows. In section 2 our system setup is described. In section 3, the datasets together with the preprocessing steps are presented. In section 4, obtained results are detailed. Finally, in section 5 a discussion about the proposed system is outlined.

2 System Setup

In our approach, we trained multiple classifiers and combined their results into an ensemble model using majority vote.

English Ensemble Setup

The setup of our system optimized for the English classification tasks consisted of the following classifiers:

- Random Forest
- Support Vector Machine (1)
- Support Vector Machine (2)
- Logistic Regression
- BiLSTM

Spanish Ensemble Setup

Due to time restrictions, we used three classifiers for the Spanish tasks:

- Random Forest
- Support Vector Machine (1)
- Logistic Regression

These time restrictions occurred, because we decided in the last moment to run our system for the Spanish task too. However, we did not have hate speech specific word embeddings, nor trained a BiLSTM model for the Spanish task. Therefore, we decided to run only three classifiers for both the Spanish tasks.

2.1 Random Forest (RF)

For our RF model we executed a grid search starting with the following parameters: character n-grams with range: 2-3, 2-4, 1-3, 1-4; word n-grams with range 1, 1-2, 1-3, 1-4 and all combinations of them. In the end we used a tf-idf vectorizer with character n-grams with range 2-4. As for our parameters also following a grid search we used 400 estimators, entropy as our split criterion/estimator, balanced for our class weight and a random seed of 1337. Due to time restrictions, we used the same parameters for the Spanish tasks.

2.2 Support Vector Machine (SVM 1)

Within this subpart of our ensemble model, we used a SVM model from the scikit-learn library (Pedregosa et al., 2011). We used a *linear* `kernel`, and a *weighted* `class_weight`. This model used vectorized character n-grams in range 2-4 using a tf-idf vectorizer as its input.

2.3 Support Vector Machine (SVM 2)

We used a second SVM classifier within our ensemble model, but this time with word embeddings as its input. This choice is motivated by the hypothesis that introducing different predictions given by models trained differently could lead to more insights. We tested four pre-trained embedding representations, which are the following: the 300-dimensional `GloVe` embeddings and the 25-dimensional `GloVe Twitter` representations by Pennington et al. (2014); a 400-dimensional and 100-dimensional word embedding created from tweets (Van der Goot). Using the `GloVe` embeddings proved to be superior within our work. The results of each word embedding can be found in Table 6.

2.4 Logistic Regression (LR)

Following our grid search testing our LR model with a tf-idf vectorizer with the following parameters: character n-grams with range: 2-3, 2-4, 1-3, 1-4; word n-grams with range 1, 1-2, 1-3, 1-4 and all combinations of them, we got the best performance using a tf-idf vectorizer with character n-grams with range 2-4. Due to time restrictions, we used the same parameters for the Spanish tasks.

2.5 BiLSTM

Our BiLSTM classifier was only optimized for the English classification task. Hence we decided not to use it in our Spanish setup. In combination with the BiLSTM model we used an attention mechanism, as proposed by Yang et al. (2016).

LSTM models can handle input sequentially and therefore can take word order into account. We combine this with a bidirectional model, which allows us to process the tweets both forwards and backwards. For each word in the tweets, the LSTM model combines its previous hidden state and the current word's embedding weight to compute a new hidden state. After using dropout to shut down a percentage of neurons of the model, we feed the information to the at-

	Hate Speech		Target Range		Aggressiveness	
	0	1	0	1	0	1
Trial data	50	50	87	13	80	20
Train data	5217	3783	7659	1341	7440	1559
Dev data	573	427	781	219	796	204
Test data	3000					
Total	13100					

Table 1: Distribution of English data, labels of the test data were not specified.

	Hate Speech		Target Range		Aggressiveness	
	0	1	0	1	0	1
Train data	2643	1857	3371	1129	2998	1502
Dev data	278	222	363	137	324	176
Test data	1600					
Total	6600					

Table 2: Distribution of Spanish data. No trial data was available, and test data labels were not specified.

tention mechanism. This mechanism emphasizes the most informative words in the article and gives these more weight.

Our final model uses 512 units in the hidden layer of the BiLSTM, a batch size of 64, the Adam optimizer in combination with the default learning rate of 0.001 and a dropout of 0.4. We trained our model for 10 epochs, of which we saved the model with the lowest validation loss.

3 Data and Preprocessing

For this shared task, the data distribution is seen in Table 1 and Table 2 for the train and development data, we assumed the trial data to be train data too. After release of the test data, the distribution would be 69% train, 8% development, and 23% (3000 sentences) test data for the English task, and for the Spanish task 68% train, 8% development, and 24% (1600 sentences) test data. For final submission, we combined the train and development data to train our system on.

The meaning of the binary encoding is as follows, for Hate Speech (HS) and Aggressiveness (AG): 0 or 1, absent and present respectively. For Target Range (TR): 0 or 1, whole group and individual respectively. We notice that there is more data available for the English task than the Spanish one.

With regard to preprocessing, we did this in the following fashion:

- Tokenized with the NLTK TweetTokenizer.
- Replaced URLs with a placeholder suitable for our English embeddings.
- Replaced mentions with a placeholder suitable for the available English embeddings (van der Goot and van Noord, 2017).
- Converted words to lowercase.
- Filtered out stopwords using the stopwords from NLTK, either English or Spanish.
- Removing single characters, excluding emoji's.

For the BiLSTM, we did not do any preprocessing. We deemed this might affect the learning curve of the system, since a BiLSTM algorithm often performs well with lots of different data. So, without preprocessing there will be less loss of information and thus a better performing system.

We tested how the preprocessing affected our scores, results are in Table 3 and Table 4. We used the train and development data available to test the preprocessing. We started using all the preprocessing, and in a cumulative way, excluded a preprocess step one by one. So in the end, we would only have tokenization left.

Interesting is that the scores of the RF and SVM 1 model are higher, for both English and Spanish data, when we exclude preprocessing steps. At the step of replacing URLs and usernames with placeholders, we expected the scores to be higher if excluded. Because if the same URL or username occurs often in the training set, and that specific URL or username is always corresponding with a hateful or non-hateful message, our system could wrongly classify a comment in the development set containing that same URL or username. The scores also increase when we exclude lowercasing or remove single characters in addition to the placeholder steps. However, if we omit either lowercasing or characters alone, the scores do not get better than if we use all preprocessing. This also explains the higher score with the LR model, but if we only disregard the character preprocessing step, the score also does not get better.

4 Results

In this section, we state our results on the test set, as well as the results of our ensemble model and individual models on the development set. Our final system for the English task consists of all five models shown in the English Ensemble Setup, each given a result being either 0 or 1, and run a majority vote on it for a final result. For the Span-

Table 4: Scores with changes in preprocessing for Spanish, csores in bold means that it was higher than using all preprocessing of the respective system.

ish task, the final system contains three models, described in the Spanish Ensemble Setup.

The results on the the various tasks we participated in are listed in Table 5. For the English task, we achieved a much lower accuracy and macro f1-score than for the Spanish task. Assuming the data has been distributed fairly for both languages, it could be that the quality of the test data is lower than the train and development data.

These scores were lower in comparison to our results of the individual classifiers on the development set which are listed in table 3 and 4.

5 Discussion

We compared multiple classification algorithms and combined them into an ensemble model to get a more robust and accurate system. Initially, our system performed reasonably well on the development set, but when tested on the final test set our performance dropped a fair bit. Overall, the drop in performance was to be expected. During the final evaluation of the test set our system predicted over 80% as hate speech. Looking at the data we thought a large part of the remaining 20% could also be classified as hate speech. Also the majority class baseline (Basile et al., 2019) ranked second for accuracy, supporting our expectations.

From our results we can conclude that using a bigger ensemble model for the English tweets performs mediocre in comparison to a smaller ensemble model for detecting hate speech in Spanish tweets.

English Task A	accuracy	macro F1

In the future, we would like to try to improve the performance of our Spanish model, of which our development was cut short due to time restrictions. We would also like to test our models with more high quality data. It would be interesting to find out whether this helps to improve our models' performance.

Abstract

This paper describes the GSI-UPM system for SemEval-2019 Task 5, which tackles multilingual detection of hate speech on Twitter. The main contribution of the paper is the use of a method based on word embeddings and semantic similarity combined with traditional paradigms, such as n-grams, TF-IDF and POS. This combination of several features is fine-tuned through ablation tests, demonstrating the usefulness of different features. While our approach outperforms baseline classifiers on different sub-tasks, the best of our submitted runs reached the 5th position on the Spanish subtask A.

1 Introduction

Information available in social networks is the result of many interactions between users and their activity on the net. Unfortunately, hate speech and other misuses are proliferating on the Internet. Hate speech authors justify their conduct based on the freedom of speech argument. Thus, a debate over hate speech legislation and freedom of speech has been generated (Herz and Molnar, 2012).

The task to decide if a piece of text contains hate speech is not trivial, even for humans. Being subject to different interpretations and opinions, the manifestations of hate speech become difficult to define. Based on previous hate speech statements (Fortuna and Nunes, 2018; Schmidt and Wiegand, 2017), this phenomenon could be defined as offensive or humorist content in form of text, video, or images that attacks, diminishes, incites violence or hate against groups or individuals, based on actual or perceived specific characteristics such as physical appearance, religion, descent, national or ethnic origin, sexual orientation, gender identity, or any other.

Hate speech topic has gained impact and popularity in recent years, which is reflected not only by the increased media coverage but also by the growing political attention. Regarding the specific forms of hate speech that we deal with, sexism and racism victims increased during 2017 according to the FBI hate crime statistics[1].

For this reason, participating in SemEval2019 Task 5 (Basile et al., 2019) is such an interesting challenge. The proposed task consists in Hate Speech detection in Twitter messages featured by two specific different targets intrinsically related to the phenomena mentioned above, immigrants and women. The task is enriched by adding a multilingual perspective fostering the research for both English and Spanish messages.

The system proposed relies on a supervised classifier using different text features combined with several strategies with the aim of finding an optimal performance. The remainder of this paper is structured as follows. After this introductory section, Section 2 reviews related work. Following, the proposed classification model is described in Section 3. Then, Section 4 presents the experimental results, and finally, Section 5 concludes the paper with a final discussion.

2 Related Work

Most of our literature review from the field is referenced by previous survey research (Fortuna and Nunes, 2018; Schmidt and Wiegand, 2017).

Multiple procedures have been implemented, since more traditional feature engineering, such us n-grams (Waseem and Hovy, 2016) or Part-of-Speech (POS) (Davidson et al., 2017) to more complex deep learning architectures (Yuan et al., 2016; Badjatiya et al., 2017).

According to the analyzed bias which motivates hate speech, general hate speech (Silva et al., 2016) is considered by the majority, however,

[1] https://ucr.fbi.gov/hate-crime/

there is large research that focuses particularly on racism (Kwok and Wang, 2013) and sexism (Hewitt et al., 2016). Though it is not exactly a form of hate speech, cyberbullying is a very related problem with some study research (Cortis and Handschuh, 2015).

3 System Overview

The system relies on a supervised machine learning algorithm. This final classification step is fed by a data processing pipeline formed by the preprocessing and the feature extraction modules. Regarding the implementation, Python has been used, with the additional capabilities provided by the libraries scikit-learn (Pedregosa et al., 2011), NLTK (Bird and Loper, 2004), and GSITK (Araque et al., 2017) [2]. Figure 1 illustrates the system architecture from a general perspective.

3.1 Preprocessing

In this phase, the raw text is taken and cleaned using common NLP techniques (Manning et al., 1999): removal of punctuation marks, special characters, URLs, and stop-words. Tweet preprocessing relies on tokenization, user mentions normalization, the appearance of hashtags, URLs, and all caps words flagged supported by the tools provided by GSITK. In addition, tokens are lemmatized using the Porter stemmer (Porter, 1980).

3.2 Feature Engineering

Different features have been taken into account during the feature engineering stage. Such features are divided into subcategories: statistical features, content analysis, word embeddings, semantic features, and linguistic features.

3.2.1 Statistical Features

We collected word and character n-grams evaluating both approaches, Bag-of-Words (BOW) and Term Frequency - Inverse Document Frequency (TF-IDF). The reason to include character n-grams comes from the Twitter domain, where texts are short and misspelling may occur; this can be attenuated at the character level (Schmidt and Wiegand, 2017). Apart from the mentioned reasoning, previous research (Mehdad and Tetreault, 2016) has shown the effectiveness of character n-grams in the problem of offensive language.

[2] https://github.com/gsi-upm/semeval2019-hatespeech

Besides tokens included within the text corpus, the system also includes frequencies from external lexicons that are thought for hate speech[3], sentiment analysis (Hu and Liu, 2004; Liu et al., 2005), and subjectivity analysis (Pang and Lee, 2004).

3.2.2 Content Analysis

As seen, sentiment and subjectivity information has been included. Hate speech can be considered as subjective content, and a relation between subjectivity, sentiments, and emotions can occur. Besides, hate speech is expected to have a negative polarity, so text subjectivity and polarity provided by the TextBlob (Loria et al., 2014) library were included in the analysis.

Topic modeling methods were added to the study, particularly, Latent Dirichlet Allocation (LDA) (Blei et al., 2003) in order to extract the topic of each tweet in combination with the appearance of hashtags (topics) inside the corpus.

3.2.3 Word Embeddings

In order to solve the lack of semantic of words in n-grams features, word distributed representations based on word embeddings models are evaluated. Pre-trained word vectors convert words into vector space where semantically similar words tend to appear close by each other. In this system, a vector is extracted for each word in the input text; then, as done in (Araque et al., 2017), the average pooling operation is performed on all word vectors, resulting in a vector of the same dimensions as the original word vectors.

3.2.4 Semantic Features

A central part of the system consists of a method (Araque et al., 2019) that exploits the semantic similarity measure that a word embedding model provides, via cosine similarity. In general lines, this approach uses a lexicon to which the input text is projected, employing the similarity measure obtained from an embedding model.

The method considers a selection of words S that constitutes a lexicon vocabulary to which the input documents are projected. Given a text document (e.g., tweet), a similarity value between the input word vectors of that document and each of the words in S is computed. After iterating over all input words and all lexicon words, a matrix $m \times |S|$ is obtained, where m is the number of input words in a particular document. Following,

[3] https://hatebase.org/

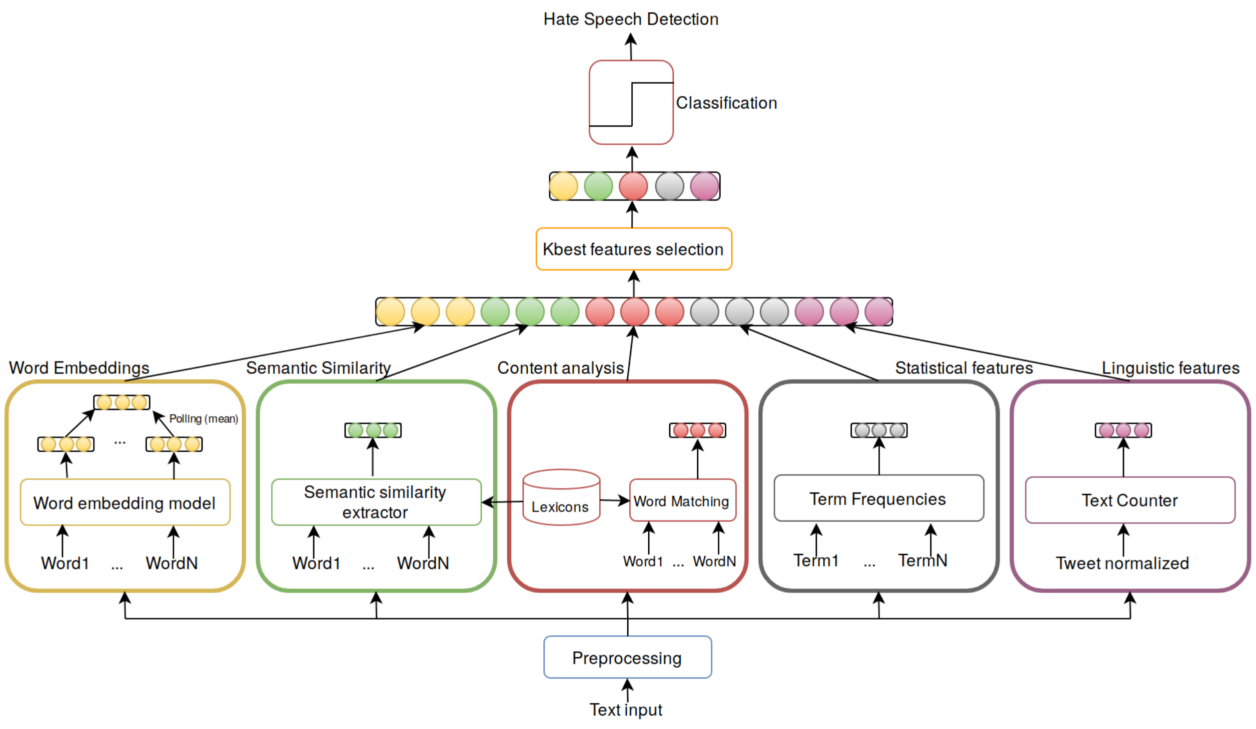

Figure 1: System Overview

the maximum pooling function is applied column-wise, obtaining the semantic similarity feature vector of dimensionality $|S|$.

In this work, the previously mentioned lexicons have been used, as well as a domain-oriented word selection, which have been extracted from the dataset. In this last approach, words were filtered by its frequency of appearance considering the document annotation, being the cutoff frequency an adjustable parameter.

3.2.5 Linguistic Features

The last set of features used are related to linguistic aspects. The proposed system considers the number of sentences, length from the tweet, POS stats, as well as some Twitter-related features such as the count of hashtags, URLs, mentions, all caps words, emojis, and exclamations.

3.3 Classification

Finally, the furthest step in the data processing pipeline makes use of a machine learning classifier. There are many options among machine learning models that can be used. In this project, we have evaluated the performance of three different types of algorithms: Logistic Regression, Support Vector Machines (SVM) with linear kernel, and Random Forest.

4 Experiments

This section presents the results obtained by the proposed system in the competition, considering both test and development phase submissions. Firstly, a data exploration has been carried out in order to analyze the data distribution, possible features to feed the classifier, and deficiencies in the data source. The evaluation of the different feature extraction approaches and the hyper-parameter tuning has been done by using a cross-validation grid search. Special attention has been paid in the regularization parameter of the algorithms: “C” parameter in the Logistic Regression and Linear SVM case and “maximum depth” of the trees in the Random Forest case. Finally, the system is trained, and the evaluation metrics are computed. This workflow has been repeated several times from the feature extraction step, changing the set of features in every iteration.

4.1 Sub-task A

The goal of this task is to classify both Spanish and English tweets as hateful or not hateful. Systems are evaluated using standard evaluation metrics, including accuracy, precision, recall, and F1-score, but predictions are ranked by F1-score metric alone.

Team	**Accuracy**	**Precision**	**Recall**	**F-score**
		English		
Best	0.506	0.65	0.566	0.457
SVM baseline	0.492	0.595	0.549	0.451

Bigrams, trigrams, similarity, and embeddings (2)	0.796	0.794	0.791	0.792
Embeddings, similarity, Twitter stats, and LDA (3)	0.784	0.781	0.782	0.782

Table 2: Development set results for Task A

Task A data was partitioned into train, development, and test sets. Train and development sets were used to obtain the best feature combination by training over the train set and testing over the development one. Finally, for the final submission, the predictions for the test set were obtained with a system trained over both train and development sets.

Test results, which represent the official submission, as well as development phase results are presented in Tables 1 and 2 respectively. Task organizers included two baselines (Basile et al., 2019) in the competition, a linear SVM based on a TF-IDF representation and a trivial model that assigns the most frequent label from the training set to all instances in the test set.

The Spanish-oriented system relies on linguistic features (excepting POS), semantic similarity with a domain-oriented lexicon, sentiments (using the sentiment vocabulary weighted by the TF-IDF measure), word embeddings, topic modeling (both LDA and hashtags), and word and character TF-IDF n-grams. These features are filtered according to the ANOVA F-test, selecting the best 3,000. Linear SVM has been the selected machine learning algorithm for classification. On the other hand, the English-oriented system considers the same feature set excluding word embedding representation; the number of selected features has been set at 17,500. In contrast to the previous system, a Logistic Regression model was used to perform the classification.

Team	F-score(HS)	F-score(TR)	F-score(AG)	F-score (Avg)	EMR

(3)	0.782	0.836	0.783	0.800	0.714

Table 4: Development Results for Task B

4.2 Sub-task B

The goal of this task is firstly to classify hateful tweets (i.e., tweets identified as hate speech against women or immigrants) as aggressive or not aggressive, and secondly to identify the target harassed as individual or generic (i.e., single person or group). Systems are evaluated by two criteria: partial match and exact match (Basile et al., 2019), but predictions are ranked by exact match metric alone.

For this task, the data has been delivered in the same way than sub-task A, so we emulated the same workflow than before, but in this case, considering solely hateful tweets. In this case, there are different distributions (Basile et al., 2019) along languages and sets, but different labels show a similar layout. This result goes in line with the work presented in (ElSherief et al., 2018), which states that directed hate speech is more informal, angrier, and often explicitly attacks the victim. Regarding the language, Spanish-speaking people tend to be more aggressive and more direct towards specific individuals. Seeing this skewed distribution, we outlined the idea to balance aggressiveness and directed messages by oversampling hateful tweets with not hateful ones, assuming that not hateful tweets are not aggressive nor directed.

As done previously, Tables 3 and 4 present official and development results, respectively. The Spanish-oriented system in this task is identical to that from Task A, but finally selecting 2,500 features. For the English case, in light of aggressiveness and target tweets, a different combination of features have been chosen. In order to detect aggressive tweets, all features except semantic similarity have been used, filtering the 32,500 best. Otherwise, for target messages, the complete set of features (sentiments and subjectivity were included by means of TF-IDF and semantic similarity) are used just considering the 2,500 best. Finally, different models were applied for each label, Logistic Regression for Target label and Linear SVM for the Aggressive one. The same algorithm selection was made in the Spanish case.

4.3 Discussion

In general terms, the results obtained are auspicious: the best submitted system achieved the 5th position in the Spanish Task A, 0.5% points under the best result obtained in the same task. For the Spanish Task B, the proposed model outperforms the baseline. In contrast to this, results in English Task A are lower than expected, where there was not any team that surpassed the 50% threshold in terms of F-score. As a general trend, test set results are worse than development results, which may indicate that our systems suffer over-fitting, and cannot generalize properly. This observation is enforced by attending to the English Task B, where no system has surpassed the baseline.

Since the data distribution is equal along languages in Task A (Basile et al., 2019), the difference in performance across languages may be due to Spanish speaking people are more explicit when typing any utterance with hate speech goals. As previously mentioned, we have observed that this type of hate speech messages show more aggressiveness. Language characteristics may be involved since the Spanish language has a morphologically-richer nature than English.

The presented results constitute the outcome of exhaustive experimentation of a variety of feature combination tests. In contrast with earlier work, semantic similarity and word embeddings representations do not produce such high performance results when compared to other domains such as sentiment analysis (Araque et al., 2019) and sleep disorder detection (Suarez et al., 2018) tasks. This circumstance suggests that hate speech detection is still an open challenge and more research must be done into the specific characteristics of such an exciting task.

Attending to the Spanish case, sentiment information and character n-grams were features that helped in a meaningful manner, confirming the issues raised in Sect. 3. For the English case, the improvement of the proposed features was incremental. While subjectivity and emojis had a relevant role in the results, this improvement was not as high as in the Spanish case. In light of the complexity of the hate speech domain, it could be argued that attending to word context instead of isolated words could help in the analysis. Indeed, n-grams include this type of information to some extent, but capturing the grammatical dependencies within a sentence (Chen, 2011) or template based strategies (Warner and Hirschberg, 2012) could enhance the performance.

5 Conclusions

This paper described the GSI-UPM hate speech detection system presented to participate in SemEval-2019 Task 5, which revolves around analyzing text messages from Twitter. In order to tackle this, a machine learning based approach has been developed. The different features that feed this system have been thoroughly evaluated, considering its suitability in the field of hate speech detection. It has been seen that both novel and traditional approaches do not yield so promising when used separately. Nevertheless, properly combining several types of features, as well as with content analysis features (e.g., sentiments and subjectivity) can improve the system to the point of reaching a reasonably good performance.

Concerning the achieved goals, the highest ranking was 5th place on the Spanish sub-task A, being 0.5% apart from the best performing system. This is, undoubtedly, a promising result that highlights the capacity of the proposed method to obtain nearly state-of-the-art performance in this task. When comparing with the same sub-task in the English case, in which we scored lower, it is necessary to study further the applicability of the system to different languages.

As future work, several lines of work could be addressed. Firstly, we plan to implement deep learning architectures which have shown to obtain better results in previous research (Zhang and Luo, 2018; Zhang et al., 2018). In addition, in order to afford imbalanced distributions, data augmentation (Hemker, 2018) techniques could be explored. Also, context-aware approaches could represent an improvement (Dinakar et al., 2012), since having general knowledge of hate speech (e.g., anti-LGBT or racism) may boost the performance of learning systems.

HATEMINER at SemEval-2019 Task 5: Hate speech detection against Immigrants and Women in Twitter using a Multinomial Naive Bayes Classifier

Nikhil Chakravartula
Teradata, Hyderabad
nikhil.chakravartula@gmail.com

Abstract

This paper describes our participation in the SemEval 2019 Task 5 - Multilingual Detection of Hate. This task aims to identify hate speech against two specific targets, immigrants and women. We compare and contrast the performance of different word and sentence level embeddings on the state-of-the-art classification algorithms. Our final submission is a Multinomial binarized Naive Bayes model for both the subtasks in the English version.

1 Introduction

Twitter is a micro-blogging platform where people exchange ideas using short messages called tweets. Users can propagate their notions, including hatred against an individual or a group, to the entire global population with a latency of a few seconds. This poses a unique challenge of developing systems that can automatically identify and mitigate hate speech. Although twitter condemns hate speech through its hateful conduct policy[1], enforcing it is difficult. There are several reasons for this. Tweets often contain emoticons, emojis, language slangs, hashtags and other noisy data. Often, offensive and abusive language may be erroneously perceived as hate speech and hence it is important to distinguish offensive, abusive and hateful languages (Davidson et al., 2017; Waseem and Hovy, 2016). These problems are exacerbated by the fact that even humans find it difficult to delineate offensive and hateful language.

Many approaches have been put forward to detect hate speech. Bag of words and ngram features are effective in hate speech detection (Burnap and Williams, 2015; Warner and Hirschberg, 2012) as well as the detection of abusive and offensive content (Nobata et al., 2016). Gitari et al. (2015) used lexical resources to look up certain words that contribute significantly to hate speech but such features, when used in isolation may not be very effective. SVM (Burnap and Williams, 2015), Naive Bayes (Kwok and Wang, 2013) and Logistic Regression (Davidson et al., 2017) are some of the classifiers used in this domain.

Most of the above methods are targeted to detect general hate speech. Through this task, we aim to identify hate speech, specifically against *immigrants and women*. Frenda et al. (2018) used lexicon resources to identify misogynistic comments. Ahluwalia et al. (2018) used an ensemble of random forest, gradient boosting and logistic regression with bag of words, ngram and lexical features to discern hatred against women. We did not find significant work in detection of hate speech in English against immigrants.

2 Shared Task Description

The SemEval 2019 Task 5 is divided into two subtasks.

1. Subtask A, where systems must predict whether a tweet is hateful (HS=1) against immigrants and women.
2. Subtask B, where systems must first classify hateful tweets as aggressive (AG=1) or not, and secondly to identify the target harassed as an individual (TR=1) or generic.

We used the datasets provided by the organizers. Table 1 describes the composition of the dataset. Further details of the task are available in the task description paper (Basile et al., 2019).

3 System Description

3.1 Pre Processing

We perform the following pre-processing operations on the text before feature engineering.

[1]https://help.twitter.com/en/rules-and-policies/hateful-conduct-policy

	HS=1	TR=1	AG=1
Train	57.9%	17.3%	14.9%
Dev	42.7%	20.4%	21.9%

Table 1: Dataset composition. HS: Hate Speech TR: Target AG:Aggressiveness

- All text is converted to lower case.
- All URLs, mentions, emojis and smileys are removed from the tweets. We used a python package tweet-preprocessor[2] to achieve this.
- All contractions are replaced with their full form. For example, *don't* will be replaced by *do not* and *can't* will be replaced by *can not*.
- All punctuation marks are removed.
- All numerical sequences are removed from the text.
- **Hashtag segmentation and spell correction:** Hashtags provide insights about a specific ideology by a group of people. These notions provide vital information for text classification, especially in the case of hate speech against immigrants and women. For example, hashtags like *#endimmigration*, often come from a group of people who are against immigrants. Segmentation (Segaran and Hammerbacher, 2009) of the hashtags is essential to allow the classifier to treat *#buildthatwall*, *#buildthewall*, *#buildthedamnwall*, *#buildwall*, etc with the same importance. After segmentation, *#buildthatwall* becomes *build that wall*, *#buildthedamnwall* becomes *build the damn wall* etc. Many tweets contain abusive words in elongated form, such as *f****kkkk*. We perform spell corrections (Jurafsky and Martin, 2018) on these words to reduce the vocabulary size and to account for better results. Text8[3] is utilized to generate unigram and bigram word statistics with ekphrasis (Baziotis et al., 2017) to perform both these operations.
- **Stemming**: Stemming is the process of reducing a word to its base root form. We used Porter Stemmer[4] from NLTK (Steven Bird and Loper, 2009) to stem. Stemming is used in combination with the Naive Bayes classifier. For other classifiers, pretrained word embeddings without stemming are used.

[2]https://github.com/s/preprocessor

[3]http://mattmahoney.net/dc/textdata.html

[4]https://tartarus.org/martin/PorterStemmer/

3.2 Feature Engineering

The following features are considered in our experiments.

- **Bag of words (BoW):** Bag of words is used to represent the presence of word n-grams.
- **Word Embeddings:** Glove840B - common crawl, GloveTwitter27B - twitter crawl (Pennington et al., 2014) and fasttext - common crawl (Mikolov et al., 2018) pre-trained word embeddings are used to analyze their impact on the classification.
- **Sentence Embeddings:** Infersent (Conneau et al., 2017) is used to produce sentence level embeddings. InferSent is a sentence embedding method that provides semantic representations for English sentences. It is trained on natural language inference.

4 Experiments

In this section, we describe the experimental settings used in our research. All our code is publicly available in a github repository.[5]

4.1 Evaluation Metrics

The evaluation metrics for subtask A are precision(HS), recall(HS) and F_1-score(HS). Macro averaged F_1-score(HS,TR,AG) and Exact Match Ratio (EMR) are the evaluation metrics for subtask-B. Submissions are ranked based on F_1-score(HS) and EMR for subtask-A and subtask-B, respectively.

4.2 Methodology

All the experiments are developed using the Scikit-Learn (Pedregosa et al., 2011) machine learning library. Five-fold cross validation score on the train set used to evaluate our models. We ran several experiments on various classification algorithms. The best performing classifiers were Naive Bayes, logistic regression, SVM and XG-Boost. The following are the details of the classifier settings.

[5]https://git.io/fhFGR

WordVector	Logreg			SVM			XGB		
	F_{avg}(HS)	$F_{avg(HS,TR,AG)}$	EMR	F_{avg}(HS)	$F_{avg(HS,TR,AG)}$	EMR	F_{avg}(HS)	$F_{avg(HS,TR,AG)}$	EMR
glove	0.58	0.57	0.49	0.54	0.54	0.45	0.61	0.56	0.44
fasttext	0.58	0.56	**0.53**	0.55	0.52	0.45	0.61	0.56	0.43
glove twitter	0.69	0.67	0.48	**0.69**	0.61	0.45	0.69	0.65	0.44
glove + infersent	**0.73**	**0.70**	0.47	0.66	**0.64**	**0.46**	**0.72**	**0.68**	**0.46**

Table 2: Pretrained word and sentence embeddings results. For each classifier family, the best score is made bold.

Word ngrams	Stem	Binary	$F_{avg(HS)}$	F_{avg} (HS,TR,AG)	EMR
1,2	false	true	0.69	0.66	0.45
1,2	false	false	0.68	0.66	0.45
1,2	true	true	**0.69**	**0.67**	**0.47**
1,2	true	false	0.68	0.66	0.45
1,3	false	true	0.69	0.66	0.45
1,3	true	true	0.69	0.66	0.47
1,4	false	true	0.69	0.66	0.45
1,4	true	true	0.69	0.66	0.47

Table 3: Multinomial Naive Bayes Classifier results with word ngram range, stemming and binarization

Classifier	$F_{1(HS)}$	F_1 (HS,TR,AG)	emr
glove twitter+logreg	0.70	0.70	0.48
glove twitter+XGB	0.69	0.66	0.55
glove+infersent+ XGB	0.72	0.69	0.55
glove+infersent+ logreg	0.72	0.72	0.53
stem+ NB binarized+ word-ngrams(1.2)	**0.74**	**0.73**	**0.57**

Table 4: Results on the dev set

- **Logistic Regression, SVM and XGBoost** Word or sentence level embeddings are fed as inputs to these classifiers. In the absence of a sentence embedder, we averaged all the word vectors to get a vector representation of the tweet. For logistic regression, the solver is liblinear (Fan et al., 2008) and L2 norm is used for penalization. For SVM, inputs are normalized using a soft scaling scheme and the kernel used is a Radial Basis Function (Buhmann and Buhmann, 2003). The default parameters are kept as is for XGBoost[6]. Table 2 shows the results.

- **Naive Bayes classifier:** Multinomial Naive Bayes classifier, along with the bag of words generated with CountVectorizer[7] gave better results than other Naive Bayes variations. Different runs are carried out to tune the parameters as shown in Table 3.

[6]https://xgboost.readthedocs.io/en/latest/python/python_api.html

[7]https://scikit-learn.org/stable/modules/generated/sklearn.feature_extraction.text.CountVectorizer.html

5 Results and Analysis

We wanted to submit a single system for both the subtasks. Hence, our goal was to maximize all three metrics: F_1(HS), F_1(HS,TR,AG) and EMR. The results show that there is no single variation that defeats the others in all the metrics combined. Logistic regression with glove and infersent performed the best in F_1(HS) and F_1(HS,TR,AG), but only with an acceptable EMR. Regarding the XGBoost family, glove with inferesent version outperforms the rest in all the metrics. Stemmed-binarized Naive Bayes classifier with ngram range (1,2) performed better in F_1(HS) and EMR in the Naive Bayes family. The Glove-Twitter version of logreg and XGboost aren't too far behind as well. We applied all these high performing models on the dev set to analyse their performance further. The results are shown in Table 4. Naive Bayes comfortably achieved the highest score on the dev set on all the three metrics as shown in Table 4. Hence, we finalized the Naive Bayes model as our official submission. This submission scored an F_1(HS) of 0.405 in subtask-A, F_1(HS,TR,AG) of 0.54 and EMR of 0.296 in subtask-B.

6 Conclusion and Future Work

The aim of this research was to detect hate speech against two specific targets, immigrants and women. We described a naive bayes classifier system and also elucidated our trials of using different pre-trained word and sentence level embeddings on the state-of-the-art classification algorithms. In the future, we would like to include lexicon-based, Parts Of Speech features to further investigate the performance of these classifiers. We would also like to evaluate how deep learning approaches respond to this task.

HATERecognizer at SemEval-2019 Task 5: Using Features and Neural Networks to Face Hate Recognition

Victor Nina-Alcocer
Department of Computer Systems and Computation
Universitat Politècnica de València, Spain
vicnial@inf.upv.es

Abstract

This paper presents a detailed description of our participation in task 5 on SemEval-2019[1]. This task consists of classifying English and Spanish tweets that contain hate towards women or immigrants. We carried out several experiments; for a finer-grained study of the task, we analyzed different features and designing architectures of neural networks. Additionally, to face the lack of hate content in tweets, we include data augmentation as a technique to increase hate content in our datasets.

1. Introduction

HatEval (Basile et al., 2019) aims to identify cases of aggressiveness and hate speech towards women and immigrants in social media considering tweets messages written in English and Spanish. This task defines two main sub-tasks:

- Task1. Hate Speech Detection against Immigrants and Women: predict whether a tweet in English or in Spanish is hateful or not hateful.
- Task2. Aggressive behavior and Target Classification: to identify if a tweet is aggressive or not aggressive, and to identify the target harassed as individual or generic.

To tackle the subtasks mentioned above we will use Natural Language Processing (NLP) and Machine Learning (ML) fields to propose two approaches. The first approach pretends to know more about valuable features that allow us to get a good understanding of its embedded knowledge. To get this knowledge we study four features that we consider important: its structure, its embedded emotions, patterns on its pos tagging and skip-grams. Each of these features will allow us to know if tweets have some patterns that can be used to discriminate tweets that contain hate or not.

The second approach will try to recognize patterns using weights among neurons. To implement this focus we designed several architectures of neural networks (NN), which were fed with different kinds of corpora that were processed considering many aspects such as, lemmatization, stemming, normalized hashtags, etc.

This work is organized into three sections. The first section provides an introduction to this paper. The second one describes the proposed approaches, the experiments conducted, and the results that we achieved. The third section presents some conclusions.

2. Systems Description

In this section, we present the main features of the two approaches considered in this paper and its respective experiments.

The organizers provided a training dataset of 9000 and 4500 tweets written in English and Spanish labeled with hate speech (HS), Aggressive behavior (AG) and Target (TR). For what concerns HS the distribution is almost balanced among hate(42 %) and no-hate (58 %) tweets in both languages. Regarding AG and TR, the distribution is skewed towards tweets that do not contain TR (75 %) or AG(67 %) respectively. In order to asses, the performance of the systems, tests set of 3000 and 1600 unlabeled tweets were provided. The official evaluation metrics to evaluate the systems were: For the task1, accuracy (Acc.), precision (P), recall (R), and F1-score. For task2, The models were evaluated using EMR and F1-score as describe in (Basile et al., 2019)

2.1. Based on Classical ML

With this approach, we try to face hate detection through classical machine learning algo-

[1]http://alt.qcri.org/semeval2019/index.php?id=tasks

rithms. Firstly, we established a baseline (called «our baseline») using Term frequency - Inverse document frequency (TF-IDF) scheme based on words and Support Vector Machine (SVM) as a supervised learning model. This baseline gives us an idea of whether the experiments that consider new features or simply the use of other machine learning algorithms help us to achieve good results.

Preprocessing: The preprocessing consisted of ridding of URLs, numbers, users, times, date, email, percents. But, we decided to keep normalized hashtags, elongated words, repetitions, emphasis, and censored words. Next, we present an example to show a raw and normalized version of a tweet:

Raw tweet:

@KamalaHarris Illegalsssssssss Dump their Kids at the border like Road Kill and Refuse to Unite! They Hope they get Amnesty, Free Educatioon and Welfare Illegal #FamilesBelongTogether in their Country not on the Taxpayer Dime Its a SCAM #NoDACA #NoAmnesty #SendThe https://t.co/Ks0SHbtYqn[2]

Normalized tweet:

illegals dump their kids at the border like road kill and refuse to unite they hope they get amnesty free education and welfare illegal familesbelongtogether in their country not on the taxpayer dime its a scam nodaca noamnesty sendthe

Feature Extraction and Selection. As in (Schmidt and Wiegand, 2017) our models considered a set of features. The first one takes into account the *structure of tweets*, with this focus we are going to consider and count if tweets have hashtags, punctuation marks, presence and its *Unicode Common Locale Data Repository* (CLDR)[3] version of emojis, capital letters, number of words, numbers of user and so on. To get the second group of features was necessary to consider *pos tagging* as described (Bretschneider et al., 2014), but analyzing some patterns on how people usually write or use hate content in tweets as was mentioned by (Silva et al., 2016), for instance, we noticed in the dataset that people usually use this pattern to denigrate a woman: "eres una maldita zorra" now to discover some pattern we show its pos tagging representation below:

eres ***AUX*** *una* ***DET*** *maldita* ***ADJ_Gender=Fem*** *puta* ***NOUN_Gender=Fem*** *zorra* ***ADJ_Gender=Fem*** *.* ***PUNCT_PunctType=Peri***

As we know a sentence is composed by verbs, prepositions, adjectives, adverbs and so on. In this particular sentence shown above, we see that is composed by auxiliaries, determiner, adjectives, noun and a punctuation mark. All these tags plus the gender of each word will give us a piece of important information to discriminate hate towards women and immigrants. The third feature that we consider important is to try to *find out if a word is pejorative, derogative, offensive or vulgar*. To get this aim we created a lexicon with these four categories already mentioned before. In short, we selected words that we called "seeds" then we start to get synonyms or related words using several sources[4]. Using this method we got more than 4900 words classified in the four mentioned categories. Some of the words and its respective categories are shown in Table 1.

Word	Pejorative	Derogative	Offensive	Vulgar
* solterona (es)	✓	-	-	-
* puta/puta de quinta (es)	✓	-	✓	-
* idiota (es)	-	✓	-	-
* huevon (es)	-	-	✓	-
* asswhore (en)	-	-	✓	-
* fucknigga/nigga (en)	-	-	✓	-
* pisslamist (en)	-	-	-	✓
* dogfucker (en)	-	-	-	✓

Table 1: Categories considered in our hate_lexicon.

We noticed that extending a little bit more the four categories in the third feature, we can improve slightly our results. Therefore, we take into account *the percentage of embedded emotions* in tweets, for this goal we used Linguistic Inquiry and Word Count (LIWC)[5]. And we chose some additional categories (sexual, anxiety feeling, anger and so on.) that help us to discriminate between tweets which contents hate or not. And finally, we have considered using TF-IDF schemes over skip-grams (bigram and trigrams) (Davidson et al., 2017).

In these experiments, we used scikit-learn to test several machine learning algorithms and its respective parameters. Some algorithms that we used

[2]This raw tweet belongs to the original training dataset and it was intentionally rewritten with typos to illustrate which considerations were taken into account to its normalization.

Table 2: Results achieved using LinearSVC algorithm for English and Spanish development datasets.

were: RandomForestClassifier (Breiman, 2001), LogisticRegression, Naive Bayes (Kibriya et al., 2004), LinearSVC (Hearst, 1998) and so on (Fortuna, 2017). A summary of applying this approach to the developing dataset and its respective results are shown in Table 2. This table shows just results using LinearSVC because it was the algorithm that achieved good results. Other variations of corpus like stemming or lemmatization version were not used because we did not achieve good results.

Basically, we can highlight in table 2, that the use of skip-grams does not help a lot, this fact is due to the lack of skip-grams contained in tweets, for instance, in the tweet mentioned before, the skip-trigram «illegals dump kids» is just repeated once in the whole dataset. A similar situation happens with skip-bigrams and skip-trigrams. On the other hand, the use of the structure and emotions (lexicon) embedded in tweets help to improve our baseline in both languages respectively. We used down arrow symbol ↓ to show that the value is below of our baseline, so is not valuable include it.

2.2. Based on NN

This second approach tackle hate speech detection trough neural networks (Schmidt and Wiegand, 2017). In this stage, we used several neural networks architectures which works enough well with text, some of them are: Convolutional Neural Networks (CNN) (Jacovi et al., 2018), Long short term memory (LSTM) and its variations: Peephole, Bidirectional (BILSTM) and Gated Recurrent Unit (GRU) (Lu and Salem, 2017). We tested these architectures with different corpora which were slightly modified, in some cases we used a corpus with stop words, or simply a stemming or a lemmatized version of words. Additionally, we used other variations to see which of them help us to improve the performance of the system, the next paragraph describes how the corpora were processed.

Preprocessing: Is valuable to mention that the preprocessing of raw tweets was slightly different for machine learning and NN, because we saw that keeping an identical preprocess for both approaches do not help a lot. So we decided to customize the preprocess for each focus as we describe in section 2.1 and section 2.2. Swear words were kept for both focuses because they helped to achieve better results. Furthermore, emojis were normalized using its CLDR short name, For instance, we changed 😊 for ':smiling_face_with_smiling_eyes:' cleaned (without any additional symbol).

For this particular preprocess for NN were taken to account many aspects that were already considered for ML's preprocessing. Perhaps the main difference is when we process the hashtag. For instance, its version normalized for the raw tweet shown in section 2.1, would be:

illegals dump their kids at the border like *road kill and refuse to unite they hope they get amnesty free education and welfare illegal families belong together in their country not on the taxpayer dime its a scam no daca no amnesty send the*

As is shown, this version separates the content of hashtags, additionally, we correct typos using dictionaries[6]. For instance, we changed "familes" by "families" in the above tweet.

This preprocess used for NN was used for ML too, but we noticed that accuracy got down in our experiments. Then we decided to keep the original way of hashtags for ML (no splitting).

The results shown in Table 3 were achieved using the developing datatset with the preprocess commented in section 2.2. Summing up, stop words, normal words (no stemming, no lemmatization), normalized hashtags, spelling corrections were considered. Furthermore, word embeddings (Mikolov et al., 2013) (Goldberg, 2015) as efficient word representation were used for all the experiments in this stage.

Carrying on several experiments we realized that Convolutional Neural Networks performed well enough compared to other architectures, see Table 3. Therefore, we named this architecture as *architecture A*. This architecture is compound by an input embedding layer, followed by and spatial dropout and next to a convolutional layer with a set up of 256 filters and kernel size of 2. Next a globalmaxpooling is defined and finally, a dense layer of 2 neurons with softmax is used to get the results. The good performance of this architecture encouraged us to use different word embeddings to improve accuracy, the results of these experiments are shown in Table 4.

As we can see in Table 4, there is a lack of results on the Spanish language, this fact is due that we could find in Spanish all the corresponding resources exploited for experiments with English portion of the data. Sometimes some authors publish word embeddings for this specific language but mostly this embeddings does not fit with our study case due to the language used in twitter is kind of informal and use a lot of slang, swear words and so on. And this important aspect reduces the performance of our system.

Data Augmentation: As we commented at the beginning of section 2, we noticed a slight skew in favor of tweets that do not contain HS, AG or TR. To deal with this unbalanced training dataset, like in (Risch and Krestel, 2018) we adopted a technique which allows us to increase the number of tweets with hate content. To do this we analyzed some ways to get synonyms or similar words. Firstly, we try to use synonyms only if these synonyms do not change the meaning of the whole sentence. This fact is challenging because is kind of hard to use synonyms to increase our dataset. For instance, the next tweet: *"Hurray, saving us $$$ in so many ways potus realDonaldTrump #LockThemUp #BuildTheWall #EndDACA #BoycottNFL #BoycottNike"* has to be cleaned and it has to just keep words to get its synonyms. The result to process the tweet above is: *"hurray saving us in so many ways lock them up build the wall end daca boycott nfl boycott nike"*. Now, we just have to get synonyms for each word, in our case using some resources such as: wordnet, dictionaries and so on. It is important to highlight that wordnet and dictionaries contain a formal language and those have a lack of slang or informal language used in tweets. Therefore, we decided to use word embeddings to get the most similar words, Additionally, we defined a threshold[7] to control that the synonym was so close to the original word. In our case, the threshold has been defined as *0.7* and the results for the tweet mentioned before are shown in Table 5.

Some remarkable facts that we saw in our experiments are: if we keep a threshold over 0.9 for sure we would not be able to get synonyms because with a high threshold we are just recovering almost the same words used on the original sentence. On the other hand, if we keep a threshold under 0.5 we will get synonyms or similar words that are not coherent and additionally those new words change the meaning of the whole sentence. For instance, in the syn3 with a threshold 0.3, the original word (us) was changed by (states), we assume that it refers to the country called the United States, that sometimes is written like *us*, this is just an example of how many of these words change the meaning of the sentence when is used a lower threshold. Unfortunately, this approach was not able to achieve good results. But we noticed that is valuable go deeper with this focus.

[6]https://www.dictionary.com

[7]most_similar function return the top n similar words and their respective scores. In our case we assume, if the score is close to 1 then more similar is the word.

Table 5: Similar words that were gotten using word embeddings.

Official Ranking

Table 6 shows the official results published by the organizers of HatEval. We submitted 10 runs for each task, the runs that achieved good results were run01 and run07 for English and run05 and run10 for Spanish. As we see too the performance of our the four runs or systems achieved high values over their respective baselines. Run01 and Run05 use TF-IDF scheme, run01 uses just structure features, meanwhile, run05 uses pos tagging and embedded emotions. Features that we have already described in section 2.1. Both runs achieved good results using Support Vector Machine. The system used in run07 is the *architecture A* which was already described in section 2.2. Run10 used an embedding layer as input, followed by an LSTMPeephole layer and finally a dense layer of 2 neurons with softmax is used. The last two runs that use neural networks were fed with a corpus described in section 2.2. As we notice both approaches perform enough well, but architectures that use neural networks work slightly better than focuses that use classical machine learning algorithms.

	Task1		**Task2**	
	English			
	Acc.	**F1-score(avg)**	**EMR**	**F1-score(avg)**
SVC off. Base.	0.492	0.451	0.308	0.578

vmna (run07)	0.515	0.481	0.353	0.569
	Spanish			
SVC off. Base.	0.705	0.701	0.605	0.736
vmna (run05)	0.721	0.718	0.621	0.739
vmna (run10)	0.735	0.729	0.632	0.747

Table 6: Official results for task1 and task2.

Having the golden labels we realize that our proposed system misclassified several tweets. As we can see in the next examples:

1. ** (original tweet) Estas navidades mi polla mereces*
   ** (Engish version) you deserve my dick for Christmas*
   Language: Spanish
   Golden Label: no-hate (0)
   our system(run05): hate (1)

2. ** (original tweet) @shakhepri69 @KuriMelon21 @HoruSenpai @crafter657 oye puta basura, cállate*
   ** (Engish version) @shakhepri69 @KuriMelon21 @HoruSenpai @crafter657 shut the fuck up, bitch*
   Language: Spanish
   Golden Label: no-hate (0)
   our system(run05): hate (1)

3. ** (original tweet) @GMA @TVMarci His own fault #SENDTHEMBACK*
   ** (Spanish version) @GMA @TVMarci su culpa #SENDTHEMBACK*
   Language: English
   Golden Label: no-hate (0)
   our system(run01): hate (1)

All three examples have been labeled as hate by our classifier. On the first example, after preprocessing, the system just kept the words navidades (Christmas), polla (dick) and mereces (deserve). And looking for these words in our lexicons just the last two words were found, so the system marked the tweet as hate-content. The same situation happened with example 2 and 3, just the words puta (bitch), basura (trash), callate (shut up) and culpa (fault), send (enviar), back (regreso) were found. As (Zhang and Luo, 2018) noticed, that some times hate and no-hate tweets have no enough features to be differentiated. Doing a manual analysis in the datasets we notice that fact to in several tweets.

3. Conclusions

This work proposed two main approaches. The first one, take into account some features that can be considered to feed classical machine learning algorithms, some of these features are: structure, embedded emotions, pos tagging, and skip-grams. On the other hand, the second approach consists of designing several neural networks architectures to test a variety of corpora and word representations. Moreover, we face an unbalanced dataset using a technique called data augmentation. To get similar words were used pre-trained word embeddings with a tuned few thresholds. Using data augmentation our results did not improve but we noticed that is a promising field to study. Furthermore, looking at the results in Table 6 we appreciate that both approaches contribute to achieving good results, perhaps a deep study in both approaches can help us to understand and improve our results. As a future work, it is interesting to explore more deep learning or neural networks and design more complex architectures.

Abstract

This paper describes the system we developed for SemEval 2019 on Multilingual detection of hate speech against immigrants and women in Twitter (HatEval - Task 5). We use an approach based on an Attention-based Long Short-Term Memory Recurrent Neural Network. In particular, we build a Bidirectional LSTM to extract information from the word embeddings over the sentence, then apply attention over the hidden states and finally feed this vector to another LSTM model to get a representation from de data. Then, the output obtained with this model is used to get the prediction of each of the sub-tasks with models based on neural networks and linguistic characteristics.

1 Introduction

Nowadays, the number of content generated by users on social networks is growing rapidly. In this context, the problem of detecting and limiting the dissemination of the Hate Speech is becoming a matter of great importance. Therefore, many efforts are dedicated to studying and treating this phenomenon. A large number of workshops on this topic have been developed in recent years, which reflects the interest of many researchers.

Some examples are the Workshop on Trolling, Aggression and Cyberbullying (Kumar et al., 2018), that included a shared task on aggression identification; the tracks on Automatic Misogyny Identification (AMI) (Fersini et al., 2018a) and on Autohorship and Aggressiveness Analysis (MEX-A3T) (Álvarez-Carmona et al., 2018) proposed at IberEval 2018; the Automatic Misogyny Identificationtask at EVALITA 2018 (Fersini et al., 2018b), the Workshop on Abusive Language (Waseem et al., 2017) and the GermEval Shared Task on the Identification of Offensive Language (Wiegand et al., 2018).

The proposed works have used different features and models. Among them, models based on deep learning, such as Recurrent Neural Networks (RNN) and Convolutional Neural Networks (CNN) have been widely used.

This paper presents a strategy based on RNN, which is an extension of previous models proposed for the tasks MEX-A3T and EVALITA 2018 (Cuza et al., 2018; la Peña Sarracén et al., 2018). Those models use an Attention-based LSTM inspired by the work (Yang et al., 2016). In this work the authors use a hierarchical attention network for document classification and their experiments show that the architecture outperforms previous methods. This last model has two levels of attention mechanisms applied at the word and sentence level, enabling it to attend differentially to more and less important content when constructing the document representation.

The aim of the proposed extension in this work is not only the hate language identification, but also the study of other features of hateful messages. In this case, the model based on the Attention mechanism and the LSTM is used as a representation of the input. This representation is then used to detect the hate language with a fully connected network. In addition, it is combined with some linguistic characteristics to analyze the other features of hateful messages. The objective has been defined for the HatEval[1] shared task on SemEval 2019.

The HatEval (Basile et al., 2019) task consists in Hate Speech identification in messages from Twitter in Spanish and English. The main objective focuses on detecting the hate expressed against women and immigrants in particular. The task is divided into two related subtasks: a binary classification as a first sub-task about Hate Speech de-

[1]https://competitions.codalab.org/competitions/19935

tection, and another one where other features of hateful contents is investigated:

- TASK A - Hate Speech Detection against Immigrants and Women: Predicting whether a tweet with a given target (women or immigrants) is hateful or not (HS).
- TASK B - Aggressive behavior and Target Classification: Classifying hateful tweets as aggressive or not (AG), and second identifying the target harassed as individual or generic (TR).

The paper is organized as follows. Section 2 describes the proposed methodology. Experimental results are then discussed in Section3. Finally, we present our conclusions with a summary of our findings in Section 4.

2 Methodology

In this work, a simple preprocessing is performed in which the text is cleaned. First, emoticons, hashtags, urls, and other strings that do not represent alphabetic sequences are eliminated. Then, the texts are represented as vectors with a word embedding model. We used pre-trained word vectors of Glove (Pennington et al., 2014), trained on 2 billion words from Twitter for English. On the other hand, for Spanish we used the word vectors of fasttext (Bojanowski et al., 2017).

In general, we propose a model that consists of a Bidirectional LSTM neural network (Bi-LSTM) at the word level in the input. At each time step the Bi-LSTM gets as input a word embedding. Afterward, an attention layer is applied over each hidden state. The attention weights are learned using the concatenation of the current hidden state of the Bi-LSTM and the past hidden state of another LSTM. In this way, a representation (R) of the input is obtained from the last LSTM to get the prediction of each of the subtasks, as shown in Figure 1.

2.1 Sub-task A

For the sub-task A, which consists in the identification of hate in tweets (HS), R is used as input of a Fully Connected Neural Network (FCNN) of two dense layers with the relu activation function. The class (hatefull or not) is obtained in an output layer with two units, relative to the number of classes, with the softmax activation function.

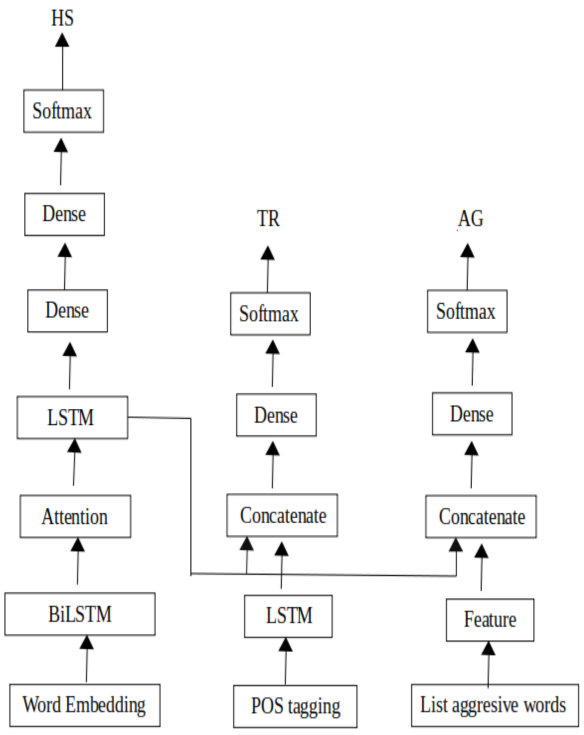

Figure 1: General architecture

2.2 Sub-task B

In the sub-task B the aim is to analyze some features of hateful messages, as discussed above. On the one hand, identifying against whom is directed the hate language (TR) and on the other hand, detecting whether a message with hate language is also aggressive.

For the task of detecting the target of hate (TR), the information of the part-of-speech tagging process of the tweets is used. The sequence of labels is analyzed with a LSTM RNN, obtaining a vector. Then, this vector is concatenated with R (from subtask A) and it is used as input to a dense layer with the relu activation function. Finally, the output layer has two neurons with the softmax activation function. In this way, the prediction corresponding to the offensive target in the tweets is obtained.

In the case of the task of classifying a hateful tweet in aggressive or not, a linguistic resource that consists of a dictionary of aggressive words is used. In this way, a linguistic characteristic is added to R according to the number of words in the tweet that appear in the dictionary. In addition, a one hot vector corresponding to the POS tags present in the tweet is added. With this new vector, the prediction is obtained in a similar way to the previous task, using another dense layer with the relu activation function.

3 Results

For the evaluation of the results of the task, different strategies and metrics are applied. For the sub-task A, systems are evaluated using standard evaluation metrics, including accuracy, precision, recall and F1-score. The submissions are ranked by F1-score. For the sub-task B, systems are evaluated with two criteria: partial match and exact match (EMR). In partial match, each dimension to be predicted (HS, TR and AG) is evaluated independently of the others using standard evaluation metrics including accuracy, precision, recall and F1-score, and then combined. In exact match, all the dimensions to be predicted are jointly considered. The submissions are ranked by the EMR measure.

Table 1 shows the results obtained for each of the languages in the sub-task A. In addition, the results of the system positioned in the first place of the ranking are shown for each of the metrics. In the same way, the results obtained for the sub-task B are shown in Table 2.

Language	Task A			
	Acc	P	R	F1-score
English	0.453	0.545	0.516	0.39
Best-English	0.653	0.69	0.679	0.651
Spanish	0.723	0.717	0.722	0.718
Best-Spanish	0.731	0.734	0.741	0.73

Table 1: Results for the sub-task A

Language	Task B	
	F1-score	EMR
English	0.532	0.268
Best-English	0.467	0.57
Spanish	0.74	0.618
Best-Spanish	0.755	0.705

Table 2: Results for the sub-task B

As can be seen, the results for English are very far from the best results obtained in the competition, reaching a low position in the ranking of the participating systems. On the other hand, the results for Spanish are better, reaching the eighth position in the ranking for task A and the eleventh for task B. However, these results are not good enough, which reveals that possibly the complexity of the model used is a problem. Therefore, a better approach might be to simplify the model in order to reduce the number of parameters to train. On the other hand, we think that it is very important for improving the results, to find discriminatory linguistic features, able of capturing the nature of the texts with hate; and to make a fined tunned of paramaters for each language.

4 Conclusion

In this paper we presented our solution for HatEval task in SemEval 2019. We used an approximation that combines a BiLSTM RNN with an attention mechanism to obtain a text representation vector. This vector is used as input in each of the models designed for each of the subtasks in which HatEval is divided. The results obtained were not very good, far away from the results obtained by the best system in the competition. As a conclusion of the analysis, it is believed that a better approximation would be to simplify the proposed model to reduce the number of parameters to train. Also, searching for discriminating linguistic features, which manage to capture the nature of texts with hate, should help to obtain better results.

Abstract

In this paper, we describe our approach to detect hate speech against women and immigrants on Twitter in a multilingual context, English and Spanish. This challenge was proposed by the SemEval-2019 Task 5, where participants should develop models for hate speech detection, a two-class classification where systems have to predict whether a tweet in English or in Spanish with a given target (women or immigrants) is hateful or not hateful (Task A), and whether the hate speech is directed at a specific person or a group of individuals (Task B). For this, we implemented a Convolutional Neural Networks (CNN) using pre-trained word embeddings (GloVe and FastText) with 300 dimensions. Our proposed model obtained in Task A 0.488 and 0.696 F1-score for English and Spanish, respectively. For Task B, the CNN obtained 0.297 and 0.430 EMR for English and Spanish, respectively.

1 Introduction

With the growth of users in social networks, there was also an increase in the odious activities that permeate these communicative structures. According to Nockleby et al. (2000), hate speech can be defined as any communication that deprecates a person or a group based on some characteristics such as race, color, ethnicity, gender, nationality, religion or other features. And the main motive that encourages users to spread hate on social networks is anonymity, so users can spread hate words to a particular target. For this reason, the hatred propagated can generate irreversible consequences, where young people who approach with cyberbullying and homophobia, mainly, commit suicide.

Nowadays, social networks like Twitter[1], Facebook[2] and YouTube[3] are pressured to develop tools to fight the proliferation of hate in their networks. A good example of this is the German government that threatened to fine social networks by up to 50 million euros if they did not fight the spread of hate (Gambäck and Sikdar, 2017).

However, while there is plenty of available content on social networks, the task of detecting hate speech remains difficult, largely because of the use of different sets of data for work, lack of benchmarking, and efficient approaches. Waseem, for example, bring a study focused on the detection of racism and sexism, whereas Nahar et al. 2012 and Sanchez and Kumar 2011) conducted a survey on detecting bullying. For the detection of homophobia, misogyny and xenophobia, the number of papers is still limited, one can cite a recent paper (Sanguinetti et al., 2018), where the authors sought to identify hate speech against immigrants. However, it is important that new research is publicized, because only in this way will it be possible to fight against hate in social networks.

Introducing a brief definition of hate speech and the importance of combating it, SemEval-2019 proposed a task in which it challenges participants to develop systems for detecting hate speech against women and immigrants on Twitter from a multilingual perspective , for English and Spanish.

The task was articulated around two related subtasks for each one of the languages involved: a basic task about hate speech, and another where refined hate content resources will be investigated to understand how existing approaches can handle the identification of especially dangerous forms of hatred, that is, those in which incitement is directed against an individual rather than against a group of people, and where aggressive behavior of

[1]https://twitter.com/

[2]https://www.facebook.com/

[3]https://www.youtube.com/

the perpetrator can be identified as a prominent feature of the expression of hatred. In order to reach this goal, this work proposed to develop a Convolutional Neural Network with the use of word embeddings.

The paper is organised as follows: previous work on hate-speech identification is discussed in Section 2. Section 3 presents details about the task, data sets and evaluation methods. Section 4 describes the methodology for categorizing hate speech based on deep learning, while experiments and results are reported in Section 5. Finally, Section 6 summarises the discussion.

2 Related Work

Some computational methods to detect hate speech are presented in this section. An example is the work of Badjatiya et al. (2017) that applied several algorithms of machine learning and deep learning, among them: Logistic Regression, Support Vector Machine, Random Forest, Gradient Boosted Decision (GBDT), CNN and Long Short-Term Memory (LSTM). As a baseline they used char n-grams and bag-of-words, and as word embeddings they used GloVe and FastText. The objective was to classify if a tweet is racist, sexist or none, and the best result was 0.930 of F1-score, which was obtained through a LSTM model with Random Embedding and GBDT.

Another work that also follows a line of ternary classification was proposed by Malmasi and Zampieri (2017), where the purpose is to classify a tweet as hateful, offensive (but not hateful) or offensive language. For this, the researchers proposed an approach based on n-grams and word skip-grams using Support Vector Machine with cross-validation, the best result achieved was 0.78 of accuracy.

Gambäck and Sikdar (2017) developed a Convolutional Neural Network to classify hate speech on Twitter. In this case, the authors used 4 categories: racism, sexism, both (racism and sexism) and non-hate-speech. The structure of CNN was constructed with convolutional layers and pooling of 4 modes: character 4-grams, word vector based on semantic information built using word2vec (Mikolov et al., 2013a), randomly generated word vectors and word embeddings with character n-grams. In the classification phase, the softmax function and cross-validation with 10-folds were applied, the model based on word2vec embeddings best performed with 0.783 of F-score.

A recent study developed by Gaydhani et al. (2018) sought to address the difference between offensive language and hate speech, then the authors proposed several machine learning models based on n-grams and TF-IDF. The models were analyzed considering several n-values in n-grams and TF-IDF normalization methods. Consequently, the best result among several approaches was 0.956 of accuracy.

3 SemEval-2019 Task 5

In this section we will describe some details about data sets, tasks, and evaluation methods.

3.1 Dataset

The data for the task consists of 9000 tweets in English for training, 1000 for develop and 2805 for test. For Spanish, 4469 tweets for training, 500 for develop and 415 for test. The data were structured in 5 columns: id, text, Hate Speech (HS), Target Range (TR) and Aggressiveness (AG). See an example in the Table 1 (Basile et al., 2019). If the $@username$ is a woman, we have a case of feminicide.

id	text	HS	TR	AG
93874	@username stupid wish you die.	1	1	1
18267	Leftwing filth Deport them all. #Sendthemback	1	0	1
18345	1,500 migrants have died in Mediterranean in 2018	0	0	0

Table 1: Example of hate speech. Some examples are also taken from the data.

3.2 Task A

The task A is a two-class classification problem in which participants have to predict whether a tweet, in English or Spanish, with a particular target (women or immigrants) is hateful or not hateful – Hate Speech (1/0).

3.3 Task B

The purpose of this task is to: (i) classify hate tweets into English and Spanish, where tweets with hate speech, against women or immigrants, were identified as aggressive or non-aggressive, and (ii) identify the harassed target as just one person or group of individuals.

3.4 Evaluation

For the results evaluation of both tasks A and B, different metrics were used in order to allow more refined conclusions.

Task A. The systems will be evaluated according to the following metrics: accuracy, precision, recall and F1-score. The equations below show how the calculations are done. In the case of this task, the scores will be classified by F1-score. For better understanding, we will show the following definitions:

- *True positive* (TP): means a correct classification as odious. For example, the royal class is hateful and the model ranks as hateful.
- *True negative* (TN): means a correct classification as not hateful. For example, the royal class is not hateful and the model ranked as not hateful.
- *False positive* (FP): means a wrong classification as odious. For example, the royal class is not hateful and the model rated it as hateful.
- *False negative* (FN): means a wrong classification not hateful. For example, the royal class is hateful and the model ranked as not hateful.

$$Accuracy = \frac{TP + TN}{TP + FN + FP + TN} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

$$F1\text{-}score = \frac{2 * Precision * Recall}{Precision + Recall} \quad (4)$$

Task B. In this task, the evaluation metrics are two: partial match and exact match. The strategy for the partial match is to evaluate the Hate Speech, Target Range and Agressiveness classes independently of each other using the metrics defined above. However, each system will include all measures and a summary of the performance in terms of macro-average F1-score, calculated according to the Equation 5. The exact match considers the predicted classes together, thus computing the Exact Match Ratio (Kazawa et al., 2005). Given the set of data consisting of n multi-label samples (Xi, Yi), where Xi denotes the i-th instance and Yi corresponds to the labels to be predicted (HS, TR and AG), the Exact Match Ratio (EMR) is calculated according to Equation 6.

$$F1\text{-}score = \frac{F_1(HS) + F_1(AG) + F_1(TR)}{3} \quad (5)$$

$$EMR = \frac{1}{n}\sum_{i=1}^{n} I(Yi, Zi) \quad (6)$$

where Zi denotes the set of labels predicted for the i-th instance and I is the indicator function.

4 Methodology

In this section, we describe the details of our proposed methods, including data preprocessing, neural networks and word embeddings.

4.1 Preprocessing

This step consists in eliminating noises and terms that have no semantic significance in classes prediction. For this, we performed the removal of links, numbers, special characters, and *stop words* (words with low discriminative power, for example, "is", "that" etc.) and standardized in lowercase.

4.2 Word embeddings

Word Embeddings (Bengio et al., 2003) is a supervised statistical language model trained using deep neural networks. The purpose of this language model is to predict the next word, given the previous words of the sentence. The vector embeddings was a great advance in relation to the strategies based on the bag-of-words, which justifies its use in several works (Nakov et al., 2016; Poria et al., 2015; Cliche, 2017; Zhou et al., 2018; Rotim et al., 2017). For the proposed task, we use the GloVe (Pennington et al., 2014) and FastText (Joulin et al., 2016) model with 300 dimensions.

For the English language, we made use of the Stanford pre-trained GloVe (Pennington et al., 2014) where word embedding were trained with Wikipedia 2014 and Gigaword 5, while FastText (Joulin et al., 2016) was trained in Wikipedia 2017, UMBC webbase corpus and statmt.org news.

For the Spanish language, the GloVe vocabulary was computed from SBWC (Pennington et al., 2014; Cardellino, 2016), while FastText was computed from the Spanish Wikipedia (Bojanowski et al., 2016).

4.3 Convolutional Neural Networks

Initially, the Convolutional Neural Network architecture was designed for image processing, however it has been commonly used in the sentiment analysis (Wang et al., 2016; Cambria et al., 2016; Rosenthal et al., 2017; dos Santos and Gatti, 2014; Poria et al., 2015).

For the purpose of the task, a CNN was implemented based on the architecture proposed by (Zhang and Wallace, 2015), and this implementation can be divided in two steps: feature extraction and classification. In the feature extraction step, only two layers of convolution and two layers of pooling were used, with tanh activation function. Four filters were used, 2 of 3 dimensions and 2 of 4 dimensions. Each filter refers to the classic n-grams technique (extremely used in bag-of-words based models), which consists of processing a group of n words, in order to consider not only isolated words in a tweet, but also the context in which they are inserted. The filters are applied under the vector representation of the input tweets (embedding layer), using the concept of Back propagation to adjust the weights dynamically. According to Poria et al. (2016), these filters can extract lexical, syntactic or semantic features automatically. Finally, the two layers of convolution and pooling are concatenated and directed to the next step.

In the classification stage, we used two dense layers, the first one has 512 neurons, relu function of activation and dropout of 0.5. The second has a neuron and sigmoid activation function, phase where classification occurs. For the training, the loss and optimization functions used were binary_crossentropy and RMSprop (Hinton et al., 2012) (with learning rate 0.001), respectively.

5 Results

In this section we will discuss the results obtained by using a CNN for the detection of hate speech and the target of hate.

Task A				
English				
Model	**F1**	**P**	**R**	**Acc**
CNN-FastText	0.488	0.628	0.574	0.520
Spanish				
Model	**F1**	**P**	**R**	**Acc**
CNN-GloVe	0.696	0.708	0.712	0.696

Table 2: Results obtained related to Task A.

We obtained 0.488 of F1-score for English and 0.696 for Spanish with our CNN model using word embeddings, as shown in Table 2. This result also suggests that the combination of CNN and GloVe provides better results for this task.

English			
Class	**F1**	**P**	**R**
hateful	0.617	0.465	0.916
not hateful	0.359	0.792	0.232
Spanish			
Class	**F1**	**P**	**R**
hateful	0.685	0.598	0.802
not hateful	0.707	0.817	0.622

Table 3: Confusion matrix concerning task A.

The Table 3 displays the results of F1-score, Precision and Recall reached by class for each language. The F1-score can be used to measure the performance of the classifier, in this case CNN ranked the hateful class better, obtaining 0.617 of F1-score, while the result for not hateful class was 0.359 of F1-score in the English language.

From the perspective of the Spanish language, CNN obtained good results in the classification of both classes, hateful and not hateful, with 0.685 F1-score and 0.707 F1-score, respectively.

Task B		
English		
Model	**F1**	**EMR**
CNN-FastText	0.577	0.297
Spanish		
Model	**F1**	**EMR**
CNN-FastText	0.609	0.430

Table 4: Results obtained related to Task B.

Recapitulating the idea of task B, where the goal is to identify the target of the hate speech, that is, whether it is a single person or a group of individuals. Knowing that there is hate speech in the tweet (HS is 1), then one must detect if the target is only one person (TR is 1) or if it is a group of individuals (TR is 0), and if there is presence of aggressiveness in speech (AG is 1) or not (AG is 0). In this case, the EMR measure shows a percentage in which it corresponds to an accuracy rate, that is, it measures how much the model has managed not only to classify the hate speech, but also the target and the aggressiveness. The Table 4 shows the results of task B, where it was possible to obtain 0.297 EMR for English and 0.430 EMR for Spanish.

6 Conclusion

In this paper, we introduced the system that we proposed for SemEval-2019, task 5. Our goal was to experience an architecture that was adapted from a CNN using word embeddings. The task was to detect hate speech against women and immigrants on Twitter from a multilingual perspective, English and Spanish. We participate in two subtasks directed to the two languages, and we obtain the 18th position in the ranking of task A and the 19th position of task B in the English language. In the Spanish language, we obtain the 24th position in the ranking for both tasks.

The success of deep learning depends on finding an architecture to fit the task. Furthermore, as deep learning has scaled up to more challenging tasks, the architectures have become difficult to design by hand. In this paper, a CNN was implemented based on the architecture proposed by Zhang and Wallace 2015 and a fine-tuning of hyperparameters was not done for the proposed tasks (tasks A and B). In addition, other features were not exploited as sarcasm and irony, inherent in this type of domain. We intend to explore these and other features in future work.

Another discussion can be raised regarding the best performance to have happened in Spanish. The main hypothesis is related to the nature of the corpus used. It is observed that the test set of Spanish is smaller than that of English, besides being a corpus with "simpler texts to be classified" (Spanish texts have few signs of sarcasm). Such analyzes need further studies and will be evaluated in future work.

For future work as well, it would be interesting to explore systems that use different parameters for CNN and other word embeddings, such as Word2Vec (Mikolov et al., 2013b). It would also be interesting to construct an LSTM with attention mechanism proposed by Lin et al. (2017) and compare its performance.

Abstract

In this paper, we describe our submissions to SemEval-2019 contest. We tackled subtask A - "a binary classification where systems have to predict whether a tweet with a given target (women or immigrants) is hateful or not hateful", a part of task 5 "Multilingual detection of hate speech against immigrants and women in Twitter (HatEval)". Our system JCTDHS (Jerusalem College of Technology Detects Hate Speech) was developed for tweets written in English. We applied various supervised ML methods, various combinations of n-gram features using the TF-IDF scheme. In addition, we applied various combinations of eight basic preprocessing methods. Our best submission was a special bidirectional RNN, which was ranked at the 11th position out of 68 submissions.

1 Introduction

Hate Speech is usually defined as communication that contains contempt or hatred towards a person or a group of people on the basis of some characteristic e.g., color, ethnicity, gender, nationality, race, religion, and sexual orientation.

The phenomenon of hate speech in social media has grown in recent years (Eadicicco. 2014). A strong connection between hate speech and actual hate crimes has been shown in Watch (2014). In light of the huge amount of information in social media, early detection of people using hate speech could prevent them from carrying out their hate speech. Therefore, the detection of hate speech in social media has become an issue of increasing importance (Moulson. 2016).

In this paper, we describe our six models (each model with another team member as the first author) submitted to task 5-A for tweets written in English. The full description of this task is given in Basile et al. (2019).

The structure of the rest of the paper is as follows. Section 2 introduces a background concerning hate speech, tweet classification, and data preprocessing. Section 3 presents, in general, the description of Task 5. In Section 4, we describe the submitted models and their experimental results. Section 6 summarizes and suggests ideas for future research.

2 Background

2.1 Hate Speech

Waseem and Hovy (2016) introduced a list of criteria founded in critical race theory and used them to label a publicly available corpus of more than 16k tweets with tags about both racial and sexist offenses. Nobata et al. (2016) developed a machine learning based method to detect hate speech on online user comments from two domains. They also built a corpus of user comments annotated accordingly to three subcategories (hate speech, derogatory, profanity). Schmidt and Wiegand (2017) introduced a survey of the NLP methods that were developed in order to detect hate speech. Davidson et al. (2017) presented a multi-class classifier to distinguish between three categories: hate speech, offensive language, and none of these two. The analysis of the predictions and the errors shows when they can reliably separate hate speech from other types of offensive language (e.g., tweets with the highest predicted probabilities of being hate speech tend to contain multiple racial or homophobic slurs) and when this differentiation is more difficult (e.g., many tweets misclassified as hate speech contain terms that can be considered racist and sexist; however it is apparent that many Twitter users use this type of language in their everyday communications). Anzovino et al. (2018) built a labeled corpus containing 2,227 misogynous (hate speech against women) tweets and no-misogynous tweets and explored various NLP features and ML models for detecting and classifying misogynistic language.

2.2 Tweet Classification

Tweet classification is the task to automatically classify a tweet into one of a set of predefined classes. This research domain has been growing rapidly in recent years. Twitter as one of the leading social networks presents challenges to the researchers since tweets are informal, short, and contain various misspellings, shortenings, and slang words (HaCohen-Kerner et al., 2017).

2.3 Data preprocessing

Data preprocessing is an important step in data mining (DM) and ML processes. In data files, it is common to find typos, emojis, slang, HTML tags, spelling mistakes, irrelevant and redundant information. Analyzing data that has not been carefully cleaned or pre-processed might lead to misleading results.

Not all of the preprocessing types are considered effective by all text classification (TC) researchers. For instance, Forman (2003), in his study on feature selection metrics for TC, claimed that stop words frequently occur and are ambiguous and therefore should be removed, However, HaCohen-Kerner et al. (2008) demonstrated that the use of word unigrams including stop words lead to improved TC results compared to the results obtained using word unigrams excluding stop words in the domain of Hebrew-Aramaic Jewish law documents.

In our system, we applied various combinations of eight basic preprocessing types: C - spelling Correction (The spelling correction is performed using an autocorrect library, written by McCallum (2014)[1]), H – HTML Tags Removal, L – converting to Lowercase letters, P – Punctuation removal, S – Stopwords Removal, R – Repeated characters removal (repeated characters were removed and only one character was left), T – sTemming, and M - leMmatizion) in order to check whether they improve TC or not.

3 Task Description

Task 5 deals with two tasks related to hate speech detection in Twitter with two specific targets, women and immigrants, for tweets in English and Spanish. We participated only in Task 5-A for tweets written in English, i.e., a two-class classification task where we have to predict whether a tweet with a given target (women or immigrants) is hateful or not hateful.

The datasets of Task 5-A consists of Train, Dev and Test datasets. The Train dataset contains 9,000 categorized tweets: 3,783 HS (hateful speech) tweets and 5,217 NHS (not hateful speech) tweets. The Dev dataset first published without labels, and they were added only in the final evaluation phase. The Dev set contains 1,000 tweets: 427 HS tweets, and 572 NHS tweets. The Test dataset contains 3,000 uncategorized Tweets.

4 The Submitted Models and Experimental Results

We have submitted six models (one for each author) to task 5-A for tweets written in English. The general TC algorithm is as follows.

1. Using a TF-IDF scheme, find the optimal number of word n-grams and combination of pre-processing types.
2. Apply various supervised ML methods including RNN models and others to find the best accuracy results.

Table 1 presents the main characteristics and results of our six submitted models in descending order according to their F1-Macro (F-M) score on the test set. Figure 1 presents our final RNN model using n-gram features in layer N.

elyashiv12 @ gmail.com	None	RNN contains 128 LSTM units, and Dropout layer (0.3). GloVe of 200d used for embedding	None	None	0.751	0.49	15 \ 68
kerner@ jct.ac.il	None	Bidirectional RNN with 4 hidden layers. Each layer contains128 LSTM units and Dropout layer (0.4). GloVe of 200d used for embedding	None	None	0.754	0.48	21 \ 68
ShalomRo chman	CHLPRS	Bidirectional RNN with 4 hidden layers. Each layer contains128 LSTM units and Dropout layer (0.4). GloVe of 200d used for embedding	200 char bigrams, no skips	SVM (SGD Variant)	0.749	0.42	42 \ 68
benda1237 @ gmail.com	CHLPRS	Bidirectional RNN with 4 hidden layers. Each layer contains128 LSTM units and Dropout layer (0.4). GloVe of 200d used for embedding	200 word unigram, no skips	SVM (SGD Variant)	0.713	0.41	41 \ 68
ecahn	CHLPRS	Bidirectional RNN with 2 hidden layers. Each layer contains128 LSTM units and Dropout layer (0.4). GloVe of 200d used for embedding	300 char bigrams, no skips	SVM (SVC Variant)	0.759	0.38	54 \ 68

Table 1: Results of our 6 models in task-A.

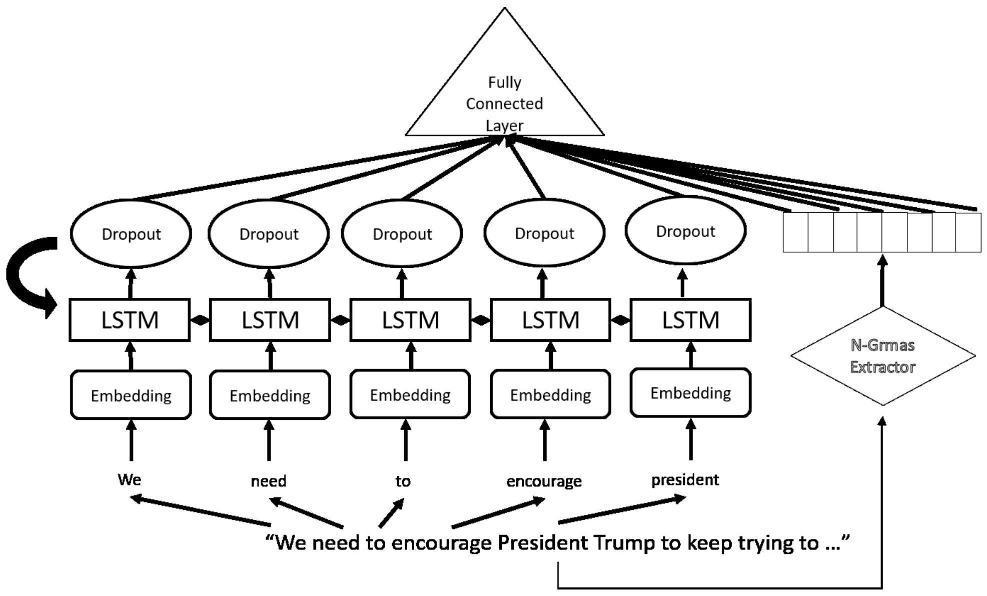

Figure 1: Final RNN model with n-gram features in layer N.

Analysis of the results presented in Table 1 shows that our best Macro F-measure score (as opposed to F1 of hate speech alone) for the test set (0.5) was obtained by a bidirectional RNN with 4 hidden layers, 128 LSTMs, 0.4 Dropout and a GloVe (Pennington et al., 2014) of 200d special for Twitter as an embedded layer. The best combination of pre-processing types was found to be CHLPRS, which means to activate all pre-processing types.

In our experiments, we used the following framework Python 3.6 with Keras[2] and Scikit-Learn in PyCharm IDE (Pedregosa et al., 2011) using the TF-IDF scheme called TfidfTransformer[3]). The accuracy of each ML model was estimated by a 5-fold cross-validation testing. The vocabulary words were used as zero-vectors during the word-to-embedding conversion. The Fully connected layer (FC) is the last layer in RNN models. It performs the final classification. The activation function of the FC layer is the sigmoid function. We used the RMSProp optimizer and 30 epochs for each model.

5 Conclusions and Future Research

In this paper, we describe our submissions to Task 5-A of SemEval-2019 contest. Our system JCTDHS (Jerusalem College of Technology Detects Hate Speech) was developed for tweets written in English. We used a TF-IDF scheme and we performed various combinations of six pre-processing methods to improve the performance.

Our best submission for Task 5-A was a bidirectional RNN with 4 hidden layers while each layer contains128 LSTM units, a dropout layer (0.4), and a GloVe (Global Vectors for Word Representation) of 200d that was used for embedding. GloVe was developed by the Stanford NLP Group (Pennington et al., 2014). It applies a co-occurrence matrix and by using matrix factorization.

This submission was ranked at the 11th out of 68 submissions for tweets written in English.

Future research proposals are as follows. It is known that many tweets include acronyms (abbreviations) that are presented in different forms. Acronym disambiguation (HaCohen-Kerner et al., 2010A), i.e., selecting the correct long form of the acronym depending on its context will enrich the tweet's text and will enable better TC.

More ideas that may contribute to better classification are implementing TC using (1) additional feature sets such as stylistic feature sets (HaCohen-Kerner et al., 2010B) and key phrases that can be extracted from the text files (HaCohen-Kerner et al., 2007) and (2) additional deep learning models.

Abstract

This paper presents the *Know-Center* system submitted for task 5 of the SemEval-2019 workshop. Given a Twitter message in either English or Spanish, the task is to first detect whether it contains hateful speech and second, to determine the target and level of aggression used. For this purpose our system utilizes word embeddings and a neural network architecture, consisting of both dilated and traditional convolution layers. We achieved average F1-scores of 0.57 and 0.74 for English and Spanish respectively.

1 Introduction

The ever-increasing number of message board forums, social media platforms and other websites that allow user comments enable participants to express their opinions freely and sometimes even anonymously. This barley restricted access in combination with the unmanageably vast amount of user-generated content unfortunately also creates an environment, which is vulnerable to profanity and hateful speech, rendering it hostile to the individuals or groups of people targeted. This problem is of increasing importance (Kettrey and Laster, 2014) and calls to establish systems that allow for automated detection of such behavior.

While detecting abusive language by it self is already a challenging task, (Malmasi and Zampieri, 2018) showed that it is even harder to differentiate between its subtypes. Messages containing profanity, sexism, racism and other forms of hateful speech may be formed using very similar vocabularies. Additionally, these subtypes may overlap, making data sets dependent on the subjective judgments of annotators. This may be particularly true for finding a threshold distinguishing aggressive and none-aggressive speech. In a task organized as part of COLING 2018 (Kumar et al., 2018) 15,000 participants were asked to detect aggressive behaviour in a data set of Facebook posts. Even the best system only obtained a weighted F1-score of 0.64.

Task 5 of the SemEval-2019 workshop (Basile et al., 2019) aims to accelerate the research and development of such systems. It comprises two distinct subtasks. The first subtask is devoted to detect hateful speech against immigrants and women in Twitter messages. For the second subtask, messages that are detected to be hateful are investigated further. Here, the goal is to identify aggressive behaviour and the target, women or immigrant, harassed. Given the multilingual nature of the task, systems for both English and Spanish are required. For the design and evaluation of these systems, training data sets for both languages are provided. The English data set consists of 9000 annotated messages whereas the Spanish data set consists of 4500.

Closely related, another task is hosted at the SemEval-2019 workshop, dealing with offensive language in social media and the individuals and groups targeted by it (Zampieri et al., 2019).

The rest of the paper is organized as follows. In the next section we give an overview of work that has been done in the field of detecting hateful and abusive speech. Section 3 describes our submitted system, including the pre-processing performed as well as the classifier trained on the data sets provided. In section 4 we show the results of our system and compare them with those of other participants in this challenge. Section 5 contains a brief summary.

2 Related Work

The problem of abusive behaviour in online media has been addressed in various fields. (Olteanu et al., 2018) address the causes for hateful speech

and in particular the effects of violent attacks performed by extremist groups and individuals. They were able to show, that such events majorly fuel hateful comments on Twitter and Reddit.

For the detection and classification task multiple methods have been previously explored. One approach involves the identification of words and parts of words in the form of character n-grams, that are the most indicative of hateful speech (Waseem and Hovy, 2016; Nobata et al., 2016). A potential downside of such approach might be that the meaning of a word may depend on the context it is used in (Sood et al., 2012). Chen et al. (2012) tried to overcome this issue by employing word n-grams. However, this is associated with an increase in feature space.

Another approach is to employ word embeddings in order to capture similarities between words (Badjatiya et al., 2017). Extending this method, Djuric et al. (2015) used paragraph2vec (Le and Mikolov, 2014) to encode whole messages and detect hateful messages in the embedding vector space. In addition to these lexical features, linguistic and syntactic features can be extracted. These may include the length of messages, average length of words, number of punctuations, Part-of-Speech (PoS) tags and dependency relationships (Nobata et al., 2016).

Recent work on this topic include different neural network architectures to classify text. Here either recurrent neural networks (RNNs) like LSTMs and GRUs, convolutional neural networks (CNNs) or both have been researched (Zhang and Luo, 2018; Zhang et al., 2018; Badjatiya et al., 2017).

3 System Description

Following the latest developments in the field of text classification, our system utilizes different convolutional filters in order to extract features. In the following sections we will describe the steps performed to pre-process the raw text messages and the network architecture used.

3.1 Pre-Processing

Given the raw Twitter messages, several steps of pre-processing are applied. First we follow the suggestions of Pennington et al. (2014), which involves the replacement of certain characters by tags. User mentions are replaced by `"<user>"`, numbers by `"<number>"`, web links by `"<url>"` and repeating characters like `"!!!"` by `"! <repeat>"`. Furthermore, words that are written using uppercase characters only are replaced by the same word in lowercase, followed by `"<allcaps>"`. Hashtags like `"#IllegalImmigrants"` are replaced with `"<hashtag> illegal immigrants"`, splitting the text before each uppercase character. The resulting text is then padded with `"<space>"` to match the length of the longest message.

The sequences are then encoded using pre-trained word embeddings. For English, the 200-dimensional GloVe embeddings from Pennington et al. (2014) are used, because they were trained on Twitter messages and include vectors for the tags mentioned above. For Spanish, the 300-dimensional GloVe embeddings trained on the Spanish Billion Word Corpus (Cardellino, 2016) are used. Unknown words were replaced by `"<unknown>"` in English and `"desconocido"` in Spanish. These embeddings are then directly fed to our neural network classifier.

In order to compare our model to traditional approaches as discussed above, we also implemented a second pre-processing pipeline. This takes the padded sequences, applies stemming and extracts *n*-grams tuples with *n* being in the range from one to four words. These tuples are then vectorized using *TF-IDF*.

3.2 Classification

The detection of hate speech as well as the classification of aggressive behavior and the target harassed can be seen as three independent binary classification tasks. Hence, we can use the same model for each individual subtask and language. The only exception to this is the size of the input, since the the English embedding is 200-dimensional, whereas the Spanish embedding is 300-dimensional.

The network itself employs five different filter types, as shown in Figure 1. All of them are 1-d convolutions, meaning that the windows spread along all dimensions of the embedding size and only move along the words in a message. The first three are traditional convolutional filters with a window size of two, three and four words. These can be seen as n-gram feature extractors. The other two filters have a window size of two, but are dilated with dilation rates of two and three. By skipping words in between two other words, these filters may extract word combinations that may otherwise be missed due to the low importance of the words in the middle. All filter types use a stride of one, same padding and rectified linear units (ReLUs) as activation functions. For each of the five filter type, 100 filters are used. Max-pooling with a filter size of four and a stride of four is performed on all, to reduce dimensionality. In the next layer, the filter maps are concatenated and global max-pooling is performed. This flattens the filters in a non-parametric way and extracts the most pronounced features along all filters. Finally, these features are fully connected

Model	EN	ES
CNN + DIL	**0.78**	**0.82**
CNN	0.77	0.80
SVM	0.63	0.68
LogReg	0.65	0.68
SVM (*n*-gram *TF-IDF*)	0.76	0.81
LogReg (*n*-gram *TF-IDF*)	0.76	0.77

Table 1: Comparison of model performance (F1-score) on the training set for subtask 1 (hate speech detection).

with one output neuron, which uses the sigmoid activation function. The network is trained for ten epochs using the Adam optimization algorithm (Kingma and Ba, 2014) and a batch size of 32.

We found this model to yield the best performance, comparing it to various other approaches. For the test set we selected ten percent of the training data points randomly and stratified. The results of this comparison can be seen in table 1. In order to evaluate the effectiveness of dilated convolutions we removed them from the model, leaving just the three regular convolutional filter types. As a result the F1-scores dropped by 0.01 in English and 0.02 in Spanish. Furthermore, logistic regression and SVM classifiers were trained both on the word embeddings and the *n*-gram based *TF-IDF* features. On the training data our approach performs slightly better than these. One reason for this very marginal improvement over the traditional approaches may be the size of the training set. In order to train a model with a high number of parameters like ours large data sets are majorly beneficial.

4 Results

Here we show the performance of the *Know-Center* system on the challenge's official test sets and compare it with the performances of the other participants. The results are shown in Tables 3 and 2 for the English and Spanish tasks respectively. The provided rankings refer to the average F1-scores over all subtasks, namely hate speech detection, target classification and aggression classification.

As illustrated, the *Know-Center* system achieved F1-scores of 0.45 and 0.72 in identifying hate speech in English and Spanish. For the target classification, we achieved F1-scores of 0.69 and 0.81. In detecting aggressive behavior, our system

#	Team name	AVG	HS	TR	AG

Table 2: F1-scores for each subtask in Spanish (subtask 1: hate speech detection (HS), subtask 2: target (TR) and aggression (AG) classification) as well as the overall average (AVG) per team, including their rank (#)

#	Team name	AVG	HS	TR	AG
1	scmhl5	0.63	0.60	0.71	0.59
2	alonzorz	0.61	0.52	0.75	0.57
3	MITRE	0.61	0.53	0.74	0.58
4	SINAI-DL	0.61	0.52	0.71	0.60
5	YNU_NLP	0.61	0.50	0.71	0.62
17	SVC baseline	0.58	0.45	0.70	0.59
20	**Know-Center**	**0.57**	**0.45**	**0.69**	**0.57**
42	MFC baseline	0.42	0.37	0.45	0.45

Table 3: F1-scores for each subtask in English (subtask 1: hate speech detection (HS), subtask 2: target (TR) and aggression (AG) classification) as well as the overall average (AVG) per team, including their rank (#)

achieved F1-scores of 0.57 and 0.70.

This is particularly interesting when comparing these results with the once obtained on the training data. Here the Spanish model performs similarly, but the English model does not. In general, the F1-scores obtained in the Spanish subtasks are better across all teams, even though less teams participated in it. One reason for that may be differences between training and test set. Besides that, our model uses high dimensional features, given the size of the word embeddings and the message length. For this, the size of the training set is very small, which makes it difficult to train a model with a high number of parameters such as ours. Even though a validation set was used during training, the possible homogeneity of the training set may have led to an over-fitting of the model.

5 Conclusion

We framed the tasks an a binary text classification problem, for which we developed a classification method that we used to participate in both subtasks of task 5 of the SemEval-2019 workshop. The classifier makes use of word embeddings and CNNs to identify hate speech in Twitter messages, determine the target and aggressive behavior. The same pre-processing and network architecture has been used for all tasks and languages. Averaged over all subtasks we achieved F1-scores of 0.57 and 0.74 for English and Spanish respectively.

Abstract

This paper describes our contribution to the SemEval-2019 Task 5 on the detection of hate speech against immigrants and women in Twitter (hatEval). We considered a supervised classification-based approach to detect hate speech in English tweets, which combines a variety of standard lexical and syntactic features with specific features for capturing offensive language. Our experimental results show good classification performance on the training data, but a considerable drop in recall on the held-out test set.

1 Introduction

The exponential growth of social media such as Twitter, Facebook, Youtube and community forums has created a variety of novel ways for all of us to communicate with each other, but this opportunity to freely communicate online has unfortunately also given a forum to people who want to denigrate others because of their race, colour, gender, sexual orientation, religion, etc. While there has been an increasing interest in automatic hate speech detection in social media, the problem is far from solved, partly due to the low consensus on what exactly constitutes hate speech, how it relates to offensive language and bullying and thus the low reliability of hate speech annotations (Ross et al., 2017). Davidson et al. (2017) for example observe that their classifications of hate speech tend to reflect their own subjective biases: while racist and homophobic insults are considered hateful, they tend to see sexist language as merely offensive. When we consider the different approaches that address hate speech, we can observe that -apart from simple methodologies that rely on lookup in a dictionary of hateful terms (Tulkens et al., 2016) - most methods cast the problem as a supervised classification task either using a more standard machine learning approach or deep learning methods (Pitsilis et al., 2018). This was also the approach we took for our hate speech detection system.

We participated for both subtasks proposed for English for Task 5 (Basile et al., 2019), being TASK A, which was defined as a binary classification task where systems have to predict whether a tweet with a given target (women or immigrants) is hateful or not hateful, and TASK B, where systems are asked first to classify hateful tweets as aggressive or not aggressive, and second to identify the target harassed as individual or generic (i.e. single human or group).

2 System Description

We designed a cascaded classification-based approach, where a first classifier categorizes a tweet as being hateful or not, while in a second step the hateful tweets are classified as (a) being aggressive or not, and (b) the target as being individual or generic. For the second step we built separate classifiers for both subtasks (a) and (b).

2.1 Preprocessing

We applied the Twitter-specific tweetokenize (Suttles, 2013)[1] module for tokenization and preprocessing. With this module, we were able to ensure all unicode emojis would be preserved. It also allowed us to add emoticons to the module's lexicon, to avoid splitting them up. We used the module with standard settings: allcaps were maintained; @mentions were replaced by "USERNAME"; urls replaced by "URL". We decided to preserve hashtags and numbers (but replacing phonenumbers and times by "PHONENUMBER" and "TIME", respectively), as well as quotes and stopwords. Finally, we applied a function to tokenize

[1]`https://github.com/jaredks/tweetokenize`

the hashtags, but this proved insufficient, as it did not tokenize camelcased hashtags correctly.

2.2 Featurization

We aimed to develop a rich feature set that focused on lexical information with some syntactic and non-linguistic features included. This featurization pipeline is based on work in cyberbullying detection and analysis (Van Hee et al., 2018). The whole set of features listed below was used to build all three classifiers. We did not apply any feature selection.

Bag-of-words features: We included binary token unigrams, bigrams and trigrams, along with character trigrams and fourgrams. The latter provide robustness to the spelling variation typically found in social media.

Lexicon features: We computed positive and negative opinion word ratio and overall post sentiment using both the MPQA (Wilson et al., 2005) and Hu and Liu's (Hu and Liu, 2004) opinion lexicons. We added positive, negative and neutral emoji counts based on the BOUNCE emoji sentiment lexicon (Kökciyan et al., 2013). We also included the relative frequency of all 64 psychometric categories in the Linguistic Inquiry and Word Count (LIWC) dictionary (Pennebaker et al., 2007). Furthermore, we included diminisher, intensifier, negation, and "allness" lexicons which relate to a negative mindset in the context of suicidality research (Osgood and Walker, 1959; Gottschalk and Gleser, 1960; Shapero, 2011) as well as a proper name gazetteer.

Syntactic features: Two binary features were implemented indicating whether the imperative mood was used in a post and whether person alternation occurred (i.e. combinations of first and second person pronouns).

2.3 Experimental Setup

As mentioned in Section 2, we built three different classifiers to tackle the various subtasks: (1) determine whether a tweet is hateful or not, (2) for tweets classified as hateful, determine whether the target is individual or generic and (3) for tweets classified as hateful, determine whether the tweet is aggressive or not. As the classification algorithm we used LIBSVM (Chang and Lin, 2011) with linear kernel. For each classification task, we performed a grid search to find the optimal cost parameter using 5-fold cross-validation (CV) on the training data. The resulting hyperparameter ($c = 0,03125$) was applied in four different experimental setups: LIBSVM with RBF kernel not normalized, RBF kernel normalized, linear kernel not normalized and linear kernel normalized. These experiments revealed the setup with the linear kernel using normalized data as the best performing system. Table 1 presents the 5-fold CV results for this system on the training set. The experimental results on the training data show good detection results of hate speech (F-score of 71.7% on the positive class), very good results for the classification of the target as being generic or individual (average F-score of 87.5%) and lower classification performance for the classification of aggressive tweets (average F-score of 66.2%).

2.4 Competition Results and Analysis

Table 2 lists the results of our optimized linear kernel system for Task 1, whereas Table 3 shows the results for all three subtasks. As is clear from the results for task 1, our system undergenerates, resulting in a recall of only 6.8%, as opposed to 74.3% on the training data.

Upon closer inspection of the classification errors made by our system for task 1 (hate speech or not), it is possible to distinguish a few broad error categories. In order to reveal possible causes for our low recall, we will focus on hate speech that was not detected by the classifier.

2.4.1 HS Towards Women

Prediction: NOT, Gold: HS. Firstly, we consider the tweets targeted at women. For most of the tweets misclassified by our system as not containing hate speech, it is unclear which features of the text may have caused confusion, as is illustrated by example 1:

(1) That bitch on the spoiled whore list Thought she could play games with Drake but forfeit

Similar examples include at least one offensive term and are clear instances of hate speech. There are, however, some tweets containing some elements which may explain the erroneous classification.

Insults which contain a metaphorical element (such as "meat" in the example below) are hard to classify for our system:

(2) Open your mouth & take the <u>meat</u> like a hoe you bitch ass

	#instances	Recall	Precision	F-score
	TASK 1: hateful or not			
Hateful	4210	74.3	69.2	71.7
Not Hateful	5790	78.7	82.6	80.6
Macro Avg	10000	76.5	75.9	76.2
	TASK 2: individual or generic			
Individual	1560	83.4	82.8	83.1
Generic	2650	89.9	90.3	90.1
Macro Avg	4210	86.7	86.6	86.6
	TASK 3: aggressive or not			
Aggressive	1763	61.1	53.0	56.8
Not Aggresive	2447	69.1	75.7	72.2
Macro Avg	4210	65.1	64.4	64.5

Table 1: Cross-validation results on the training data with the linear kernel with optimised hyperparameter settings.

	Recall	Precision	F-score
	TASK 1: hateful or not		
Hateful	6.8	55.9	12.1
Not Hateful	96.1	58.6	72.8
Macro Avg	51.4	57.3	42.5
Accuracy	58.5		

Table 2: Final results task 1 of best system (optimized linear kernel with normalization).

	Recall	Precision	F-score

	TASK 3: aggressive or not		
Macro Avg	50.1	90.1	44.7
Accuracy	80.2		

Table 3: Final results of best system (optimized linear kernel with normalization).

Finally, we have noticed that tweets containing self-directed or self-referential insults are often misclassified as not containing hate speech:

(3) @USERNAME 1o million, one cent less, i am a liei8ng son of a bitch and my mom is a whore

Some of the errors can be explained by the ambiguity inherent in the tweet in question. First of all, our system has some difficulty distinguishing between genuine insults and jocular insults between friends. For example, this tweet has been classified as not containing hate speech:

(4) @USERNAME you hoe you need to be checked for aids bitch.

On the other hand, many tweets have been correctly classified as not containing hate speech. These usually contain positive words like ”love” and ”friend”:

(5) Lana i love you bitch. Put that flag back up hoe [USA flag emoji] #lustfoflife

There are also some edge cases, where there is ambiguity as to the intent of the tweeter. It makes sense that our undergenerating system is not preferred in cases such as these:

(6) @USERNAME Bitch RT me one more time & not answer my text [face with steam from nose]

A second error type of ambiguous tweets is that of the tweet containing an intensifier, which is usually ”bitch”, for example:

(7) i’m so salty i tried to go in a store with no shoes on and the ladies like ”you have to have shoes” BITCH IM NOT VCARRYING A DISEASE

A third type of ambiguity occurs when there is some kind of reference to or citation of an existing text containing offensive language. For instance, Tweets sometimes contain references to well-known vines. Some of these are correctly classified by our system (first example, classified as NOT HS), while others are not (second example, misclassified as NOT HS):

(8) I love you...bitch. I ain't never gonna stop loving you...bitch. You're my best friend in the whole wide world and I can't wait to hug you

(9) when ugly hoes try to come for you .... Bitch DISGUSTING

A fourth category of errors caused by ambiguity occurs whenever the tweeter is making a general remark, characterized by the use of plural form (”bitches”, ”niggas”). These tweets usually begin with a phrase indicating the sentiment of the speaker (”I'm tired of”) and can contain an intensifier.

(10) I'm tired of bitches wearin no clothes then got the nerve to say niggas is insecure like bitch I'm tryn help you not look like a hoe

We would like to finish this section with some general remarks on this part of the task, with the focus on HS targeted towards women. After close inspection of the results, we noted the difficulty of annotating such data. First of all, tweets with jocular intent are not always easy to distinguish. We did observe that tweets containing references to birthdays tended not to be hate speech, for example:

(11) @USERNAME happy birthday bitch! Hope you have a fab day you hoe n get on lifts soon [car emoji] URL

Second, the truly ambiguous tweets, those which confuse both man and machine, appear to be those in which there is potential ironic intent. This is mostly the case whenever there is overexaggeration (the reaction to the colleague's question is disproportionate to the topic of tie dye t-shirts):

(12) This bitch at work had the nerve to ask why are all y'all wearing tye die.. because u lil whore it's lit

Third, lots of tweets include references to real-life situations (e.g. someone quoting an insult they have received); or to memes (like the ”Me: X, Also Me: X” meme in the second example):

(13) Fat whore!!! Ugly bitch!!! Me: URL

2.4.2 HS Towards Immigrants

Prediction: NOT, Gold: HS. Once again, our system undergenerates on detecting hate speech targeted at immigrants. First of all, many tweets contained the offensive term ”shithole”. The fact that this is a compound term may explain why our classifier was unable to pick up on ”shit” as offensive:

(14) @JoShawTx a_meluzzi #BanMuslims #BanIslam #SendThemBack to their shitholes!! #CloseTheBorders

Our classifier was not able to pick up on hate speech in tweets containing a metaphorical meaning. For example:

(15) Bloody foreign hornets coming over here killing our bees. #brexitmeansbrexit #sendthemhome #controlourborders

Finally, it is clear that this part of the task requires a classifier which is better able to pick up on derogatory use of the terms ”invasion/invader”, ”illegal alien” and is able to deal with contracted insults like ”rapefugee”:

(16) @ShadilayAlways Illegal invaders that deserve to be deported, as usual. #DeportThemAll #BuildTheWall #KAG #SupportICE

(17) @AhsanNasir5 @enough14 @AZeckenbiss Gtfo off europe. Here is no place for you, you rapefugee.

It turns out our system was only able to correctly classify the tweet as containing hate speech when it also contained other offensive words:

(18) This fuck is a weak cunt and puy his fellow country men in a bad way with the rapefugee invasion. Deport THEM ALL.

3 Conclusion

We applied a supervised classification-based approach to the task of hate speech detection against women and immigrants, incorporating a variety of standard lexical and syntactic information with specific features for capturing offensive language. Our results revealed good classification performance on the training data, but a lower performance on the evaluation set, with a notable drop in recall for all subtasks. A detailed error analysis revealed a number of tendencies, but inherently ambiguous tweets (irony, references to memes and vines, etc.) appeared to be the major cause of classification errors for hate speech towards women. Hate speech against immigrants seems to be characterized by compound terms containing offensive parts (e.g. ”rapefugee”, ”shitholes”).

Abstract

In this paper, we present our contribution to SemEval 2019 Task 5 *Multilingual Detection of Hate*, specifically in the Subtask A (English and Spanish). We compare different configurations of shallow and deep learning approaches on the English data and use the system that performs best in both sub-tasks. The resulting SVM-based system with lexico-semantic features (n-grams and embeddings) is ranked 23rd out of 69 on the English data and beats the baseline system. On the Spanish data our system is ranked 25th out of 39.

1 Introduction

Hateful, abusive, or offending statements which target individuals or groups on the basis of characteristics such as gender, nationality, or sexual orientation are called *hate speech* (Basile et al., 2019). Social media is particularly affected by hate speech, as it is known to poison the communication climate, build up negative sentiment towards groups of people, or even lead to real-life consequences (Warner and Hirschberg, 2012; Waseem and Hovy, 2016; Schmidt and Wiegand, 2017; Wojatzki et al., 2018; Benikova et al., 2017; Ross et al., 2017).

In this work, we present our submission to the *SemEval 2019 Task 5: Multilingual Detection of Hate* (Subtask A) for English and Spanish. The objective in Subtask A was to build a system which is able to predict whether given tweets in English or in Spanish are hateful or not hateful towards women or immigrants.

We develop a hate speech detection system by experimenting with a range of classifiers which are either based on engineered features or on neural network architectures. We systematically compare the performance of these different detection systems and for our final submission (for both English and Spanish) we use the model that performs best on the English training data. Our best system is a SVM equipped with n-gram features and fastText (Mikolov et al., 2018) embeddings. Our system obtains the 23rd rank (out of 69) on the English dataset and the 25th rank (out of 39) on the Spanish dataset.

2 System Description

For our submission, we compare a wide range of different neural and non-neural systems in terms of their performance. Our actual submission system is the system that performed best in this evaluation. We will now describe both our neural network approaches and the feature-engineering approaches for detecting whether tweets are hateful towards women or immigrants (Subtask A). We developed and evaluated the approaches for the English dataset and applied the best performing system as-is to the Spanish data. We now first briefly describe the provided data and then discuss the prediction approaches in more detail.

Dataset In Subtask A, the English training set consists of 9,000 tweets and the development set consists of 1,000 tweets. The Spanish training set consists of 5,000 tweets, the development set consists of 500 tweets. In the test data, there are 2,971 English and 1,600 Spanish tweets. For each tweet, the task organizers provided a binary annotation indicating whether a tweet is hateful or not hateful towards a given target (i.e. women or immigrants). An example for the label hateful (towards immigrants) is the tweet:

> *This immigrant should be hung or shot! Period! Animal. https://t.co/wFcGoLCqJ5*

An example for the label not hateful is the following tweet:

Don't mess with these migrant dads #SkimmLife https://t.co/swVmkTlFRz via @theSkimm.

For more details on the dataset and its creation, we refer to the overview paper of the shared task (Basile et al., 2019).

Preprocessing In almost all of our classification approaches, we vectorize the tweets based on word occurrences. Hence, we tokenize the tweets with the twitter specific tokenizer provided by Owoputi et al. (2013). We decided not to remove or normalize social media specific phenomena such as @-mentions, #-hashtags, URLs, and emojis as we hypothesize that these phenomena may provide useful signals for classification. For example, it is conceivable that a reference to the twitter-handle of Donald Trump (*@realDonaldTrump*) may indicate hatred towards immigrants.

2.1 Feature Engineering Approaches

We now report on those approaches that are based on traditional machine learning algorithms and that represent the train and test instances using manually crafted and engineered features. The explored machine learning algorithms are: SVM (LibSVM by Chang and Lin (2011), XGBoost (Chen and Guestrin, 2016), RandomForest (Witten et al., 2016) and Vowpal Wabbit.[1]

We implement the classifiers using the text classification framework DKPro TC (Daxenberger et al., 2014) which includes all of the above-mentioned classifiers. We use the following features to represent the tweets:

N-grams As a baseline feature, we represent the tweets using word and character n-grams. We experiment with n-gram sizes in the range from 1-3 for word n-grams and 2-5 for character n-grams. To reduce the feature space, we only use the n-grams that are most common in the (English and Spanish) training data. We experiment with the frequency cut-off values of 200, 500 and 1,000.

Hateword lists We hypothesize that the presence of specific hate or insult words gives an indication of whether a tweet constitutes hate speech. Hence, we check if the words in the tweets occur in lists of hate or insult words. We use the word lists provided by Wiegand et al. (2018), which contain a basic word list and a extended word list. There are 1,650 words in basic list with binary labels (abusive or not), and 8,478 words in extended list with a numeric weight. We extract abusive words to use in the following features: a) a **boolean hateful** feature if a posting contains any word contained in the basic list, b) a **hatefulness ratio** of total words to hateful words, and c) the sum of the **hatefulness weights** based on the extended list.

[1] https://github.com/VowpalWabbit/vowpal_wabbit

Sentiment We also suspect that the tone in which a tweet is composed can be an indication for hate speech. For instance, we assume that tweets that have a strong positive sentiment are rarely hate speech. To measure the overall sentiment of tweets, we use the tool by Socher et al. (2013) to compute a sentiment score for each tweet. The computed sentiment score uses a five-degree scale from very positive to very negative.

Word embeddings We use pre-trained word embeddings to enhance our tweet representation with a semantic component. For computing semantic features, we first average the 300-dimensional (Spanish or English) word embeddings provided by Mikolov et al. (2018) of all words of a tweet. Next, we use every dimension of the averaged vector as a feature.

2.2 Neural Network Approaches

Besides traditional machine learning approach, we also experiment with neural network architectures: multilayer perceptrons (MLP), convolutional neural networks (CNN), bi-directional LSTMs and a combination of LSTMs and CNNs (LSTM + CNN). We initialize all setups with the 300-dimensional word embeddings provided by Mikolov et al. (2018), which were trained on the common crawl corpus. Furthermore, in all setups, we use a dropout of 0.25 after the embedding layer and update network weights using the *Adam* optimizer (Kingma and Ba, 2014). For all architectures, we have optimized the hyperparameters (e.g. number and size of layers) on an held-out development set. We here report only the best-found parameterization.

MLP Besides the final softmax layer, our MLP has a total of 6 densely connected layers. Starting from the input, the layers have 256, 128, 64, 32, 16 and 8 nodes. We use *relu* as activation function in all layers.

CNN Our CNN uses three stacked convolutional layers that use a filter size of two. The first layer has 128 nodes, the second 64 and the third 32. Subsequently, we apply *max pooling*, a dense layer with ten nodes and the final softmax classification layer.

LSTM At the core of our LSTM is a bidirectional LSTM layer with 128 nodes. This layer is followed by two dense layers (40 and 10 nodes) and the softmax layer.

LSTM + CNN For the combination of LSTM and CNN, we put our CNN model on top of LSTM model.

All of the above-described architectures are implemented using deepTC (Horsmann and Zesch, 2018) with the Keras (Chollet et al., 2015) and Tensorflow (Abadi et al., 2015) backend.

BERT We also experiment with Bidirectional Encoder Representations from Transformers (BERT), which recently excelled in a number of NLP tasks (Devlin et al., 2018). For our experiments, we use the provided pre-trained multilingual-cased BERT-Base model,[2] a maximum sequence-length of 128 and batches of 32 instances. In the described configuration, BERT yields an accuracy of 0.66 after fine-tuning for the second time. As we observe that the performance of BERT begins to decrease from the third fine-tuning, we do not fine-tune the model furthermore.

3 Model Selection and Results

We evaluate each of the proposed prediction approaches in a 10-fold cross-validation on the English training dataset to determine the best performing one. As baseline, we use an SVM equipped with word unigram feature.

For all our approaches, we optimize the hyperparameters (e.g. SVM's slack variable or number of layers in neural networks) and feature configurations (e.g. frequency cut-offs for n-gram features) on the training data and report the best performance for each approach. We start with fine-tuning the n-gram features. We test a wide range of different combinations of n-gram sizes and frequency cut-offs with different classifiers. We report the results in Table 1. We use **wn** and **cn** as the abbreviations of word n-grams and character n-grams.

	macro-F_1	Best n-gram Combination

LibSVM	0.780	wn=1 / topk=1000
		cn=2-4 / topk=200

Random Forest	0.771	wn=1-2 / topk=500
		cn=2-4 / topk=1000

XGBoost	0.764	wn=1-2 / topk=1000
		cn=2-5 / topk=1000

Vowpal Wabbit	0.742	wn=1-3 / topk=1000
		cn=2 / topk=200

Table 1: Results for Fine-tuned n-gram Features.

	macro-F_1	accuracy
Baseline	0.693	0.692
LibSVM	0.787	0.794
LSTM + CNN	0.744	0.768
MLP	0.741	0.750
CNN	0.740	0.746
LSTM	0.674	0.688
BERT	0.660	0.660

Table 2: Results for 10-folds Cross-validation on the Training Dataset for English.

We find that SVM has the overall best performance based on cross-validation, and we continue our experiment (hateword lists, sentiment, word embeddings) using LibSVM with the best n-gram setup. We compare this best feature-engineered system in Table 2 with the neural approaches.

Overall, we observe that the approaches based on feature engineering tend to outperform the neural approaches. As our SVM classifier performs best, we select it as our official submission and also apply it to the Spanish data. Interestingly, in our experiments, BERT and and LSTM perform worst by a considerable margin. However, the combination of LSTM and CNN shows to be competitive with feature engineering approaches.

In Table 3, we show how our system performs on the official test data. We observe a dramatic drop of 30.5 percentage points between performance on the English training and test set. We attribute this loss to the over-fitting to the training data. Nevertheless, our system is able to outperform the most frequent class baseline substantially and especially on the Spanish data the absolute difference to the top-scoring system is low (about 3 percentage points). This means that our system is indeed effective in the task at hand, but also that hate speech detection is a very challeng-

[2] https://storage.googleapis.com/bert_models/2018_11_23/multi_cased_L-12_H-768_A-12.zip

	English	Spanish
Most Frequent Class	0.367	0.370
SVM (baseline)	0.451	0.701
SVM (ours)	0.475	0.696
Top-scoring Team	0.651	0.730

Table 3: Results in Terms of macro-F_1 on the English and Spanish Testset.

Feature Set	macro-F_1
All Features	0.785
-N-grams	0.724
-Word Embeddings	0.778
-Hatefulness Ratio	0.785
-Boolean Hateful	0.785
-Sentiment	0.787
-Hatefulness Weights	0.787

Table 4: Feature Ablation for Our SVM Classifiers.

ing task.

Feature ablation To understand how important the individual features are for our system's performance, we conduct an ablation test for our feature set. We show the results of this ablation in Table 4. The results show that the absence of all features except n-grams and word embeddings leads to an improvement in performance. Consequently, we only use n-grams and word embeddings for our final model. The results also show that n-grams are the most important feature for our model.

4 Distribution of Hate Indicators

When comparing the performance of our system between the training data and test data, we notice a dramatic drop of 30.5 percentage points on macro-F_1. To better understand this drop, we examine the distribution of words for which we suspect that they are good indicators for hate speech – i.e. words which both occur frequently in the data and are commonly seen as a highly offensive words. We examine a frequency distribution of all words and find that the word *'bitch'* meet these criteria. However, the distribution of this word is significantly different in train data and test data. To see whether this is a special case, we examine another high frequency word *'fuck'*. The result is shown in Table 5.

Furthermore, we inspect how these words are distributed across the classes hate speech and not hate speech in both the train and the test set. We visualize this analysis in Table 6.

	Train	Test
Bitch	1,115 in 9,000	1,134 in 2,971
Fuck	675 in 9,000	260 in 2,971

Table 5: Distribution of postings contain *Bitch* and *Fuck*.

	Train		Test	
	Hate Speech		Hate Speech	
Word	Yes	No	Yes	No
Bitch	0.78	0.22	0.44	0.57
Fuck	0.59	0.41	0.57	0.44

Table 6: Hate/not-hate Class Distribution of Postings Contain *Bitch* and *Fuck*.

For the word *'bitch'*, we observe that – in the training data – its occurrence is strongly correlated (the probability is about 0.8) with the class hate speech. In the test set, however, this correlation is considerably weaker. As a result, it is very likely that our classifier will learn that *'bitch'* is a strong evidence for hate speech. As the correlation is different in the test data, this heuristic is likely to lead to misclassification. We conclude that our classifier, which makes strong use of lexical features, is too sensitive to such distributions. Note, that we do not find such a shift for the word *'fuck'*.

5 Conclusion

We present **ltl.uni-due** our submission to SemEval 2019 Task 5 *Multilingual Detection of Hate*. For building our system, We systematically compare a wide range of approaches – including neural network approaches such as LSTMs and BERT and approaches which are based on feature engineering. In our experiments a comparably simple classifier – a SVM equipped with lexico-semantic features (n-grams and word embeddings) – outperforms all other approaches. A comparison between performance on training and test data as well as a quantitative analysis of the dataset shows that our comparably simple classifier is prone to over-fitting, but nevertheless delivers competitive performance in this highly challenging task.

Abstract

This paper presents our approach to the Task 5 of Semeval-2019, which aims at detecting hate speech against immigrants and women in Twitter. The task consists of two subtasks, in Spanish and English: (A) detection of hate speech and (B) classification of hateful tweets as aggressive or not, and identification of the target harassed as individual or group. We used linguistically motivated features and several types of n-grams (words, characters, functional words, punctuation symbols, POS, among others). For task A, we trained a Support Vector Machine using a combinatorial framework, whereas for task B we followed a multi-labeled approach using the Random Forest classifier. Our approach achieved the highest F1-score in sub-task A for the Spanish language.

1 Introduction

Hate speech is defined as any communication that disparages a person or a group based on some characteristics. Given the enormous amount of content generated by users on the web, and in particular in social networks, the problem of detecting hate speech is becoming fundamental. Early detection of this kind of language can help to limit its dissemination over the web and to fight against misogyny and xenophobia.

The goal of the task (Basile et al., 2019) is to detect hate speech on Twitter in a multilingual perspective, for Spanish and English. The task is divided into two related subtasks for each of the languages: (task A) detection of hate speech, and (task B) identifying whether the objective of hatred is a person or group of people. In addition, this second task questions if the author of the message pretends to be aggressive, harmful or even incites violence, in several aspects.

From a machine learning perspective, the task can be seen as a binary classification problem. In order to solve the tasks, we evaluated several machine learning algorithms: Support Vector Machines, Logistic Regression, Multinomial Naive Bayes, Decision Trees and, Random Forest.

For text representation, we extracted linguistically motivated patterns and several types of n-grams (characters, words, syntactic and, aggressive words, among others). The pre-processing steps and the experiments carried out to solve this task are explained in the following sections.

2 Related work

In recent years, the automatic detection of aggressive behavior in social media is gaining a lot of attention. This is consistent with political and social concern about hatred and harassment through these media. Several evaluation campaigns have been recently organized related to hate speech detection such as the hate speech identification task at Evalita (Bosco et al., 2018), the aggressiveness detection task at IberEval (Álvarez-Carmona et al., 2018), and the misogyny identification task (Anzovino et al., 2018) at Evalita (Fersini et al., 2018), among many others.

Our work is based on previous work on aggressive detection of tweets in Mexican Spanish (Gómez-Adorno et al., 2018), which was presented in the MEX-A3T 2018 Workshop (Álvarez-Carmona et al., 2018). It follows a classical machine learning approach, a logistic regression algorithm is trained on linguistically motivated characteristics and various types of n-grams (characters, words, syntactic and aggressive words). Furthermore, an oversampling technique (SMOTE) is used to overcome the problem of unbalanced data, which allowed them to achieve better results in the training corpus, but did not generalize well in the test corpus.

When concerning to hate speech detection related methodologies, Djuric et al. (2015) presented a list of criteria based on the critical race theory to identify racist and sexist slander, whereas Chatzakou et al. (2017) implemented a solid methodology for the extraction of text, user and attributes based on a social media network.

Djuric et al. (2015) used the generated list to annotate a publicly available corpus of more than 16k tweets. They analyzed the impact of various extra-linguistic features along with character n-grams for the detection of hate speech. In turn, they elaborated a dictionary based on the most indicative words in their data.

Chatzakou et al. (2017) studied the properties of bullies and aggressors, and the characteristics that distinguish them from normal users. They found that stalkers post with less frequency, participate in fewer online communities and are less popular than users with standard models of behaviour. Their research shows that machine learning classification algorithms can accurately detect users who exhibit bullying and aggressive behavior, with more than 90% of accuracy.

3 Corpus

For the development phase of the competition, the organizers (Basile et al., 2019) distributed the tweets in four files. Statistics referring the corpus for Spanish and English are presented in Table 1.

For the competition evaluation phase, we have put together the training and test corpus of the competition development phase, in table 2 we present details of the resulting corpus.The test corpus of this phase consists of 1,600 tweets for Spanish and 3,000 for English.

4 Methodology

This section shows in detail how tweets are processed for further classification. It is very important the text to be processed in an appropriate format, so that its manipulation can be done in a simpler and less complex way and an optimal precision can be obtained for the automated methods. Additionally, there are several methods for increasing the characteristics of the system, in order to feed the classifier and have more elements when it comes to analyzing your data.

4.1 Pre-processing

Several researchers show that pre-processing is useful for several natural language processing (NLP) tasks (Montes-y-Gómez, 2001; Justicia de la Torre, 2017), especially when the corpus is made of social network data (Pinto et al., 2012; Gómez-Adorno et al., 2016b). Before the extraction of features, the following pre-processing steps are applied in order to improve the representation of n-grams and to reduce the errors of part-of-speech (POS) labeling:

1. The type of single quotes in the English tweets was standardized. This step was prior to the substitution of abbreviations, thus allowing a correct replacement of the equivalent text.

2. All tweets were standardized to lowercase, which avoids having multiple copies of the same words.

3. The mentions to users (@user) were removed.

4. Url's were removed.

5. Emojis were removed.

6. Following the methodology of Gómez-Adorno et al. (2016a), the abbreviations, contractions and, slangs were replaced by the equivalent text for both Spanish and English. It is important to mention that the vocabulary used in these lexical resources is based on social networks.

		Hateful	Individual target	Aggressive	Total
Spanish	Training	1,838 (41.12%)	1,117 (24.99%)	1,485 (33.22%)	4,469
	Testing	222(44.4%)	137 (27.4 %)	176(35.19%)	500
English	Training	3,783 (42.03%)	1,341 (14.89%)	1,559 (17.32%)	9,000
	Testing	427(42.7%)	219 (21.9 %)	204(20.40%)	1,000

Table 1: Corpus statistics for Task A and B in the development phase

	Hateful	Individual target	Aggressive	Total
Training Spanish	2,060 (41.45%)	1,254 (25.23%)	1,661 (33.42%)	4,969
Training English	4,210 (42.10%)	1,560 (15.60%)	1,763 (17.63%)	10,000

Table 2: Corpus statistics for Task A and B in the evaluation phase

7. Function words (or stopwords) were removed.

8. We replaced the figures that appear in tweet by a single digit (0), since the numbers do not contain semantic information that could be relevant for the task.

9. For hashtags, we had the following criteria: if there was a word detected as hateful/aggressive in the text of the hashtag, the complete hashtag was replaced by that word. If no sign of aggressiveness/hatred was found, then the hashtag was removed.

10. Certain rare and special characters were detected in the tweets and they were replaced by a blank space.

11. In the tweets in English, words such as ”&amp” or the character ”&” were detected, which represented a conjunction, in which case it was replaced by the word ”and”.

12. We deleted punctuation, since it does not add any additional information when processing text data. Therefore, eliminating all cases helps to reduce the size of the training and test data.

13. The sequences of several blank spaces, tabs and line breaks were standardized to a single blank space.

4.2 Features

We took into account several features for the representation of tweets:

- **Character n-grams.** Are capable of detecting the morphological composition of a word (Kulmizev et al., 2017). For natural language processing tasks, where many words are likely to be poorly written, the n-grams of characters are especially powerful (Sanchez-Perez et al., 2017) to detect patterns in such spelling mistakes (Kulmizev et al., 2017). For this approach, a variation of n from 3 to 5 is included.

- **Word n-grams.** Capture the identity of a word and its possible neighbors (Kulmizev et al., 2017). In the experiments, the combination of the n-grams with n varying from 1 to 4 helps to improve the results.

- **POS tags n-grams.** Are sequences of continuous part-of-speech (POS) tags. They capture syntactic information and are useful, for example, to identify the user's intentions in tweets (Gómez-Adorno et al., 2018). We have experimented with various combinations of POS n-grams in the data, finding that a range of 2 to 4 provides the best results in the development set.

- **Aggressive word n-grams.** For this work, we gathered a lexicon of aggressive words containing those words obtained by (Gómez-Adorno et al., 2018) and other words we extracted from the training corpus. We built bigrams and trigrams only with the words of this lexicon.

- **Skipgrams.** We capture groups of 2 words with skips of 2 to 4 words.

- **Function words n-grams.** The frequency of this words is one of the best characteristics to detect hate speech and aggressiveness. Prior to the pre-processing of the corpus, we built function words n-grams from 2 to 4 tokens for both languages. We used the stopwords list from NLTK.

- **N-grams of punctuation symbols.** With this feature we approached the coherence and cohesion to the written text. It helps to detect certain patterns in the analysis of hatred and aggressiveness. Prior to the corpus pre-processing, we built n-grams of 2 to 4 punctuation symbols.

- **Language patterns.** We performed a linguistic analysis of the entire training corpus to detect language patterns that can help to distinguish if the tweets are directed to a person or group of people. We considered two types of patterns: morphological structures, and recurrent lexical patterns.

  - Gómez-Adorno et al. (2018) established that certain morphological combinations can help the classification of tweets. Taking into account this technique, the following combinations were detected: verb + adjective, adjective + verb, noun + adjective, adjective + noun and pronoun + verb.
  - Lexical patterns formed with the series of aggressive words detected in the tweets.

4.3 Classifier

For task A, we used a combinatorial framework (μTC) developed by Tellez et al. (2018). The framework approaches any text classification problem as a combinatorial optimization problem; where there is a search space containing all possible combinations of different text transformations (tokenizers) and weighting schemes with their respective parameters, and, on this search space, a meta-heuristic is used to search for a configuration that produces a highly effective text classifier. Considering all the combinations established in the implementation[1] of (μTC), we added the features described in Section 4.2 and the preprocessing techniques in Section 4.1. Once, the best feature space, we trained an SVM with linear kernel.

For task B, we used the sklearn.multiclass[2] module that implements meta-estimators to solve multi-class and multi-label classification problems, decomposing these problems in binary classification problems. In this sense, the multi-label classification assigns a set of target labels to each sample. In particular, we used the Random Forest algorithm, which showed a better performance than the other algorithms of machine learning that we examined. We performed 10-fold cross-validation experiments to select the best features, weighting scheme and, frequency threshold. The final configuration of the system implements a binary weighting scheme, and considers only those characteristics that occur at least 10 times throughout the corpus and that occur in at least 50 documents in the corpus.

5 Results

The performance measure used for task A is the F1 score. Table 3 and Table 4 show the results using the SVM algorithm for both cases, the development phase and the official results of the final evaluation phase. We obtained the best overal F1 score for task A in Spanish, however, for task A in English the results were much lower.

6 Conclusions

We presented an approach for the detection of hate speech, aggressiveness and harassed objective as individual or group in Twitter in Spanish and English.

We implemented a Support Vector Classification algorithm since it presented a better prediction with respect to other methods. In the case of multi-label classification, the Random Forest algorithm was used. Both algorithms were trained on a combination of linguistic patterns features, a lexicon of aggressive words and different types of n-grams (characters, words, POS tags, aggressive words, word jumps, function words, and punctuation symbols).

The results obtained in Task A when using only the μTC original implementation were improved by the addition of extra features such as the aggressive words n-grams, the punctuation symbols n-grams, and the function words n-grams. Remember that the μTC framework is composed of several easy-to-implement text transformations which allowed us to obtain a high-performance classification model. The main advantage of this technique is that it automatically adjusts the parameters of the model.

Abstract

This paper describes MITRE's participation in SemEval-2019 Task 5, *HatEval: Multilingual detection of hate speech against immigrants and women in Twitter*. The techniques explored range from simple bag-of-ngrams classifiers to neural architectures with varied attention mechanisms. We describe several styles of transfer learning from auxiliary tasks, including a novel method for adapting pre-trained BERT models to Twitter data. Logistic regression ties the systems together into an ensemble submitted for evaluation. The resulting system was used to produce predictions for all four HatEval subtasks, achieving the best mean rank of all teams that participated in all four conditions.

1 Introduction

The popularity of social media allows anyone to post their thoughts and opinions for all to see. While the vast majority of these communications are benign, there are those who express hateful or threatening messages online. The identification of hate speech (Fortuna and Nunes, 2018; Schmidt and Wiegand, 2017) on platforms like Twitter is of particular interest for law enforcement and to social media companies who wish to remove accounts with offending content from their sites. Automating the identification of hate speech will allow platforms to flag and remove content much more quickly and effectively.

In this effort we explored neural transfer learning techniques, including word embeddings and fine-tuning of models trained with diverse auxiliary tasks. We built and compared models employing soft attention over sequences and multi-headed self-attention. We also present a novel task to aid in performing additional pre-training of BERT (Devlin et al., 2018) for domain adaptation to Twitter data.

2 Task, Data and Evaluation

HatEval was a shared task organized within SemEval-2019 (Basile et al., 2019). The primary task was detection of hate speech in Twitter, specifically against immigrants and women. This multilingual shared task was organized into two sub-tasks, each presented in both English and Spanish, for a total of four sub-task evaluations.

Task A The first sub-task was simply to identify tweets containing hate speech against immigrants or women. The official metric used for this binary classification task was *macro-averaged F1 score*, in which the F1 scores are calculated for both the positive *hate speech* and negative *not hate speech* classes and then those two scores are averaged.

Task B The second sub-task involved the detection of two specific aspects of hate speech: whether it is targeted at an individual vs. a group of people, and whether it expresses aggression on the part of the author. In this annotation scheme, there is a dependency between these two categories and the hate speech label used in Task A, as tweets could only be labeled as positive for targeting or aggression if they were positive for hate speech. The official metric used for Task B was *Exact Match Ratio* (EMR), which is the proportion of tweets that are labeled correctly for all categories (hate speech, targeting, and aggression). Another way to think of this is as a five-class classification problem where the classes are (H=0, T=0, A=0), (H=1, T=0, A=0), (H=1, T=0, A=1), (H=1, T=1, A=0), (H=1, T=1, A=1). EMR on predicting the three classes separately is equivalent to accuracy on this five-class classification.

Dataset Characteristics The English datasets consisted of 9000 tweets for train, 1000 for dev, and 3000 for test. The Spanish datasets were half the size of the English, with 4500 tweets for train, 500 for dev, and 1500 for test.

Cursory examination revealed drastic differences between the training and test sets, particularly in English. The pejorative term *bitch* appeared in 12% of the training tweets vs. 48% of the test tweets. The hashtags *#BuildThatWall* or *#BuildTheWall* appeared at rates of 6% and 23% in train and test, respectively. Likewise, *#MAGA* was in over 12% of the test set tweets but in under 3% of the training set messages. Thus the English test set appears to be dominated by a handful of heavily represented phenomena.

Different annotation strategies appear to have been used on the training and test sets as well. While tweets mentioning *#BuildThatWall* or *#BuildTheWall* were annotated as hate speech 98% of the time in the training set, this number is 35% on the test set. Similarly, tweets containing *bitch* were labeled as hate speech 78% of the time in the training set vs. 43% of the time in the test set.

The use of hashtags differs markedly between languages. Hashtags are much more frequent in the English training data than the Spanish training data, with English tweets 2.6 times more likely to contain at least one tag, and with tags occurring in English at 4.1 times the rate in Spanish. In the English training data, the most frequent ten hashtags were 23% of the overall total and tended towards American political topics. In Spanish, the top ten tags account for only 8% of the total, exhibiting a much longer and sparser tail.

3 System Overview

For each task, we created an ensemble of systems, each of which independently predicted the classes. The component systems are described in the following eight sections, after which we describe the procedure for building and testing the ensembles. All component systems described below treated Task B as a five-class prediction problem, and with the exception of two BERT-based systems, were trained to address Task A and Task B simultaneously.

Data and resources SemEval organizers provided training and development sets for English and Spanish. Planning to build ensembles, we shuffled and split out 10% of the training for calibrating models in the ensembles (*calibration set* from here on). Components were trained using the remaining 90% of the training sets provided, with hyperparameter search and validation using the full development sets or via cross-validation. We did not use any additional supervised datasets.

The *BiLSTM*, *Name Embedding*, and *Hashtag Prediction* models incorporated pre-trained `word2vec` (Mikolov et al., 2013) language-specific embeddings that we trained on 1558 billion English and 444 million Spanish tweets collected from 2011 to 2018. In both cases we applied `word2phrase` twice to identify phrases of up to four words, and trained a skip-gram model of size 256, using a context window of 10 words and 15 negative samples per example.

For Task A, all of our component systems and ensembles included a post-processing step to select the best threshold score for classifying hate speech in order to achieve the maximum macro-averaged F1 score on the development set.

3.1 BiLSTM with Attention

We trained several heavily regularized single-layer Bidirectional LSTM (Hochreiter and Schmidhuber, 1997) models to learn a tweet representation with soft attention (Bahdanau et al., 2014) over a sequence of pre-trained token embeddings. Hyperparameter experimentation with Spearmint (Snoek et al., 2012) suggested that a shallow network with attention outperformed deeper, stacked networks and networks without attention. Our attention layer learns to weight context-aware representations of each timestep of the input.

We trained one architecture for the English tasks and two architectures for Spanish, although the second was ablated from our Task A ensemble. The models were identical in structure and differed only in hyperparameters. All models were constructed with spatial dropout over a frozen embedding layer, followed by an embedding transform, one bi-directional LSTM layer with dropout, an attention layer, and a fully-connected hidden layer with dropout.

In each of these models, the NLP representation was used as input to a small prediction network of latent predictions and residual connections described in Section 3.5.

3.2 Name embeddings

This model added a name embedding input to our BiLSTM described above, in an effort to better model the demographics of the individuals addressed within a tweet.

We trained our name vectors using the word2vec objective. Each context was made up of multiple usernames a single Twitter user had employed during a multi-year longitudinal sample of random tweets streamed from the platform. This resulted in a vocabulary of approximately two million name pieces, which includes common names as well as alternate spellings using special characters, symbols, emoji, and other text entered in the *user name* field.

We extracted all substrings of at least length 3 from each username mention in a tweet and included any of them that were in our name embedding vocabulary as input to our model. We applied a learned transformation to each embedding and created a weighted combination with an attention layer. This was concatenated with a hidden representation constructed with the BiLSTM architecture described in Section 3.1. This concatenation was the input to the prediction network described in Section 3.5.

The Spanish name embedding was comprised of dropout over frozen embeddings, a dense embedding transform, and an attention layer. For English, only an attention layer over the frozen embeddings was used. The hyperparameters from our best English model were used in the BiLSTM architecture for both languages.

3.3 DeepMoji

The DeepMoji model developed by Felbo et al. (2017) predicts the emoji removed from an English-language tweet text. The authors train their RNN model on 1274 million tweets for a set of 64 emojis. Using varying degrees of fine-tuning and newly initialized layers, they test their distantly supervised models on several benchmark datasets for detecting emotion, sentiment, and sarcasm. The model's best results used their *chain-thaw* fine-tuning method, which iteratively unfreezes and trains layers for the new objective. The authors distribute their trained model for the emoji prediction task.

We experimented with both *chain-thaw* training and models that were frozen until the final layer of abstraction in DeepMoji. The pre-trained model has a vocabulary that omits many of the hashtags and usernames that were important for our task. Our best model used 0.75 dropout over the output of a frozen DeepMoji model and three fully connected layers of sizes 512, 256, and 128 before the annotation constraint adapter. *Chain thaw* models performed poorly and were ablated from our Task A submission. DeepMoji models are only included in our English ensembles.

3.4 Hashtag prediction network

Following Zarrella and Marsh (2016), we implemented a recurrent neural network classifier that was pre-trained via an auxiliary masked hashtag prediction task. We extracted 30 of the top hashtags found in the training data, with 15 selected from both the hate speech positive and negative classes. Then we searched for the fifteen nearest neighbors of each tag via cosine similarity in embedding space, using vectors described in Section 3. After removing duplicates, this resulted in 136 English and 132 Spanish hashtags. We downloaded up to 1,000 recent tweets containing each hashtag from Twitter's public search API, resulting in 11,539 English tweets and 12,504 Spanish tweets. Tweets were stripped of the target hashtag(s), and each corpus was divided into a training and development set using a 90/10 split.

The sequence of vector representations of the tokens in each tweet served as the input to a neural network with a 128 LSTM units followed by a dense softmax layer over the possible candidate hashtags. Both the word embeddings and the recurrent layer were tuned. These models correctly predicted development set hashtags with 50.3% accuracy on the English data and 56.6% accuracy on the Spanish data.

The trained weights were extracted from this network and used to initialize the five-way hate speech classifier for Task B, described in Section 2, which additionally saw as input the one-hot representations of the 600 most frequent unigrams and 300 most frequent bigrams in the training data, each followed by a fully-connected dense layer. The size of each fully connected layer and amount of dropout were experimentally determined using Spearmint (Snoek et al., 2012) to maximize performance on the competition metrics on our development set.

3.5 Annotation constraint adapter

Both Task A and Task B had annotation constraints based on latent variables. In Task A, hate speech (H) was not marked as true unless the tweet was directed at women (W) or immigrants (I). In Task B, aggression (A) and individual targeting (T) were not marked as true unless hate speech directed at women or immigrants was present. Even though W and I are not directly represented in our

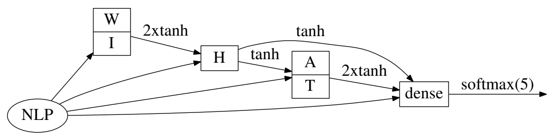

Figure 1: An annotation constraint adapter.

datasets, we believe they are latent variables that can be discovered in the NLP representation. Figure 1 shows an adapter we placed at the end of several systems to encourage the network to learn these constraints. While it doesn't enforce the constraints, it sets up a principled graphical model that encourages the network to learn them. Of course, nothing prevents the network from learning to model other things with this topology. Fair comparisons to stacked dense layers with the same number of parameters showed that the network with this topology performed better.

The upside to the design of a network like this is that the removal of the H switch might yield more general-purpose A and T classifiers.

3.6 Pre-training BERT with Twitter data

Pre-trained language models such as BERT (Devlin et al., 2018) have been demonstrated to achieve state of the art performance on a range of language understanding tasks. BERT uses a transformer encoder model (Vaswani et al., 2017) and pre-trains the model using two complementary objectives: masked language model, and next sentence prediction. The pre-trained model may then be fine-tuned on labeled data (in this case the HatEval dataset) to perform a downstream task.

For English, we used the BERT-Large model, which has 24 layers, 1024 hidden layer size, and 16 self-attention heads. For Spanish, we used the smaller multilingual BERT, with 12 layers, 768 hidden layer size, and 12 self-attention heads. The English BERT is trained on Wikipedia and BooksCorpus (Zhu et al., 2015), while the multilingual model is trained on Wikipedia from multiple languages. As the language in these sources is likely to be quite different from the language commonly used on Twitter, we elected to perform additional pre-training using a corpus of tweets collected during the same time period as the HatEval training dataset (October 2017 - September 2018). All of the pre-training experiments described below started from the TensorFlow model checkpoints downloaded from (Google Research, 2018).

Since the tweets in our collection are not sequential, they cannot be used for the next sentence prediction that BERT uses to learn sentence relationships. We therefore began by running 20k steps of additional pre-training using only the masked language model task.

		none	MLM	descriptions	names
En	A	79.1	**81.2**	79.7	NA
En	B	66.4	**69.0**	67.9	NA
Es	A	80.7	81.9	**83.3**	82.7
Es	B	74.6	75.0	**76.2**	74.4

Table 1: Scores achieved with pre-training schemes. Due to time constraints, the name-based training was only done on Spanish models.

Next, we hypothesized that replacing the next-sentence prediction task with a task involving predicting some attribute of the *author* of the tweet would provide the model with latent information about the nature of tweets that would allow it to discriminate between different classes of tweets more accurately. We performed 20k additional pre-training steps with the *user description* from the author's Twitter profile standing in for the second sequence in the sentence prediction task. In other words, we trained the network to determine whether a given pair of (tweet text, author description text) were sampled from the same tweet. Finally, we pre-trained a BERT model with the *screen name* of the Twitter user as the secondary prediction task.

Table 1 shows the validation scores for our five-class model under our different pre-training schemes: No additional, pre-training on masked LM only, pre-training MLM + Twitter user descriptions, pre-training MLM + Twitter user screen names. Additional pre-training resulted in increased validation scores on all four tasks, and incorporating user descriptions in place of the next sentence prediction task further resulted in increased scores for both Spanish tasks.

3.7 Maximizing ensemble diversity

During development, we noticed some of the neural network models with high capacity had significantly variance in prediction accuracy based on training with different subsets of the training data, hyperparameter settings or just differences in parameter initialization. Such variance would suggest using model bagging (Breiman, 1996) or other form of variance reduction. However, given the relatively long training times for some of the neural network models, especially those based on

$\sigma\|w\|$	w	feature

Table 2: Top LR *word* and character features.

BERT, using ensemble methods such as bagging directly proved too cumbersome as part of the model development workflow. Instead, we employed a form of negative correlation learning (Liu and Yao, 1999) to train a small ensemble of neural network classifiers within a single architecture. A term was added to the fine tuning cross entropy loss function which encouraged diversity among all pairs of classifiers following Opitz et al. (2016).

3.8 Logistic Regression

Logistic regression (LR) systems were developed as a baseline against which the neural approach would be compared. Had annotators used very simple features such as words or phrases to make decisions, they would have been found in the course of LR training. Some of the systems were good enough to include in the final ensembles.

The vocabulary of the LR system was limited to the training set. Many feature sets were explored during model search. The best models preferred feature *sets* rather than *counts* or *term frequencies*. Word n-grams of length 1-3 and character n-grams to length 8 were all considered, along with skip bigrams. The specifics of the best resulting feature sets are in Table 3. Table 2 shows the most important features from an English Task A LR system, sorted by feature *influence*, the product of feature function standard deviation and model weight. The second column is model weight, with negative weights contributing to a (H=1) decision.

In all cases, a bias term was added and Liblinear (Fan et al., 2008) was used to compute the model. L2 regularization was used to encourage generalization. Cross-validation was used to pick the regularization parameters.

3.9 Ensemble

Many systems were created, and final ensembles were constructed by incremental ablations. An initial *all-in* ensemble was created and tested, then it was tested with each component removed. This process was iterated on the best performing ablated sets until gains were no longer observed. Approximately two thousand total ensembles were created through the ablative search. Two systems were ablated in Task A EN, three in Task A ES, one in both Task B conditions. Those systems are not described in this paper.

Ensembles were constructed using logistic regression on either the classifier outputs or the classifier outputs and final probabilities from the model. One oddity to note is that the ensembles using the probabilities performed better for Task A and the ensembles ignoring the probabilities performed better in Task B.

Table 3 shows ensemble compositions for each of the four tested conditions. The first column, labeled *influence*, indicates the influence that the particular component has on the ensemble. It is the number of cases in which that component's contribution *changes* the outcome of the ensemble. It is calculated by zeroing out all LR weights for that particular component and noting the difference. In English, the BERT models had the most influence, while in Spanish, the influence was more evenly distributed across the components.

4 Results

Table 3 shows performance of our component models and ensembles. The *calibration set factored* column shows the performance of the component on our calibration data. This is the *macro averaged F1* score for Task A and *Exact Match Ratio* for Task B. The *calibration set ablated* column shows the performance of the ensemble when that component is removed and the ensemble parameters are re-optimized. Finally there are the scores we calculated after the evaluation period for each of our components using the released reference sets.

The official scores achieved by our ensembles

Table 3: Ensembles and Components

are 49.6% and 72.9% Macro F1 on HatEval Task A English and Spanish, respectively, and 39.9% and 67.1% EMR on Task B English and Spanish. A full reporting of results is present in Basile et al. (2019). A breakdown of test results shows that our system achieves hate speech detection F1 of 63.9 and 72.7 in English and Spanish, respectively, which ranked 2nd (of 68) and 1st (of 39) within Task A. The rankings within Task B were similar, with mean macro F1 of 61.4 and 77.2 in English and Spanish, respectively, ranking 2nd (of 42) and 1st (of 24). Finally, we note that only 22 out of the 74 participants submitted entries in all four subtasks. Of those 22 teams, these results represent the top mean rank across all subtasks.

5 Conclusion

An ensemble of models was used to classify tweets according to whether they contained hate speech, aggression, and targeting of individuals. The novel contributions include using *name embeddings*, substituting twitter author profile prediction for next sentence prediction in BERT pre-training, and augmenting BERT's fine-tuning loss function with a diversity term to create an ensemble.

There is a discrepancy between the official test set results and our held-out calibration set, particularly in the English subtasks, which we attribute to dataset divergences like those called out in Section 2.

OscarGaribo at SemEval-2019 Task 5: Frequency Analysis Interpolation for Hate in Speech Detection

Òscar Garibo i Orts
Universitat Politècnica de València / 46025 València Spain
osgaor@alumni.upv.es

Abstract

This document describes a text change of representation approach to the task of Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter, as part of SemEval-2019[1]. The task is divided in two sub-tasks. Sub-task A consists in classifying tweets as being hateful or not hateful, whereas sub-task B requires fine tuning the classification by classifying the hateful tweets as being directed to single individuals or generic, if the tweet is aggressive or not. Our approach consists of a change of the space of representation of text into statistical descriptors which characterize the text. In addition, dimensional reduction is performed to 6 characteristics per class in order to make the method suitable for a Big Data environment. Frequency Analysis Interpolation (FAI) is the approach we use to achieve rank 5th in Spanish language and 9th in English language in sub-task B in both cases.

1 Introduction

Social media has become a new standard of communications in the last years. Every year more and more people actively participate in the content creation, sometimes under the shield of anonymity. Social media has become a complex communication channel in which usually offensive contents are written. Supervising the content and banning offensive messages currently is a subject of high interest for social media administrators. Offensive speech can be addressed to individuals or groups due to the race, sexuality, religion and some other characteristics. In this task two of these characteristics will be used as target for offensive speech, women and immigrants. This problem will be considered as an Author Profiling task, since the main goal is building a system which would ideally detect author whose content is offensive to women and/or immigrant. Author Profiling is widely studied and some new ideas arise from time to time (Rangel et al., 2016). We have developed a new representation method for text that reduces the dimensionality of the information for each author to 6 characteristics per class. This representation, Frequency Analysis Interpolation, is used to codify the texts for each user and this codified information is used as input data to support vector machines with linear kernel. In a Big Data environment, reducing the number of characteristics from thousands to 6 per class allows an efficient way to deal with high volumes at high speed. With this will in mind a previous method was tested which can be checked at (Garibo, 2018).

2 Corpus

Two corpora have been created to be used in SemEval Task5, HatEval (Basile et al., 2019). One in each of the 2 different languages which are subject of study (i.e. English and Spanish). For each language, a training and an evaluation datasets have been provided. The contents of both datasets are individual tweets, that have been collected and manually annotated.
The goal of this task is to identify tweets which contain hate against women and immigrants. The task has two related subtasks:

1. Task A. Hate Speech Detection against Immigrants and Women: a two class classification where systems have to predict whether a tweet with a given target (women or immigrants) is hateful or not hateful. This is labeled as a 1 in HS column.

2. Task B. Agressive Behaviour and Target Classification: where systems are asked first

Language	Training	Evaluation
English	10,000	3,000
Spanish	5,000	1,600

Table 1: Number of tweets per dataset.

Language	Training	Evaluation
English	4,210	1,260
Spanish	2,790	660

Table 2: Number of Hate tweets per language.

to classify hateful tweets (e.g., tweets where Hate Speech against women or immigrants has been identified) as agresive or not agresive, labeled as AG column in the datasets, and second to identify the target harassed as individual or generic (i.e. single human or group), labeled as TR column in the datasets.

3 Methodology

Our goal was to develop a method that was language independent and that required no prior knowledge of the language used by the authors. We started implementing Term Frequency (TF) representation for each tweet in the corpus, counting how many times each word appears in each author, each tweet in this case, and globally for all tweets. We denote TF$_{\text{a}}$ as the term frequency vector for author a.

$$TF_{\text{a}} = TF_{(w_1,a)}, TF_{(w_2,a)}, \ldots, TF_{(w_m,a)} \quad (1)$$

TF is used since this way we could represent a priori class dependent probability for each term for each class simply by counting the number of times a term occurs for each class, and dividing this amount by the number of times this term shows for all classes. Let F be the frequency term vector for all classes.

$$F = \sum_{a \in A} TF_{\text{a}} \quad (2)$$

In order to achieve that, one vector per class is generated. The vector length is the number of words in the vocabulary. For each word, we divide the number of times this word shows for this class, and divide it by the number of times the word shows in all classes. We denote C$_{\text{k}}$ as the term frequency vector for class k that belong to the set of all classes K.

1	0	0	100
1	0	1	101
1	1	0	110
1	1	1	111

Table 3: Labels for the SVM.

$$C_{\text{k}} = \sum_{a \in A_{\text{k}}} TF_{\text{a}} \forall k \in K \quad (3)$$

These vectors are then used to codify the texts. Each word in the text is substituted by the a priori probability for each class in as many arrays as classes.
Once we have codified the text, six statistic values are calculated for each of the classes:

1. Mean.
2. Standard Deviation.
3. Skewness.
4. First Tertile's length.
5. Second Tertile's length.
6. Third Tertile's length.

At this point, for every author, 6 characteristics per class are calculated and concatenated in a single vector. This vector is used to feed the Support Vector Machines with Linear kernel. LinearSVC support vector machine from Pythons Sklearn library is used to train the model and, of course, to predict the results. In order to provide with the labels for the support vector machines to learn the different labels were concatenated to build a 5 class classifier. In Table 4 the 5 classes which were provided to the support vector machine are shown. The same encoding procedure has to be performed for the test dataset. One vector is created for each author. This vector contains the six characteristic mentioned above for every class, concatenated.

4 Evaluation results

Task A is evaluated using standard evaluation metrics, including accuracy (Acc), precision (P), recall (R) and F1-score (F1), while submissions were ranked by F1-score. The metrics were computed as follows:

$$Acc = \frac{numberofcorrectlypredictedinstances}{totalnumberofinstances} \quad (4)$$

$$P = \frac{numberofcorrectlypredictedinstances}{numberofpredictedlabels} \quad (5)$$

$$R = \frac{numberofcorrectlypredictedinstances}{numberoflabelsinthegoldstandard} \quad (6)$$

$$F1 = \frac{2 * P * R}{P + R} \quad (7)$$

FAI has not achieved great results for Task A. Since the change of representation depends on the vocabulary that is used, subtle sentences which can denote hate in the speech but which are not using explicit offensive vocabulary might have been mislabeled. For example, polysemic words can be causing mislabelling, since FAI only considers the per class term frequency, but no context is taken into account. Because the method is language independent, the differences of performance between both languages (English and Spanish) depends on the term frequency for each class observed for the train dataset.

Task B is evaluated using the Exact Match measure where all the dimensions to be predicted will be jointly considered computing the Exact Match Ratio . Given the multi-label dataset consisting of n multi-label samples (xi,Yi), where xi denotes the i-th instance and Yi represents the corresponding set of labels to be predicted (HS 0,1, TR 0,1 and AG 0,1), the Exact Match Ratio (EMR) will be computed as follows:

$$EMR = \frac{1}{n}\sum_{i=1}^{n} I(Yi, Zi) \quad (8)$$

Where Zi denotes the set of labels predicted for the i-th instance and I is the indicator function.

Our method has performed better in TASK B than Task A. Once we provide with more refined labeling, the method tends to catch better the use of aggressive language. This can be seen in the results for both languages for Task B in tables 5 (English) and 6 (Spanish).

As in Task A, the difference of performance of FAI for Spanish and English datasets depends on the term frequency for all classes. Different results have to be expected for different languages.

5 Conclusions and future work

We have used FAI, a method developed under the scope of Author Profiling tasks to approach HatEval Task. FAI has shown to get better results for multi-class classification in the context of this task. Prior testing performed with our method has been done under different environment, since there were always lots of tweets (minimum 100) per author. Thus, there was much more vocabulary to learn from, and more vocabulary per author. We have to point that our method can easily be updated with new data, since the only required task to be done is recomputing the a priori probability vectors once the new labeled data is available, and train the machine learning algorithm, support vector machines in this specific case. As future work we think of exploring new configurations of our method. Since only the last submission was evaluated we still do not know if we can go any further and do better with simple adjustments. One of the immediate ones is to remove some of the vocabulary from the vocabulary we use to codify the tweets. We have seen in our in house testing that some problems require the more the better vocabulary, for example age identification, whereas some others work better if low used words are removed from the vocabulary, for example removing words used by less than 1% of the authors.

Abstract

We evaluate the viability of multilingual learning for the task of hate speech detection. We also experiment with adversarial learning as a means of creating a multilingual model. Ultimately our multilingual models have had worse results than their monolignual counterparts. We find that the choice of word representations (word embeddings) is very crucial for deep learning as a simple switch between MUSE and ELMo embeddings has shown a 3-4% increase in accuracy. This also shows the importance of context when dealing with online content.

1 Introduction

The Internet has been surging in popularity as well as general availability. This has considerably increased the amount of user generated content present online. This has, however, brought up a few issues. One of the issues is hate speech detection, as manual detection has been made nearly impossible by the quantity of data. The only real solution is automated hate speech detection. Our task is detection of hate speech towards immigrants and women on Twitter (Task A).

Hate speech can be defined as "Any communication that disparages a person or a group on the basis of some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristics." (Basile et al., 2019) This proves to be a very broad definition, because utterances can be offensive, yet not hateful (Davidson et al., 2017). Even manual labeling of hate speech related data is notoriously difficult as hate speech is very subjective in nature (Nobata et al., 2016; Waseem, 2016).

The provided dataset consists of collected messages from Twitter in English or Spanish language. Hate speech datasets are very prone to class imbalances (Schmidt and Wiegand, 2017). The provided dataset does not suffer from this problem. The English data contains 10,000 messages with 42.1% of the messages labeled as hate speech. The Spanish data contains 4969 messages and similarly to the English part, 41.5% were labeled as hate speech. This gives us a dataset with 14969 messages of which 6270 are categorized as hate-speech. We have not used any additional sources of training data for our models. More information about the data can be found in the Task definition (Basile et al., 2019).

Most research dealing with hate speech has been done in English due to labelled dataset availability. However, this issue is not unique to English-based content. In our work, we explore multilingual approaches, as we recognize data imbalance between languages as one of major challenges of NLP. Multilingual approaches could help remedy this problem, as one could transfer knowledge from a data-rich language (English) to a data-poor language (Spanish).

1.1 Background

We focus on neural network approaches, as they have been achieving better performance than traditional machine learning algorithms (Zhang et al., 2018). We explore both monolingual and multilingual learning paradigms. Multilingual approaches enable us to use both English and Spanish datasets for training.

The most popular input features in deep learning are word embeddings. Embeddings are fixed length vectors with real numbers as components, used to represent words in a numeric way. The input layers to our models consist of MUSE (Conneau et al., 2017) or ELMo (Peters et al., 2018) word embeddings.

MUSE embeddings are multilingual embeddings based on fastText. They are available in different languages, where the words are mapped into the same vector space across languages, i.e. words with similar meanings across languages have a similar vector representation.

ELMo provide a deep representation of words based on output of a three layer pre-trained neural network. The representation for a word is based on the context in which the word is used. However, they are not multilingual representations.

To work around the monolinguality of ELMo, we use a technique called *adversarial learning* (Ganin and Lempitsky, 2014). Adversarial networks consist of three parts:

- *Feature extractor* responsible for creating representations belonging to the same distribution regardless of input data distribution i.e. of the language the messages are in. This transformation is learned during training.
- *Classifier* responsible for the classification i.e. labeling hateful utterances.
- *Discriminator* responsible for predicting the language of a given message.

During backpropagation, the loss from classifier ($\mathrm{L_{cls}}$) is computed the standard way. The loss from discriminator ($\mathrm{L_{dis}}$) has its sign flipped and is multiplied by *adversarial lambda* (λ). The discriminator works *adversarialy* to the classificator.

$$Loss = L_{cls} - \lambda L_{dis} \tag{1}$$

The loss from the discriminator encourages the feature extractor to create indistinguishable representations for messages across languages. This is most often implemented by a gradient reversal layer.

2 Implementation details

2.1 Preprocessing

Traditionally, neural network models have a very simple preprocessing pipeline. However, internet communication is very bloated (URLs, mentions, emoji etc.). As such we have decided to remove all the noise from the messages.

At first, we remove URLs and name mentions from messages. These contain no useful information for our prediction. Afterwards, we transform malformed markup characters such as *&gt* into their one character representations (>). We also remove the hash symbol from hashtags as it can be problematic for tokenizers to work with. Next we employ demojization. We use a Python library called *Emoji*[1]. For example, this let us change the unicode representation of a thumbs up emoji into :thumbs_up:, which is then parsed into usable text 'thumbs up'. The next step is tokenization and stop words removal. For this step, we use a library called *spaCy*[2]. We chose this library as it has support for both English and Spanish and we aim to have the same preprocessing pipeline for different languages. We also remove lone standing non-alphanumeric characters, which are often found after tokenization. As the last few steps, we change all characters into lowercase, change numbers into a number token. Sentence size is limited to 64. This was enough for nearly all of the tweets after preprocessing.

2.2 Tested architectures

For MUSE, we use pretrained embeddings made available by Facebook research. We also use pretrained ELMo representations (Che et al., 2018; Fares et al., 2017), which support English as well as Spanish. Both can be found on GitHub [3] [4]. The embeddings were not modified during training.

We examine two different model architectures: LSTM based one and a CNN+LSTM hybrid. The combination of two learning paradigms, two model architectures and two different input representations sum up to 8 different models. All of the models use cross-entropy as the loss function.

2.2.1 Monolingual approaches

Monolingual models were used and trained independently on English and Spanish parts of the dataset.

LSTM-based approach

We use both word-level and char-level representations with ELMo. The representations are then independently fed into a bidirectional LSTM layer of size 64. The output of each of these layers is then fed into an attention layer.

Next, the outputs are concatenated into a single vector and used as an input of a fully connected layer with 20 cells with ReLU activation function. The last layer is a softmax layer with L1 and L2 regularization used for final predictions. The output is then the probability of classes for predicted

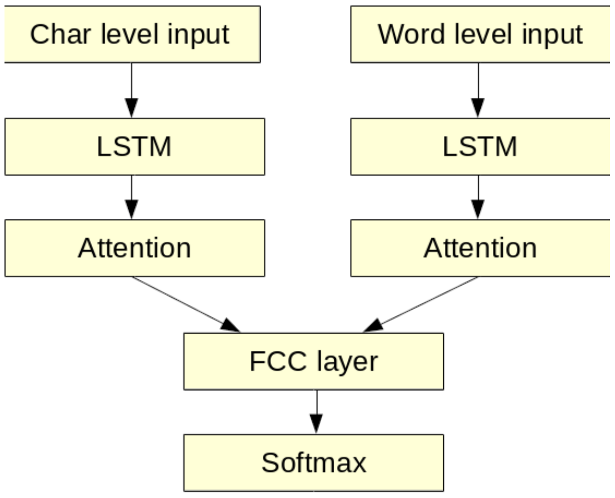

Figure 1: LSTM-based ELMo monolingual model

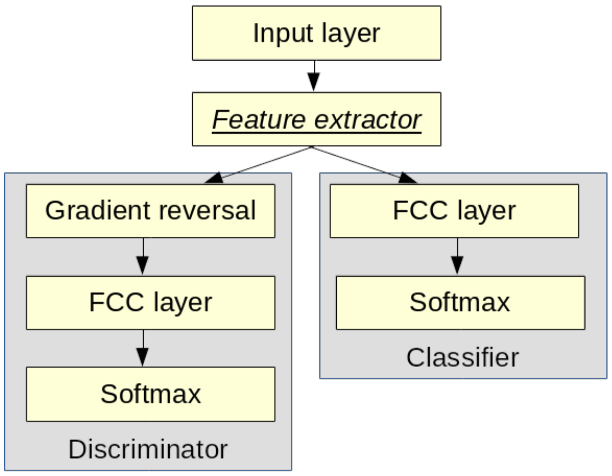

Figure 2: Base adversarial model

variable (non hate speech or hate speech). The model can be seen on Figure 1.

For MUSE, we have only word-level information available. As we have only one input, we only need one LSTM and attention layer. Otherwise, the models are the same.

CNN-based approach

The input layer is fed into a convolutional layer. This layer performs a 1d convolution with 100 filters and a kernel size of 4 with a relu activation function. This is then max pooled with a pool size of 4 and stride of 4. These layers can be understood as a feature extrator part of the model. These extracted features are then fed into a monodirectional LSTM layer with size of 64. The output is global max pooled and fed into the last softmax layer. For ELMo we have used the average representation of all its layers.

2.2.2 Multilingual approaches

Multilingual models were trained on concatenated English and Spanish data.

Multilingual MUSE models

With MUSE embeddings a multilingual approach is straightforward. We use both the approaches previously mentioned (LSTM and CNN+LSTM) without any further changes, as they are implicitly multilingual.

Multilingual ELMo models

The base architecture of our model can be seen on Figure 2. After the input layer is a feature extractor. We have used either an LSTM with attention or a 1d convolutional layer with max-pooling as described in previous sections. The discriminator and classifier include a single FCC layer with a final softmax layer in both cases. The FCC layers have 32 cells each.

The difference between them is the presence of a gradient reversal layer in the discriminator. The gradient is multiplied by -0.25 during backpropagation. This value for adversarial lambda was found empirically. Both the classifier and discriminator were trained simultaneously.

Table 2: Results on Spanish dataset (Task A)

outperform the baseline monolingual LSTM based model with ELMo. Not even in a multilingual setting of averaging results between languages. Multilingual MUSE has not shown any significant increase in performance compared to monolingually trained MUSE.

The results show how potent ELMo embeddings are. Online content can often be offensive and vulgar, while still being non-hateful. This is often enough for a model to classify an utterance as hate speech (Davidson et al., 2017; Hemker, 2018). In these situations, ELMo has an advantage, as the representations are built entirely in the context of a sentence as a whole.

The adversarial models achieved the worst performance. On first glance, judging by accuracy, the models seem to perform on a very average level. After further analysis, we can see that their performance was very poor and inconsistent, e.g.the LSTM based model achieved only 0.123 recall on spanish dataset. The model labeled only a few messages as hate speech and even those not very successfully. The relatively high accuracy was a result of data distribution, as 55.6% of the data was non-hate speech.

We can also see that only in this category the CNN based models outperformed LSTM based models. This implies that for adversarial learning to work, one has to use a very robust feature extractor. It is also the only time that the performance on English was higher than on Spanish. This is the result of data scarcity, as the extractor had a hard time creating truly multilingual representations. This could also be seen during training as the discriminator hovered around 90% accuracy.

For our task submission, we have used the monolingual LSTM model based on ELMo, which we considered as our baseline model. We have achieved results shown in Table 3.

Language	Acc	Pre	Rec	F1	Place
English	0.47	0.59	0.54	0.42	44
Spanish	0.71	0.7	0.7	0.7	18

Table 3: Results on test dataset

4 Conclusion and future work

In this paper we have evaluated a few simple neural network models in a monolingual and multilingual context. We have included our unsuccessful models to inspire further research in this direction.

We conclude that the quality of word representations used has a significant impact on the performance of a model. Changing between MUSE and ELMo resulted in a 3 - 4% increase in accuracy even when MUSE based models could benefit from multilingual training. The contextual nature of ELMo representations make them much more flexible and less domain constrained than traditional word embeddings. Simple models (as the one we proposed) are able to achieve decent results this way. We can also see that using adversarial learning needs a lot of available data to be at all viable.

We believe that more research should be put into multilingual solutions. The feature extractor needs more training data to create truly ambiguous representations of utterances between languages. We will look into testing our model with more training data to evaluate the value of adversarial learning for multilingual hate speech detection or pretraining the feature extractor on a different task with more data available.

Abstract

This paper describes our contribution to SemEval 2019 Task 5: Hateval. We propose to investigate how domain-specific text classification task can benefit from pretrained state of the art language models and how they can be combined with classical handcrafted features. For this purpose, we propose an approach based on a feature-level Meta-Embedding to let the model choose which features to keep and how to use them.

1 Introduction

In this paper, we describe our system for Task 5 of SemEval 2019 (Basile et al., 2019), namely Multilingual detection of hate speech against immigrants and women in Twitter (HatEval). In this task, participants were asked to automatically classify English and Spanish tweets as hateful or not for Subtask A, and to predict if these tweets are aggressive or not, then identify whether the target is generic or individual for Subtask B. We participated in all subtasks for both English and Spanish.

Our main interest in this competition is to evaluate how a domain-specific dataset can take advantage of unsupervised data and moreover, how very different features can be combined efficiently in a deep neural network to improve classification. For this purpose, we propose to exploit state of the art pretrained deep learning models in text classification and classical features into an architecture that allows combining them dynamically.

Our work consists of three steps: features creation, dynamic meta-embedding and finally combining this information to classify tweets. The next sections are organized as follows: in section 2, we will briefly cover the related work, in section 3 we will explain our model, then in section 4 we will expose our experiences, and finally we will introduce our results in section 5.

2 Related Work

A successful classical approach for tweets classification and sentiment analysis is to use neural networks on top of pre-trained word embeddings. Word embeddings are trained with unsupervised data with a method called distant supervision (Go et al., 2009). Deriu et al. (2016) use Convolutional neural networks on top of those word embeddings while Cliche (2017) is using an ensemble of CNNS and LSTMs. Both solutions won respectively SemEval task 4 in 2016 and 2017.

For tasks more closely related to SemEval Task 5, Sánchez Gómez (2018) won the IberEval 2018 Aggressiveness detection task with an Ensembling of several SVMs models. The Ensembling is done with a Genetic Algorithm. Cuza et al. (2018) propose a model with a Bi-LSTMs network with attention layers on top of pre-trained word embeddings. Their solution got the 2nd place.

On the Mysogyny detection task in IberEval 2018, Pamungkas et al. (2018) won with an SVM trained on a lot of handcrafted features. They used stylistic, structural and lexical features to represent information such as Hashtag Presence, Link Presence, Swear Word Count, Swear Word Presence, Sexist Slurs Presence and Woman-related Words Presence. SemEval 2019 Task 5 is a combination of those two IberEval 2018 tasks.

However, a recent trend in Natural Language Processing has been the use of Transfer Learning from universal sentence embedders to tackle text classification tasks such as Hate Speech detection. This approach is particularly useful when little supervised data is accessible.

The main goal of these universal sentence embedding methods is to embed a sentence in a fixed sized vector that encodes as best as possible the sentence semantic and syntactic information. There are various universal sentence embedding approaches such as the Skip-Thought Vectors (Kiros et al., 2015) that adapt the skip-gram Model of the original Word2Vec to the sentence level, or Infersent (Conneau et al., 2017) that uses a model trained in a supervised fashion on a Natural Language Inference Task.

However, the most promising approaches are probably those based on language models. OpenAI (Radford et al., 2018) propose such a solution called GPT based on the Transformer architecture (Vaswani et al., 2017). In their work, a Transformer is trained in a generative unsupervised manner on a Language Modeling task. The model tries to continuously predict the following word of a text given the rest of the text. Another approach, BERT (Devlin et al., 2018) is also based on the Transformer architecture, but the unsupervised learning scheme is a bit different. The idea is to counter the left-right bias that may arise with classical language modeling. During the training phase, the model tries to predict words hidden randomly in the text and it also tries to tell whether two sentences are following each other or not. These models are trained on datasets such as Wikipedia and BooksCorpus (Zhu et al., 2015).

Both approaches give good results on the GLUE benchmark (Wang et al., 2018), which is a language understanding benchmark based on a diverse range of NLU tasks. Models that present high scores on this benchmark should have a good Transfer Learning capability.

Since the emergence of Word Embeddings with the Word2Vec (Mikolov et al., 2013) in 2013, numerous Word Embeddings approaches were developed such as Glove (Pennington et al., 2014), FastText (Bojanowski et al., 2017) or more recently Elmo (Peters et al., 2018). Evaluating the quality of such Word Embedding in a fair manner is a difficult task and these embeddings approaches may perform best in various situations. Dynamic Meta-Embeddings (Kiela et al., 2018) is a sentence representation method that lets a neural network figure out which Word Embedding from an ensemble to use depending on the situation.

3 Model Description

Universal sentence embedding is a way to share knowledge across different tasks. It is particularly helpful in situations with very small training dataset such as SemEval2019 Task 5 (10000 tweets in the training and development set). A pretrained sentence embedding model aims at a general syntactic and semantic understanding of the tweets.

However, the vocabulary and expressions used in this task are really context-specific so it seems necessary to be able to bring some of this specific content into the universal model. Moreover, we argue each sentence representation can potentially bring additional information to the others. Hence, instead of selecting the best sentence representation for our task, we propose to let a model find the best combination of multiple sentence representations with a Dynamic Meta Embedding approach. This latter works as follows.

From a sentence s, we have n sentence embedding types with different length d_i, leading to a set $\{s_i\}_{i=1}^{n} \in \mathbb{R}^{d_i}$.

Similarly to (Kiela et al., 2018), each sentence embedding is projected to a same d'-dimensional space with a learned linear function $s'_i = P_i s_i + b_i$. where $P_i \in \mathbb{R}^{d' \times d_i}$. These projections are then combined with a weighted sum

$$s_i^{final} = \sum_{i=1}^{n} \alpha_i s'_i$$

where $\alpha_i = g(s'_i)$ are scalar weights which depend on projected sentence embeddings s'_i:

$$\alpha_i = g(s'_i) = \phi(a \cdot s'_i + b)$$

where $a \in \mathbb{R}^{d'}$ and $b \in \mathbb{R}$ are learned parameters and ϕ is a softmax function, so that $\sum_{i=1}^{n} \alpha_i = 1$.

All α_i can be seen as importance weights. When averaging them on all the train dataset, they can be exploited to select important features representations.

For embedding sentences, we propose to use state of the art pretrained models: Bert and GPT. Since they are general sentence embeddings, we finetuned them on our specific tasks to get more specific embeddings (we also tried without finetuning them but got very poor classification results).

Beside these sentence embeddings, we created several classical sentence representations. We constructed all the features suggested by Pamungkas et al. (2018) (see the paper for more details) and some extra features as follows:

- ***Language Model Perplexity*** Perplexity score of each tweet according to the language model kenlm[1] ;

[1] https://github.com/kpu/kenlm

- ***BayesianEncodingHashtag*** Probability of hashtag according to the target class ;
- ***hashtagUrlPresence*** One-Hot encoding on presence of urls and hashtags in tweets ;
- ***Abreviation*** Abreviation counting from a custom lexicon ;
- ***BagOfPOSTagging*** Counting the different POS tags in each tweet ;
- ***NMF*** Non-negative Matrix Factorization on the co-occurrence matrix of words ;
- ***LDA*** Latent Dirichlet Allocation on the tweets ;
- ***BagOfEmojiFeatures*** One-Hot encoding on presence of emojis in tweets ;
- ***nbWords*** Number of words in each tweet, normalized by mean ;
- ***Textstat*** Readability features according to the python package textstat[2] ;
- ***nbChar*** Number of characters in each tweet, normalized by mean.

However, the importance weights from the dynamic weighted sum of our model show that most of these representations were not of interest for the predictions, and were reducing the F1-score. Hence, we made a feature selection based on these weights for each subtask. In the next subsections, we detail the different sentence representations we used for each subtask.

3.1 Pre-processing

We didn't use a lot of pre-processing besides lowercasing, in order to benefit from the representations capabilities of BERT and GPT. These models are using BPE encoding (Sennrich et al., 2015), so the models are based on subword units and not on words. This way, out of vocabulary words such as those with spelling mistakes or very context-specific ones may still be processed in a useful way by the model. However, a kind of spelling mistake correction might have been useful. The main pre-processing scheme we used is the replacement of usernames and urls by a specific token.

We normalized the most frequent hashtags in order to keep only one spelling (for instance #buildthatwall and #buildthewall were processed to have the same spelling). We also processed the most frequent abbreviations by replacing them with their full form. Finally we tried a splitting words approach on the hashtags in order to help the BPE encoding to get sensible of subword units. This did not improve performance, so this preprocessing was not kept in our final submission.

3.2 Subtask A en: Hateful or not

This subtask consists in classifying each English tweet as hateful or non hateful. For each tweet, the following features have been selected and given as inputs to our model:

- Bert embeddings: 3 different finetuned pretrained Bert embeddings[3], one for each target class (HS, TR, AG). Leading to 3 sentence representations of 768 features.
- GPT embeddings: 3 different finetuned pretrained GPT embeddings[4], one for each target class (HS, TR, AG). Leading to 3 sentence representations of 768 features.
- Hate Word Count: Count the presence of words into a lexicon extracted from HateBase[5], leading to 1 feature
- Bag of Emojis: Count the presence of Emojis grouped by type, leading to 155 features (number of emojis)

3.3 Subtask B en: Target and Aggressivity

Subtask B consists in predicting in addition to the hate speech, the target of the hate speech (TR - a group or an individual) and the aggressiveness (AG). We used the same approach, architecture and features to predict the labels TR and AG. Each label is predicted independently. However, we added a simple post-processing correction based on the predictions we made for HS: if a tweet is classified as not hateful, we set the target to generic (TR prediction to 0) and labeled the tweet as not aggressive (AG prediction to 0). This rule has been deducted from the way tweets are labeled: non hateful tweets are always classified as generic and not aggressive.

3.4 Subtask A/B es

We used the same model for the Spanish dataset and translated Spanish tweets to English with machine translation. In doing this, we could employ the same type of features as we used for English.

Dev ES	500	222	137	176
Test ES	1599	660	423	474

Table 1: Hate speech dataset.

For the subtask B, the same corrections were applied for TR and AG using HS predictions.

4 Experimental Setup

4.1 Data

For each language, a training, a development and a test set were provided. These datasets were manually annotated using Figur8[6] crowdsourcing platform. Statistics on label distribution can be found in Table 1.

4.2 Parameter settings

Our model is implemented in PyTorch[7] and trained on 2 GPU Tesla V100. For the finetuning of Bert and GPT, we used the default parameters of their respective repository but trained on 10 epochs.

For the learning of the Meta Embedding model, we used a batch size of 64 and Adam optimizer with a variable learning rate (the Noam decay introduced in Vaswani et al. (2017)). The dropout rate is set to 0.6. To avoid over-fitting issues and to be able to reproduce and compare our results, we used Scikit-learn[8] implementation of Stratified Shuffle Split, with 10 splits on the concatenated train and dev dataset. Our results metrics are the means of the values obtained on the 10 splits.

5 Results

This section presents the evaluation of the SemEval-2019 Task 5: HatEval. The official measure for this task was the macro F1-measure. Note that for the Subtask B, evaluation was based on two criteria (each dimension evaluated independently or jointly), however the final ranking was based solely on the second criteria (Exact Match Ratio on the three labels). More details about the evaluation system can be found in the task description paper (Basile et al., 2019).

We saved the best epoch model for each of the 10 splits and we used them to make our final prediction for the test dataset. Then we used our 10 models to classify each tweet: to predict a tweet as hateful, at least half (5) of the models have to agree with this class. The same goes for subtask B to predict TR and AG, with in addition the post-processing described in subsection 3.3. Macro F1-scores and EMR scores with this agreement rule on the English development splits and test datasets are respectively presented in Table 2 and Table 3. This latter is our final submission for the competition. We can see a surprising decreasing of macro F1-score for the predictions on the test dataset of about 35 points compared to the predictions on our experimentation splits. We discuss about this result in the next section.

Table 4 and Table 5 show the results on the Spanish datasets. We can see that the finetuned BERT model gives good results on the test dataset (3 points better in macro F1 than the leader on subtask A) whereas it was worse than the other models on the splits dataset on our experiments. Our hypothesis is that the other models may have overfitted on the train dataset (especially the GPT model). Our Meta-embedding model seems to have been penalized by the GPT overfitting.

6 Discussion

6.1 Unsuccessful approaches

During this competition, we experimented many additional methods that did not successfully improve the results:

- We created an important quantity of features manually as described in section 3. However, most of them were not useful for the prediction according to the weights extracted from our model. We suppose this is either because the features from finetuned BERT and GPT models are able to capture most of the information provided by the other features or because it is difficult to blend handcrafted features with the ones obtained from BERT and GPT.

- We tried others universal sentence embedding models besides GPT and BERT such as InferSent and ULMFiT (Howard and Ruder, 2018) but without very good results. As

Model	HS (subtask A)	TR	AG	EMR (subtask B)
GPT	82.33%	82.27%	71.10%	66.74%
BERT	82.87%	82.88%	74.11%	68.61%
Meta-Embedding (our submission)	**84.16%**	**83.93%**	**75.01%**	**70.55%**

Table 2: Mean results on English development splits.

Model	HS (subtask A)	TR	AG	EMR (subtask B)
GPT	**51.50%**	**73.78%**	**60.42%**	36.20%
BERT	48.84%	73.39%	59.16%	36.03%
Meta-Embedding (our submission)	49.60%	72.40%	57.80%	**37.40%**
Baseline SVM	45.00%	69.70%	58.70%	30.80%

Table 3: Final results on English test dataset.

SemEval task 5 is very specific vocabulary-wise, it is possible that universal models such as InferSent and ULMFit were not trained on enough data to provide good features representations of the tweets.

- For the Spanish dataset, we also tried the BERT Multilingual model which was released during the competition, but we also had lower results than using translation.

- We tried augmenting the dataset with external resources, especially with a similar labeled dataset[9] of tweets with hate speech and offensive language. Nevertheless, this method was decreasing the results, probably due to different labeling rules.

- Inspired from the back-translation proposed in (Edunov et al., 2018), we augmented the dataset by automatically translating each tweet to an other language (French, Spanish, Chinese) and back translated it to the initial language (English). This method can be assimilated to a transfer learning approach that should bring more variability in the dataset, and should improve the generalization ability of the model. Our tests did not show relevant improvement in F1-score but were decreasing the variance. Nevertheless, we did not develop enough this approach to conclude on its potential benefits.

- About our post-processing choice for Task B, we based it on the fact that our model for HS prediction was better than the models for TR and AG. Considering how much the performance on the HS task decreased on the test set compared with the decreasing on the TR and AG tasks it was probably not the best choice. A multi-label model might have been useful for this task considering the evaluation metric (each label prediction should not be independent).

- Finally, we tried to train our model on both English and translated Spanish datasets, but that did not improve our results.

[9]https://github.com/t-davidson/hate-speech-and-offensive-language/tree/master/data

6.2 About the testing set

The previous section shows an important difference on HS in terms of prediction quality (F1-score) between the development and the test datasets. This score difference seems to be experienced by every participant according to the development and test leaderboards. It seems that the test dataset contains a lot more of difficult tweets to classify in comparison with the train and development datasets. Our hypothesis is that the test dataset has not been collected like the other datasets (train and development) or that data were sorted in a particular way after the collection, which could explain such results.

In this setup it is interesting to see that the features extracted from the finetuned GPT generalize a little better (with a HS F1-score of 51.50) than our submited model (49.6 HS F1-score). Adding more features might have induced more overfitting on the training set.

Since the end of the competition, the state of the art on Natural Language Understanding on the GLUE Benchmark is a new model. It is a Multi-

Model	HS (subtask A)	TR	AG	EMR (subtask B)
GPT	81.67%	86.17%	79.77%	70.10%
BERT	78.21%	81.63%	75.48%	65.22%
Meta-Embedding (our submission)	**83.19%**	**86.79%**	**81.01%**	**74.98%**

Table 4: Mean results on Spanish development splits.

Model	HS (subtask A)	TR	AG	EMR (subtask B)
GPT	66.42%	74.17%	67.66%	51.53%
BERT	**76.88%**	**81.08%**	**76.55%**	**65.85%**
Meta-Embedding (our submission)	71.70%	80.90%	76.00%	63.50%
Baseline SVM	70.10%	78.10%	72.60%	60.50%

Table 5: Final results on Spanish test dataset.

Task Model based on BERT (Liu et al., 2019). It seems that the Multi-Task Learning approach improves the universality of BERT. We think that such a model could also improve our architecture on this task because a model trained in a Multi-Task manner should in theory be more robust to overfitting.

7 Conclusion

In this work, we investigated how a model could merge features obtained from unsupervised language models such as GPT and BERT with domain specific hand-crafted features. We presented an approach based on a feature-level Meta-Embedding to let the model choose which features to keep and how to use them. Our method systematically outperforms models based only on BERT or GPT features on our evaluation datasets, however it is not always the case on the test datasets. For instance, on the Spanish test dataset, BERT alone gives better results and on the English test dataset subtask A, GPT slightly outperforms our submission.

Our idea was that the data used for SemEval 2019 Task 5 is very domain-specific and present a peculiar vocabulary. We thought that universal sentence embeddings methods would not work very well since such vocabulary was probably not present during their unsupervised training and the sentence quality is also probably different. However, our results tend to show that it is not the case. For instance, a model using only BERT features would have been 1st on the Spanish task A. The BPE used as a pre-processing for these models is probably helping to deal with out-of-vocabulary words. On top of that, it seems that big unsupervised language models are able to learn data representation that generalize really well to unseen domains.

Abstract

Misogyny and xenophobia are some of the most important social problems. With the increase in the use of social media, this feeling of hatred towards women and immigrants can be more easily expressed, therefore it can cause harmful effects on social media users. For this reason, it is important to develop systems capable of detecting hateful comments automatically. In this paper, we describe our system to analyze the hate speech in English and Spanish tweets against Immigrants and Women as part of our participation in SemEval-2019 Task 5: hatEval. Our main contribution is the integration of three individual algorithms of prediction in a model based on *Vote* ensemble classifier.

1 Introduction

With the growing prominence of social media like Twitter or Facebook, more and more users are publishing content and sharing their opinions with others. Unfortunately, the content often contains hate speech language that can have damaging effects on social media users. This fact concerns to social media platforms like Facebook since according to an EU's report, it removes 82 percent of illegal hate speech on the platform, up from 28 percent in 2016[1].

Normally, hate speech can be aimed at a person or a group base on some characteristic such as race, sexuality, color, ethnicity, physical appearance, religion, among others (Erjavec and Kovačič, 2012). Currently, two of the targets most affected by these types of offensive comments are immigrants and women (Waseem and Hovy, 2016). In particular, when the hate speech is gender-oriented, and it specifically targets women, we refer to it as misogyny (Manne, 2017) and when the hate speech is against immigrants, we refer to it as xenophobia (Sanguinetti et al., 2018).

Recently, a growing number of researchers have started to focus on studying the task of automatic detection of hateful language online (Fortuna and Nunes, 2018; Fersini et al., 2018b), moreover, some academic events and shared tasks have taken place focusing on this issue (Fersini et al., 2018a). It is consider as a difficult task for social media platforms. For example, popular social media such as Twitter, Instagram or Facebook are not able to automatically solve this problem and depend on their community to report hateful speech content.

The severe consequences of this problem, combined with the large amount of data that users publish daily on the Web, requires the development of algorithms capable of automatically detecting inappropriate online remarks.

In this paper, we describe our participation in SemEval-2019 Task 5: Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter (hatEval) (Basile et al., 2019). In particular, we participate in task A in English and Spanish. It is a binary classification task and the objective is predict whether a tweet with a given target (women or immigrants) is hateful or not hateful.

The rest of the paper is structured as follows. In Section 2 we explain the data used in our methods. Section 3 presents the details of the proposed systems. In Section 4, we discuss the analysis and evaluation results for our system. We conclude in Section 6 with remarks and future work.

2 Data

To run our experiments, we used the Spanish and English datasets provided by the organizers in SemEval19 Task 5 : HatEval (Basile et al., 2019). The datasets contain tweets with several fields. Each tweet is composed for an identifier (id), the

[1]https://cnb.cx/2RGmEwel

text of the tweet (text), the mark of hate speech (HS), being 0 if the text is not hateful and 1 if the text is hateful, the mark of recipient of text (TR), being 1 if the target is a single human and 0 if the target is a group of persons and the last field (AG) is the mark that identifies if the text is aggressive whose value is 1, else 0 in the case opposite. During pre-evaluation period, we trained our models on the train set, and evaluated our different approaches on the dev set. During evaluation period, we trained our models on the train and dev sets, and tested the model on the test set. Table 1 shows the number of tweets used in our experiments for Spanish and English.

Dataset	train	dev	test
Spanish	4,500	500	1,600
English	9,000	1,000	3,000

Table 1: Number of tweets per HatEval dataset

We only take into account the fields text and HS for our experiments because we participate in task A in English and Spanish.

3 System Description

In this section, we describe the systems developed for the Hateval task 5, subtask A in English and Spanish.

3.1 Our classification model

In first place, we preprocessed the corpus of tweets provided by the organizers. We applied the following preprocessing steps: the documents were tokenized using NLTK library [2] and all letters were converted to lower-case. In second place, an important step is converting sentences into feature vectors since it is a focal task of supervised learning based sentiment analysis method. Therefore, our chosen statistic feature for the text classification was the term frequency (TF) taking into account unigrams and bigrams because it provided the best perfomance.

During our experiments, the scikit-learn machine learning in Python library (Pedregosa et al., 2011) was used for benchmarking. Our classification model based on *Vote* ensemble classifier combined three individual algorithms: *Logistic Regression (LR)*, *Decision Tree (DT)* and *Support Vector Machines (SVMs)*. We have tested with other models such as *naive bayes* and *multilayer perceptron* but we have obtained better results with the combination of the three algorithms mentioned above. In Figure 1, it can be seen our model. We train our model with the train and dev set and we evaluated it with the test set. There are many combinations to implement a model when we apply different classifiers with several parameters. Therefore, one of the most important step was to find the best individual classifiers for the problem. After doing several experiments with each classifier independently, we came up with SVMs, LR and DT classifiers. In order to improve the performance of each classifier, we choose the best optimization of the parameters in each of them.

[2] https://www.nltk.org/

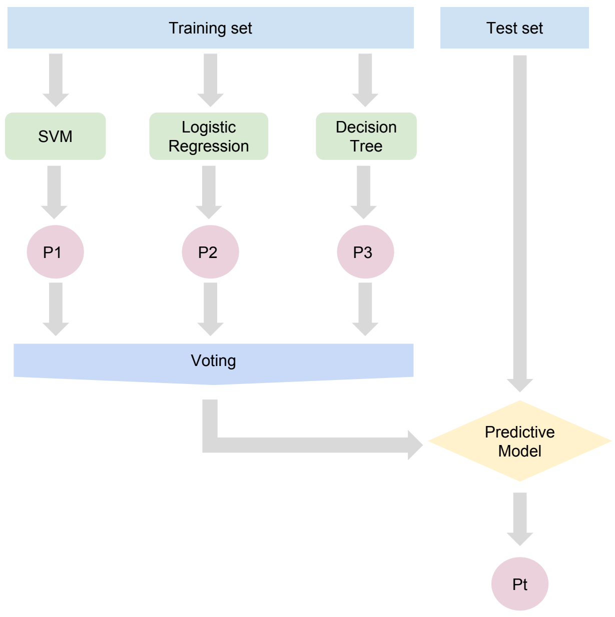

Figure 1: Systems architecture.

3.2 Classifiers

1. *Logistic Regression* is an statistical method for prediction binary classes. It computes the probability of an event occurrence utilizing a logit function. In order to optimize the parameters of LR in our English and Spanish experiments, we used the penalty parameter equal to l1 regularization.

2. *Decision Tree* is a flowchart-like tree structure where an internal node represents features, the branch represents a decision rule, and each leaf node represents the outcome. In order to optimize the parameters of DT in our English and Spanish experiments, we leave

User name (r)	Test

sabino (71)	0.652	0.521	0.35	0.447

Table 3: System Results per team in subtask A of hatEval task in English.

the default parameters.

3. *Support Vector Machines* is a linear learning technique that finds an optimal hyperplane to separate our two classes (hateful and not hateful speech). Many researchers have reported that this classifier is perhaps the most accurate method for text classification (Moraes et al., 2013) and also is widely used in sentiment analysis (Tsytsarau and Palpanas, 2012). In order to optimize the parameters of SVMs in our English and Spanish experiments, we used the parameter C equal to 0.6 and the kernel used was linear.

4. *Vote* is one of the most straightforward ensemble learning techniques in which performs the decision process by applying several classifiers. Voting classifier combines machine learners by using a majority vote or predicted probabilities for the classification of samples. The predictions made by the submodels can be assigned weights. In our case, the weights are distributed as follows: 2 for LR and SVM and 1 for DT.

4 Experiments and analysis of results

During the pre-evaluation phase we carried out several experiments and the best experiments were taken into account for the evaluation phase. The system has been evaluated using the official competition metrics, including Accuracy (Acc), Precision (P), Recall (R) and F1-score (F1). The metrics have been computed as follows:

$$P = \frac{\text{number of correctly predicted instances}}{\text{number of predicted labels}} \tag{1}$$

$$R = \frac{\text{number of correctly predicted labels}}{\text{number of labels in the gold standard}} \tag{2}$$

$$F1 = \frac{2 * P * R}{P + R} \tag{3}$$

$$Acc = \frac{\text{number of correctly predicted instances}}{\text{total number of instances}} \tag{4}$$

The results of our participation in the subtask A of hatEval task during the evaluation phase can be seen in Table 2 for Spanish and in Table 3 for English.

In relation to Spanish results, it should be noted that we achieve a high position in the ranking outperforming the baseline result. Our position in the ranking is 14th of 41 participating teams. Therefore, we consider that the chosen individual classifiers in the voting system are appropriate to build the metaclassifier.

Therefore, our chosen statistic feature for the text classification was the term frequency (TF) taking into account unigrams and bigrams because it provided the best perfomance. One important feature to consider is the use of bigrams in TF, because during the pre-evaluation phase we noted that our results outperformed when we took into account the bigrams comparing it only to the unigrams.

In relation to English results, using the same system as for Spanish we achieved worse results and we did not outperform the baseline. However, we are ranked 40th out of 71 participating teams.

5 Conclusions

In this paper, we present the system we developed for our participation in SemEval-2019 Task 5: Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter (hatEval). Specially, we have participated in subtask A in Spanish and English.

Our system was developed focus on Spanish. Therefore, we achieve better results in this language. On the one hand, one of the reasons could be the different employment of misogynistic or xenophobic words in one language with respect to the other (Canós, 2018). For example, the word "puta" in Spanish, can be consider a misogynistic word or in a bigram like "puta madre" can be similar to the word "fantastic". On the other hand, the way to insult women is not the same as the way to insult immigrants. For these reasons, systems make mistakes and should be considered different systems for these targets (immigrants and women).

Another important issue is that the participation in Spanish subtask is lower than the participation in English subtask. For this reason, we will continue developing systems in Spanish since it is one of the most spoken languages in the world and we consider a very challenging task.

Abstract

This paper describes the participation of the SINAI-DL team at Task 5 in SemEval 2019, called HatEval. We have applied some classic neural network layers, like word embeddings and LSTM, to build a neural classifier for both proposed tasks. Due to the small amount of training data provided compared to what is expected for an adequate learning stage in deep architectures, we explore the use of paraphrasing tools as source for data augmentation. Our results show that this method is promising, as some improvement has been found over non-augmented training sets.

1 Introduction

We have participated in SemEval 2019 Task 5, named *HatEval* (Basile et al., 2019), which encourage participants to identify hate speech in tweets. The small amount of training data provided makes difficult to train a deep architecture, so strategies like transfer learning and data augmentation are explored in our work. A trained model for word embeddings in the two languages targeted by the tasks have been considered as transfer learning approach. Paraphrasing the tweets has also been tested for data augmentation, doubling the number of tweets available for training the network.

Our results are promising for English, but no improvements have been found for Spanish. Further analysis on the results and the quality of the paraphrasing tools used is needed, but the scores obtained in English encourage us to consider paraphrasing as a promising help in deep learning for natural language processing.

The paper is organized as follows: Section 2 introduces the two main strategies used to train the neural network: data augmentation and transfer learning. In Section 3, task data is analyzed in order to define hyperparameters values. Section 4 describes the neural network architecture applied. Section 6 gives more details on the paraphrasing approach used to generate more training data. Experiments and results are given in Section 7. Finally, Section 8 closes the contribution with some conclusions and proposals for future work.

2 Data augmentation and transfer learning

Nowadays, deep neural architectures are populating the scientific playground in many scenarios: image recognition speech recognition (Graves et al., 2013) and synthesis (Ze et al., 2013), and, of course, text classification (Zhang et al., 2015). But these supervised learning algorithms demands for valid use different requirements that sometimes are difficult to meet. One of the most difficult to overcame in some cases is the need for a large and varied learning dataset. When there is lack of data, two main strategies can be followed: *transfer learning* and *data augmentation*.

- Transfer learning. This approach proposes to train the network on different task that is learned over a large set of available data of similar nature. For example, train a language model over a Wikipedia dump. Then, last layers can be replaced by those that fit the target task, for instance, sentiment analysis, and then trained on the limited dataset for that task.

- Data augmentation. This approach is commonly used in image recognition, by applying different transformations over training images (rotation, shearing, blurring, mirroring...). In this way, we can augment the size of the training data in several orders of magnitude, making the learning process more feasible and robust.

We will use both of them in our system for hate speech detection.

3 Data analysis

Organizers provided data consisting of a set of tweets annotated as hateful (1) or not hateful (0) -*HS* label-, with a person (1) or group (0) as target -*TR* label- and as aggresive (1) or not aggresive (0) -*AG* label-. The distribution of tweets per language and dataset is shown in Table 1.

Language	Train	Dev	Test	Total
EN	9,000	1,000	3,000	13,000
ES	4,500	500	1,600	6,600

Table 1: Distribution of tweets per dataset.

We analyzed training and development data to see whether the distribution of labels were similar, obtaining a positive result, which is desirable to guarantee the validity of the model fit. Figure 1 presents ring charts corresponding to the relative values of labels distribution across samples and datasets. Labels are represented using a binary codification of *HS*, *TR* and *AG* annotations. For example, 111 codification corresponds to hateful tweets towards a person and with aggressive content.

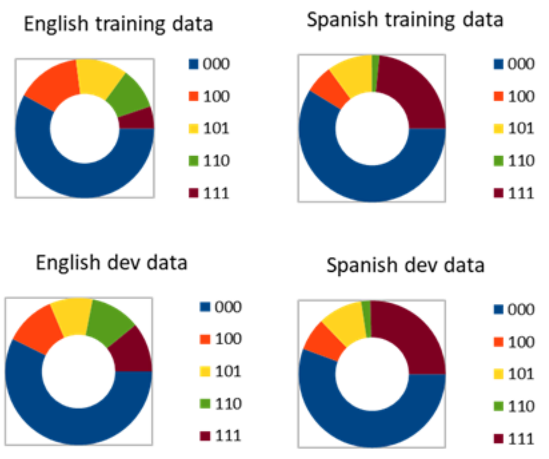

Figure 1: Datasets distribution per label.

In addition, we also analyzed the length of the tweets to decide which window size to use in our experiments. For this, a cumulative histogram for each dataset was generated according to different tweet lengths in order to select a size that would cover a high rate of tweets.

The sizes that cover 80 % and 90 % of tweets are summarize in Table 2 as quantiles 0.8 and 0.9 respectively. A value of 44 for quantile 0.8 means that 80 % of the tweets have a length of 44 or less. Taking into consideration the results we decided to select a window size of 40 words.

Data	Quantile 0.8	Quantile 0.9
train_EN	35	45
dev_EN	44	51
train_ES	37	46
dev_ES	38	49

Table 2: Length of tweets covering 80 % and 90 % of cases.

4 System description

We have implemented the proposed neural network using the Keras[1] library for Python, running on TensorFlow over a NVIDIA Titan X card. Each model took approximately 25 minutes to get trained and few seconds to classify development or test sets. The architecture of our neural network follows a sequence of layers as follows:

1. First layer: An embedding layer that is loaded with pre-trained weights, and converts each word into a 200-dimensional vector for English or a 300-dimensional one for Spanish.

2. Second layer: A bi-directional LSTM recurrent network with 512 activations and a dropout value of 0.5.

3. Third layer: A dense network with 128 activations and the *ReLU* function as activation function. A dropout of 0.5 is also applied after this network.

4. Fourth layer: last classification layer, with 3 activations on the sigmoid function, as we are in a multi-label classification task.

The model has been trained with the hyperparameters values specified in Table 3.

The text have been preprocessed as follows:

1. Lower case is applied.

2. Hashtags are splitted into several tokens according to a camel case approach. For example, "*#MeToo*" is converted into the terms "*<BOH>me too <EOH>*".

[1]`http://keras.io`

Parameter	value
Batch size	512
Loss function	binary cross-entropy
Optimization algorithm	Adam
Sequence length	40 terms
No. Epochs	100

Table 3: Hyperparameters.

3. Mentions are replaced by the token <*MENTION*>.

4. Unknown terms (those not found in the embedding dictionary) are replaced by the token <*UNK*>.

5. A final token <*EOT*> is added at the end of the tweet.

5 Transfer learning

We have taken already trained word embeddings for the first layer, allowing the weights of the these foreign models to get retrained during the learning process. We have used pre-trained GloVe (Global Vectors for Word Representation) models (Pennington et al., 2014) for the to targeted languages, English[2] and Spanish[3]. These are the models of word embeddings that we have transferred to the first layer in our architecture:

- For English we have used the weights from the GloVe Twitter model provided by the Stanford NLP Group, which is built over 2 billion tweets (27B tokens, 1.2M vocab, uncased, 200-dimensional vectors, 1.42 GB download).

- For For Spanish we have downloaded the GloVe model of the Spanish Billion Word Corpus(Cardellino, 2016), which generated 855,380 vectors of 300 dimensions.

Although FastText (Bojanowski et al., 2017) is considered the state-of-the-art for word embeddings representation, as it considers character n-grams instead of whole word forms, we have opted for GloVe due to the amount of available pre-trained models.

6 Data augmentation

The main problem with the dataset mentioned in the previous section is that there is a strong class imbalance between the samples with labels *"000"* and the samples with a different labeling. As Figure 1 illustrates, most of the samples were labeled as not hateful tweets towards a group and with not aggressive content, meaning that this class is highly dominated. Class imbalance introduces two key limitations: firstly, significant differences between accuracy and recall for some classes; and secondly, many machine learning models are prone to overfit on the majority class.

There are a number of ways to counter class imbalance, such as down-sampling the majority class, up-sampling the minority, and other hybrid solutions.

For each tweet, our system expand the information using paraphrasing. To express the same message with different words, we applied a online tool like RewriterTools[4]. For instance, the paraphrase of the tweet *"EU's hailed migrant plan 'a road to Hell' Czech Republic refuses involvement"* was *"EU's hailed migrant layout 'a avenue to Hell' Czech Republic refuses involvement"*.

Different configurations were created with the test data and the system, with the aim of obtaining results and analyzing the behavior of the different modules.

7 Experiments and results

We have performed several experiments to find good hyperparameters, but also evaluated the two main strategies proposed in our approach: transfer learning and data augmentation. In order to verify how transfer learning is good enough, i.e. how the predefined weights for GloVe could be further adjusted or not, we have checked the performance of the model trained on the official training set and evaluated on the development dataset on. Results in Table 4 shows that a small but consistent improvement is obtained if weights can be readjusted.

Next, we have empirically evaluated how paraphrasing helps to produce a better model or not. On these experiments the embeddings are always trainable. The paraphrasing tools allowed us to double the number of tweets in the training dataset. Thus, for English we have 18,000 tweets and

train_aug_ES	dev_ES	0.767844

Table 5: Experiments on data augmentation

9,000 for Spanish. Table 5 shows the results obtained. Here different effects are noticiable. For English a slight improvement on macro F-Score metric is reported, and for Spanish the effect is very negative.

We have submitted predictions on the test set on models trained only on task B, so for task A we have submitted only predicted labels for HS column. For English, the training data has been the augmented official training set with paraphrased tweets. For Spanish, only the training tweets provided by the organizers have been used to produce the model. The official results obtained in this task are shown in Table 6

8 Conclusions and future work

Our proposal explores how transferred embeddings and data augmentation may help in a text classification task like HatEval. Paraphrashing does not report clear benefits. This can be due to the quality of the paraphrasing and the fact that new generated tweets are not very realistic. Other augmentation strategies could be explored, like forward-backward translation. We have found also the models trained exhibits high variance. That means that we are overfitting the model on training data, so despite the use of the dropout technique, early stopping, fewer parameters or more training data could help to produce a more robuts model. Another possible improvement is on how final labels are decided. Our system takes the final outputs of the last sigmoid layer as probabilities, so when the value is higher than 0.5 for a class, then the label is 1, 0 otherwise. We could try to set the thresholds using a SVM classifier on this sigmoid vector.

Subtask	F1 (avg)	EMR	rank/total

Abstract

In this paper, we present our approach to detection of hate speech against women and immigrants in tweets for our participation in the SemEval-2019 Task 5. We trained an SVM and an RF classifier using character bi- and trigram features and a BiLSTM pre-initialized with external word embeddings. We combined the predictions of the SVM, RF and BiLSTM in two different ensemble models. The first was a majority vote of the binary values, and the second used the average of the confidence scores. For development, we got the highest accuracy (75%) by the final ensemble model with majority voting. For testing, all models scored substantially lower and the scores between the classifiers varied more. We believe that these large differences between the higher accuracies in the development phase and the lower accuracies we obtained in the testing phase have partly to do with differences between the training, development and testing data.

1 Introduction

An unwanted phenomenon that can be found across social media, is the publication of texts with hateful content. In SemEval-2019 Task 5 (Basile et al., 2019), it is defined as any communication that disparages a person or group. We focused on immigrants and women, which are two of the most targeted groups of people who are victims to this kind of discourse.

The micro-blogging service Twitter is a medium on which posts containing hateful content can be found in abundance. In order to filter out tweets with such content, machine learning and neural network techniques can be used to discriminate tweets which do contain hate speech from tweets which do not. Among the characteristics of Twitter data we can point out its noisiness and the use of emojis and hashtags, which can be taken into account for the classification task.

In this paper, we tried to solve this problem for English, by incorporating a variety of classification algorithms including Support Vector Machine (SVM), Random Forest (RF), and Bidirectional Long Short-Term Memory (BiLSTM). For the classical machine learning classification algorithms (SVM and RF) we used character n-grams and for the BiLSTM we used word embeddings trained on a huge amount of Twitter data. By combining these three models into an ensemble learning model, we achieved our best results on the development data, so we submitted this model for this shared task.

We start the paper by discussing some earlier work done in this field. Then, we describe the dataset we used for this task. In chapter 4, we present our approach. In chapter 5, we continue with the results of our methods and the discussion. Finally, we end with a conclusion and future work in chapter 7.

2 Related work

There has been done a lot of research regarding the automatic detection of hate speech on social media, in particular Twitter. A great deal of different approaches to solve this task had been implemented in different works. The majority of these studies was done on English texts. It is clear that there is quite some overlap between each of these approaches. However, direct comparison of previous approaches is not straightforward, as different datasets were used.

Most papers tried one or multiple different classifiers, albeit with different features, but in general SVM classifiers usually achieve the best performance (Saleem et al., 2016; Davidson et al., 2017).

Some papers divided the 'hate' class into two classes. For example, Watanabe et al. (2018) and Davidson et al. (2017) used the classes ‘offensive’ and ‘hate’, and Del Vigna et al. (2017) classified comments as ‘weak hate’ and ‘strong hate’.

Both the j48graft algorithm in Watanabe et al. (2018), and the SVM and LSTM in Del Vigna et al. (2017) performed better on a binary classification rather than a multiclass classification. Davidson et al. (2017) also tried different classifiers including Naive Bayes, decision trees, SVM and logistic regression. Their logistic regression and SVM classifiers achieved the best results. Waseem and Hovy (2016) tried different features for a logistic regression classifier, among which the character n-grams up to length of four in combination with the user’s gender information performed the best.

Other approaches are based on neural networks, like Zhang and Luo (2018). Their base convolutional neural network with a gap window (skipped CNN) had higher results than their SVM.

3 Data

The data provided by the organizers were collected from Twitter and manually annotated via the Figure Eight[1] crowdsourcing platform. All tweets contain a numeric ID, text of the tweet, and three labels with binary values (0 or 1). The first label indicates whether it is hate speech or not, the second if the target is a generic group of people or a specific individual and the third whether the tweeter is aggressive or not. The second and third labels can only be 1 if the first tag (hate speech or not) is 1 as well. However, we only used the first tag, since we only participated in task A, which is detecting hate speech.

The dataset for English contains 9,000 tweets for training, 1,000 for development and 3,000 for testing. Some tweets in the testing dataset were duplicates and removed from the dataset, resulting in 2,971 tweets. For each dataset, 57% of the tweets was labeled as non-hate speech and the rest as hate speech. For the testing phase, both training and development data were used for training the models.

[1]https://www.figure-eight.com/platform/

4 Method

4.1 Preprocessing

Before training the classifiers, we did some preprocessing steps over the data.

One of the reasons we did these preprocessing steps was that many words were not available in our word embeddings for the BiLSTM. Also, we could reduce the dimensionality of the character n-gram features for the RF and SVM by the following deletions and changes:

- Lower casing text
- Removing usernames
- Removing punctuation (except ‘#’)
- Replacing each URL by ‘URL’
- Replacing each number by ‘0’

Tokenization was done based on whitespace, as tokenization on tweets is non-trivial and wrong tokenization might actually hurt performance.

4.2 Models

Different machine learning models were evaluated and compared, among which Naive Bayes, k-nearest neighbours, RF, SVM, bagging and boosting models, and BiLSTM. Out of these models, the SVM, RF and BiLSTM proved to perform the best. The SVM and RF were implemented using Python’s scikit-learn library (Pedregosa et al., 2011) and the BiLSTM was implemented using Python’s Keras[2] library.

Finally, these models were combined in a majority voting ensemble model. The models are explained in more detail in the next sections, as well as the baseline models.

The architecture of our approach is shown in figure 1.

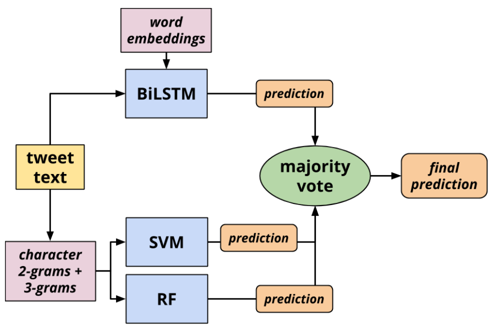

Figure 1: Architecture of our final approach.

[2]http://keras.io/

4.2.1 Baseline

We compared our results to two different baselines provided by the shared task organizers: a linear SVM with default parameters based on a tf-idf representation, and a classifier which assigns the most frequent label in the training set (MFC).

4.2.2 SVM

For the SVM, we tried different types of n-grams as features, including character and word n-grams. In the development phase, the combination of character bi- and trigrams gave the best results. These bi- and trigrams were represented as a tf-idf vector as input for the classifier.

During development, we also fine tuned the hyperparameters of the SVM classifier. The parameter values we changed for the final model were:

- C = 100
- kernel = 'linear'
- probability = True

4.2.3 RF

Just like the SVM classifier, we tried several different features during training for the RF, and again, the character level bi- and trigrams performed the best.

While developing, we fine tuned the parameters of the RF classifier. We experimented with different values and ratios for the number of trees and the maximum depth of the trees. Finally, we found that the following combination of parameter values led to the best performance:

- number of trees = 100
- max tree depth = 49

4.2.4 BiLSTM

In the recent years, neural network algorithms and its variants, proved to give excellent results for many NLP tasks including classification problems. Considering this, we tried a BiLSTM classifier and we used word embeddings taken from van der Goot and van Noord (2017) that were specifically trained on Twitter data. The embeddings were trained with Google's word2vec[3] (Mikolov et al., 2013) tool with 100 dimensions. In the process of training the model, we updated the initial values. The words that were not in the word embeddings were assigned values of 0 for their vector. Moreover, 6,515 words of all 26,026 unique tokens in the dataset (including the test set) were not included in the word embeddings. Among these words one can find unusual hashtags with CamelCasing (e.g. *#SendAllIllegalsHome*), use of repeated emojis and uncanonical usage of words of which some of them can be related to spelling errors.

Finally, we trained the model using a 3 layer BiLSTM model ran with 8 epochs and the following settings:

- 50 hidden units
- batch size = 300
- *adam* optimizer
- dropout rate = 0.2

4.2.5 Ensemble model

The predictions of the RF, SVM and BiLSTM were used in an ensemble model. For each final prediction, the majority vote (MV) of these predictions was taken. This means that the prediction (0 or 1) with the most votes is chosen as final prediction.

In addition to the previously described MV ensemble model, another one was made which uses the confidence scores of the SVM and RF, indicating the chance of being a 0 or 1. Finally, the average of these confidence values and the binary value of the BiLSTM was used to determine the final prediction.

5 Results and Discussion

Table 1 shows the accuracy, precision, recall and F-score for task A (hate speech detection) of the MFC, SVM (baseline), RF, SVM (character n-grams) and BiLSTM separately, as well as the final MV ensemble models and our official results. The official results differ from the other MV because after submission we did small changes in preprocessing and aggregated the development and training data for training the models.

57.3% of the data in each of the datasets (training, development and testing), was annotated as non-hate speech. Therefore, the accuracy of the MFC baseline was 57.3% as well. However, only one of the participants in this shared task managed to beat this baseline.

The accuracies and F-scores were substantially lower on the testing data than on the development data and the scores between the classifiers varied

[3]https://code.google.com/archive/p/word2vec/

Table 1: Evaluation measures (in percentage) of all models for development and testing on task A (hate speech detection). Precision and recall are averaged over the two classes.

	Development				Testing			
Model	Accuracy	Precision	Recall	F-score	Accuracy	Precision	Recall	F-score
MFC baseline*	57.2	32.8	57.3	41.7	**57.9**	28.9	50.0	36.7
SVM baseline*	72.0	71.9	72.1	71.9	49.2	59.5	**54.9**	**45.1**
RF	73.6	73.8	73.6	72.9	42.7	50.0	42.7	29.9
SVM (char. n-grams)	74.0	73.9	74.0	73.9	47.0	63.3	47.0	37.3
BiLSTM	72.2	72.6	72.2	72.3	49.7	65.1	49.7	42.5

Submitted ensemble (MV)	-	-	-	-	46.0	58.1	52.6	39.2

*The baselines for development are re-implemented, so they could be differently compared to the organizer's baseline.

more. This phenomenon can be explained by the fact that the testing data differed a lot from the training data. The organizers stated that before splitting the entire dataset, the data were not shuffled, which can be an explanation for these differences. These differences between the training and test data can lead to overfitting during training and parameter optimization.

During the development phase, character n-grams were the best features for the SVM, but in the testing phase it scored lower than the baseline SVM with a tf-idf representation of word unigrams. Furthermore, the MV ensemble model, combining the binary predictions of the three classifiers, got the highest scores on the development set. As a result, we submitted this MV ensemble model, without confidence scores. In contrast to the development phase, both ensemble models did not perform better on the testing data than the BiLSTM model alone. The BiLSTM performed the best (50% accuracy and 43% F-score) on the test data, but still below the baseline. Furthermore, all models had a higher precision than recall for testing, which also can be attributed to the imbalanced distribution of the data.

Finally, there were some issues with the annotation of the training and testing data. One could find instances of tweets that contain hate speech but were annotated incorrectly in our opinion. Moreover, as it was stated before, only one of the participants outperformed the MFC baseline.

6 Conclusion and future work

For the task of hate speech detection, we incorporated a variety of classifiers (SVM, RF and BiLSTM) and experimented with a range of different features and parameters. At the end we combined the predictions of these models in ensemble models. For development, the SVM, RF and BiLSTM reached similar performances and the ensemble model performed slightly better than these models individually. However, all models scored substantially lower on the test data than on the development data. As a result, we think that our approach led to overfitting on the development set without being able to generalize on the test set.

For future work, there are some ways to improve the results besides experimenting with different classification algorithms. Firstly, Twitter data is noisy and there are many uncanonical words and emojis. We tried to tackle this problem by using word embeddings that were trained on Twitter data for the BiLSTM and character n-grams for the RF and SVM. Another strategy to try is to normalize the data into a more canonical form and feed it to the classifiers. Furthermore, more experiments could be done by incorporating different features and exploiting other information that is available in the data. For example, RF and SVM classifiers trained on word embeddings and the use of certain punctuation marks, emojis and hashtags as separate features could be tried.

Finally, as it was stated in the previous section, we believe there were some issues with the dataset. Moreover, hate speech is hard to define and there is no clear agreement on the definition. This is why we can be skeptical about the annotation procedure. Therefore, we believe better datasets are necessary for the hate speech detection task.

Abstract

The massive growth of user-generated web content through blogs, online forums and most notably, social media networks, led to a large spreading of hatred or abusive messages which have to be moderated. This paper proposes a supervised approach to hate speech detection towards immigrants and women in English tweets. Several models have been developed ranging from feature-engineering approaches to neural ones. We also carried out a detailed error analysis to show main causes of misclassification.

1 Motivation

Social media networks such as Facebook, Twitter, blogs and forums, have become a space where users are free to relate events, personal experiences, but also opinions and sentiments about products, events or other people. This massive growth of user generated web content, along with the interactivity and anonymity the internet provides, may lead to a large spreading of hatred or abusive messages which have to be moderated.

In spite of no universally accepted definition of hate speech and the way it differs from offensive language, there are some common elements that seem to arise. In particular, these messages may express threats, harassment, intimidation or "disparage a person or a group on the basis of some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristic" (Nockleby, 2000).

In this paper, we focus on automatic hate speech detection towards *two different targets* – immigrants and women and we propose several multi-target hate speech detection systems. The task is performed over a collection of English tweets annotated as conveying hate speech against both immigrants and women, as part of HateEval@SemEval2019 (Basile et al., 2019). The first challenge involves building a binary classifier able to determine whether a tweet with a given target (women or immigrants) is hateful or not hateful. For this, we propose both features-based models (relying on both language-dependent and language independent features) and a neural model. We also performed a detailed error analysis to identify main causes of misclassification. Our analysis shows that errors come from several factors, which show the complexity of the task: the presence of irony and sarcasm, the lack of context and implicit hate speech. We also identified tweets for which we question the original label when taking into account the class definition.

The paper is organized as follows. Section 2 briefly presents the current state of the art. Section 3 describes our data and models, while Section 4 analyses the experiments we carried out on multi-target detection. We conclude by providing some perspectives for future work.

2 Related work

Hateful speech can be expressed at different linguistic granularity levels going from lexical to discursive (Cameron, 1992). Both sexism and racism can be expressed explicitly or implicitly (see the following tweets from our data) using different pragmatic devices, including:

- Negative opinion, abusive message: *Stop tweeting about football. You're a girl and you opinion doesn't count. #WomenSuck.*
- Stereotype: *Illegals are dumping their kids heres o they can get welfare, aid and U.S School Ripping off U.S Taxpayers #SendThemBack ! Stop Alowing illegals to Abuse the Taxpayer #Immigration.*
- Humor, irony, sarcasm: *Where is this? Brazil? Uganda? Sudan? Nope, it is France.*

Got to love that cultural enrichment thing going on. #openborders #refugeesnotwelcome #slums.

For most of the harassment and hate speech detection tasks, the classifiers still rely on supervised learning, and when creating a new classifier, one may directly feed different types of features to the classical algorithms (Naive Bayes, Logistic Regression, Random Forest, SVM) or use deep learning methods that will automatically learn abstract features from data instances. Due to the noise present in the data (especially on social media), many authors choose to combine n-grams (due to their high prediction rate) with a large selection of additional features: linguistic features that take into consideration the POS information, dependency relations (long-distance relationship in between words), or word embeddings, which have the advantage of having similar vector representations for different, but semantically similar words. Several approaches incorporate sentiment analysis as a supplementary classification step, assuming that generally negative sentiment relates to a hateful message (Dinakar et al., 2012; Sood et al., 2012).

Although within the Automatic Misogyny Identification shared task at IberEval 2018 the best results were obtained with Support Vector Machine models with different feature configurations, there are also a few notable neural networks techniques deployed in order to detect hate speech in tweets that outperform the existing models: in (Badjatiya et al., 2017) the authors used three methods (Convolutional Neural Network (CNN), Long short-term memory and FastText) combined with either random or GloVe word embeddings. In (Zhang and Luo, 2018) the authors implemented two deep neural network models (CNN + Gated Recurrent Unit layer and CNN + modified CNN layers for feature extraction) in order to classify social media text as racist, sexist, or non-hateful.

3 Multitarget hate speech detection systems

Automatically labelling tweets as hateful or not hateful is a challenging task because the language of tweets is full of grammatically and/or syntactic errors, it lacks conversational context, might consist of only one or a few words and because they can be indirectly hateful (by employing techniques such as sarcasm, satire or irony) it makes the task of text-based feature extraction difficult.

3.1 Data

Our data comes from two corpora. The first one, is an already existing corpus containing English tweets annotated for hate speech against immigrants and women, as part of the HatEval task at SemEval2019 (Basile et al., 2019). The second one was created as a result of the conclusions we had drawn after analyzing the data, i.e. we observed that for most of the tweets, even though the message appeared to be positive, just by having a certain hashtag used, it becomes negative. The hashtag importance is also supported by a simple experiment that includes in the pre-processing step hashtag removal. This leads to a decrease in accuracy by 4% and F-score by 5%. Thus we created a new dataset (DATASET++) by collecting the most used hashtags (we used scrape-twitter[1]) in both hateful (#buildThatWall) and non-hateful tweets (#refugees), as well as the most used hashtags in the misclassified tweets[2].

Table 1 shows the distribution of the tweets for the task of hate speech detection.

Task	#hate	#nonHate	Total
DATASET	5 512	7 559	13 071
DATASET++	17 989	21 921	39 909

Table 1: Tweet distribution in the corpora

For the task at hand, several models have been built, all tested using 10-cross-validation. In the next sections, we detail our models and then provide our results.

3.2 Models

Baseline (**B**)**.** In all the experiments, we used Bag of Words (BoW) model as lexical features. Due to the noise in the data, we performed standard text pre-processing by removing user mentions, URLs, RT, stop words, degraded stop words and the words containing less than 3 characters, and we stemmed all the remaining words by using the Snowball Stemmer[3].

Feature-based models. We experimented with several state of the art features that have shown to

[1]https://www.npmjs.com/package/scrape-twitter

[2]#maga, #usa, #trump, #sendThemBack, #immigration, #noDaca, #deportThemAll, #meToo, #stopTheInvasion, #illegalAliens, #apathyKills, #withImmigrants

[3]http://snowballstem.org

be useful in hate speech detection and we relied on a manually built emoji lexicon that contains 1 644 emojis along with their polarity. We also tested whether by identifying the users opinion we can better classify his attitude as hateful or non-hateful by making use of HurtLex (a multilingual hate word lexicon divided in 17 categories) (Bassignana et al., 2018) and a lexicon containing 1 818 profanity English words created by combining a manually built offensive words list, the noswearing dictionary [4] and an offensive word list[5].

We experimented with several combinations of the features above and we used the best performing ones for training four classifiers:

- C_1 : combines the length of the tweet with the number of words in the HurtLex lexicon with a Baseline architecture
- C_2 : combines the number of words in the offensive lexicon, the number of positive and negative emojis and emoticons and the presence of URLs with a Baseline architecture, but applied on the extended dataset
- C_3 : combines the number of words in the offensive lexicon, the number of positive and negative emojis and emoticons and performs linear dimensionality reduction by means of truncated Singular Value Decomposition and used Random Forest only for intermediate classification, whose output were then combined and passed onto a final Extreme Gradient Booster classifier
- C_4 : the same as C_3 but applied on the extended dataset

Neural model. The last model (C_5) used a Bidirectional LSTM with an attention mechanism. For the task at hand, we used pre-trained on tweets Glove embeddings (Pennington et al., 2014).

4 Results

We tried several machine learning algorithms in order to evaluate and select the best performing one. Hereby, the hate speech system baseline is a Random Forest classifier. Table 2 shows how the experiments were set up and presents the results in terms of accuracy (A), macro-averaged F-score (F), precision (P) and recall (R). For each of the systems we present the results obtained on 10-cross validation (using the provided train, trial and dev datasets) and the official results.

Among the five systems, C_2 represents our best performing one during the development phase [6], while C_5 performed best in the evaluation phase.

Due to a significant decrease in both accuracy and F-score on the official test data, we also investigated the influence of the data distribution in the train and test datasets. The results obtained after shuffling and re-splitting the data (while keeping the original distribution of the tweets) are also presented in Table 2. It is important to realize that these results were obtained by using a train-test configuration on a random test, not by using cross validation. These results are comparable to the ones obtained during the development phase.

As we encountered a significant decrease in the system's performance in the official test, we decided to conduct a deeper analysis in order to identify the main causes of errors.

5 Discussion

Error analysis shows that in the misclassification of hateful instances intervene several factors: the presence of off-topic tweets, the lack of context (as some words that trigger hate in certain contexts may have different connotations in others) and implicit hate speech that employs stereotypes or metaphors in order to convey hatred.

Although the results of the system employed on the extended dataset seemed promising, we couldn't see any improvement on the official test dataset. This might be as a result of not having any information on the actual distribution of the tweets (the number of tweets that convey hate towards immigrants and the number of tweets that convey hate towards women, information that might have been useful when extending the dataset), neither on the way the annotation was done and our definition of hate speech (and the way it differs from offensive language) might have been different. We also identified tweets for which we question the original label when taking into account the class definition. Below, we have provided some examples.

Example 1: The first tweet (annotated as not hateful), containing the users opinion on Poland

Table 2: Hate speech detection results. Best results are presented in bold font while * marks the system submitted for the official ranking.

receiving immigrants, seems more hateful than the second tweet (hateful), in which the user depicts a series of events.

- If Germans want rapefugees [7] they can keep them. Poland will not accept a single rapefugee. Not even one!!! Poland remains proud and firm! https://t.co/VHoFrxFjB1
- GERAMNY: African rapefugee climbs into house, steel expensive goods, rook a knife and abuse a girl of the family. https://t.co/fVXhWMYcE8

Example 2: Although in the first tweet (not hateful) the user talks about Donald Trump, which doesn't fit in the targeted categories, the annotation raises problems when trying to classify tweets such as the second one (annotated as hateful).

- I love my religious brothers and sisters, but @realDonaldTrump, FUCK YOU, YOU'RE NOT EVEN A REAL THEOCRAT YOU FAT USLESS BITCH.
- @menzemerized_ Worse i have proof. A picture i took of you and one you took of me on the same night. Useless ungreatful kunt!

6 Conclusion

This paper proposed several models that can be used in order to identify messages that convey hate towards women and immigrants, incorporating a variety of features for capturing offensive language. Our results revealed good classication performance on the training dataset, but a lower performance on the evaluation data, with a notable decrease in both accuracy and F-score. Error analysis shows that this decrease is mainly due to the lack of context to infer hateful intents, and the way hate speech was defined in the manual annotation of the dataset.

As the meaning of a message might change in different contexts (as it can be highly dependent on knowledge about the world), in our future work we plan on studying ways to retrieve contextual information.

[7] Accordind to Urban Dictionary, the term rapefugee is usually used when referring to the Muslim refugees coming into Europe in a derogatory way, as refugees are perceived as being more likely to raping people.

Abstract

This system paper is a description of the system submitted to “SemEval-2019 Task 5” Task B for the English language, where we had to primarily detect hate speech and then detect aggressive behaviour and its target audience in Twitter. There were two specific target audiences, immigrants and women. The language of the tweets was English. We were required to first detect whether a tweet is containing hate speech. Thereafter we were required to find whether the tweet was showing aggressive behaviour, and then we had to find whether the targeted audience was an individual or a group of people.

1 Introduction

Hate speech attacks a person or a group on the basis of attributes such as race, religion, ethnic origin, national origin, sex, disability, sexual orientation or gender identity. In the same time, flames (such as rants, taunts, and squalid phrases) are offensive/abusive phrases which might attack or offend the users for a variety of reasons. This is very pertinent due to rise of text messaging through the Internet or cellular phones, which has become a major medium of personal and commercial communication.

Aggression is overt, often harmful, social interaction with the intention of inflicting damage or other unpleasantness upon another individual. It may occur either in retaliation or without provocation. In humans, frustration due to blocked goals can cause aggression. Human aggression can be classified into direct and indirect aggression; whilst the former is characterized by physical or verbal behavior intended to cause harm to someone, the latter is characterized by behavior intended to harm the social relations of an individual or group.

Hate speech and offensive language are pervasive in social media. Online communities, social media platforms, and technology companies have been researching heavily in ways to cope with this phenomena to prevent abusive behavior in social media. This is due to text messaging through the Internet or cellular phones, which has become a major medium of personal and commercial communication.

One of the most effective strategies for tackling this problem is to use computational methods to identify hate speech and aggression in user-generated content (e.g. posts, comments, tweets etc.). This topic has attracted significant attention in recent years of various Natural Language analysts.

The SemEval 2019 task 5 (Basile et al., 2019) was a classification task where we were required to classify a tweet as containing hate speech or otherwise. However, there were some additional challenges presented, which involved automatic detection of aggression, and classification the target audience as an individual or group of people.

To solve the task in hand we built a bidirectional LSTM based neural network for prediction of the three classes present in the provided dataset. In the first subtask our system categorized the instances into `HS` and `NOT`. In the second subtask our system categorized instances into `AGR` and `NOT`. In the third subtask our system categorized instances into `IN` or `GRP`.

The paper has been organized as follows. Section 2 describes a brief survey on the relevant work done in this field. Section 3 describes the data, on which, the task was performed. The methodology followed is described in Section 4. This is followed by the results and concluding remarks in Section 5 and 6 respectively.

2 Related Work

Papers which have been published in the last two years include the surveys by (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018), the paper by (Davidson et al., 2017) presenting the Hate Speech Detection dataset used in (Malmasi and Zampieri, 2017) and a few other recent papers such as (ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018).

We were guided by the work of (Zhang et al., 2018) who used a CNN+GRU based approach for a similar task. We use an approach which was influenced by this work but used an LSTM based approach.

A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017). For studies on languages other than English see (Su et al., 2017) on Chinese and (Fišer et al., 2017) on Slovene. Finally, for recent discussion on identifying profanity vs. hate speech see (Malmasi and Zampieri, 2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language.

Previous editions of related workshops are TA-COS[1], Abusive Language Online[2], and TRAC[3] and related shared tasks are GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018).

3 Data

The dataset that was used to train the model is the HatEval dataset (Basile et al., 2019). It was collected from Twitter; the data being retrieved the data using the Twitter API by searching for keywords and constructions that are often included in aggressive messages.

Label	Meaning
HS	Whether the tweet contains hate speech or not
TR	Whether the tweet containing profanity is targeted against some individual/group/others
AG	Whether the tweet contains aggressive behaviour or not

Table 1: Labels used in the dataset

The dataset provided consisted of tweets in their original form along with the corresponding `HS`, `TR` and `AG` labels. The dataset had 9000 instances of training data and 1000 instances of development data. Our approach was to convert the tweet into a sequence of words and then run a neural-network based algorithm on the processed tweet.

Value	HS	TR	AG
0	5217	2442	2224
1	3783	1341	1559
All	9000	3783	3783

Table 2: Distribution of the labels in the training dataset

Value	HS	TR	AG
0	573	208	223
1	427	219	204
All	1000	427	427

Table 3: Distribution of the labels in the development dataset

The provided training and development data were merged and shuffled to create a bigger training set, and we refer to the same as training data when we discuss our methodology.

Value	HS	TR	AG
0	5790	2650	2447
1	4210	1560	1763
All	10000	4210	4210

Table 4: Distribution of the labels in the combined dataset

4 Methodology

The first stage in our pipeline was to preprocess the tweet. This consisted of the following steps:

1. Removing mentions
2. Removing punctuations
3. Removing URLs
4. Contracting whitespace
5. Extracting words from hashtags

The last step (step 5) consists of taking advantage of the Pascal Casing of hashtags (e.g. `#PascalCasing`). A simple regex can extract all words; we ignore a few errors that arise in this procedure. This extraction results in better performance mainly because words in hashtags, to some extent, may convey sentiments of hate. They play an important role during the model-training stage.

We treat the tweet as a sequence of words with interdependence among various words contribut-

[1] `http://ta-cos.org/`

[2] `https://sites.google.com/site/abusivelanguageworkshop2017/`

[3] `https://sites.google.com/view/trac1/home`

ing to its meaning. Hence we use an bidirectional LSTM based approach to capture information from both the past and future context.

Our model is a neural-network based model. First, the input tweet is passed through an embedding layer which transforms the tweet into a 128 length vector. The embedding layer learns the word embeddings from the input tweets. This is followed by two bidirectional LSTM layers containing 64 units each. This is followed by the final output layer of neurons with softmax activation, each neuron predicting a label as present in the dataset. For subtasks 1, 2 and 3, we train separate models containing 2 neurons for predicting `HS(0/1)`, `TR(0/1)` and `AG(0/1)` respectively. Between the LSTM and output layers, we add dropout with a rate of 0.5 as a regularizer. The model is trained using the Adam optimization algorithm with a learning rate of 0.0005 and using crossentropy as the loss.

We note that the dataset is highly skewed in nature. If trained on the entire training dataset without any validation, the model tends to completely overfit to the class with higher frequency as it leads to a higher accuracy score.

To overcome this problem, we took some measures. Firstly, the training data was split into two parts — one for training and one for validation comprising 70 % and 30 % of the dataset respectively. The training was stopped when two consecutive epochs increased the measured loss function value for the validation set.

Secondly, class weights were assigned to the different classes present in the data. The weights were approximately chosen to be proportional to the inverse of the respective frequencies of the classes. Intuitively, the model now gives equal weight to the skewed classes and this penalizes tendencies to overfit to the data.

5 Results

We participated in English Task B of Semeval 2019 task 5 (HatEval) and our system ranks fourth among the competing participants.

We have included the automatically generated tables with our results. We have also included the provided baselines generated by MFC and SVC classifiers respectively. The SVC baseline is generated by a linear SVM based on a TF-IDF representation. The MFC baseline assigns the most frequent label in the training set to all instances present in the test set. We have used these baselines for comparison.

Table 9: AG Metrics

6 Conclusion

Here we have presented a model which performs satisfactorily in the given tasks. The model is based on a simple architecture. There is scope for improvement by including more features (like those removed in the preprocessing step) to increase performance. Another drawback of the model is that it does not use any external data other than the dataset provided which may lead to poor results based on the modest size of the data. Related domain knowledge may be exploited to obtain better results.

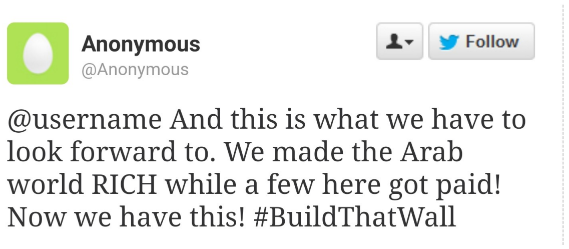
Abstract

The detection of hate speech, especially in online platforms and forums, is quickly becoming a hot topic as anti-hate speech legislation begins to be applied to public discourse online. The HatEval shared task was created with this in mind; participants were expected to develop a model capable of determining whether or not input (in this case, Twitter posts in English and Spanish) could be considered hate speech (designated as Subtask A), if they were aggressive, and whether the tweet was targeting an individual, or speaking generally (Subtask B). We approached this Subtask by creating a LSTM model with an embedding layer. We found that our model performed considerably better on English language input when compared to Spanish language input. In English, we achieved an F1-Score of 0.466 for Subtask A and 0.462 for Subtask B; In Spanish, we achieved scores of 0.617 and 0.612 on Subtask A and Subtask B, respectively.

1 Introduction

Social media plays an important role nowadays and dominates everyday life. Social networks like Facebook, Twitter and Instagram are platforms where people express thoughts, feelings and emotions regarding themselves or others. This can lead to different opinions colliding and creating conflicts. Often, feelings are not expressed objectively and can be offensive to other users. In order to make social media more comfortable, so called hate speech needs to be detected and removed. Hate speech is here defined as: Any communication that disparages a person or a group on the basis of some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristics (Basile et al., 2019). To assure there is no spread of illegal hate speech, the EU has created a code of conduct for social media platforms (European Union, 2018) that needs to be followed. According to these EU regulations, social media platforms must regulate hateful speech. In addition, social media occupies an increasingly larger portion of public discourse; even without these EU regulations, it seems that these platforms should have some methods for controlling violent discourse.
For these reasons, the HatEval shared task (Basile et al., 2019) was created. The task is divided into two subtasks; Subtask A is hate speech detection against immigrants and women, a binary classification problem where a tweet is classified as either hateful or not hateful. Subtask B is determining whether a given tweet is aggressive, and whether it is targeting an individual, or not referring to any particular person. Further, each of these Subtasks is evaluated on English tweets and using Spanish tweets. We were provided a 9000-tweet English training set, and a 5000 tweet Spanish training set. The training sets were manually tagged as hateful or not hateful, aggressive or not aggressive, and targeted or not targeted - examples of tweets marked as hateful can be seen in Figures 1 and 2 below.



@username And this is what we have to look forward to. We made the Arab world RICH while a few here got paid! Now we have this! #BuildThatWall

Figure 1: Example of a hateful English tweet.

In this paper, we detail our methods for approaching these problems. We will first cover related works before detailing our specific solutions for Subtask A and Subtask B; we will then cover our model (and previously attempted

models) and present our results. Hate speech detection is naturally a far reaching topic, and in conclusion we will discuss the implications of our work for the field in general.

2 Related Work

To begin, we attempted to take a brief survey of previous work in the field of hate speech detection. Since this is, at heart, a binary classification task, we saw that there were many established approaches to solving this problem - various machine learning techniques, according to our research, were shown to be valid, such as Recurrent and Convolutional Neural Networks (RNN and CNNs) (Stammbach et al., 2018), Support Vector Machines (SVMs) (Malmasi and Zampieri, 2017), Long Short Term Memory models (LSTMs) (Zhang et al., 2015; Risch et al., 2018), as well as simpler linear regression approaches (Kent, 2018). In our estimation, we determined that LSTM approaches were most successful (Golem et al., 2018; Del Vigna12 et al., 2017), and took such an approach in the creation of our model. Some other approaches were too computationally expensive; in addition, we felt that, due to the nebulous nature of hate speech determination, the additional information captured by an LSTM model would be worthwhile in these tasks. We also determined that, for such a task, the use of non-word features would be superfluous, as previous work had shown them to decrease performance (Stammbach et al., 2018), and this was supported by other works on simple classification tasks, even when LSTMs or RNNs were not used (Malmasi and Zampieri, 2017). Research showed that various features, including emoticons, sentiment analysis, and number of characters tended to hurt performance (Kent, 2018).
Predictably, most work done on this topic has focused on English language data; we found only a few papers on Spanish language hate speech detection (Álvarez-Carmona et al., 2018; Fersini et al., 2018), which we attempted to use to ensure our model would function across language boundaries.

3 Model

At the outset, we employed a simple unidirectional, 1-layer LSTM model. As we saw preliminary results we altered our model accordingly. We also attempted to use a 2-layer LSTM model, and settled on a 1-layer LSTM model with a simple embedding layer, using mainly the *Keras* (Chollet et al., 2015) library.

3.1 Pre-Processing

Based on our research, we saw that limited pre-processing of the data set could improve performance; to that end, the following pre-processing steps were taken:

- replace usernames with username markers
- remove punctuation and special characters (@ / , ; . : ? ¿ ¡ ! $)
- lowercase

We made the decision not to omit hashtags; while usernames do not necessarily convey information pertinent to the tweet itself, it was determined that hashtags are frequently used for meaningful purposes and must be considered when attempting to classify Twitter data. We attempted to expand our pre-processing efforts when dealing with Spanish language data after seeing early results (replacing characters such as ‘ñ´ with ‘n´ for example), but without success; such efforts hurt our model more than they helped.

3.2 Recurrent Neural Network

Our model used character based representations of all data. We used an embedding layer with input dimension of 5000 and an output of 28; input length was determined by finding the length of the longest item in the data set, and padding all representations to this length. Additionally, we used an LSTM layer with 64 units, with a dropout rate of 0.1 (determined after simple trial and error tests), and our model employed a sigmoid activation function and a binary cross entropy loss function. Our model was trained for 50 epochs on the English language dataset, and 20 epochs on the Spanish language dataset.

Models	F1-score
1-Layer LSTM	0.31
2-Layer LSTM	0.42
1-Layer LSTM w/ Embedding	0.69

Table 1: Development set F1-scores for preliminary testing of models.

4 Evaluation

We first evaluated our preliminary models using the development data set, specifically using results of Subtask A in English to determine which of our beginning approaches was most successful. After this determination, we expanded upon our best working model (the simple LSTM model with embedding layer), and proceeded to use this approach to handle all tasks in both languages. We calculated the F1-score for each of our models, and used this for our evaluations. As shown in Table 1, the 1-Layer LSTM model with Embedding outperformed our other two models significantly and achieved an F1-Score of 0.69 on the development set.

tasks	Accuracy	Precision	Recall	F1-score	EMR
Subtask A (En.)	0.488	0.548	0.533	0.466	N/A
Subtask B (En.)	0.565	0.497	0.482	0.462	0.173
Subtask A (Sp.)	0.630	0.618	0.617	0.617	N/A
Subtask B (Sp.)	0.680	0.629	0.608	0.612	0.428

Table 2: Results for Tasks A and B in English and Spanish.

The average results for each metric are shown in Table 2. The final ranking for Subtask A for English, as well as Spanish, was based on the F1-score. Our F1-score was 0.466 for English, which ranked us 27th out of 69 teams that submitted a result for this Task. Since we had some problems with the Spanish data set, we could only submit one solution for Subtask A, which placed us 36th out of 39 teams.

Evaluation for Subtask B was based on two criteria - partial match and exact match. For partial match, each dimension that needs to be predicted, is being looked at independently and therefore the usual evaluation metrics are being used (Precision, Accuracy, Recall and F1-Score). For the exact match all the dimensions to be predicted are jointly considered. Ranking was solely based on the score of the *Exact Match Ratio* (EMR). For English we achieved an EMR score of 0.173, which ranked us second to last, even if our average F1-score was higher than other systems'. Since we had the same problems as in Subtask A, we again were only able to submit one file in Subtask B for Spanish, where we achieved an EMR of 0.428 and an average F1-Score of 0.612. The significant difference for the F1-Score between English and Spanish comes from the fact that there was less training data for Spanish compared to English.

5 Conclusion & Future Work

We created a simple LSTM model and applied it to all tasks - detecting hate speech, determining aggression, and determining targeted or general speech, achieving F1-scores of 0.466 and 0.462 for Subtask A and B in English, and scores of 0.617 and 0.612 for Tasks A and B in Spanish. In our work, we saw that our model performed considerably better on English language data when compared to Spanish language data. We were not able to reduce this discrepancy with additional pre-processing of Spanish language data. The difference in performance may be explained by the nature of Spanish language discourse online - perhaps there is greater accent- or dialect-based difference in Spanish when compared to English (Çöltekin and Rama, 2018), which could confound attempts to train a model off of a Spanish language corpus that does not specifically control for dialect.

There is still much work to be done in the field of hate speech evaluation. It is possible that a large improvement in performance would be seen if word representations were used instead of character representations; much of the vocabulary of online communication and discourse involves the use of colloquialisms, informal speech, and metaphorical language, which word based representations could perhaps better capture. Further, contextual information from the rest of a particular tweet could also help in determining whether or not a given word is being used in a malicious way; this information could have been captured through the use of n-gram models or contextual word representation methods. Using meta-information about a particular user, topic, or hashtag could have also improve performance (Schmidt and Wiegand, 2017); such methods go outside the scope of the shared task, but it is conceivable that a platform such as Twitter could consider previous tweets of a given user, or perhaps topic modelling methods, in a commercial hate speech detection model (for example, it seems rational to consider a tweet with a topic such as 'right wing politics' more likely to be hate speech than a tweet with the topic 'gardening'). The use of lexical resources like lists of slurs have also shown to be effective in combination with other features (Schmidt and Wiegand, 2017; Davidson et al., 2017). Work could also be done in hate speech detection in long form documents; it goes without saying that a model that can effectively detect hate speech in short, one- to three-sentence tweets will not necessarily perform as well on longer corpora, such as articles. In these cases, context-based word representations, n-gram models, etc. could become even more valuable.

Abstract

In this paper, we describe our contribution in SemEval-2019: subtask A of task 5 "Multilingual detection of hate speech against immigrants and women in Twitter (HatEval)". We developed two hate speech detection model variants through Tw-StAR framework. While the first model adopted one-hot encoding n-grams to train an NB classifier, the second generated and learned n-gram embeddings within a feedforward neural network. For both models, specific terms, selected via MWT patterns, were tagged in the input data. With two feature types employed, we could investigate the ability of n-gram embeddings to rival one-hot n-grams. Our results showed that in English, n-gram embeddings outperformed one-hot n-grams. However, representing Spanish tweets by one-hot n-grams yielded a slightly better performance compared to that of n-gram embeddings. The official ranking indicated that Tw-StAR ranked 9th for English and 20th for Spanish.

1 Introduction

Under the guise of free speech, social media systems have been misused by some users who embed hatred, offensive, racist or negative stereotyping contents within their shared posts. Unfortunately, online Hate Speech (HS) is spreading widely, forming a serious problem that can lead to actual hate crimes (Matsuda, 2018). Many countries adopted laws prohibiting HS where people convicted of using HS can face large fines and even imprisonment. Although Twitter has its anti HS policy[*], the increasing size of the daily-shared tweets in addition to multilingualism and informal writing issues evoke the necessity for automatic HS detection in tweets.

Hate speech detection problem has been addressed as a machine learning classification task. Recent studies proposed multiple HS detection models with different characteristic in terms of features, classification algorithms and implementation architectures. While some HS models employed hand-crafted features generated by NLP tools and external semantic resources, other models adopted text embedding features that are automatically learned from the corpus itself. Both feature types were fed to train either traditional classifiers such as Support Vector Machines (SVM), Naive Bayes (NB) and so forth, or more complicated deep learning-based classifiers such as Convolutional Neural Network (CNN), Long Short-Term Memory (LSTM) and Recurrent Neural Network (RNN) (Schmidt and Wiegand, 2017). The variety of hand-crafted features enabled obtaining reliable performances. However, generating such features based on morphological NLP tools or semantic resources remains laborious. In contrast, embedding features are easier to generate and can yield good HS classification results when used within deep learning architectures (Yuan et al., 2016). Nevertheless, producing good performances via deep neural systems requires providing large-sized labeled training data, tuning many hyper parameters and high computation/time cost. In line with Tw-StAR framework (Mulki et al., 2017, 2018a), we propose, here, an HS model based on the hypothesis that, pairing between n-gram embeddings and less-complicated architectures i.e. feedforward neural network can lead to an efficient HS detection with least complexity.

2 Hate Speech Detection Models

According to the used features, HS detection models can be classified into hand-crafted-based and text embeddings-based.

[*]support.twitter.com/articles/20175050

2.1 Hand-Crafted-based Models

Being a user-generated content, HS terms tend to have variant writing shapes. (Waseem and Hovy, 2016) handled this issue by using char-grams to train an LR classifier. Combining char-grams with extra linguistic features such as word n-grams and user's gender improved the performance.

Additional user-related features were studied in (Unsvåg and Gambäck, 2018) within a multilingual HS detection task. Single and combined features were fed into an LR classifier. The study showed that specific user features favorably impact the performance.

The winning system (Pamungkas et al., 2018) in misogyny detection contest (Fersini et al., 2018) examined several sets of hand-crafted features including stylistic, lexical and structural. The features were formulated within one-hot/sparse encoding vectors and fed into an SVM classifier. It was noted that using features from HurtLex lexicon (Bassignana et al., 2018) enriched the lexical features set and enhanced the performance.

2.2 Text Embeddings-based Models

In these models, the input text is represented using dense, low-dimentional and real-valued vectors. In (Nobata et al., 2016), a comprehensive comparison was conducted among three embedding feature types: doc2vec (Le and Mikolov, 2014), word2vec and pretrained word embeddings against hand-crafted features. Using a regression model trained with the previous features, it could be noted that while doc2vec embeddings outperformed the other embedding features, combining them with all other features could further enhance the HS content recognition.

(Badjatiya et al., 2017) explored CNN, LSTM and FastText models to learn embedding features needed to classify HS contents. These models were trained by embedding features and evaluated against each other and towards SVM, LR and GBDT classifiers trained with hand-crafted features. Moreover, the authors explored training an GDBT classifier with word embeddings learned via various deep models. While CNN was the best-performing deep model, using the word embeddings learned via LSTM to train the simple less-complicated GDBT classifier improved the results.

In (Gambäck and Sikdar, 2017), context-aware word embeddings learned by word2vec, char 4-grams and a combination of both were used to train a CNN-based classifier. The proposed model was compared with an LR classifier trained via n-gram features (Waseem and Hovy, 2016). The results showed that regardless of the used embeddings type, CNN model outperformed the baseline model. Moreover, word2vec embeddings were of the best classification performance among the other embedding features.

3 Tw-StAR HS Detection Model

To detect HS in English and Spanish datasets provided by (Basile et al., 2019), Tw-StAR (see Figure 1) was applied through the following steps:

3.1 Preprocessing

- Initial preprocessing: includes removing the non-sentimental content such as URLs, usernames, digits, hashtag symbols and punctuation from both datasets (Mulki et al., 2018b).

- Stopwords removal: for English and Spanish, we removed stopwords using 1,012 English stopwords and 731 Spanish stopwrods derived from Terrier package[†] and snowball[‡], respectively.

- Lemmatization: we adopted Treetagger lemmatizer (Schmid, 1999); as it was used successfully for English and Spanish in (Mulki et al., 2018a). TreeTagger forms a language-independent tool to annotate texts with part-of-speech and lemma information.

- Hate indicatives tagging: Multi-word terms (MWT) are meaning indicators of a sentence/document (Henry et al., 2018; Bechikh-Ali et al., 2019). In our case, they can represent the entities discussed within a tweet. As our objective is to infer HS in tweets, we believe that recognizing MWT can assist in identifying the important entities related to hate speech or victims of hate speech. This has been practically noticed among the MWT extracted from the training set as we can mention: african_migrant, Iraqi_refugee_terrorist, Muslim_refugee, immigration_negative_effect. It should be noted that, MWT were extracted from hate tweets contained in the training set. Later, the extracted MWT were replaced in both training

Figure 1: Tw-StAR framework

and dev/test sets with the tag “HateWord”. MWT identification process was performed through two steps: (a) Shallow syntactic parsing where each word was tagged with its syntactic category using Treetagger that supports English and Spanish, and (b) MWT extraction conducted based on specific syntactic patterns of noun and adjective combinations using this schema:

$$MWT=(Adj|N)^*(N|NP)(N|Adj|NP)^*$$

where * denotes a list of 0 or more elements, the MWT length varies between 2 and 4 words. Adj, N and NP refer to adjective, noun and proper noun, respectively.

3.2 Feature Extraction

Two types of features were generated to train both model variants of Tw-StAR.

- One-hot n-grams: are generated by subjecting the preprocessed tweets to tokenization. Three N-grams schemes including unigrams, bigrams and trigrams were adopted. For a certain n-grams scheme, a tweet’s feature vector is constructed via examining the presence/absence of this scheme among the tweet’s tokens. Thus, the feature vectors are formulated as one-hot encoding vectors with binary values “1” (presence) or “0” (absence). Term frequency (TF) property was employed to reduce the features size according to predefined frequency thresholds.

- N-gram embeddings: Based on word embeddings initialized randomly at the embedding layer of Tw-StAR Feedforward neural model, n-gram embeddings are produced by applying a composition function over a specific number of word embedding vectors. In our experiments, we used the additive composition function, known as Sum Of Word Embeddings (SOWE). While composing an n-gram embedding vector, by performing an element-wise sum over word embedding vectors, SOWE considers the co-occurrence information of the n-gram words and totally ignores the local word order.

3.3 Hate Speech Classification

Using the generated features a Naive Bayes (NB) classifier and a feedforward neural network model were trained:

- Naive Bayes model: with one-hot n-gram features, we used an NB classifier implemented as a multinomial NB decision rule together with binary-valued features.

- Feedforward neural network : this model was developed with the following layers:
  - Embeddings layer receives the n-grams generated for each input tweet and map their constituent words into their corresponding word dense representations. N-grams are produced by going through the tweet using a sliding window of a fixed size (N) such that each word of the tweet is considered. All the resulting n-grams (shingles) are then fed to the model with supervision information included where each n-gram is associated with 2-dimension labels HS [1,0] or NOT [0,1] that represent the polarity of the tweet from which the n-gram is derived.
  - Lambda layer composes n-gram embeddings by applying SOWE over the word embeddings resulting from the embedding layer.
  - Hidden layer introduces non-linear discriminating features to the model with Relu activation function.
  - Output layer is equipped with a softmax function to induce the estimated probabilities of each n-gram output label (HS/NOT). Considering the whole tweet, HS scores and NOT scores predicted for all n-grams of the tweet are summed, then each of which is divided by the number of n-grams, contained in a tweet, yielding two values for the potential HS and NOT scores of the tweet. The label of the tweet is, thus, decided according to the greater among these two values.

4 Results and Discussion

Having the data preprocessed and hate indicatives specified and tagged in both training and dev/test sets, two HS models were used.

The first model is an NB classifier from NLTK[§] trained with one-hot n-gram features. We generated three n-gram schemes: unigrams (uni), unigrams+bigrams (uni+bi) and unigrams+bigrams+trigrams (uni+bi+tri). NB was first trained using all n-gram features, then by a reduced number of features obtained via term frequency (TF) with two threshold: 2 and 3. Among several runs with various n-gram schemes and TF values, we adopted the best-performing scheme: uni+bi and TF threshold: 2.

The second model combines n-gram embeddings within a feedforward neural network. The window size 8 was, empirically, selected to produce 8-gram embeddings. Similarly, the embeddings dimension value was set to 100. For training, backpropagation algorithm and "Adam" optimizer (Kingma and Ba, 2014) were used.

Table 1 lists the results obtained using Train and Dev sets of English and Spanish tweets where the language, embeddings, average recall, average f-measure and accuracy are referred to as (Lang.), (emb.), (R.), (F1) and (Acc.), respectively.

Considering Table 1, both feature types performed well for HS detection in English. However, n-gram embeddings were better with an F1 of 94% against 87% scored by one-hot n-grams. We can explain that by the ability of n-gram embeddings to capture the semantic word regularities regardless of the local word order; which is appropriate to handle the informal English used on Twitter; where varying word orders can infer the same semantics (Iyyer et al., 2015).

Regarding the Spanish dataset, while the HS classification performances produced by both feature types were quite comparable, one-hot n-grams achieved slightly better results with an F1 77% and accuracy of 78% compared to 72% and 72% scored by n-gram embeddings, respectively. This could be attributed to the differences in vocabulary introduced by the different spoken varieties of Spanish found in the tweets (Maier and Gómez-Rodríguez, 2014). Hence, SOWE may miss the synonymous and semantic relations among such different words having same/close semantics which, in turn, leads to less expressive n-gram embeddings.

Having the best-performing features identified for English and Spanish, we adopted one-hot n-grams for Spanish and n-gram embeddings for English in the official submission. Table 2 lists the official results of Tw-StAR against the top three ranking systems where (L.), (Acc.), (Eng.), (Sp.), (R.) and (F1) refer to language, accuracy, English, Spanish, recall and f-measure, respectively.

Considering Table 1 and Table 2, we observe that Tw-StAR exhibit a robust performance for the Spanish dataset, while the evaluation measures degraded for the English dataset. We believe that, this could be attributed to the lack of homogeneity between the train/dev and test sets of English data.

5 Conclusion

We developed two HS detection models for multilingual tweets. With two feature types used, we investigated how likely n-gram embeddings can rival one-hot n-grams in HS detection. Upon training NB and a feedforward neural net with one-hot n-grams and n-gram embeddings, respectively, n-gram embeddings exhibited a better performance in English while the vocabulary differences in Spanish made n-gram embeddings less expressive. For future work, we aim to target HS in underrepresented languages such as Arabic and Turkish.

Abstract

This paper describes the system developed at the University of Alicante (UA) for the SemEval 2019 Task 5: Multilingual detection of hate speech against immigrants and women in Twitter. The purpose of this work is to build a strong baseline for hate speech detection by means of a traditional machine learning approach with standard textual features, which could serve as a reference to compare with deep learning systems. We participated in both task A (Hate Speech Detection against Immigrants and Women) and task B (Aggressive behavior and Target Classification) for both English and Spanish. Given the text of a tweet, task A consists of detecting hate speech against women or immigrants in the text, whereas task B consists of identifying the target harassed as individual or generic, and to classify hateful tweets as aggressive or not aggressive. Despite its simplicity, our system obtained a remarkable macro-F1 score of 72.5 (sixth highest) and an accuracy of 73.6 (second highest) in Spanish (task A), outperforming more complex neural models from a total of 40 participant systems.

1 Introduction

Due to the massive rise of users in social media, the presence of verbal abuse, hate speech and bully-attitudes has increased over the years. A clear example is Twitter, where users find ways to anonymously harass and offend other individuals or collectives. This is especially troublesome as hate speech and hate crime are strongly related. Therefore, an early detection of hate speech could help prevent the subsequent hate crime. Online platforms like Twitter have been seeking to combat hate speech on their site, but it still requires a lot of manual work because there is not a reliable automatic method that can correctly identify hate speech behaviour. Building such automatic (or semi-automatic) systems is therefore essential to effectively fight this problem.

Hate speech detection is still a challenging task due to a number of reasons. First, hate speech content tends to be ambiguous and context-dependant (Chatzakou et al., 2017). Moreover, hate speech can cross sentence boundaries and be present in sarcastic comments in the same voice as the people that were producing abusive languages. These and other issues for detecting hate speech are discussed in more detail in Nobata et al. (2016).

In order to deal with these issues, over the past few years several techniques to detect hate speech and abusive language online have been proposed.[1] Previous works made use of heterogeneous features such as bag of words, n-grams, punctuation, as well as lexical features and user-related features (Chatzakou et al., 2017). In addition to these features, previous approaches showed the effectiveness of using word embeddings to detect abusive language in social media (Djuric et al., 2015) and exposed how sentiment analysis can also contribute to hate speech and offensive language detection (Nahar et al., 2012).

In this paper we build on these earlier works and propose a comprehensive framework to develop a traditional machine learning-based approach to hate speech detection, with the purpose of serving as a strong baseline for future systems using deep learning techniques. Our framework will be based on a linear classifier with standard textual features. As we will show throughout the paper, n-grams provide a reliable starting point when facing hate speech classification, and the performance can be further improved when combined with word em-

[1]Although related, it is important to distinguish between hate speech and abusive or offensive language. While the former is used to express hatred towards a targeted group based on characteristics such as race, ethnicity, gender, and sexual orientation, the latter can be used in the usual language of some users without being hateful (Davidson et al., 2017).

beddings and sentiment analysis features.

In particular for this work, we focus on hate speech against women and immigrants, following the Task 5 of SemEval 2019 (Basile et al., 2019). Indeed, race and gender hate speech has become an increasingly important issue in social media, as it stands for 50% of the targets of hate speech in Twitter (Silva et al., 2016). Code and pre-trained models are available at `https://github.com/CPerelloC/UA-SemEval`.

2 Hate Speech Detection System

In this section we present our hate speech detection model. The main goal of our model is to identify hate speech given a piece of text, in this case a tweet. A high-level overview of our model is presented in Section 2.1 and the set of features that are used in our model are described in Section 2.2.

2.1 Model

Our model consists of a linear classifier based on Support Vector Machines (SVM), which have proved to provide competitive results in text categorization since their conception (Joachims, 1998). The SVM classifier is trained on tweets containing hate speech annotations. During training, the model is fed with features relevant to hate speech detection. Then, in the test phase the goal of our model is to classify unannotated tweets with the categories learned during the training phase. In the following section we describe the main features used in our SVM classifier.

2.2 Features

For the main task A (hate speech detection), we distinguish three groups of features[2]:

- *Bag-of-n-grams*: Bag-of-n-grams features, which have been already used for hate speech detection (Chatzakou et al., 2017), are often reported to be highly predictive and can be combined with other features to improve performance. We make use of unigrams, bigrams and trigrams, represented in the feature vectors by their frequency in a tweet.

- *Sentiment analysis*: Hate speech and sentiment analysis are closely related, and we can assume that negative sentiment usually pertains to a hate speech message (Schmidt and Wiegand, 2017). To integrate this feature into our model, we simply add the output of a pre-trained sentiment analysis classifier.

- *Word embeddings*: Word embeddings are low-dimensional vector representations of words and are used extensively in natural language processing (Goldberg, 2016). In particular, Bayot and Gonçalves (2016) showed that word embeddings provide a useful generalization signal in text classification when used in a similar setting. In our case, we add the average of the embeddings in a tweet as an additional feature in our SVM classifier.

For task B, we use two simple extra features with specific information about each subtask:

- For *target classification* (individual or group), we use the count of the plural nouns in the tweet as a feature.

- For *aggressive behaviour*, we use the count of the insults in the tweet as a feature. We hypothesize that a high level of insults may involve violent behaviour. To this end, we filter a database from insults collected at `https://hatebase.org/`.

2.3 Feature selection

One of the main issues in text classification is the high dimensionality of the feature space (Yang and Pedersen, 1997). For instance, over 300K and 150K features were initially obtained using the bag-of-n-grams features alone on, respectively, the English and Spanish training sets from Task A (see Section 3.1). Besides the computational cost to train a model with such a large amount of features, an additional issue is the noise that could be introduced by including many irrelevant features. Thus, it is generally desirable to reduce the feature space, without sacrificing classification accuracy.

The feature selection method used in our system is based on word frequency, understanding a word as an n-gram. The system first delimits the n-grams by a frequency number to significantly reduce the feature space before preparing the vectors for the SVM. Then, highly sparse features (i.e. containing zero in more than 99.9% of the samples) are removed.[3]

[2]We use an extra standard feature to these three groups, the *length of the tweet* in words.

[3]This was achieved by leveraging the *VarianceThreshold* tool from *scikit-learn* (Pedregosa et al., 2011): `https://scikit-learn.org/stable/modules/feature_selection.html`

3 Evaluation

In this section we describe the experimental setup (Section 3.1) of our system along with the results obtained (Section 3.2), including a brief analysis of errors detected in the evaluation phase (Section 3.3).

3.1 Experimental setup

In the following we present the datasets considered, details about the text preprocessing and feature selection procedures, the pre-trained models used as part of our model, and how parameter tuning was performed.

Datasets. We used the two datasets made available as part of the SemEval-2019 Task 5 competition: one for English and another for Spanish. The datasets consist of training, development and test splits. For English, the number of tweets for each split is 9100, 1000 and 2971 for training, development and test, respectively. Conversely, the Spanish splits contain 4600, 500 and 1600 tweets.

Preprocessing. Each tweet is tokenized using the *spaCy* NLP library[4]. We experimented with various preprocessing variants and decided to work with raw words as tokens (i.e., without applying lemmatization), removing punctuation and URLs but keeping emojis and stopwords (pronouns and articles can be relevant in the context of hate speech classification).

Feature selection. As explained in Section 2.3, a feature selection procedure is applied on the n-gram features to reduce their noise and size. After the feature selection is performed for the bag-of-n-grams features, the featured space is reduced from 336,669 to 4,605 in English task A, and from 177,003 to 4,217 in Spanish task A.

Pre-trained models. Regarding sentiment analysis, we used as features the polarity [-1.0, 1.0] and the subjectivity [0.0, 1.0] of a tweet according to *TextBlob*[5] (Loria et al., 2014). Note that Textblob is only optimized for English input and was not used for the Spanish tasks. We leave the exploration of Spanish sentiment analysis systems for future work.

As far as word embeddings are concerned, we made use of Spanish and English 100-dimensional FastText word embeddings (Bojanowski et al., 2017) trained on two large Twitter corpus from Spain and United States, respectively (Barbieri et al., 2016).

Parameter tuning. We experimented with several kernels and parameter configurations to train the Support Vector Machines, including polynomial and linear kernels. Since our system is trained with a large amount of features, it is hard to find an optimal parameter configuration for the polynomial kernel. Therefore, we decided to use a linear kernel, as the SVM training was faster and implied tuning less parameters. We fine-tuned the C parameter of the SVM using as validation the development set of the task. This parameter tuning was performed using bag-of-n-grams as features and on the Spanish dataset only. The value of C that achieved the highest accuracy in the development set was $C = 2^{-5}$ for Task A and Task B-target classification, and $C = 3$ for Task B-aggressive behaviour, which were fixed across all experiments.

3.2 Results

In the following we present our results for Task A (Section 3.2.1) and Task B (Section 3.2.2).

3.2.1 Task A

Task A consists of detecting hate speech (HS) against women or immigrants in the text. Systems were evaluated according to standard classification metrics such as accuracy and macro-F1 score.

Table 1 shows our Task A results in the development and evaluation sets comparing different sets of features described in Section 2.2. As can be observed in the table, the highest accuracy and macro-F1-score obtained in the development phase were, respectively, 78.4 and 77.9 using all features (i.e., n-grams, tweet length and word embeddings for Spanish) and 72.8 and 72.0 with n-grams for English (the same features including sentiment analysis in this case). The sentiment analysis feature provided a small improvement when combined with n-grams on the English development set, but had a negligible influence on the test set. In general, except for the word embeddings which seem to generalize better, all features performed close to a random baseline in English. A further analysis should be required to explain

MFC baseline	-	-	*57.9*	*36.7*	-	-	*58.8*	*37.0*

Table 1: Task A results using different sets of features. The row marked with ∗ was submitted to the task.

the difference between development and test results, which affected most participating systems. Some possible explanations are discussed in the Analysis section (Section 3).

Unlike in English, in Spanish our system obtains the best result with the configuration that performed best in the development set. Our official submission (n-grams and tweet length as features) ranked sixth in terms of macro-F1 and second in terms of accuracy among all 40 participating systems. In the English task, with the addition of word embeddings as feature, our system would have ranked third in terms of macro-F1.

3.2.2 Task B

Task B consists of identifying the target harassed as individual or generic (TR), and to classify hateful tweets as aggressive or not aggressive (AG). In addition to the individual macro-F1 scores for these two subtasks (i.e., TR and AG), two global scores based on the average macro-F1 scores and Exact Match Ratio (EMR) (Kazawa et al., 2005) are reported. The EMR score measures the percentage of instances which are correctly labeled in all subtasks, i.e., HS (hate speech), TR (target) and AG (aggressiveness). As previously explained, our official submission consisted of n-grams and sentiment analysis features, with the addition of the two extra features mentioned in Section 2.2: a count of plurals in each tweet for TR and a count of insults for AG.

Table 2 displays the results of our system on Task B. As can be observed, results for TR are better for Spanish than English, which could be attributed to the fact that Spanish uses more plural forms than English. Regarding AG, the reason could be that the insult database was more accurately filtered for Spanish than English. These results, however, show the general trend of participating systems in the task.

Finally, we noted that training only on the portion of tweets where hate speech is present is beneficial. In our official submission we used all tweets for training, irrespective of whether they were hateful or not. Using all tweets for training was clearly adding a lot of noise to the training, and without it, a significant increase in the performance was obtained. Table 3 shows the results using the full training set and the training set including tweets considered as hateful. As an example, in the Spanish test set, the macro-F1-scores using only hateful tweets for training were 92.8 and 87.8, which means an absolute improvement of 16.9 and 14.3 percentage points for target classification and aggressive behaviour, respectively.

3.3 Analysis

When analyzing the errors of our system, we found a number of cases where irony was present. It is worth noting that sometimes hate speech is expressed through irony, and therefore does not imply an aggressive behaviour. Moreover, offensive language does not necessarily imply hate speech, which poses an additional challenge to these systems. Here are some sample tweets of hate speech without aggressive behaviour from the development set:

> "Say it loud, say it clear, illegal #immigrants are not welcome here."

> "Poland: our country is safe because we haven't taken in refugees"

Finally, given the disparity of results between English development and test sets, we analyzed possible causes for this behaviour. In Task A, we obtained the best performance by only using word embeddings. One of the reasons for these results

	F1(HS)	F1(TR)	F1(AG)	F1(avg)	EMR
English Dev	71.8	72.7	60.9	68.5	56.9
English Test	48.0	68.2	54.4	56.8	31.2
Spanish Dev	77.9	80.6	81.6	80.0	68.4
Spanish Test	72.2	75.9	73.5	73.9	62.9

Table 2: Task B results in the development and evaluation phases.

Training	**English Test**		**Spanish Test**	
	F1(TR)	F1(AG)	F1(TR)	F1(AG)
Full	68.2	54.4	75.9	73.5
Only hateful	**88.0**	**70.9**	**92.8**	**87.8**

Table 3: Macro-F1 results in Task B by using different types of training data.

could be that, in the development set 64.8% of the vocabulary of the test set was present in the training set, whereas in the test set only 54.8% of the vocabulary overlapped with the vocabulary of the training set. This reduction in the overlapping vocabulary between training and test handicaps the performance of n-gram based systems, which heavily relies in vocabulary overlap. Word embeddings are less affected by this condition since they can capture synonymy relations and therefore are able to generalize better. This could explain why using word embeddings alone attained the best performance in this experiment, as the n-grams were not helpful.

4 Conclusion and future work

In this paper we described our system presented at SemEval 2019 Task 5. The system follows a traditional machine learning approach based on feature engineering, making use of n-grams, sentiment analysis and word embeddings as its main features. The results obtained show how word embeddings, when combined with n-grams and sentiment analysis, can improve the performance of the system. In Spanish task A, our proposed system obtained a remarkable macro-F1 score of 72.5 (sixth highest) and an accuracy of 73.6 (second highest). In view of these results, we have achieved our objective of building a strong baseline for hate speech detection.

Future directions of this work include incorporating users' features to the model, studying how the pronouns and the context of the tweet may affect hate speech classification, and comparing the resulting system with deep neural network approaches, which have recently gained popularity in text classification tasks.

Acknowledgments

Abstract

In this paper we apply a range of approaches to language modeling — including word-level n-gram and neural language models, and character-level neural language models — to the problem of detecting hate speech and offensive language. Our findings indicate that language models are able to capture knowledge of whether text is hateful or offensive. However, our findings also indicate that more-conventional approaches to text classification often perform similarly or better.

1 Introduction

SemEval 2019 Task 5 focuses on detecting hate speech in social media text, while Task 6 considers identifying offensive language. Despite the differences between hate speech and offensive language, each of these tasks can be viewed as a binary classification problem. In each case, gold-standard training data is provided on which supervised approaches can be trained.

In this paper we consider whether approaches to classification based on language models — including word- and character-level neural language models, as well as more-conventional (word-level) n-gram language models — are able to distinguish between hateful and not hateful, and offensive and not offensive, language. We find that these approaches outperform a most-frequent class baseline, indicating that language models can capture some knowledge of whether text is hateful or offensive. However, for task 5 — for which the testing data was made available for follow up experiments — we also find that more-conventional approaches to supervised classification, such as naive Bayes and fastText (Joulin et al., 2017), often give similar or better results.

2 Related Work

Social media such as Twitter and Facebook are widely used, and hate speech has become prevalent in these platforms. In response to this, a substantial amount of research has recently focused on detecting such disturbing comments.

Prior work on hate speech and offensive language detection has mostly focused on supervised machine learning techniques (Mathur et al., 2018; Davidson et al., 2017). A recent shared task on identifying aggression in social media (Kumar et al., 2018) observed there is no significant difference between the performance of neural networks and linear classifiers. Furthermore, this shared task received just one lexicon-based approach, and its performance was not promising. Moreover, all of these approaches required expensive feature engineering and pre-processing.

Instead of engineering specific features to use in supervised classifiers, we can instead employ language models to model the type of text we want to detect. Language models have previously been applied for the purpose of text classification (e.g., Bai et al., 2004; Howard and Ruder, 2018). Among different types of language models, recurrent neural network (RNN) language models with LSTM and GRU units have shown promising results for sequence modeling (Mikolov et al., 2012). To the best of our knowledge, RNN language models have not been widely used for detecting hate speech or offensive language. The most closely related work is that of Mehdad and Tetreault (2016), which used both word-level and character-level RNNs to detect abusive language. In their experiments, Mehdad and Tetreault found that character-level language models outperformed word-level language models. A further advantage of character-level language models is that they are able to model out-of-vocabulary words (Mikolov et al., 2012).

3 Task 5: HatEval

SemEval 2019 Task 5 includes two sub-tasks: (A) detecting hate speech in English and Spanish tweets, and (B) classifying hate speech tweets as aggressive or not, and as targeting an individual or group. We only consider sub-task A. In Section 3.1, we describe the approaches we considered for this task, and in Section 3.2 we present our results.

3.1 Approaches

3.1.1 Word-level LMs: n-gram and LSTM

For each language, we grouped the training instances based on their gold standard labels — giving us two corpora per language — with one consisting entirely of hateful tweets, and the other consisting of not hateful tweets. For each language, we then trained two language models (LMs), one on the hateful instances, and the other on the non-hateful instances. Given a test instance, we calculate the probability of the tweet under each LM. If the LM that was trained on the hateful text gave a higher probability then we labeled the instance as hateful, otherwise we labeled it as non-hateful. The two word-level LMs that we considered are an n-gram LM and a long short-term memory (LSTM) LM. The n-gram model was a 3-gram model with Kneser-Ney smoothing trained using Kenlm (Heafield et al., 2013) with its default settings. We tuned the parameters for the LSTM model on the English development dataset using grid search. Specifically we considered the following settings for the embedding size (256, 512, 1024), number of hidden units (128, 256, 512), and number of epochs (1,2,3,4,5). The final parameters for the LSTMs used on the test datasets were 1 hidden layer, an embedding size of 1024, 128 hidden units, and they were trained using a batch size of 2 and 1 epoch.

3.1.2 Character-level LM

This approach is the same as the previous word-level LM approach, except that character-level, as opposed to word-level, LMs are trained. We use a publicly available TensorFlow implementation of a character-level RNN language model.[1] The following parameters are used: a two-layer GRU with one-hot character embeddings and a hidden layer size of 64 dimensions. The batch size, learning rate, and dropout are set to 20, 0.002, and 0, respectively. The hidden layer size and unit were tuned on the development data. Specifically we considered hidden layer sizes of 64, 128, and 256, and an LSTM and GRU for the unit. The other parameters are their default settings.

3.1.3 Neural LMs with Class Token

In the previous approaches, two separate LMs are trained — one on the hateful tweets, the other on the non-hateful ones. In contrast, in this approach a single LM is trained.

We append a special token to the end of each tweet in the training data representing its gold standard class. We randomly shuffle the order of the tweets in the training data, and then train a LM model on them. At test time, we feed a tweet (which has not been augmented with a special token indicating its class) to the LM. We then query the LM for the probability of the special tokens representing the hateful and non-hateful classes, and classify the tweet as the class corresponding to the special token with higher probability.

We consider both word-level and character-level neural LMs for this approach. For the word-level LM we again use an LSTM. We performed a grid search to tune its parameters using the English development dataset. Specifically we considered the following settings for the number of layers (1,2), embedding size (128, 256, 512), number of hidden units (128, 256, 512), and number of training epochs (1,2,3). The final model consisted of two hidden layers, an embedding size of 512, 128 hidden units, and was trained using a batch size of two for three epochs. For the character-level LM we use the same model as in Section 3.1.2, with the same parameter settings.

3.1.4 Baselines

In addition to the most-frequent class and SVC baselines provided by the shared task (Basile et al., 2019), we also compare our approaches against multinomial naive Bayes[2] and fastText (Joulin et al., 2017). We use the default settings for fastText, and do not attempt to tune it to this task.

[1]https://github.com/crazydonkey200/tensorflow-char-rnn

[2]Note that the likelihood term in multinomial naive Bayes corresponds to a unigram LM for each class. As such it is similar to the LM-based approaches we consider, but also incorporates a class prior.

	English								Spanish							
	Dev				Test				Dev				Test

Table 1: Macro average F1-score (F), macro average precision (P), macro average recall (R), and accuracy (A) on Task 5 subtask A using word-level n-gram and LSTM LMs, a character-level LM (Char), a word-level LSTM and character-level LM augmented with a special class token (LSTM+CT and Char+CT), multinomial naive Bayes (NB), and fastText on the development and test sets. The SVC and most-frequent class (MFC) baselines provided by the shared task are also shown. The best result for each language, dataset, and evaluation measure is shown in boldface.

3.2 Results

The English and Spanish training sets contain 9,000 and 4,500 tweets, respectively, labelled as being hateful or non-hateful. The development and test sets contain 1,000 and 2,971 tweets, respectively, for English, and 500 and 1,600 tweets, respectively, for Spanish. Further details of the datasets are provided in Basile et al. (2019).

Results are shown in Table 1.[3] The character-level LM, which performed best on the development data, corresponds to our official submission for the shared task. In terms of F-score, for both languages, all LM-based approaches outperform the most-frequent class baseline. This indicates that LMs are able to capture information about whether a tweet is hate speech or not. However, more-conventional approaches to classification perform similarly to, or better than, the LM-based approaches. Focusing on the test data, for English, although the LSTM with class token approach achieves the best F-score of 0.49, fastText achieves only a slightly lower F-score of 0.47. For Spanish, fastText and SVC achieve the best F-score of 0.70, while the best LM-based approaches, the n-gram and character LMs, obtain an F-score of 0.66.

4 Task 6: OffensEval

SemEval 2019 Task 6 includes 3 sub-tasks. In contrast to Task 5, we participated in all subtasks of Task 6. Sub-task A is a binary classification task to determine if a tweet is offensive or non-offensive. Sub-task B is to classify tweets that are offensive into two groups of targeted — a post containing an insult or threat to an individual, a group, or others — or untargeted — a post containing non-targeted profanity and swearing. Finally, sub-task C is a three-way classification task in which targeted tweets (from sub-task B) are classified as targeting an individual, group of people, or other.

Because of the similarities between hate speech and offensive language, we apply approaches that we used for Task 5 to Task 6. We used the development data for Task 5 for model tuning and selection, and only considered the three best models for Task 6: the word-level n-gram and LSTM language models and the character-level language model. We describe these approaches in Section 4.1 and report results over the test data in Section 4.2.[4]

4.1 Approaches

4.1.1 Word-level LMs: n-gram and LSTM

Similar to Task 5, for each sub-task of Task 6, we group the training instances based on their gold-standard classes. We then train one LM on the documents from each class. I.e., in the case of sub-task A we train one LM on tweets labeled offensive, and another LM on tweets labelled non-offensive. At test time we measure the probability

[3]The SVC baseline was only provided for the test data.

[4]We do not report results for the development data because we used Task 5 data for model tuning and selection.

	Sub-task A		Sub-task B		Sub-task C	
Method	F	A	F	A	F	A
n-gram	**0.62**	0.66	0.45	0.50	**0.43**	0.44
LSTM	0.55	0.59	0.54	0.73	0.40	**0.48**
Char	0.59	0.63	**0.61**	0.88	-	-
MFC	0.42	**0.72**	0.47	**0.89**	0.21	0.47

Table 2: Macro-average F1-score (F) and accuracy (A) for each sub-task of Task 6 using word-level n-gram and LSTM LMs, a character-level LM (Char), and a most-frequent class baseline (MFC). The best result for each sub-task and evaluation measure is shown in boldface.

of a test tweet under each LM, and then classify it as the class corresponding to the LM giving the highest probability. Note that sub-task C is a three-way, as opposed to binary, classification task, and so we therefore train three LMs for this sub-task.

We consider the same word-level LMs as for Task 5 — an n-gram LM and an LSTM LM. We tuned the parameters for the LSTM on the English development dataset of Task 5, sub-task A, using grid search as described in Section 3.1.1. We did not further tune this model to Task 6. For the n-gram model we again use a 3-gram model as described in Section 3.1.1.

4.1.2 Character-level LM

We apply character-level LMs to each sub-task of Task 6 in the same manner as we use the word-level LMs described above. We use the same character-level LM as for Task 5, described in Section 3.1.2, with the same parameter settings. We do not attempt to further tune the parameters to Task 6.

4.2 Results

Details of the training and test data can be found in Zampieri et al. (2019). Results for the LM-based approaches described above, as well as a most-frequent class baseline, are presented in Table 2. In terms of F1-score, for each sub-task, each LM-based approach outperforms the most-frequent class baseline, with the exception of the n-gram LM on sub-task B.[5] These results, and in particular those on sub-task A, demonstrate that LMs can capture knowledge about whether text is offensive.

On sub-task A the n-gram LM achieved the best F1-score, while on sub-task B the character-level LM did. One reason for his could be differences in the size of the training data. For sub-task A, we use all of the training data (13,240 instances) to train our models. However, for sub-task B, we are limited to just those tweets that were labeled as offensive. There are only 4,400 such tweets. Although this reduction in the amount of training data caused the F1-score of the word-level LM-based approaches to decrease, the amount of training data seems to still be sufficient to train a character-level LM. The F1-scores on sub-task C are lower than for the other sub-tasks. One possible explanation for this relatively poor performance is that the training data for sub-task C is smaller than that for the other sub-tasks (3,876 instances), because the sub-task C training data is a subset of that for sub-task B.

5 Conclusions

In this paper we employed language models to the problems of detecting hate speech and offensive language in social media text. We considered a range of approaches to language modeling including word-level n-gram and neural language models, and a character-level neural language model. Our results indicated that language model-based approaches are able to capture knowledge of whether text is hateful or offensive. However, further experiments on identifying hate speech indicated that more-conventional approaches to text classification often perform comparably or better.

In this paper we only considered language models trained on the training data provided for the shared tasks. In future work, we intend to consider pre-training language models on other corpora (e.g., Twitter corpora) in an effort to improve the performance of language model-based approaches to detecting hate speech and offensive language.

[5]Due to an error in our submission for the character-level model for sub-task C, we did not receive results for this approach on this sub-task.

Abstract

In this paper we revisit the problem of automatically identifying hate speech in posts from social media. We approach the task using a system based on minimalistic compositional Recurrent Neural Networks (RNN). We tested our approach on the SemEval-2019 Task 5: Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter (HatEval) shared task dataset. The dataset made available by the HatEval organizers contained English and Spanish posts retrieved from Twitter annotated with respect to the presence of hateful content and its target. In this paper we present the results obtained by our system in comparison to the other entries in the shared task. Our system achieved competitive performance ranking 7th in sub-task A out of 62 systems in the English track.

1 Introduction

Abusive and offensive content such as aggression, cyberbulling, and hate speech have become pervasive in social media. The widespread of offensive content in social media is a reason of concern for governments worldwide and technology companies, which have been heavily investing in ways to cope with such content using human moderation of posts, triage of content, deletion of offensive posts, and banning abusive users.

One of the most common and effective strategies to tackle the problem of offensive language online is to train systems capable of recognizing such content. Several studies have been published in the last few years on identifying abusive language (Nobata et al., 2016), cyber aggression (Kumar et al., 2018), cyber bullying (Dadvar et al., 2013), and hate speech (Burnap and Williams, 2015; Davidson et al., 2017). As evidenced in two recent surveys (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018) and in a number of other studies (Malmasi and Zampieri, 2017; Gambäck and Sikdar, 2017; ElSherief et al., 2018; Zhang et al., 2018), the identification of hate speech is the most popular of what Waseem et al. (2017) refers to as "abusive language detection sub-tasks".

This paper deals with the hate speech identification in English and Spanish posts from social media. We present our submissions to the SemEval-2019 Task 5: Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter (HatEval) shared task. We participated in sub-task A which is a binary classification task in which systems are trained to discriminate between posts containing hate speech and posts which do not contain any form of hate speech. Our approach, presented in detail in Section 4, combines compositional Recurrent Neural Networks (RNN) and transfer learning and achieved competitive performance in the shared task.

2 Related Work

As evidenced in the introduction of this paper, there have been a number of studies on automatic hate speech identification published in the last few years. One of the most influential recent papers on hate speech identification is the one by Davidson et al. (2017). In this paper, the authors presented the Hate Speech Detection dataset which contains posts retrieved from social media labeled with three categories: OK (posts not containing profanity or hate speech), Offensive (posts containing swear words and general profanity), and Hate (posts containing hate speech). It has been noted in Davidson et al. (2017), and in other works (Malmasi and Zampieri, 2018), that training models to discriminate between general profanity and hate speech is far from trivial due to, for example, the fact that a significant percentage of hate speech posts contain swear words. It has been argued that annotating texts with respect to the presence of hate speech has an intrinsic degree of subjectivity (Malmasi and Zampieri, 2018).

Along with the recent studies published, there have been a few related shared tasks organized on the topic. These include GermEval (Wiegand et al., 2018) for German, TRAC (Kumar et al., 2018) for English and Hindi, and OffensEval[1] (Zampieri et al., 2019b) for English. The latter is also organized within the scope of SemEval-2019. OffensEval considers offensive language in general whereas HatEval focuses on hate speech.

Waseem et al. (2017) proposes a typology of abusive language detection sub-tasks taking two factors into account: the target of the message and whether the content is explicit or implicit. Considering that hate speech is commonly understood as speech attacking a group based on ethnicity, religion, etc, and that cyber bulling, for example, is understood as an attack towards an individual, the target factor plays an important role in the identification and the definition of hate speech when compared to other forms of abusive content.

The two SemEval-2019 shared tasks, HatEval and OffensEval, both include a sub-task on target identification as discussed in Waseem et al. (2017). HatEval includes the target annotation in its sub-task B with two classes (individual or group) whereas OffensEval includes it in its sub-task C with three classes (individual, group or others). Another important similarity between these two tasks is that both include a more basic binary classification task in sub-task A. In HatEval, posts are labeled as as to whether they contain hate speech or not and in OffensEval, posts are labeled as being offensive or not. As OffensEval considers multiple types of offensive contents, the hierarchical annotation model used to annotate OLID (Zampieri et al., 2019a), the dataset used in OffensEval, includes an annotation level distinguishing between the type of offensive content that posts include with two classes: insults and threats, and general profanity. This type annotation is used in OffensEval's sub-task B.

3 Task Description

HatEval (Basile et al., 2019) provides participants with annotated datasets to create systems capable of properly identifying hate speech in tweets written in both English and Spanish.

The training, development, trial, and test sets provided for English are composed of 9,000, 1,000, 100 and 3,000 instances, respectively. The training, development, trial and test sets provided for Spanish are composed of 4,500, 500, 100 and 1,600 instances, respectively. Each instance is composed of a tweet and three binary labels: One that indicates whether or not hate speech is featured in the tweet, one indicating whether the hate speech targets a group or an individual, and another indicating whether or not the author of the tweet is aggressive. HatEval has 2 sub-tasks:

- **Sub-task A:** Judging whether or not a tweet is hateful.
- **Sub-task B:** Correctly predicting all three of the aforementioned labels.

In this paper, we focus on Task A exclusively, for both English and Spanish. We participated in the competition using the team name UTFPR.

4 The UTFPR Models

The UTFPR models are minimalistic Recurrent Neural Networks (RNNs) that learn compositional numerical representations of words based on the sequence of characters that compose them, then use them to learn a final representation for the sentence being analyzed. These models, of which the architecture is illustrated in Figure 1, are somewhat similar to those of Ling et al. (2015) and Paetzold (2018), who use RNNs to create compositional neural models for different tasks.

As illustrated, the UTFPR models take as input a sentence, split it into words, then split the words into a sequence of characters in order to pass them through a character embedding layer. The character embeddings are passed onto a set of bidirectional RNN layers that produces word representations, then a second set of layers produces a final representation of the sentence. Finally, this representation is passed through a softmax dense layer that produces a final classification label.

For each language, we created two variants of UTFPR: one trained exclusively over the training data provided by the organizers (UTFPR/O), and another that uses a pre-trained set of character-to-word RNN layers extracted from the models introduced by Paetzold (2018) (UTFPR/W). The pre-trained model was trained for the English multi-class classification Emotion Analysis shared task

[1] `https://competitions.codalab.org/competitions/20011`

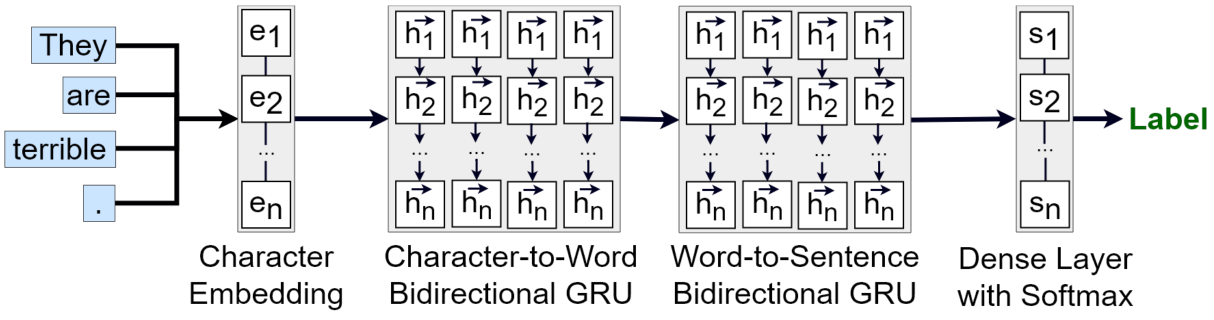

Figure 1: Architecture of the UTFPR models.

of WASSA 2018, which featured a training set of 153,383 instances composed of a tweet and an emotion label. This pre-trained model for English was used for the UTFPR/W variant of both languages, since we wanted to test the hypothesis that pre-training a character-to-word RNN on a large dataset for English can improve the performance of compositional models for both English and Spanish.

We use 25 dimensions for the size of our character embeddings, and two layers of Gated Recurrent Units for our bidirectional RNNs with 60 hidden nodes each and 50% dropout. We saved a model after each training iteration and picked the one with the lowest error on the development set. The UTFPR/W model went through the same training process as UTFPR/O, with the pre-trained character-to-word RNN layers being fine-tuned for the task at hand.

Table 1 showcases the F-scores obtained by the UTFPR systems on the trial set of Task A. Because of its superior performance, we chose to submit the UTFPR/W variants as our official entry.

	F-scores	
System	**English**	**Spanish**
UTFPR/O	0.509	0.601
UTFPR/W	0.570	0.665

Table 1: F-scores obtained for the trial set at HatEval Task A for both languages.

5 Results and Discussion

5.1 Shared Task Performance

Tables 2 and 3 feature the F-scores obtained by the UTFPR systems and the 3 best and worst performing systems at HatEval Task A for English and Spanish, respectively. Ultimately, the UTFPR/W systems submitted ranked 7th out of 62 valid submissions for English, and 31st out of 35 valid submissions for Spanish.

System	F-scores
FERMI	0.650
Panaetius	0.570
YNU_DYX	0.550
UTFPR/O	0.524
UTFPR/W	0.513
MELODI	0.350
INGEOTEC	0.350
INAOE-CIMAT	0.340

Table 2: F-scores obtained at HatEval Task A for the English language. At the top and bottom of the table are featured the top and bottom 3 systems submitted to the shared task, respectively.

System	F-scores
mineriaUNAM	0.730
Atalaya	0.730
MITRE	0.730
UTFPR/O	0.664
UTFPR/W	0.636
jhouston	.630
LU team	0.620
TuEval	0.620

Table 3: F-scores obtained at HatEval Task A for the Spanish language. At the top and bottom of the table are featured the top and bottom 3 systems submitted to the shared task, respectively.

One of the aspects we wanted to test with our participation in this shared task was the extent to which pre-training a character-to-word RNN over a larger dataset for an analogous task helped the models. Our results show that, even though using a pre-trained RNN considerably improved the performance of our models in the trial experiments, it actually compromised their performance for the

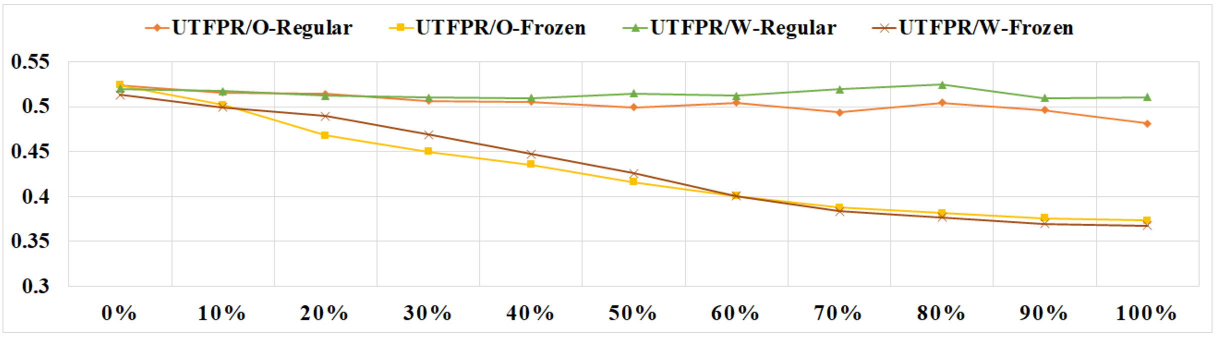

Figure 2: F-scores of our robustness experiments for English. The horizontal axis represents the proportion of noisy words in the input sentence, and the vertical axis the F-scores.

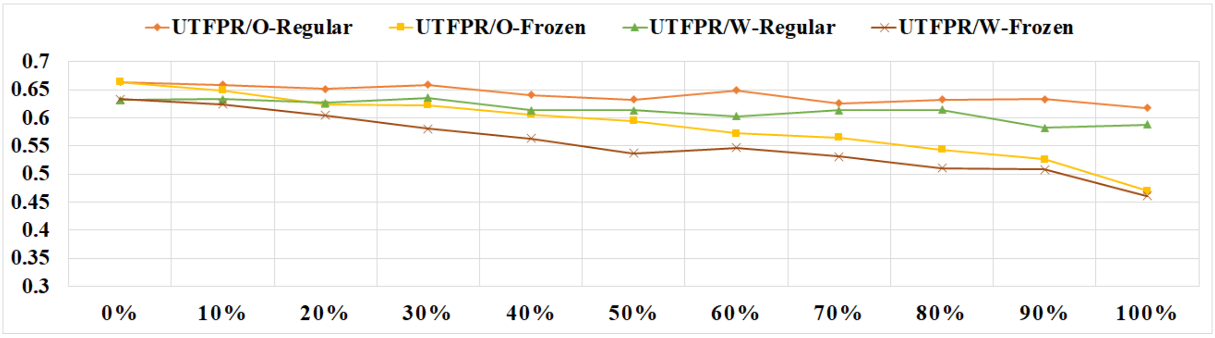

Figure 3: F-scores of our robustness experiments for Spanish. The horizontal axis represents the proportion of noisy words in the input sentence, and the vertical axis the F-scores.

test set a little. We believe that this was caused because the development set was more representative of the trial than the test set. Overall, submitting UTFPR/W instead of UTFPR/O cost us 2 ranks for English and 3 for Spanish.

5.2 Robustness Assessment

In order to test the robustness of the UTFPR systems, we had to generate different noisy versions of the test set with increasing volumes of noise artificially added to them.

To do so, we introduced a modification to $N\%$ of randomly selected words in each sentence in the datasets. The modifications could be either the deletion of a randomly selected character (50% chance) or its duplication (50% chance). We used $0 \leq N \leq 100$ in intervals of 10, resulting in a total of 11 increasingly noisy versions. The next step was to create "frozen" versions of the UTFPR models that act as if any word out of the training set's vocabulary is unknown. If a word of the test set is not present in the vocabulary of the training set, it produces a numerical vector full of 1's that represents an out-of-vocabulary word.

Figures 2 and 3 show the results obtained for English and Spanish, respectively. As it can be noticed, our compositional models are much more robust than the frozen alternatives, suffering very faint losses in F-score even when 100% of the words in the input sentence are noisy.

6 Conclusions

In this contribution, we presented the UTFPR systems submitted to the HatEval 2019 shared task. The systems are based on compositional RNN models trained exclusively over the training data provided by the organizers. We introduced two variants of our models: one trained entirely on the shared task's data (UTFPR/O), and another with a set of pre-trained character-to-word RNN layers fine-tuned to the task at hand (UTFPR/W). Our results show that, despite its simplicity, the UTFPR/O model attained competitive results for English, placing it 7th out of 62 submissions. Furthermore, the results of this shared task indicate that our models are very robust, being able to handle even substantially noisy inputs. In the future, we intend to test more reliable ways of re-using pre-trained compositional models.

Acknowledgements

We would like to thank the organizers of the HatEval shared task for providing participants with this dataset and for organizing this interesting shared task. We gratefully acknowledge the support of NVIDIA Corporation with the donation of the Titan V GPU used for this research.

Computer Science Department, University of Évora, Portugal
`(kshyp,tcg,pq,vbn)@uevora.pt`

Abstract

This paper shares insight from participating in SemEval-2019 Task 5. The main propose of this system-description paper is to facilitate the reader with replicability and to provide insightful analysis of the developed system. Here in Vista.ue, we proposed a single multilingual hate speech detection model. This model was ranked 46/70 for English Task A and 31/43 for English Task B. Vista.ue was able to rank 38/41 for Spanish Task A and 22/25 for Spanish Task B.

1 Introduction

According to the article (Bosco et al., 2017), nearly a quarter of a billion people, throughout the world, currently live in a country other than their place of birth. This is an increase of 41% from 2000 to 2015. This figure includes more than 21 million refugees often vulnerable and dissatisfied. Since 2015, Europe is facing an unprecedented refugee crisis, the by-effect of the Syrian civil war and the terrible living conditions in equatorial Africa. 1,300,000 people have generated this increased migration flow to Europe which can only but increase, putting European stable societies, so far, under pressure.

Therefore, the implications for the European society and the way we behave towards immigration, immigrant integration and social inclusion for newcomers and their children, are becoming more decisive and must be addressed either at a local or global level, considering a political and social perspective. While this phenomenon stimulates the generation and diffusion of hate speech and hate crimes, at the same time several initiatives are promoted, but they should be further improved to increase the awareness and empathy of receiving populations while avoiding polarization against immigrants.

Hate speech analysis and hate maps allow both a greater understanding of social phenomena linked to the integration of migrants, that more targeted actions to improve it. The integration of migrants is strongly linked to the new cultural context where they try to rebuild their lives. The process of acculturation depends on personal and social variables of the migrant, in large part in turn dependent on the cultural context of his/her origin, on the characteristics of the context of resettlement and on events occurring during this life period. The different migrants strategies firstly affect the different outcomes achieved. In particular, he can decide whether or not to maintain the cultural identity of origin and whether or not to establish and maintain new relationships within the new contest. This gives rise to four possible different outcomes: integration, assimilation, separation/segregation, marginalization (Berry, 1997).

1.1 Motivation

Data released by European Community about population change (Union, 2015) show that from the 1990s onwards natural population change had a diminishing role in EU demographic developments, while the role of net migration became increasingly important. In the period 2011 to 2013, net migration contributed more than 80% to total population growth, drawing an overall pattern of growth of EUs populations driven increasingly by changes in migratory flows, which hides a range of demographic situations among the EU Member States. Between 2004 and 2013, indeed the population of 11 EU Member States decreased, with the biggest reductions recorded in Germany and Romania, but a high overall increase in population numbers was recorded in the other countries like UK (a gain of 4.51 million inhabitants), Spain (3.96 million), France (3.54 million) and Italy (3.29 million). Among these countries, characterized by a negative natural population change, also compounded by negative net migration, Italy is affected by a negative natural change, that was completely offset by net migration which accounted for 108% of the total population change.

As a part of the motivation, we participated in the shared task named ”SemEval-2019 Task 5: Multilingual Detection of Hate Speech Against Immigrants and Women in Twitter”. Section 2 outlines the existing approaches in a systematic manner and the description of the task mentioned in Section 3. Paper also provides a short, comprehensive and structured overview of automatic hate speech detection in Section 4 followed my result comparison and conclusion in Section 5 and 6 respectively.

2 Related Work

For any text classification task, the most obvious information to utilize is surface-level features, such as a bag of words. Indeed, unigrams and larger n-grams are included in the feature sets by a majority of authors (Chen et al., 2012; Sood et al., 2012; Xu et al., 2012; Warner and Hirschberg, 2012; Van Hee et al., 2015). These features are often reported to be highly predictive. Still, in many works, n-gram features are combined with a large selection of other features. For example, in their recent work, (Nobata et al., 2016) report that while token and character n-gram features are the most predictive single features in their experiments, combining them with all additional features further improves performance.

Character level n-gram features might provide a way to attenuate the spelling variation problem often faced when working with user-generated comment text. For instance, the phrase ”ki11 yrslef a$$hole”, which is regarded as an example of hate speech, will most likely pose problems to token based approaches since the unusual spelling variations will result in very rare or even unknown tokens in the training data. While using Character level approaches, on the other hand, are more likely to capture the similarity to the canonical spelling of these tokens. Author (Mehdad and Tetreault, 2016) systematically compare character n-gram features with token n-grams for hate speech detection and found that character n-grams prove to be more predictive than token n-grams.

Apart from word and character based features, hate speech detection can also benefit from other surface features (Chen et al., 2012; Nobata et al., 2016), such as information on the frequency of URL mentions and punctuation, comment and token lengths, capitalization, words that cannot be found in English dictionaries, and the number of non-alpha numeric characters present in tokens.

Hate speech and sentiment analysis are closely related, and it is safe to assume that usually, negative sentiment pertains to a hate speech message. Because of this, several approaches acknowledge the relatedness of hate speech and sentiment analysis by incorporating the latter as an auxiliary classification. Author (Dinakar et al., 2012; Sood et al., 2012; Njagi et al., 2015) followed a multistep approach in which a classifier dedicated to detect negative polarity is applied prior to the classifier specifically checking for evidence of hate speech. Further, (Njagi et al., 2015) run an additional classifier that weeds out non-subjective sentences prior to the aforementioned polarity classification.

3 Task Description and Dataset

The main task (Basile et al., 2019) was to detect Hate Speech in Twitter toward two different targets, immigrants and women. The data were available in a multilingual perspective, English, and Spanish.

3.1 Task Description

The task was partition into two groups: Task A and Task B. Making a total of four subtasks (English/Spanish task A/B).

TASK A - Hate Speech(HS) Detection against Immigrants and Women: a two-class (or binary) classification where systems have to predict whether a tweet in English or in Spanish with a given target (women or immigrants) is hateful or not hateful.

TASK B - Aggressive behavior(AG) and Target Classification(TR): where systems are asked first to classify hateful tweets for English and Spanish (e.g., tweets, where Hate Speech against women or immigrants has been identified,) as aggressive or not aggressive, and second to identify the target harassed as individual or generic (i.e. single human or group).

A binary value (1/0) indicating if HS is occurring against one of the given targets (women or immigrants). If HS occurs (i.e. the value for the feature at point HS is 1), a binary value indicating if the target is a generic group of people (0) or a specific individual (1) denoted as TR. And if HS occurs (i.e. the value for the feature at point HS is 1), a binary value indicating if the tweeter is aggressive (1) or not (0) denoted as AG. Thus, making 3 columns (named HS, TR and, AG) for each tweet.

3.2 Dataset

As per detail provided by the organizing committee, all data for the competition were collected from Twitter and manually annotated mainly via the "Figur8 crowdsourcing platform". The Table 1 describes the distribution of the dataset.

Language	Task	Train	Dev	Test
English	A	9000	1000	3000
English	B	9000	1000	3000
Spanish	A	5000	500	1600
Spanish	B	5000	500	1600

Table 1: Task Dataset Distribution.

The Table 2 and 3 describes the Hate Speech Tweet data distribution/property over training and development dataset.

Task	Non-HS	HS
EN-A	5790	4210
EN-B	5790	1463 (TR=AG=0)
ES-A	2921	2579
ES-B	2921	315 (TR=AG=0)

Table 2: Task A/B Data Property of Non-HS/HS.

Lan	TR(AG=0)	AG(TR=0)	AG=TR=1
EN	984	1187	576
ES	86	498	1180

Table 3: Task B Data Property (HS=1).

4 System Description

This section will talk about the preprocessing of the data, the experimental setup, and the multilingual system architecture.

4.1 Tweet Preprocessing

Here, for EN/ES tweets, we are only removing "url" from each tweet. This is done with the help of regular expression.

```
r"http\S+", "url", tweet
```

4.2 Experimental Setup

Here, a common architecture is used for all the four subtasks. The only difference is the hyper-parameter. The Table 4 shows the experimental parameter values.

Task	Paramter	Value
EN/ES - A/B	batch_size	1
EN/ES - A/B	epochs	2
EN/ES - A/B	optimizer	Adam
EN/ES - A/B	validation_split	0.20

Table 4: Experimental Parameter.

4.3 Single Multilingual System Architecture

Author (Raiyani et al., 2018) have used simple feedforward dense architecture and able to achieve beyond the average result for finding aggression over social media (Facebook and Twitter). In particular, their model was able to stand the best performing model for English Tweets. Using a similar architectural concept, here, we are using a character-based dictionary. First of all, all the unique characters from the dataset are stored in the form of a dictionary. Then, using this dictionary, each character in the dataset are replaced by its key value. Thus, this transforms the dataset into an integer from the text. Finally, this integer data is further transformed into a binary array and fed to the Dense architecture. The Figure 1 shows the flowchart of system process. Where as the Figure 2 shows the Dense Architecture.

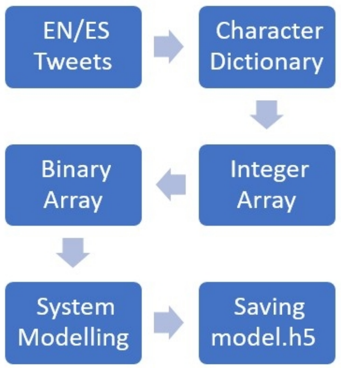

Figure 1: System Flowchart.

To store the intermediate character into the dictionary, pika library[1] was used. The number of unique characters found for English and Spanish

[1] https://pika.readthedocs.io/en/stable/

is respectively 169 and 172 (this also includes all the special character and emojis).

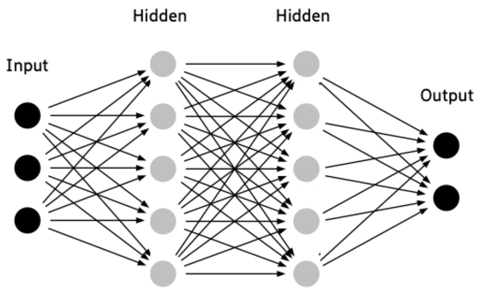

Figure 2: Feedforward Dense Architecture.

The architectural hyper parameter were selected based on trail and run. The same can be found in the Table 5 . The code of the entire task could be found in the online GitHub repository (Raiyani, 2019).

Task	Dense	Value	Activation
EN-A/B	layer 1	100	Relu
EN-A	layer 2	200	Sigmoid
EN-B	layer 2	200	Relu
ES-A/B	layer 1/2	50	Relu
EN/ES-A/B	layer 3	2	Softmax

Table 5: Architecture Parameter.

In the next section we will talk about the system performance and its global standing in the task.

5 Result Comparison and Discussion

The Table 6 shows the English task A average precision, recall, and F1 measure in reference to the baseline (SVC and MFC). The same for Spanish task A is found in the Table 7. The Table 8 shows the F1 measure over all the three parameter (namely, Hate Speech (HS), Target Classification(TR), and Aggressive(AG)). The ranking of task B is done using the value of Exact Match Ratio(EMR) (the evaluation formula could be found here[2]). The Table 9 shows the EMR value in reference to the baseline SVC and MFC.

The provided final ranking among all the subtasks are shown in Table 10.

6 Conclusion and Future Work

In this system description paper, we presented a single multilingual model for hate speech detection among immigrant and women. Through the

Table 10: System Ranking.

system ranking, we can see that for task A of both the languages, the system is performing better than MFC baseline where on task B results could be improved. Further, We consider that our system can be grown, mainly due to the following facts: (1) The system does not count any NLP feature into account (2) Due to this, many hate tweets are missed. (3) Especially, for task B, features like Part of Speech (POS) tagging and Entity Extraction (EE) can improve the result. Lastly, how to address these aspects and generate a more accurate, comprehensive and fine-grained hate speech detection remains our further work.

Acknowledgments

The authors would like to thank COMPETE 2020, PORTUGAL 2020 Programs, the European Union, and ALENTEJO 2020 for supporting this research as part of Agatha Project SI & IDT number 18022 (Intelligent analysis system of open of sources information for surveillance/crime control).

YNU NLP at SemEval-2019 Task 5: Attention and Capsule Ensemble for Identifying Hate Speech

Bin Wang, Haiyan Ding[*]
School of Information Science and Engineering
Yunnan University, Yunnan, P.R. China
hyding@ynu.edu.cn

Abstract

This paper describes the system submitted to SemEval 2019 Task 5: Multilingual detection of hate speech against immigrants and women in Twitter (hatEval). Its main purpose is to conduct hate speech detection on Twitter, which mainly includes two specific different targets, immigrants and women. We participate in both subtask A and subtask B for English. In order to address this task, we develope an ensemble of an attention-LSTM model based on HAN and a BiGRU-capsule model. Both models use fastText pre-trained embeddings, and we use this model in both subtasks. In comparison to other participating teams, our system is ranked 16th in the Subtask A for English, and 12th in the Subtask B for English.

1 Introduction

In recent years, the popularity of social networking and microblogging sites has increased, attracting more and more users. With this huge user base, social media will continue to release a large number of user-generated content. As the use of social media has grown, other undesirable phenomena and behaviors have emerged. Social media users often abuse this freedom to spread abuse or hateful posts or comments. In many cases, these user-generated content is inherently offensive or proactive, and users may have to deal with threats such as cyber attacks or cyberbullying, as well as other undesirable phenomena (Whittaker and Kowalski, 2015). So the problem of detecting and possibly limiting the spread of hate speech is becoming more and more important.

In order to solve the problem of abuse of language in social media platforms, some related research has been published, such as cyberbullying (Dadvar et al., 2013), hate speech (Warner and Hirschberg, 2012) and abusive language (Chen et al., 2012), most methods are based on surveillance methods (Schmidt and Wiegand, 2017). There are also some (racial discrimination) bias towards specific goals. In (Waseem and Hovy, 2016), the authors proposed a series of criteria based on critical race theory to identify racism and gender discrimination, they use n-gram models for research; Tulkens et al. studied racism detection in Dutch social media (Tulkens et al., 2016). A recent discussion of the challenge of identifying hate speech was proposed by Kumar et al. (Kumar et al., 2018). The results show that it is difficult to distinguish between open and covert attacks in social media.

SemEval 2019 Task 5 is proposed to identify hate speech about immigrants and women in Twitter for English or Spanish, and classify hate speech and judge whether the target is an individual or a group (Basile et al., 2019). Hate speech is often defined as any communication that attacks an individual or group through certain characteristics (such as gender, nationality, religion, or other characteristics) in social media platforms. This task gives us some text data from Twitter, we need to classify the content through computational analysis. The task has two subtasks, in which Subtask A is Hate speech detection for immigrants and women: It's a binary classification task, the system must judge whether a tweet with a specific goal (female or immigrant) in English or Spanish is hate speech; Subtask B is Aggressive behavior and target classification: This subtask is to classify the identified hate speech based on Subtask A, to judge whether it is aggressive or non-aggressive, and then to identify the target being harassed as an individual or group.

In this paper, we developped a system stacked two different neural network models: an attention-based model with LSTMs and an Capsule-based model with BiGRUs. We make some changes to

[*]Corresponding author

Hierarchical Attention Network to make it more suitable for this task, the detailed description of the Attention-LSTM model is provided in Section 2.2. Next, we build a BiGRU-Capsule model using the latest "Capsule" model proposed by (Sabour et al., 2017), the detailed description is provided in Section 2.3. In Section 2.4, we describe the use of stacking as ensemble. In Section 3.1, some details about data preprocessing for this task are described. In Section 3.2 and Section 3.3, the hyper-parameter setting and result analysis used in the whole experiment are introduced in detail.

2 Data and System Description

2.1 Data description

In this task, we only use the official training data set for training and trial data set to verify. In Subtask A, the purpose is to distinguish whether the tweet is hate speech, the data is divided into two categories(HS): 0 means non-hate speech, and conversely, 1 is hate speech. Similarly, in Subtask B, 0 is indicative of aggressiveness in categorizing hate speech(TR), 1 is non-aggressive, and in the goal of judging hate speech(AG), 0 means individual and 1 means group. In this task, we only participate in Subtask A and Subtask B in English. There are 9000 tweets in training data set, 1000 tweets in development data set, and 2971 tweets in final test data set. In the training data set, there are 5,217 labels are 0s and 3,783 labels are 1s in the label HS; in the label TR, 7659 labels are 0s and 1341 labels are 1s; and in the label AG 7440 labels are marked as 0s, 1560 are marked as 1s. Although the data of the label TR and the label AG are very unbalanced, since the ratio of 0 and 1 in the label HS is close to balance, we have not dealt with the data imbalance in this task.

2.2 Attention-LSTM Model

Here we have made some changes to HAN (Yang et al., 2017). The overall structure is shown in Figure 1. The replacement of BiGRU with LSTM (Hochreiter and Schmidhuber, 1997) is found to be significantly better than the original model for this task. The architecture of Attention-LSTM model is shown in Figure 1.

We use an LSTM to encode the sentences and to get annotations of words by summarizing information for word.

Not all words contribute equally to the expression of the emotion in the sentence. Emotion

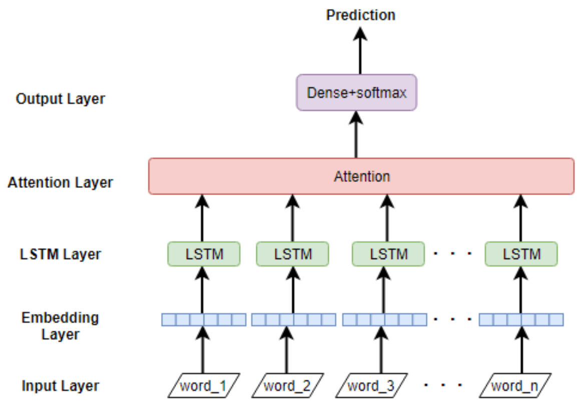

Figure 1: The architecture of Attention-LSTM Model.

greatly influences whether the sentence is hate speech, and also is helpful in identifying hate categories. There may be only a few words in a sentence that are crucial for the judgment of the goal of hate speech. So here we introduce the attention mechanism so that the system can better focus on words that are useful to identify hate speech, then it extracts those words and aggregates the representation of those important words to form a sentence vector.

First, we feed the word annotation h_i, and through a one-layer MLP to get a deeper representation u_i.

$$u_i = \tanh(W_s * h_i + b_s) \tag{1}$$

Then, we compute the similarity between u_i and word-level context vector u_s, and obtain a normalized weight α_i of importance by softmax function.

$$\alpha_i = \frac{exp(u_i^T * u_s)}{\sum_i exp(u_i^T * u_s)} \tag{2}$$

Finally, we compute the sentence vector s by a weighted sum of the word annotations h_i based on the normalized importance weights. s summarizes all the information of words in a context.

$$s = \sum_i \alpha_i * h_i \tag{3}$$

2.3 BiGRU-Capsule model

In order to improve the performance, in this system we use BiGRU and the latest capsule model (Sabour et al., 2017). The architecture of BiGRU-Capsule model is shown in Figure 2.

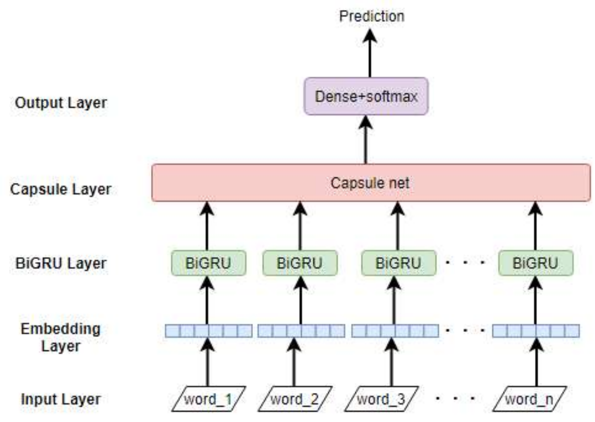

Figure 2: The architecture of BiGRU-Capsule Model.

First, we use the BiGRU layer to encode the sentences. As a variant of LSTM, GRU combines the Forget Gate and the Input Gate into a single Update Gate.

The bidirectional GRU is composed of two GRUs stacked one on top of the other. The output is determined by the state of the two GRUs.

In the capsule layer, the feature output by the previous BiGRU layer as an input to feed to the capsule network, to obtain deeper feature information. Capsule network was proposed by (Sabour et al., 2017), the main idea is to use neuron vectors instead of single neuron nodes of traditional neural networks, and finally train this new neural network by means of Dynamic Routing.

First, the "prediction vectors" $\widehat{u}_{j|i}$ are obtained by multiplying the output u_i of each capsule by a weight matrix W_{ij}.

$$\widehat{u}_{j|i} = W_{ij} * u_i \tag{4}$$

Then, all the "prediction vectors" are weighted summed to obtain the capsule s_j

$$s_j = \sum_i c_{ij} * \widehat{u}_{j|i} \tag{5}$$

where c_{ij} is the coupling coefficient between the capsules determined by "routing softmax", and the sum of the coupling coefficient of all the capsule is 1 in the layer.

Finally, we use the nonlinear "squashing" function to compress the length of the output vector of capsule between 0 and 1.

$$v_i = \frac{||s_j||^2}{1 + ||s_j||^2} \frac{s_j}{||s_j||} \tag{6}$$

where v_j is the output vector of capsule j.

2.4 Ensemble

Ensembling of several models is a widely used method to improve the performance of the overall system by combining predictions of several classifiers (Hansen and Salamon, 2002). A combination of all features leads to the best performance, they provide complementary information. Several ensembling techniques have been proposed recently: mixing experts (Jordan and Jacobs, 1991), model Stacking (Wolpert, 1992), Bagging and Boosting (Breiman, 1999) . We use Stacking in this task. The main reason is that other methods are relatively simple and may have large learning errors. Stacking is like an upgraded version of Bagging. The second layer of learning in Stacking is to find the right weight or the right combination.

The Stacking algorithm is divided into two layers. The first layer uses different algorithms to form n weak classifiers, and simultaneously generates a new data set of the same size as the original data set. This new data set and a new algorithm form the second layer classifier.

When using the Stacking strategy, we do not execute a simple logical processing of the weak learner, but add a layer of learner, that is, we will use the learning result of the Attention-LSTM model and the BiGRU-Capsule model as input, building an MLP model as second layer classifier, the MLP model has only one hidden layer, there are 200 hidden nodes in the layer, and a Dense layer as the output of the ensemble. The architecture of the ensemble model is shown in Figure 3.

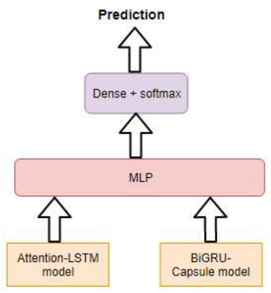

Figure 3: The architecture of the ensemble Model.

3 Experinment and Result analysis

3.1 Data Processing

The official data set is very noisy and needs to be cleaned. Preprocessing the text makes it easy for the model to extract features and representations. We perform the following preprocessing.

- Hashtags are important markers for determining sentiment or user intention. The "#" symbol is removed and the word itself is retained. e.g.: in the sentence, "#BuildTheWall and #BuildThatWall" are marked as 1 in most cases in the training data set.
- Username mentions, e.g.: words starting with "@", generally provide no information in terms of sentiment. Hence such terms are removed completely from the tweets.
- Repeated full stops, question marks and exclamation marks are replaced with a single instance with a special token "repeat" added.
- All contractions are split into two tokens by using regular expression (e.g.: "it's" is changed to "it" and "is").
- All URLs, phone numbers and date numbers are replaced respectively as "URL", "PHONENUMBER", "NUMBER".
- Emoticons (such as, ':(', ':)', ':P' and emoji etc.) are replaced as their own meanings by emotion lexicons[1].
- Tokens are converted to lower case.

3.2 Hyperparameter setting

We select the longest sentence in all cleaned data as the maximum sentence length, which is 58 characters. The processed text is then converted to word embeddings. Converting text into word embeddings represents each word of the text with a d dimensional vector (Mikolov et al., 2013). We use available pre-trained embeddings which are trained on large data set.

In the attention-LSTM model, there is mainly one LSTM layer and one attention layer. There are 300 hidden nodes in the LSTM layer. We also use the Dropout layer with rate 0.25 between the LSTM layer and the Attention layer. The purpose is to prevent over-fitting. Finally, we also use Batch normalization with a size of 0.1 behind the Attention layer, this layer is normalized for each neuron, even only need to normalize a certain neuron, rather than normalize a whole layer of neurons. The purpose is to make the model training converge faster, and the distribution of model hidden output features is more stable, which is more conducive to model learning.

In the capsule model, we build two layers of BiGRU and one layer of Capsule. In the capsule layer, our routing size is set to 5, the number of capsules is set to 10, and the size of the capsule is set to 16. For BiGRU, we set the hidden unit to 128, and a Dropout layer with size 0.25 is added between the BiGRU layer and the Capsule layer to prevent overfitting. Finally, in all models, the loss function is $binary\ crossentropy$, and the optimizer is $adam$ (Kingma and Ba, 2014).

3.3 Result analysis

For this task, we select fastText (Joulin et al., 2017), because in this task we find that the result of fastText is much better than other word vectors such as Word2vec and Glove. Table 1 is the result of different word vectors as embedding.

Word Vector	**Dim**	**macro-F1 Result**
Word2vec	300d	0.746
Glove-twitter	200d	0.763
BPEmb	300d	0.732
fastText	**300d**	**0.761**

Table 1: The result of different word vectors as embedding in the attention-LSTM model for development data set in Subtask A.

We think that the reason why fastText works better than others is that Word2vec treats each word in the corpus as an atom, and it generates a vector for each word, which ignores the internal morphological features of the word, such as: "apple" and "apples", but fastText overcomes this problem by using character-level n-grams to represent a word; fastText may have a higher dimension than Glove-twitter, indicating more features; BPemb is based on Byte-Pair Encoding, the effect of fastText is obviously better than it.

Here we compare the effects of BiGRU, LSTM and BiLSTM and find that LSTM is superior to BiGRU and BiLSTM in this model, and the results are shown in Table 2.

We compare the results achieved by our individual approaches with the submitted ensemble system in Table 3. For brevity, we only show the macro-F1 scores on the development set.

The results of our test data set and the top three results of the official rankings are shown in Table

[1]https://emojipedia.org/

Model	macro-F1 Result
Attention-BiGRU	0.751
Attention-BiLSTM	0.742
Attention-LSTM	**0.761**

4 Conclusion

In this paper, we propose a deep learning framework to classify hate speech about immigrants and women in tweets for English. The proposed approach is based on an ensemble of attention and capsule, allowing us to explore the different directions of a neural network based methodology. Each individual approach is described in detail with a view of making our experiments replicable.

In the future, we would like to experiment with handcrafted features in addition to word-vectors and lexicon features. We would also experiment with AffectiveTweets package (Mohammad and Bravo-Marquez, 2017) such as TweetToSentiStrengthFeatureVector, TweetNLPTokenizer etc., and try to extract the NER feature to further improve the model performance.

Abstract

This paper describes our system designed for SemEval 2019 Task 5 "Shared Task on Multilingual Detection of Hate". We only participate in subtask-A in English. To address this task, we present a stacked BiGRU model based on a capsule network system. In order to convert the tweets into corresponding vector representations and input them into the neural network, we use the fastText tools to get word representations. Then, the sentence representation is enriched by stacked Bidirectional Gated Recurrent Units (BiGRUs) and used as the input of capsule network. Our system achieves an average F_1-score of 0.546 and ranks 3rd in the subtask-A in English.

1 Introduction

Hate speech is an offensive language, a statement that a person or group attacks another person or group based on characteristics such as gender, race, religion, disability, or sexual orientation. Nockleby (Nockleby, 2000) defines hate speech as "any communication that disparages a person or a group on the basis of some characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, religion, or other characteristic." Given the huge amount of user-generated content on the Web, and in particular on social media, the problem of detecting, and therefore possibly limit the Hate Speech diffusion, is becoming fundamental, for instance for fighting against misogyny and xenophobia (Basile et al., 2019).

Microblog today has become a very popular communication tool among Internet users. Millions of users share opinions on different aspects of life everyday. And Twitter[1] is a social platform that is very popular all over the word and millions of people share their experiences, moods, attitudes toward life and discuss current issues (Pak and Paroubek, 2010). Many of the content is related to people's feelings, so many people begin to conduct emotional analysis and research on tweets. SemEval 2019 Task 5 is to detect hate speech on tweets. Task A is a binary classification task that predicts whether English or Spanish tweets for specific goals (women or immigrants) are hateful or not hateful (Basile et al., 2019). There are many studies that currently use tweets as a corpus for natural language processing (NLP). Text classification using traditional machine learning methods mainly includes Support Vector Machines (SVMs) (Gunn et al., 1998), Naive Bayes (McCallum et al., 1998) and Random Forests (Cutler et al., 2007), etc. In recent years, the use of deep neural networks for NLP has become mainstream, such as Convolutional Neural Networks (CNNs) for sentence classification (Kim, 2014) and Recurrent Neural Networks (RNNs) (Graves et al., 2013).

This task aims to predict whether the tweet for each ID is a hate speech about women or immigrants. Our system implements a stacked Bidirectional Gated Recurrent Units (BiGRUs) (Cho et al., 2014) based on a capsule network. The vector representations of words are obtained with fastTex. The result of the classification is through the output of a fully connected layer. The rest of this paper is organized as follows: Data Processing and analysis are discussed in section 2. Section 3 provides the details of the proposed model. Experiments and results are described in Section 4. Finally, we draw conclusions in Section 5.

2 Data Processing

This part describes the experimental data and data processing analysis of SemEval 2019 Task 5 subtask-A in English.

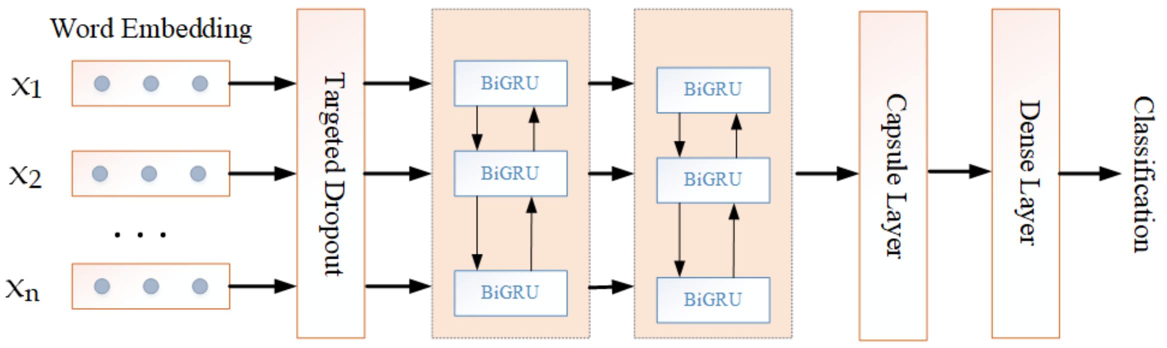

Figure 1: Neural architecture of stacked BiGRU with capsule network.

2.1 Experimental Data

This is a binary classification task of hate speech about immigrants or women. The task organizers provide training sets, development sets and test sets, respectively. Table 1 shows the data distribution of hate speech and non-hate speech in each data set. From Table 1, we can find that there are 9,000 tweets in training set, 1,000 tweets in development set and 2,971 tweets in test set.

data	hate speech	non-hate speech
training set	3,783	5,217
dev set	427	573
test set	1,252	1,719

Table 1: Distribution of labels in each datasets.

2.2 Processing Data

We perform a series of standard processing on datasets.

- All punctuation marks are removed.
- All characters are converted to lowercase.
- All hyperlinks are replaced by "url".
- All sentences are tokenized by Natural Language Toolkit (NLTK) (Bird et al., 2009).
- All numbers are replaced by "number"
- All contractions are normalized, like place "shouldn't" with "should not" and "dosen't" with "does not" and so on.
- All @specific user names are replaced with usernames, for example "@PdxPatriot1" is replaced with "username".

We consider the specific length of the sentence in the input model. If it is too long, the calculation time of the training model will increase. If it is too short, it will lose extra information. So we choose twice the average value, which is 45, as the final length of the sentence in the input model, so that the lost information will not be too much, and the calculation time will not be too long. In the training set, the development set and the test set have 473, 122, and 102 sentences respectively longer than 45, and the maximum sentence length is 65.

3 System Description

Our system can be roughly divided into two parts: the space vector representation of the words and the learning of the tweet content by the capsule network. We first map the words into a low-dimensional space vector, then feed the sentence vectors composed of these word vectors into a capsule network to learn the sentence features, and finally classify the text of the test set by a softmax function.

3.1 Word Representation

Representing a word by using a low-dimensional vector is currently the most common method in natural language processing. The fastText (Joulin et al., 2017) tool is used in our system to get the word representation of the sentences. A low-dimensional vector in fastText is associated with each word, and hidden representations can be shared between different classes of classifiers so that textual information can be used together in different classes. So fastText is a very efficient, word-based vectorization model for text classification. The pre-trained fastText embedding is used in our system[2].

3.2 Model Description

In order to enrich the word vector representation in the text, we use a stacked Bidirectional Gated Recurrent Units (BiGRUs) (Cho et al., 2014). The output of BiGRU is then used as the input to the capsule network (Sabour et al., 2017). The final result is obtained by the $softmax$ activation function in the fully connected layer. The model architecture is show in Figure 1.

Targeted Dropout Layer: *Dropout* regularization only activates some local neurons in each forward propagation, so it adds sparsity properties during training. This encourages the neural network to learn a representation that is robust to sparsification, that is, to randomly delete a set of neurons. *Targeted Dropout* (Gomez et al., 2018) sorts weights or neurons based on some measure of fast approximation weight importance and applies *Dropout* to those elements of lower importance. This approach encourages neural networks to learn more important weights or neurons. In other words, the network learns to be robust to our choice of post hoc pruning strategy. At the same time it is easy to implement with *Keras* [3].

Stacked BiGRU: To get more fine-grained sentence information, we use stacked Bidirectional Gated Recurrent Units (BiGRUs) to encode sentence information. The "stack" here refers to 2, which is 2 layers BiGRU. The information of the sentence is directional. The forward GRU can only get the information from the front to the back of the sentence, and can't encode the information from the back to the front. BiGRU better captures semantic dependencies in both directions.

Capsule Layer: The capsule network (Sabour et al., 2017) replaces a single neuron node of a traditional neural network with a neuron vector, and trains a completely new neural network in the way of Dynamic Routing, which effectively improves the low efficiency and space insensitivity of the CNN model. The capsule network is connected the same way as a fully connected network. Each capsule neuron in the previous layer is connected to each capsule neuron in the next layer. Each connection of the capsule network is also weighted. The difference is that there is a coupling coefficient on the connection of the capsule network. The coupling coefficient is determined by the iterative dynamic routing process.

4 Experiments and Results

4.1 Evaluation

To evaluate the performance of the classification system, the system uses a standard evaluation metrics that includes *accuracy*, *precision*, *recall*, and F_1-*score*. In this task we use F_1-*score* to measure the performance of the proposed method. *Accuracy* is the most intuitive performance measure and it is simply a ratio of correctly predicted observation to the total observations. *Precision* is the ratio of correctly predicted positive observations to the total predicted positive observations. *Recall* is the ratio of correctly predicted positive observations to the all observations in actual class. F_1-*score* is the weighted average of *Precision* and *Recall*. *Precision* and *recall* have equal contributions to F_1-score. The formula for F_1-*score* is defined as:

$$F_1 - score = \frac{(2 * Precision * Recall)}{(Precision + Recall)} \quad (1)$$

4.2 Hyperparameter

The *Targeted Dropout* layer has two parameters, *drop_rate* and *target_rate*. In this system, these two parameters are both set to 0.55.

For the stacked BiGRU, the first layer BiGRU *units* = 64, and the second layer BiGRU *units* = 64.

The parameters of the capsule layer are set as follows: *routings* = 5, the number of caspule is 10 and the dimension is 32.

Finally, at the full connection layer output, we added two parameters, *kernel_regularizer* and *activity_regularizer*, respectively. *Kernel_regularizer* uses l_2 regularization with a parameter of 0.001, *activity_regularizer* is l_1 regularization, and the parameter is also set to 0.001.

Usually the multi-classification problem uses *categorical crossentropy* as the loss function. But our system uses *binary crossentropy* in this binary classification.

We set *epochs* = 6 and *batch size* = 64.

4.3 Experiments and Result Analysis

We conduct several experiments to gain insight into the performance of the proposed model. First we compare the normal *Dropout* and *Targeted Dropout* performance.

It can be seen from Table 2 that the performance of *Targeted Dropout* is significantly better than that of *Dropout*. Model performance increases by 5% on average F_1-*score*.

Sets	Acc	P	R	F$_1$
Dropout	0.53	0.58	**0.61**	0.52
Targeted Dropout	**0.56**	**0.64**	0.60	**0.55**

Table 2: Experimental results on test set. The values in the table are macro averages.

To determine the specific parameters of the *Targeted Dropout*, we do a lot of comparison experiments. As can be seen from Table 3, the best parameter is 0.55. This is also the parameter we submitted to the system in the competition.

Targeted Dropout	Acc	P	R	F$_1$
0.40	0.53	0.58	0.63	0.50
0.45	0.56	0.60	0.63	0.54
0.50	0.53	0.59	**0.64**	0.49
0.55	**0.56**	**0.64**	0.60	**0.55**
0.60	0.55	0.60	0.63	0.54

Table 3: Experimental results of different Targeted Dropouts on the test set.

We compare the four network architectures based on a capsule network, LSTM, GRU, BiLSTM and BiGRU. We observe that the performance of BiGRU is better than the other three in this task. Compared to MFC baseline and SVC baseline, our method increases the average F_1-*score* by 0.18 and 0.10, respectively, as is shown in Table 4.

The values of MFC baseline and SVC baseline come from the data published by the organizer[4]. To ensure the fairness of the experiment, the parameters of the capsule network remain unchanged, using the parameters mentioned in section 4.2.

5 Conclusion and Future Work

In this paper, we present a stacked BiGRU model based on a capsule network system in the task "Shared Task on Multilingual Detection of Hate". We replace *Dropout* with *Targeted Dropout*, the effect is more obvious, indicating that *Targeted Dropout* is effective in this system. At the same time, we have conducted several experiments to find the optimal parameters of *Targeted Dropout*. Through comparative experiments, BiGRU is the best model based on capsule networks.

Due to time limit, we don't tune the parameters of the capsule network. In the future, we will adjust the parameters of the capsule network to optimize the performance of the model. Secondly, we are going to try ensemble methods such as hard voting, soft voting and stacking to find the one that works best for our task. Finally, we would like to explore transfer learning technology.

Abstract

With the proliferation and ubiquity of smart gadgets and smart devices, across the world, data generated by them has been growing at exponential rates, in particular social media platforms like Facebook, Twitter and Instagram have been generating voluminous data on a daily basis. According to Twitter's usage statistics, about 500 million tweets are generated each day. While the tweets reflect the users' opinions on several events across the world, there are tweets which are offensive in nature that need to be tagged under the hateful conduct policy of Twitter. Offensive tweets have to be identified, captured and processed further, for a variety of reasons, which include i) identifying offensive tweets in order to prevent violent/abusive behaviour in Twitter (or any social media for that matter), ii) creating and maintaining a history of offensive tweets for individual users (would be helpful in creating meta-data for user profile), iii) inferring the sentiment of the users on particular event/issue/topic . We **(CodaLab Team/User Name: murali_sr)** have employed neural network models which manipulate attention with Temporal Convolutional Neural Network for the three shared subtasks i) ATT-TCN (ATTention based Temporal Convolutional Neural Network) employed for shared sub-task A that yielded a best macro-F1 score of 0.46, ii) SAE-ATT-TCN(Self Attentive Embedding-ATTention based Temporal Convolutional Neural Network) employed for shared sub-task B and sub-task C that yielded best macro-F1 score of 0.61 and 0.51 respectively. Among the two variants ATT-TCN and SAE-ATT-TCN, the latter performed better.

1 Introduction

In the prevailing digital era, Deep Learning has penetrated almost all industry verticals and afforded several researchers an effective tool, in handling voluminous data and deriving meaningful inferences. Initially, (LeCun et al., 1998) invented Convolutional Neural Network (CNN) model for extraction of local features, which later proved to be the standard choice for Computer Vision tasks. (Hochreiter and Schmidhuber, 1997) the introduced LSTM (Long Short Term Memory) architecture, which went on to become the standard choice for Natural Language Processing (sequence) tasks due to the implicit ordering of the sequence data in words and sentences. Then several architectures, combining LSTM with CNN were introduced that went on to become successful for NLP tasks as well. Deep Learning techniques have leaped forward through multiple NLP tasks such as Modeling, Classification, Translation, Summarization, etc., and have proved to be better compared to traditional techniques.

Ever since social media has become ubiquitous there have been individuals who take gratuitous advantage of the anonymous nature of social media platforms, and engage themselves in rude and offensive communications. Such behaviour that prohibit free flow of communication and violate acceptable usage policy has necessitated to identify and capture the offensive posts, comments, etc., in order to prevent the dissemination of abusive behaviour in social media. (Zampieri et al., 2019b) focused on this aspect and organized a classification task with a particular focus on Twitter posts; unlike predictions of positive or negative sentiments, this task has three shared sub-tasks, intended to identify and capture the offense target as an entity. The task includes three shared sub-tasks that include:

i) Sub-Task A: Offensive language identification,
ii) Sub-Task B: Offense type categorization and

iii) Sub-Task C: Offense target identification.
i) Sub-Task A: Offensive language identification in which posts are categorized into Offensive or Not Offensive. Recently (Bai et al., 2018) empirically concluded that the association between sequence modeling and recurrent neural networks should be reconsidered and established that convolutional networks are ought to be considered for sequence modeling tasks. The TCN model can be extended followed by introduction of Attention to the output of Embedding layer and TCN layer
ii) Sub-Task B: Offense type categorization in which the Offense type is categorized into either targeted or untargeted. The objective here is to understand sentence structure by emulating the relationship between words. The sequence of words is crucial to capture the essence of sentence unlike the practice of mere focus on constituent parts of a sentence in the previous model. Based on (Lin et al., 2017), minor modifications are injected into the previous model employed in sub-task A, and introduced self-attention for embedding further to aggregate the relationship between words in a sentence and stacked attention layer, at the output of each dilated convolution blocks. **iii) Sub-Task C: Identification of target offense** in which the who, the offense is aimed at is identified and categorized into Individual, Group or Other. The same model used in the previous sub-task B is employed for this sub-task as well.
